(1) Sand gains and losses by a typical dune are illustrated in Figure III-4-22. Sand is transported by onshore winds to the dune where vegetation, sand fencing, or the dune itself alter the wind field and allow the sand to accumulate. If the trapping is incomplete, the same onshore winds may transport sand inland from the dune.

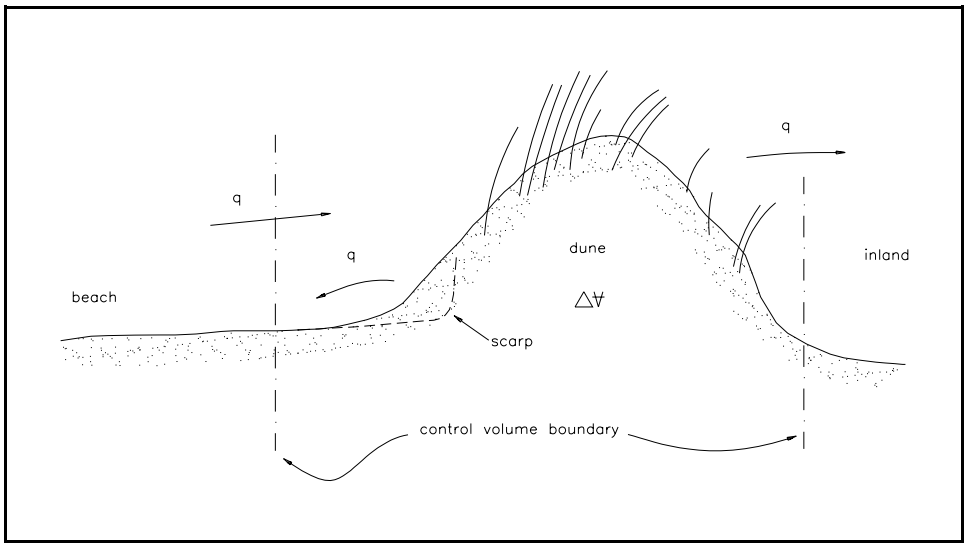

Figure III-4-22. Definition of terms, dune sediment budget

(2) If sand accumulates at the dune's seaward side and erodes from its landward side, the dune will migrate seaward. Occasional high water levels during storms may allow waves to erode the base of the dune to create a scarp. Sand eroded from the dune by waves becomes a part of the littoral transport. Following the storm, onshore winds again rebuild the dune's seaward side. During periods of offshore winds, some sand from the dune will be blown back onto the beach. Similarly, if there is an unstabilized source of sand landward of the dune, it will contribute to building the dune. The sand budget equation for the dune is given by

$$q - q_s - q_i = \rho (1-p) \frac{\Delta \forall}{\Delta t} \tag{III-4-23}$$

in which q = wind-borne sand transport rate (mass per unit time per unit length of beach), q_s = dune erosion by waves (mass per unit time per unit length of beach), q_i = the sand blown inland from the dune, $\Delta\forall$ = the volume change per unit length of beach, ρ = mass density of the sand, p = the porosity of the *in situ* dune sand, and t = time. Note that q and q_i include both sand gains and losses depending on their sign. In fact, q and q_i should each be multiplied by transport efficiency terms, which depend on wind direction and dune conditions such as the presence of vegetation and sand fencing. For example, onshore winds can efficiently transport sand, while offshore winds, which would carry sand out of the dunes, are less efficient if vegetation and fencing are present. The calculations in Example Problem III-4-8 consider only q with a transport efficiency between 0 and 1 depending on the wind direction relative to the axis of the dune. Net dune losses embodied in q_s and q_i are not included. Equation 4-23 might be rewritten

$$\eta\, q - q_s - \eta_i\, q_i = \rho (1 - p) \frac{\Delta \forall}{\Delta t} \tag{III-4-24}$$

in which η = the transport efficiency for winds at the seaward side of the dune and η_i = the transport efficiency for winds at the landward side of the dune. For the calculations in Example Problem III-4-8, η was assumed to be a function of wind direction ($\eta = 1$ for winds with an onshore component and $0 < \eta < 1$ for winds with an offshore component), and η_i was assumed zero (no inland sand losses and no inland sand source). Note that η was assumed to vary as $\cos^2\beta$ with 180 deg $< \beta <$ 360 deg, where β = the angle between the wind and the dune axis (the dunes are usually parallel with the shoreline) so that β = 270 deg represents wind blowing from the back of the dune.

d. Procedure to estimate dune "trapping factor."

(1) Unfortunately, the preceding discussion assumes knowledge of quantities that are most typically unknown and a simple approach must be taken. A "dune trapping factor" can be computed to correct predicted "potential" dune growth rates in order to obtain better estimates of actual rates. The trapping factor T_f is based on the difference between the sand grain size distribution on the dune and the size distribution on the beach in front of the dune. If R_t = a theoretical growth rate based on calculations of sand transport and R_a = the actual growth rate, the relationship is given by

$$R_a = T_f R_t \tag{III-4-25}$$

(2) The value of T_f can be found using the procedure suggested by Krumbein and James (1965) to compare the characteristics of potential beach nourishment sand with native beach sand characteristics. While the Krumbein and James (1965) procedure has been superseded by better methods to estimate beach nourishment overfill ratios, in principle it presents a way to estimate what volume of sand with a given gradation is needed to produce a unit volume of sand having a different gradation. The procedure is based on the assumption that the gradations of the sand on the beach and the sand in the dunes are both log-normally distributed and can be described by their phi-mean μ_φ and phi-standard deviation σ_φ. These parameters can be estimated using the relationships

$$\mu_\varphi = \frac{\varphi_{16} + \varphi_{84}}{2} \tag{III-4-26}$$

and

$$\sigma_\varphi = \frac{\varphi_{16} - \varphi_{84}}{2} \tag{III-4-27}$$

in which φ_{16} = the phi diameter of the 16th percentile (16 percent of the grains are finer) and φ_{84} = the phi diameter of the 84th percentile. The phi diameter is given by

$$\varphi = -\log_2 d_{mm}$$

or equivalently by (III-4-28)

$$\varphi = -3.3219 \log_{10} d_{mm}$$

in which φ = the diameter in phi units and d_{mm} = the grain diameter in millimeters. The phi-mean and phi-standard deviation are calculated for sand taken from the dune, $\mu_{\varphi D}$ and $\sigma_{\varphi D}$, and for sand from the beach in front of the dune, $\mu_{\varphi B}$ and $\sigma_{\varphi B}$, and the following parameters are calculated

$$\frac{\sigma_{\varphi\,D}}{\sigma_{\varphi\,B}} \tag{III-4-29}$$

and

$$\frac{\mu_{\varphi\,D} - \mu_{\varphi\,B}}{\sigma_{\varphi\,B}} \tag{III-4-30}$$

and used with Figure III-4-23 to determine how much beach sand is needed to produce a unit volume of dune sand. Figure III-4-23 is derived from the equation

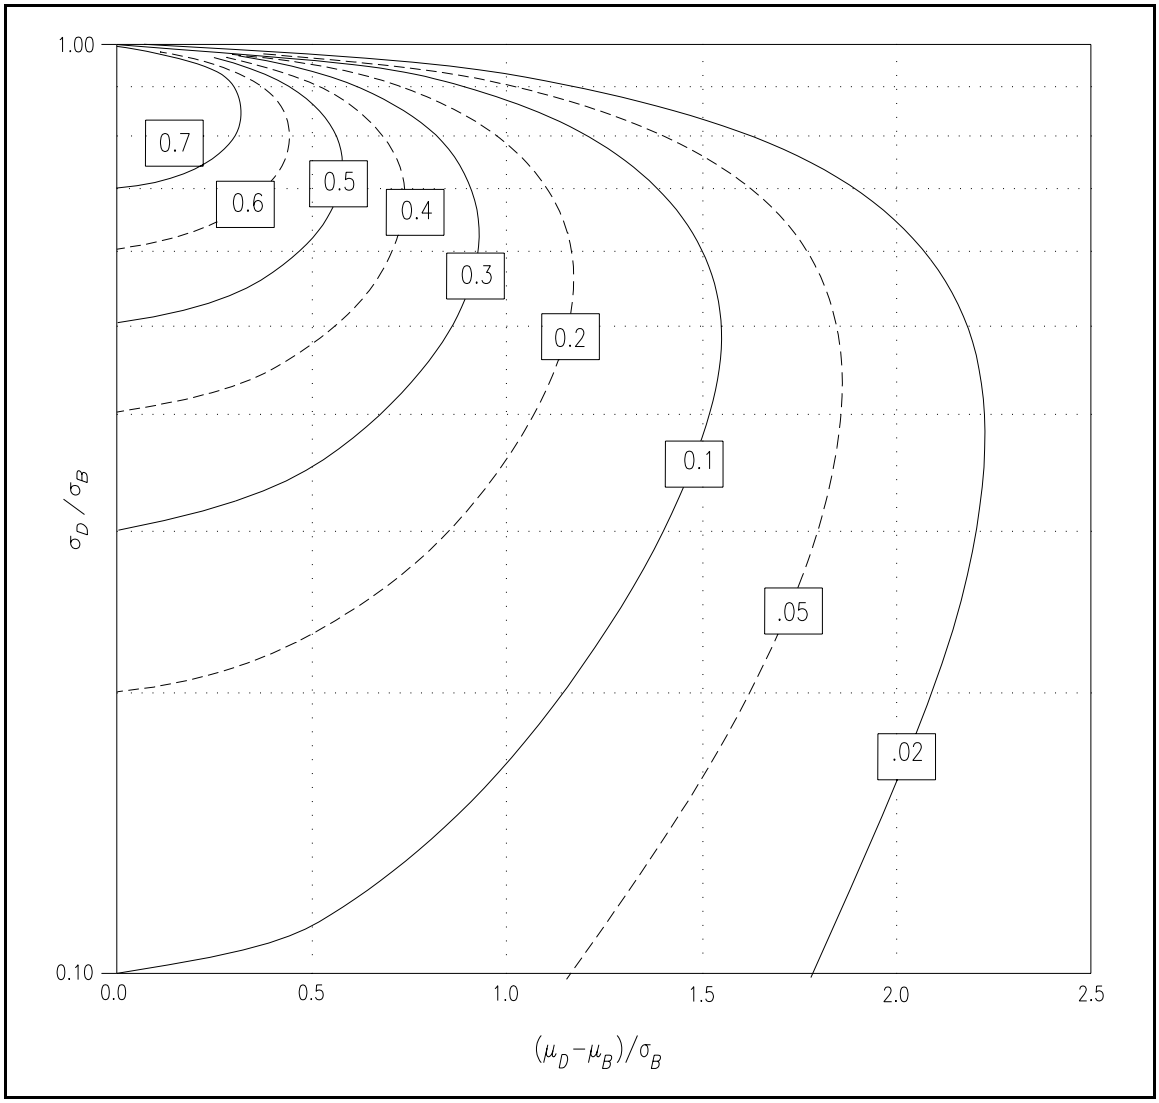

Figure III-4-23. Dune sand trapping factor T_f

EXAMPLE PROBLEM III-4-9

Find:

Determine the dune trapping factor and estimate the rate of dune growth for the sands from the beach and dune in Atlantic City with the size characteristics given below.

Given:

The dune growth rate from Example Problem III-4-8 based on the transport rates of Example Problem III-4-7 and the following data from a sand size analysis of the beach and dune sands at Atlantic City.

Beach sand: $d_{16} = 0.159$ mm $d_{84} = 0.664$ mm

Dune sand: $d_{16} = 0.173$ mm $d_{84} = 0.403$ mm

Solution:

To use the relationships for μ_φ and σ_φ, the phi diameter must be calculated for each of the above percentiles using Equation 4-28.

For the beach sand

$$\varphi = -\log_2 d_{mm}$$

or equivalently

$$\varphi = -3.3219 \log_{10} d_{mm}$$

and, therefore

$$\varphi_{16} = -3.3219 \log_{10} (0.159) = 2.65$$

Similarly

$$\varphi_{84} = 0.59$$

For the dune sand

$$\varphi_{16} = 2.53 \quad \text{and} \quad \varphi_{84} = 1.31$$

From Equation III-4-26 and III-4-27

$$\mu_{\varphi B} = \frac{2.65 + 0.59}{2} = 1.62$$

(Continued)

Example Problem III-4-9 (Concluded)

and

$$\sigma_{\varphi B} = \frac{2.65 - 0.59}{2} = 1.03$$

Similarly, for the dune sand

$$\mu_{\varphi D} = 1.92 \quad \text{and} \quad \sigma_{\varphi D} = 0.61$$

Substituting these values into Equation 4-31 gives

$$T_f = \left(\frac{0.61}{1.03}\right) \exp\left[\frac{(1.92 - 1.62)^2}{2(0.61^2 - 1.03^2)}\right] \cong 0.55$$

The trapping factor T_f can also be found from Figure III-4-23.

Consequently, the transport rate found in example problem III-4-8 should be multiplied by 0.55. The transport rate is therefore

$$R_a = 0.55\ R_t$$

or

$$R_a = 0.55\ (27.2) \cong 15.0\ \frac{\text{m}^3}{\text{m}-\text{yr}}$$

$$T_f = \left(\frac{\sigma_{\varphi D}}{\sigma_{\varphi B}} \right) \exp \left[\frac{(\mu_{\varphi D} - \mu_{\varphi B})^2}{2 (\sigma^2_{\varphi D} - \sigma^2_{\varphi B})} \right] \quad \text{(III-4-31)}$$

which is based on a comparison of the log-normal distributions of dune and beach sands. The procedure is valid only if the dune sand is finer than the beach sand and more narrowly graded (better sorted). This is generally the case since the dune sand is almost always derived from the sand on the beach in front of the dune.

(3) Some example values of the various parameters for typical beach and dune sands along with calculated dune trapping factors are given in Table III-4-14.

e. Continuity equation for wind transport of beach sand.

(1) The continuity equation for the beach sand transported by an onshore wind is developed in Figure III-4-24.

(2) At the upwind end of the fetch, the ocean and/or saturated sand precludes any wind transport. Further shoreward, the sand is dry and transportable by the prevailing wind; however, the amount in transport has not reached its potential rate predicted by the equations. In this region the wind is deflating the beach. The amount of sand leaving the Δx-long control volume exceeds the amount entering and the difference is comprised of sand eroded from the beach. Downwind along the fetch, the sand transport rate has reached equilibrium and the amount of sand entering the control volume equals the amount leaving. Here the beach is not deflating; rather the amount of sand eroded is balanced by the amount deposited. Further along the fetch, near the base of the dune, the amount of sand entering the control volume is less than the amount removed by the wind, and sand accumulates to build the dune. The change in transport rate is often due to a decrease in local wind speed induced by vegetation, sand fencing, or by the dune itself. Writing a sediment balance for the Δx control volume yields the equation

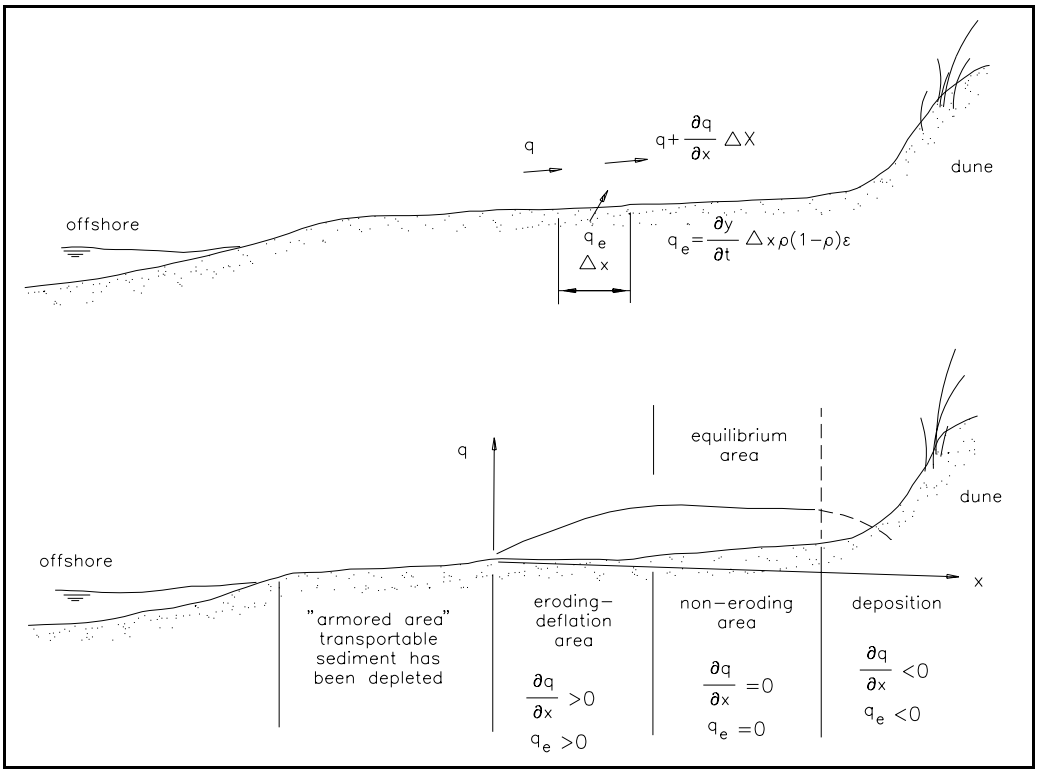

Figure III-4-24. Sand conservation equations for a beach showing deflation area, equilibrium area, and deposition area

$$q + q_e - \left(q + \frac{\partial q}{\partial x} \Delta x \right) = 0 \qquad \text{(III-4-32)}$$

in which q equals the wind-blown transport into the control volume (mass per unit time per unit length perpendicular to the direction of transport), q_e equals the amount contributed to the control volume by erosion from the beach (mass per unit time per unit length), and Δx equals the width of the control volume in the direction of transport. The first two terms are the sand influx to the control volume while the term in brackets is the efflux. Simplifying Equation 4-32 gives

$$\frac{\partial q}{\partial x} = \frac{q_e}{\Delta x} \qquad \text{(III-4-33)}$$

(3) The contribution from the beach q_e can be expressed as a deflation rate times the beach surface area

$$q_e = \frac{\partial y}{\partial t} \Delta x \, \rho (1 - p) \, \varepsilon \qquad \text{(III-4-34)}$$

in which y equals the height of the beach surface above some datum, ρ equals the mass density of the sand, p equals the porosity of the *in-situ* beach sand, and ε equals a dimensionless "erodibility factor" related to the beach sand that is potentially transportable. ε is related to the sand size gradation as well as to any conditions that increase the threshold wind speed such as soil moisture content, salt crust formation, etc. Equation III-4-33 becomes

$$\frac{\partial q}{\partial x} = \frac{\partial y}{\partial t} \rho (1 - p) \varepsilon \quad \text{(III-4-35)}$$

(4) The upwind boundary condition, $q = 0$ at $x = 0$, is applied where the sand is first transportable, i.e., at the shoreline or the point where the sand is no longer wet. Since different size fractions are transported at different rates by a given wind speed, Equation 4-35 must be applied to each range of sizes present on the beach. Unfortunately, the relationship between the size gradation parameters and the amount of surficial, transportable sand is not known. Therefore, it is not possible to establish limit depths of erosion for a given wind speed blowing over sand with a given size distribution.

(5) The amount of sand available for transport at a given wind speed depends on the gradation as well as the mean or median grain size. For a fine, poorly graded sand, once transport is initiated, there is a nearly continuous supply of sizes that can be transported. For a well-graded sand subjected to winds capable of transporting the finer fractions, fine sediments are eventually removed from the surface leaving behind the coarse fraction. See Figure III-4-21. In order to continue the transport process, higher wind speeds must occur or fine sediments must be exposed at the surface again.

f. Limited source due to gradation armoring. Beach sands generally are not uniform in size but have a gradation that is often log-normally distributed. The finer fraction at the beach surface is more easily transported than the coarser fraction. Finer sand in the gradation also has the potential to be transported at a greater rate by lower wind speeds while larger sand is transported at a slower rate, if at all. However, as finer sands are depleted from the surface layer of the beach, the remaining larger particles shelter the underlying fines and armor the beach. Then, at the upwind end of the fetch, transport of fine sand ceases and, unless the wind speed increases to remove and transport the coarser fraction, transport will cease. Further downwind, the fines leaving the control volume balance the fines entering so that transport continues. Consequently, there is a moving, upwind boundary between that portion of beach where the fines have been removed and transport has ceased, and where transport of fines continues. Each size fraction has its own boundary. As fines are removed and the coarser fraction remains behind to armor the surface, the no-transport boundary moves downwind. Note that for sand with a uniform size gradation, this armoring process does not occur while for a well-graded sand it does. Other armoring processes may occur for uniformly graded sands. Figure III-4-24 shows the location of the upwind boundary separating the armored area from the area where transport processes continue.

EXAMPLE PROBLEM III-4-10

Find:

The wind transport rate for each fraction of the sand at Atlantic City having the distribution given in Figure III-4-25. Determine the total transport by summing the transport of all fractions using the beach sand size distribution as a weight function.

Given:

The wind rose data from Atlantic City in Table III-4-9 and the beach and dune sand size distributions in Figure III-4-25.

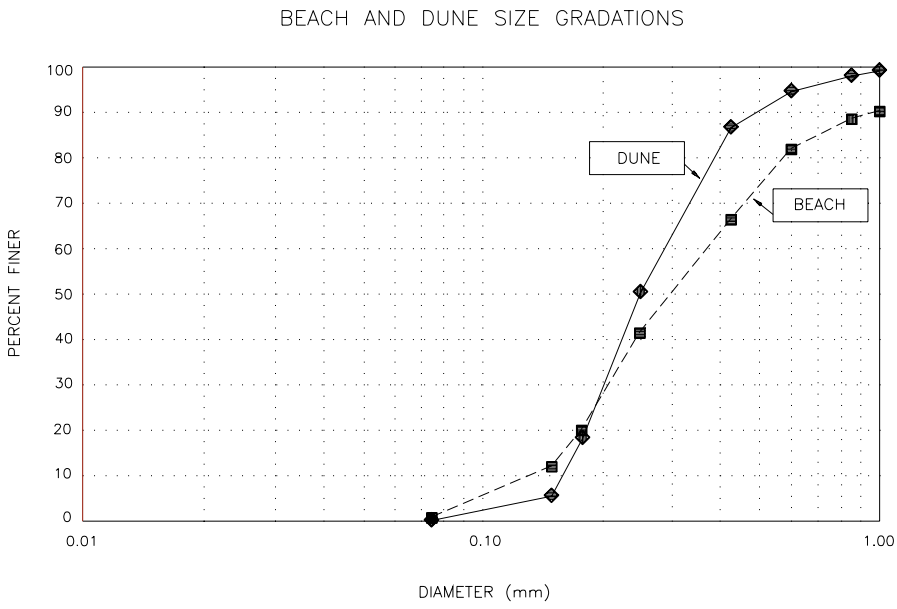

Figure III-4-25. Beach and dune and size gradations for Atlantic City, NJ

Solution:

The first step is to divide the size distribution for the beach sand into discrete increments and to determine the threshold wind speed for the upper limit of each size interval. See Table III-4-15. The volumetric transport coefficient is obtained from Figure III-4-13 entering with the appropriate sand grain diameter and elevation at which the wind speeds are measured (in this example assumed to be 10 m). The wind speeds in both miles per hour (mph) and in centimeters per second at the wind rose interval boundaries are given in Table III-4-16.

(Sheet 1 of 6)

Example Problem III-4-10 (Continued)

Table III-4-15
Size Distribution, Threshold Wind Speeds and Volumetric Transport Coefficients for Beach Sand Size Intervals, Atlantic City, NJ

0.90	0.90	0.015	1395	3.02e-14

Table III-4-17 gives the potential sand transport at the wind rose interval boundaries for each of the grain size intervals. Column 4 of the table gives the potential transport for each of the size intervals in cubic meters per meter-second. For those cases where the threshold wind speed exceeds the actual wind speed (the coarser fraction), the transport is zero. Column 5 gives the potential transport values in cubic meters per meter-year while column 6 gives the potential transport weighted by the fraction of sand within the given size interval. For example, for a wind speed of 14 mph (626 cm/sec) 77.4 m^3/m-yr of sand with a diameter of 0.2 mm could be transported. However, only 9 percent of the sand is within this size interval so that the weighted transport rate is 0.09(77.4) = 6.96 m^3/m-yr. Note that for a wind speed of 14 mph (626 cm/sec), only sand with a diameter less than about 0.2 mm will be transported. For a wind speed of 29 mph, sand with a diameter less than 0.70 mm is transported.

[1] Threshold wind speed exceeds actual wind speed and there is no transport of coarser sands.

(Sheet 3 of 6)

Example Problem III-4-10 (Continued)

Table III-4-18 is constructed from Table III-4-17 and the wind rose data. Table III-4-18 is only for winds from the north. The values in columns 2, 3, and 4 are the average transport values over the wind speed interval; hence, for example, the first value in column 3 is the average transport over the wind speed interval 14 mph < U < 29 mph, or (2.79 + 24.75)/2 = 13.77 m^3/m-yr. Similarly, the first value in column 4 is the average over the interval 29 mph < U < 35 mph, or (24.75 + 43.52)/2 = 34.14 m^3/m-sec. The values in column 5 are the weighted sums of the values across each row with the number of days that the wind was within the given speed interval used as the weight factor. Hence, the value in the first row is given by (1.395)(20/365) + (13.77)(20/365) + (34.14)(0/365) = 0.831 m^3/m-yr. Consequently, the total amount of sand transported northward is 14.218 m^3/m-yr. Table III-4-18 is for winds from the north only. Similar analyses must be done for the remaining seven compass directions. The results of the analyses for all eight compass directions are summarized in Table III-4-19 where, for example, column 2 is derived from column 5 of Table III-4-18. (Calculations for the remaining compass directions are omitted for brevity.)

Dune growth depends on the wind direction relative to the dune axis and the assumptions made regarding the ability of the dune to trap and hold sand. The procedures presented in Example Problem III-4-8 are applied to each individual grain size interval and the values summed to estimate the amount of sand trapped by the dune. Transport in each direction is multiplied by $\sin\beta$, the angle between the dune axis and the direction from which the wind is blowing, and $\cos^2\beta$, the dune trapping efficiency. These values are given at the bottom of Table III-4-20. The values in Table III-4-20 are the net contribution to dune growth by winds from the indicated directions. For example, winds from the north remove sand from the dunes since values in column 2 are negative (the wind is blowing from the dune toward the beach). For this site, most dune growth is due to southerly winds and, to a lesser extent, to southeasterly winds.

(Sheet 5 of 6)

Example Problem III-4-10 (Concluded)

For the example, the total dune growth rate is 38.63 m^3/m-yr. This represents a high rate of growth and most certainly overestimates dune growth at Atlantic City since the example assumes an unlimited supply of sand in all size intervals available for transport. As in Example Problem III-4-9, the calculated dune growth rate can be adjusted by using the trapping efficiency based on a comparison of the beach sand with the dune sand. From the preceding example, T_f = 0.55; hence, the estimated dune growth rate is $R_a = 0.55(38.63) = 21.4$ m^3/m-yr. An alternative procedure to adjust dune growth rates based on comparing the dune sand distribution with the beach sand distribution is given in Example Problem III-4-11, which follows.

Table III-4-20

TOTAL DUNE GROWTH RATE = 38.631 m^3/m-yr

(Sheet 6 of 6)

EXAMPLE PROBLEM III-4-11

Find:

The trapping efficiency for natural dune building in Atlantic City and the dune grain size distribution calculated from the results of Example Problem III-4-10 given the measured and calculated grain-size distributions for the dune sand at Atlantic City.

Given:

The dune growth rates based on the individual grain size intervals as calculated in Example Problem III-4-10 and the actual dune sand size distributions given in Figure III-4-25.

Solution:

The calculated amounts of sand trapped in the dune from each size interval are given in Table III-4-21. The values in column 2 of Table III-4-21 are found by summing across the rows in Table III-4-20. Thus, 2.111 m^3/m-yr of sand with a diameter less than 0.08 mm is trapped by the dunes. Similarly, 2.639 m^3/m-yr of sand with a diameter between 0.08 mm and 0.10 mm is trapped. The calculated size distribution of the dune sand is determined by normalizing the values in column 2 by dividing each value in column 2 by the sum of column 2. The resulting values are given in column 3, which represents the fraction of the sand in the dune within the given size interval. For example, 0.0547 or 5.47 percent of the dune sand is finer than d = 0.08 mm and 6.83 percent is between d = 0.10 mm and d = 0.08 mm, etc. Column 4 of Table III-4-21 gives the cumulative distribution.

Table III-4-21
Calculated Dune Sand Size Distribution

d (mm)	Amount Trapped in Dune (m^3/m-yr)	Normalized Amount Trapped in Dune	Cumulative Size Distribution in Dune
0.08	2.111	0.0547	0.0547
0.10	2.639	0.0683	0.1230
0.20	5.277	0.1366	0.2596
0.25	5.732	0.1484	0.4080
0.30	4.230	0.1095	0.5175

0.60	5.038	0.1304	0.8990
0.70	3.215	0.0832	0.9823
0.80	0.288	0.0075	0.9898
0.90	0.396	0.0102	1.0000
TOTAL	38.631	1.0000	

(Sheet 1 of 4)

Example Problem III-4-11 (Continued)

Figure III-4-26 shows the calculated sand size distribution in the dune along with the actual dune size distribution. The actual distribution differs from the calculated distribution because not all of the sand present on the beach is available for transport due to processes like gradation armoring, crust formation, etc. Some fines might be confined between larger grains and once the surficial fines are removed, the remaining fines are not available for transport. Also, the coarser fraction can only be transported by the less frequent high wind speeds.

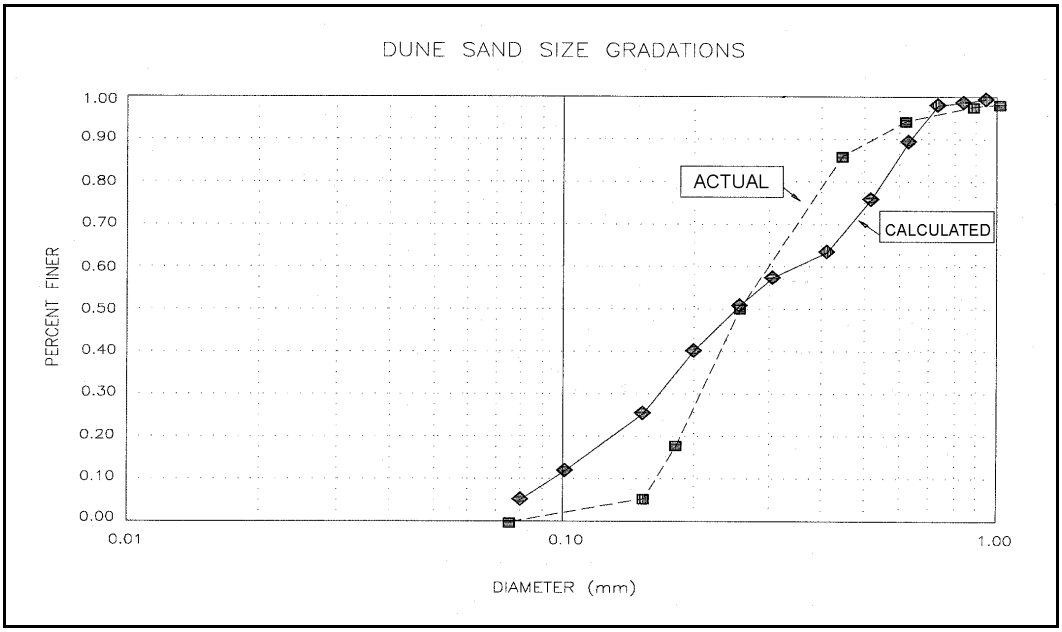

Figure III-4-26. Actual and calculated dune sand size gradation at Atlantic City, NJ

The transport rates calculated for each size interval are potential transport rates. Comparison of the calculated size distribution with the actual distribution allows a correction factor to be calculated for each size fraction. Columns 2 and 3 of Table III-4-22 present the calculated and actual size distributions, respectively. Column 4 is a calculated correction factor equal to the actual interval fraction divided by the calculated interval fraction. For example, the correction factor 0.1818 in the first row equals 0.0100/0.0547, the ratio of column 3 over column 2. Thus column 4 gives the numbers by which calculated values must be multiplied in order to obtain actual values. The amount of sand available for transport in each size interval is limited, so, in order to calculate the amount actually transported in each size interval, the correction factor values in column 4 must be normalized by dividing through by the largest value. (Column 4 would suggest that 300 percent of the amount of sand between 0.35 mm and 0.40 mm is needed to produce the observed distribution. Clearly, no more than 100 percent can be available.) The values in column 5 result. These values can be considered to be transport correction factors for each size interval. They are the values by which the transport rate in each size interval must be multiplied in order to produce the measured dune size distribution.

(Sheet 2 of 4)

Example Problem III-4-11 (Continued)

Table III-4-22
Comparison of Calculated Dune Sand Size Distribution and Actual Dune Sand Size Distribution

d (mm)	Calculated Dune Sand Size Distribution	Actual Dune Sand Size Distribution	Correction = Actual/Calculated	Normalized Correction
0.08	0.0547	0.0100	0.1818	0.0604
0.10	0.0683	0.0470	0.6912	0.2297
0.20	0.1366	0.1355	0.9891	0.3286
0.25	0.1484	0.0908	0.6135	0.2039
0.30	0.1095	0.2250	2.0455	0.6797
0.35	0.0638	0.1334	2.1175	0.7036
0.40	0.0623	0.1896	3.0095	1.0000
0.50	0.1250	0.0832	0.6656	0.2212
0.60	0.1304	0.0397	0.3054	0.1015
0.70	0.0832	0.0125	0.1506	0.0500
0.80	0.0075	0.0125	1.6026	0.5325
0.90	0.0102	0.0100	0.9804	0.3258
TOTAL	1.0000	1.0000		

Table III-4-23 gives the corrected transport rates for each size interval. Column 2 is the calculated amount in each size interval trapped in the dune. (See column 2, Table III-4-21.) Column 3 is the normalized correction factor (see column 5, Table III-4-22) and column 4 is the corrected dune growth rate for sand within the given size fraction. The sum of the values in column 4 gives the corrected dune growth rate. For the given example, the corrected dune growth rate is 12.7 m^3/m-yr. This procedure is similar to the procedure used to derive the trapping factor T_f but by matching the calculated and actual dune size distributions and without assuming that the distributions are log-normal. The value of T_f can be calculated for this example by taking the ratio of the value of the total from column 4 in Table III-4-23 to the total in column 2. This ratio is $T_f = 12.68/38.63 = 0.33$, which can be computed with the value of $T_f = 0.57$ calculated in Example Problem III-4-9.

Figure III-4-27 compares the actual dune size distribution with the calculated distribution after the correction has been applied.

III-4-7. Definition of Symbols

$\Delta \forall$	Volume change per unit length of beach [length^3/length]
ε	Erodibility factor related to beach sand that is potentially transportable [dimensionless]
η	Transport efficiency for winds at the seaward side of a dune
η_i	Transport efficiency for winds at the landward side of a dune
κ	von Karman's constant (= 0.4)
μ_φ	Mean of a sediment sample [phi units]
$\mu_{\varphi D \text{ or } B}$	Mean of a sediment sample taken from the dune or beach [phi units]
v_a	Kinematic viscosity of air [length^2/time]
ρ	Mass density of sediment grains [force-time^2/length^4]
ρ_a	Mass density of air [force-time^2/length^4]
σ_φ	Standard deviation of a sediment sample [phi units]
$\sigma_{\varphi D \text{ or } B}$	Standard deviation of a sediment sample taken from the dune or beach [phi units]
τ	Boundary shear stress [force/length^2]
φ	Sediment grain diameter in phi units ($\varphi = -\log_2 d_{mm}$, where d_{mm} is the grain diameter in millimeters)
φ_x	Sediment grain diameter of the x-percentile of a sample (x-percent of the grains are finer) [phi units]
A	Empirical constant (Equation III-4-10) [dimensionless]
A_t	Dimensionless constant (= 0.118) used in calculating the critical shear stress, u_{*_t}, for sand transport by wind (Equation III-4-20)
B	Empirical constant (Equation III-4-10) [dimensionless]
$B_{Bagnold}$	Bagnold coefficient [dimensionless]
$C_{D,land}$	Drag coefficients over land [dimensionless]
$C_{D,sea}$	Drag coefficient over sea [dimensionless]
C_z	Wind drag coefficient at height Z (Equation III-4-4) [dimensionless]
d	Standard grain size (= 0.25mm)
D	Median sediment grain diameter [length - generally millimeters]
D	Mean sediment grain diameter [length - generally millimeters]
d_{mm}	Sediment grain diameter in millimeters

d_x	Sediment grain diameter of the x-percentile of a sample (x-percent of the grains are finer) [length]
e	Base of natural logarithms
g	Gravitational acceleration (32.17 ft/sec^2, 9.807m/sec^2) [length/time^2]
G	Dry weight sand transport rate [force/length/time]
H_{land}	Height of the planetary boundary layer over the land [length]
H_{sea}	Height of the planetary boundary layer over the sea [length]
K	Empirical dimensional eolian sand transport coefficient (Equation III-4-17) [force/length/time]
K'	Eolian sand transport coefficient (Equation III-4-19) [dimensionless]
n	Empirically determined exponent (ranging from 1/11 to 1/17) (Equation III-4-15) [dimensionless]
p	Porosity of the *in situ* dune sand [percent]
q	Wind-borne sand transport rate [mass/time/length]
q_i	Sand blown inland from the dune [mass/time/length]
q_s	Dune erosion by waves [mass/time/length]
q_v	Volumetric sand transport rate [length^3/length/time]
R_a	Actual dune growth rate [length^3/length-time]
R_t	Theoretical dune growth rate [length^3/length-time]
R_T	Temperature correction factor applied to wind speed at the 10-m height (Figure III-4-7) [dimensionless]
t	Time
T_a	Air temperature [degrees Celsius]
T_f	Dune trapping factor [dimensionless]
T_s	Sea temperature [degrees Celsius]
u_*	Wind shear or friction velocity [length/time]
u_{*t}	Critical or threshold velocity for sand transport by wind (Equation III-4-20) [length/time]
u_{*tw}	Critical or threshold velocity for wet sand transport by wind (Equation III-4-20) [length/time]
U_{land}	Wind speed over land [length/time]
U_{sea}	Wind speed over sea [length/time]

U_x	Average wind speed at x-elevation [length/time]
U_z	Average wind velocity as a function of height above ground level [length]
U_{ZM}	Wind speed at the anemometer height [length/time]
U'_{10m}	Wind speed at the 10-meter height corrected for the air-sea temperature difference [length/time]
W	Fraction of water content in the upper 5mm of the sand [percent]
Z	Height at which wind speed is measured [length]
Z_0	Height of a roughness element characterizing the surface over which the wind is blowing [length]
Z_M	Anemometer height [length]
Z_R	Reference height [length]
Z_{Zingg}	Zingg Coefficient [dimensionless]

Chapter III-5
Erosion, Transport, and Deposition of Cohesive Sediments

III-5-1. Introduction

a. Cohesive sediments are those in which the attractive forces, predominantly electrochemical, between sediment grains are stronger than the force of gravity drawing each to the bed. Individual grains are small to minimize mass and gravitational attraction, and are generally taken to be in the silt (<70 μ) to clay (<4 μ) range. The strength of the cohesive bond is a function of the grain mineralogy and water chemistry, particularly salinity. Thus, a coarse silt behaves like noncohesive fine sand in fresh water, but is cohesive in an ocean environment. Similarly, a fine sand exhibits cohesion in salt water. In other words, it is easier to define cohesive sediment by behavior than by size.

b. Grain size and shape nevertheless play a significant role in the lack of permeability of cohesive sediment. As grain size decreases, so does the size of the interstitial pore spaces while drainage path length increases. The small pores result in greater resistance to flow, exacerbating the effects of the long drainage path. Clay minerals tend to form flake-shaped platelets, rather than spherical particles. These platelets deposit with the smallest dimension vertical, further reducing pores and increasing vertical drainage paths. For this reason, clay is often used as an impermeable layer in hydraulic earthworks such as dikes and channels.

c. In coastal engineering terms, the principal indicator of cohesive sediment behavior is a critical shear for erosion of bed sediment τ_c, which is significantly greater than the critical shear for deposition τ_s. In other words, once the sediment has been deposited on the bed, the cohesive bond with other bed particles makes it more difficult to remove than particle mass alone would suggest.

d. The processes and states of coastal cohesive sediment listed below are shown schematically in Figure III-5-1 and Table III-5-1.

(1) Consolidated. Stiff or hard cohesive sediment that has had centuries to drain, probably compressed beneath glaciers or other overburden.

(2) Suspension. Individual grains or flocs dispersed in the water column and transported with the water.

(3) Fluid Mud. A static or moving intermediate state between suspension and deposition, analogous to bed-load transport of noncohesive sand, that can move in the direction of flow supported by the bed. Fluid mud is the result of excess pore pressure, built up by hindered settling or wave action. Water cannot escape from the sediment deposit, and builds up the excess interstitial pore pressure necessary to support the weight of sediment above it. The whole mass of sediment and trapped water behaves like a uniform dense viscous fluid, flowing downhill or in the direction of the water flow. Fluid mud layers can often be seen on echo soundings as a false bottom in depressions in the seabed.

(4) Mud. Unconsolidated cohesive sediment that has been recently deposited. ‘Recently’ may be a matter of a few hours to several years.

e. Processes and states in Figure III-5-1 may be skipped. For example: most coastal mud, even fluid mud, is eroded before it has undergone sufficient consolidation to be defined as ‘consolidated’; many cohesive sediments do not form fluid mud, but deposit directly as stationary mud. Differences between mud and consolidated sediments occur during erosion. Transport, deposition, and consolidation are the same for both mud and consolidated cohesive sediments.

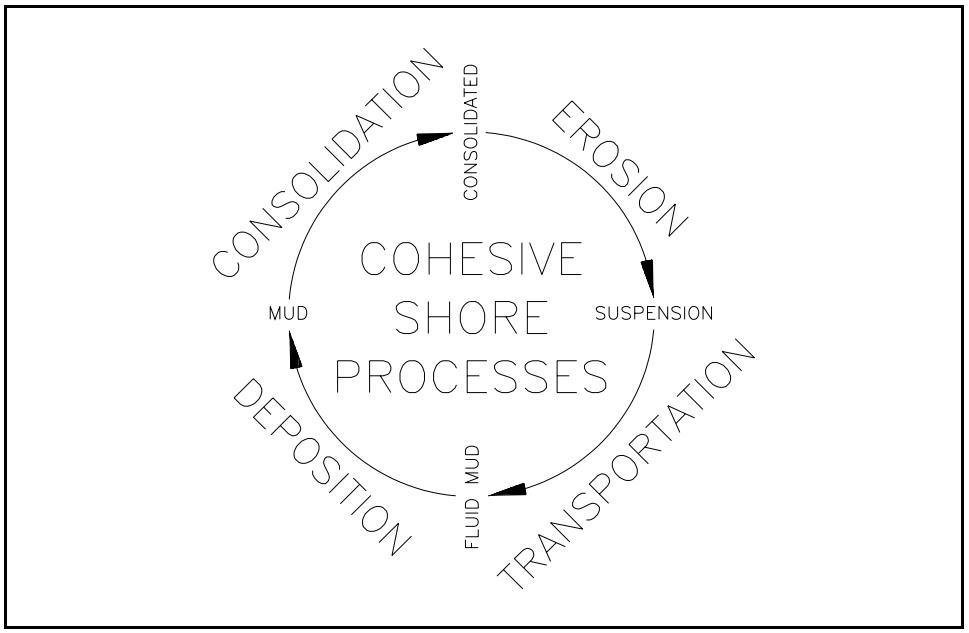

Figure III-5-1. Outline of cohesive shore processes — Any process or state may be bypassed, for example, fluid mud may be eroded without passing through (further) deposition and consolidation

Table III-5-1
Cohesive Sediment Density

	Typical Saturated Bulk Density	
Soil Description	**kg/m^3**	**lb/ft^3**
Suspension	1,020	64
Fluid Mud	1,100	70
Freshly Deposited Mud	1,300	80
Very Soft Consolidated	1,500	90
Soft Consolidated	1,600	100
Medium Consolidated	1,800	110
Stiff Consolidated	1,900	120
Very Stiff Consolidated	2,100	130
Hard Consolidated	2,200	140

III-5-2. Consolidated and Unconsolidated Shores

a. Consolidated shore.

(1) A shore is defined as consolidated cohesive when the erosion process is directly related to the irreversible removal of a cohesive sediment substratum (such as glacial deposits, ancient lagoon peats, tidal flat muds, valley and bay fill muds, lacustrine clays, flood deltas consisting of fine sediments, soft rock or other consolidated or over-consolidated deposits). Even when sand beaches are present, under the sand beach there lies an erodible surface that plays the most important role in determining how these shores erode, and ultimately, how they evolve in the long term. This differs fundamentally from sandy shores where erosion (or deposition) is directly related to the net loss (or gain) of noncohesive sediment from a given surface area.

Erosion on a sandy shore is a potentially reversible process (i.e., due to natural processes), while erosion on a consolidated cohesive shore is irreversible.

(2) Consolidated shores consist of consolidated or partially consolidated cohesive sediments which are usually covered by a thin veneer of sand and gravel, sometimes forming a beach at the shore (Part III-5-3 describes the techniques available for determining the properties of cohesive sediment). In essence, these shores are defined by an insufficient supply of littoral sand and gravel (i.e., noncohesive sediments). Consolidated shorelines may be associated with an eroding bluff or cliff face, or they may consist of a transgressive barrier beach perched over older sediments. The sand veneer often disguises the underlying cohesive substratum, and therefore, at many locations consolidated shores are incorrectly assumed to behave as sandy shores. The veneer thickness is usually in the range of a few centimeters to 2 or 3 m.

(3) Consolidated cohesive shores compose a large part of the Great Lakes, Arctic, Atlantic, Pacific, and U.S. Gulf coasts, a large part of the North Sea coast of England, and sections of the Baltic and Black Seas. Examples along the U.S. Atlantic coast include many of the barrier islands that are perched over older consolidated sediment; Riggs, Cleary, and Snyder (1995) estimate that 50 percent of the North Carolina coast is underlain by older estuarine peats and clays. Other examples along the U.S. east coast include the shores of Chesapeake and Delaware Bays. In many instances, the erosion of the shores associated with the Mississippi Delta and the transgressive barrier islands along the Texas coast is the result of cohesive processes. Cliff erosion along the South California coast and along large parts of the Beaufort Sea coast of Alaska are related to an insufficient supply of littoral sand, the hallmark of consolidated cohesive shores. Many other examples throughout the world, including erodible rocky coasts, are cited by Sunamura (1992). As awareness of the importance of the distinction of this shore type grows, and as sub-bottom investigations become more prevalent, more examples are identified. As Riggs, Cleary, and Snyder (1995) note, in many cases the shore is not just a ‘thick pile of sand.’

(4) Consolidated cohesive shores are often difficult to identify owing to the presence of a sand beach at the shore. The existence of an eroding bluff or cliff at the shore, featuring consolidated or cohesive sediment of some form, is a sure sign of a consolidated shore. However, in many cases, cohesive shores do not feature eroding bluffs. Examples include many of the barriers along the Atlantic and U.S. Gulf coasts.

(5) There are at least six ways of visually identifying the presence of underlying consolidated cohesive sediment, which would distinguish a consolidated cohesive shore from a sandy shore. A series of photos of a transgressive shoreline along the east coast of Ghana in West Africa provide examples of the different types of evidence which may indicate the presence of cohesive sediment under a sand beach. Long-term recession rates along this 7-km section of the Ghanaian coast are in the range of 2 to 8 m/year. The six distinguishing features are:

(a) The most straightforward evidence is the presence of exposed cohesive sediment on the beach. Figure III-5-2 shows a large expanse of peat exposed on the beach in Ghana. Such exposures may be infrequent and result from severe erosion events (where the overlying sand is stripped and carried offshore) or may appear between large alongshore sand waves.

(b) Pieces of clay or peat on the beach. Figure III-5-3 shows some angular clay blocks that have been removed from the seabed and transported towards the shore, along with some pieces of rubble from old buildings that have been destroyed by erosion. In many locations, clay balls can be found along the shoreline. The more rounded clay pieces probably result from transport over a greater distance, i.e., the exposed cohesive sediment may not be located in the immediate vicinity of where the clay balls are found.

Figure III-5-2. Peat exposed on a beach along the Keta shoreline in Ghana, West Africa, May 1996

Figure III-5-3. Pieces of eroded clay (and some rubble) scattered on a beach along the Keta shoreline in Ghana, West Africa, September 1996

(c) Springs or surface runoff across a beach. Figure III-5-4 shows springs near the waterline along the beach in Ghana which result from groundwater flow over the impervious underlying clay and peat sediments. In this case, the groundwater flow gradient is driven by the presence of an enclosed lagoon with water levels higher than mean sea levels on the other side of the washover terrace.

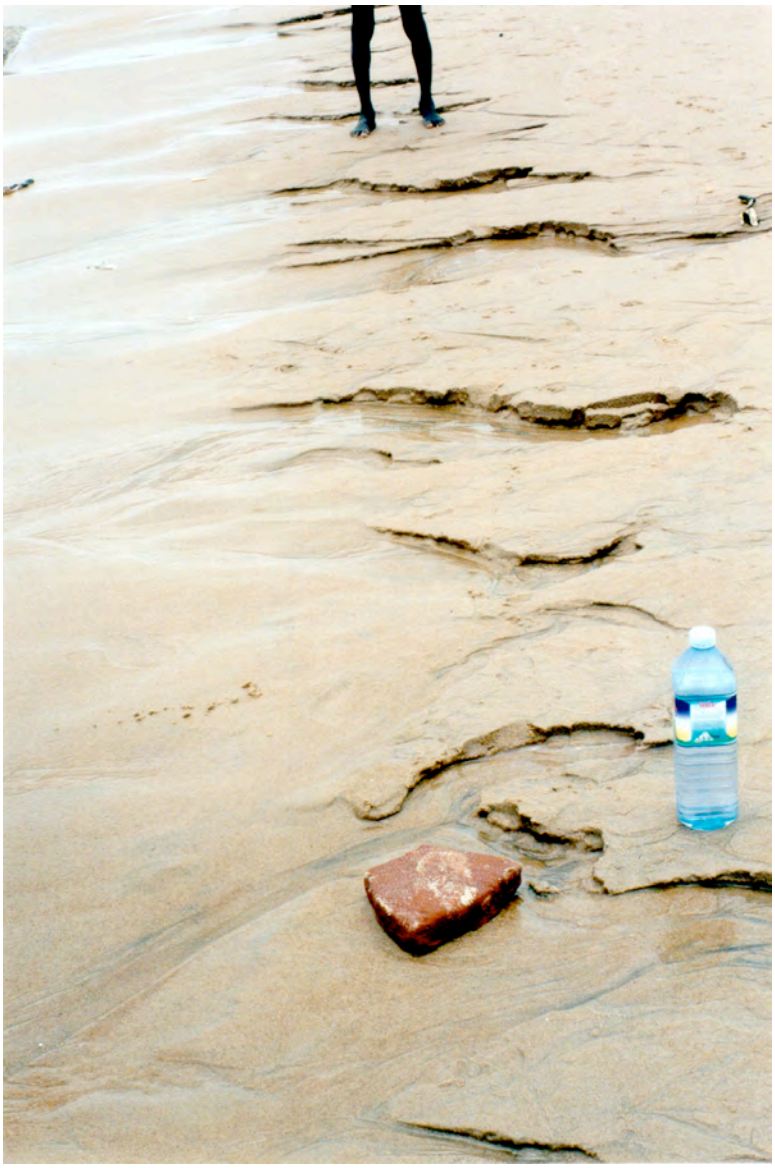

Figure III-5-4. Springs flowing over the beach surface along the Keta shoreline in Ghana, West Africa, September 1996

(d) Discoloration of water in the nearshore zone. Along eroding bluff shorelines, the water takes on the color of the bluff sediment in response to wave attack. Figure III-5-5 shows discoloration of the seawater near the shoreline caused by erosion of underlying lagoon sediments along the Ghana shoreline. At this location, this was the first evidence that easily erodible cohesive sediments existed in the nearshore zone.

(e) Permanent undulations in the shoreline planform may also signify the presence of cohesive or consolidated sediments in the nearshore zone with alongshore variability in erosion resistance. These features are best identified through oblique or overhead aerial photographs. An example along the Ghana

Figure III-5-5. Discolored water from erosion of exposed cohesive sediment along the Keta shoreline in Ghana, West Africa, July 1996

coast is shown in Figure III-5-6. These same undulations could be seen at the same location in several aerial photos taken over a 35-year period. Therefore, these features are distinguished from migrating alongshore sand waves which also occur here. Subsurface investigations at this location have subsequently revealed considerable alongshore variability in the stratigraphy of the underlying sediments, possibly relating to the presence of old channels into the lagoon inshore of the present beach.

(f) Finally, exposed cohesive sediments can often be identified in the troughs between offshore bars through a swimming or diving survey.

(6) At the site in Ghana, subsequent to the initial visual observations of evidence of the presence of underlying cohesive sediments, a series of subsurface investigations was completed to define these conditions. These included augers, boreholes, vibracores and sub-bottom profiling. Use of more detailed subsurface investigations to confirm visual observations and provide more detailed information is discussed in Part III-5-6.

b. Mud shore. Unconsolidated mud coasts are generally the result of more recent deposition of cohesive sediment. Deposition requires quiet or calm hydrodynamic conditions, where large waves are rare. Muddy shore naturally occurs as mud flats and coastal wetlands in protected waters, such as estuaries and other embayments with short fetches.

(1) Mud flat. Generally without vegetation, lying below high water in tidal areas (Figure III-5-7).

(2) Coastal Wetland. Salt marsh in saltwater, stabilized by vegetation, generally above low water in tidal areas, often above mud flats (Figure III-5-8) and mangrove. Marsh vegetation stabilizes the mud bed and provides shelter in which more sediment can deposit.

Figure III-5-6. Permanent undulations in the Keta shoreline in Ghana, West Africa, July 1996

Figure III-5-7. Mud flat in Cumberland Basin, Bay of Fundy, Canada, showing drainage gullies

Figure III-5-8. A mud 'beach' backed with eroding salt marsh at Annapolis Royal, in the Annapolis Bay of the Bay of Fundy. Basalt revetment at top of salt marsh is an attempt to halt the erosion

(3) Mangrove. Tropical coastal wetland where the vegetation, in the form of trees, can withstand relatively severe wave attack (Figure III-5-9). Depth-limited waves will penetrate a mangrove, eroding mud from around the root system in extreme storms, and endangering individual trees. Mangrove can be found between mud flats and salt marsh, and can transmit waves, which erode the adjacent salt marsh behind it.

(4) Mud 'beach.' A sloping mud shore, exposed to wave attack often following the destruction of mangrove or other wetland vegetation (Figure III-5-8). The usual cause of wetland or mangrove destruction is property developers, municipal agencies, and individuals wishing to 'reclaim' the shore. Natural destruction occurs from the seaward edge, through undermining of the root system by waves and currents.

III-5-3. Erosion Processes on Consolidated Shores

a. Erosion processes on cohesive shores are distinctly different from those on sandy shores. There are also differences between consolidated and mud cohesive shores. On consolidated shores, the erosion process is irreversible because, once eroded, the cohesive sediment (e.g., glacial till, glacio-lacustrine deposits, ice bonded sediments, soft rock or other consolidated deposits) cannot be reconstituted in their consolidated form in the energetic coastal environment. Furthermore, since the sand and gravel content is low in these deposits (often less than 20 percent), erosion is not balanced by an equal volume of deposition within the littoral zone. The eroded fine sediments (silt and clay) are winnowed, carried offshore, and deposited in deep water in contrast to the sand fraction, which usually remains in the littoral zone.

Figure III-5-9. Sand beach disappearing into mangrove on the island of Borneo. Sediment within the mangrove is cohesive mud

b. Consolidated cohesive sediment is eroded by at least four mechanisms:

(1) Through abrasion by sand particles moved by waves and low currents.

(2) Through pressure fluctuations associated with turbulence generated at various scales such as wave-breaking-induced turbulence that reaches the lake or seabed and large-scale eddies that may develop in the surf zone.

(3) Through chemical and biological influences.

(4) Through wet/dry and freeze/thaw cycles where exposed to the atmosphere.

c. Sand can also provide a protective cover to the underlying cohesive substratum. However, only when the sand cover is sufficient to protect the cohesive substratum at all times will the shore revert to a sandy classification (i.e., truly a 'thick pile of sand').

d. On consolidated cohesive shores, the rate of lake or seabed downcutting determines the long-term rate at which the bluff or cliff retreats at the shoreline. In other words, while subaerial geotechnical processes may dictate when and where a slope failure will occur, the frequency of failures over the long term is determined by the rate at which the nearshore profile is eroded (i.e. the downcutting rate). Subaqueous and subaerial erosion processes on cohesive shores are discussed in detail in Part III-5-7. In addition, the geomorphology of cohesive shores and the relationship to erosion processes is the topic of Part III-5-5.

III-5-4. Physical and Numerical Modeling

a. Laboratory or physical model experiments have been used in two ways: (1) to improve the understanding of the fundamental principles of cohesive shore erosion processes, and (2) to develop a measure of the erodibility of specific samples of cohesive sediment.

b. In the former category, scale model tests have been performed in wave flumes as described by Sunamura (1975, 1976 and 1992) for erodible rocky coasts similar to consolidated cohesive behavior, by Nairn (1986) for a section of the Lake Erie shoreline using an artificial clay, and by Skafel and Bishop (1994) and Skafel (1995) using intact samples of till removed from the Lake Erie shoreline. The tests described by Skafel and Bishop (1994) included an assessment of the relationship between wave properties (e.g., wave height, orbital velocity, type and fraction of broken waves) and local erosion rate and the relationship between sand cover and erosion rates. Laboratory experiments on erosion and deposition of mud are described in Part III-5-6c(9). The annular flume, used in both the laboratory and the field (e.g., Amos et al. 1992, Krishnappan 1993) may be regarded as a full-scale model of the response of a mud bed to shear.

c. The primary difficulty in the use of physical model experiments of cohesive shores is the scaling of the cohesive material. At present, it is not possible to accurately scale cohesive sediment with respect to its erosion resistance properties. Therefore, model tests must be interpreted qualitatively, or full-scale tests must be conducted using low wave energy conditions. Nevertheless, the noted tests have been extremely valuable in advancing the understanding of cohesive shore erosion processes both inside and outside the surf zone.

d. A technique of assessing the erodibility of intact samples of consolidated cohesive sediment in unidirectional flow conditions has been developed and applied by Kamphuis (1990), and, more recently, for the assessment of cohesive sediment samples removed from the southeast shoreline of Lake Michigan (Parson, Morang, and Nairn 1996). These tests are typically performed for both clear water and sand in flow conditions to elucidate the importance of sand as an abrasive agent. This approach for defining the erodibility of cohesive sediment samples is discussed in more detail in Part III-5-7b.

e. The development and application of numerical models for describing erosion processes on cohesive shores is not far advanced owing to the complexity of the processes involved. Most numerical models may be described as little more than numerical frameworks for interpolating or extrapolating observed behavior of cohesive sediments in water. Essentially, a numerical model of cohesive shore erosion must define the near-bed flow conditions within the surf zone, the movement of any overlying noncohesive sediment cover, as well as the erosion resistance properties of the cohesive sediment (which change with time due to exposure of sediment layers and subaerial drying). Numerical modeling of cohesive shores is summarized in Part III-5-12.

f. The best 3-D numerical mud models (e.g. Le Hir 1994) treat the water column as a continuum: from stationary consolidating bed, through fluid mud, to sediment maintained in suspension by turbulence. There are nevertheless bed sediment ‘modules,’ which use the equations presented in Parts III-5-7, 9, and 10 to calculate erosion and deposition, supplying sediment and new bathymetry to numerical hydrodynamic models that transport the sediment by advection and dispersion (Part III-5-8a).

g. All mud models need to track sediment layering - the composition and state of each sediment layer at each grid point in the model — more a bookkeeping function than numerical modeling.

h. Part III-5-13 provides some detailed guidance on the specific coastal engineering and management issues associated with cohesive shores. The success of engineering and management techniques on cohesive shores is dependent on a recognition of the fundamental differences between sandy and cohesive shore processes. Engineering techniques that may have been successful on the more familiar sandy shores, may be unsuitable or inappropriate along cohesive shores.

III-5-5. Geomorphology of Consolidated Shores

This section provides a review of the geomorphology of cohesive shores and the relationship between the land forms and the erosion processes discussed in the previous sections. The discussion is subdivided under two headings: "Controlling Factors" and "Profile Types." This section focuses on the geomorphology of consolidated cohesive sediment shores. For more detail on erosion processes along rocky coasts, refer to Sunamura (1992).

a. Controlling factors. The primary controlling factors discussed in the following paragraphs influence the geomorphology of cohesive shores:

(1) Lag deposits.

(a) Some consolidated cohesive sediment units have cobbles or boulders within their composition. For example, along the Great Lakes, glacial till may be either fine-grained or stony (i.e., containing gravel and cobbles). During the evolution of stony till shores, the cobbles and boulders that are left behind after the removal of the finer clay, silt, and sand build up to form a protective armor for the underlying till. In these cases, an erosion-resistant nearshore shelf will usually have formed. The depth of the shelf at any location is such that the lag deposit remains immobile, and therefore the depth is determined by the local wave climate and the grain size of the lag deposit. Generally, for the Great Lakes, the depth of this shelf is approximately 2 m below low water datum. Along sea and ocean coasts with large tidal ranges and longer waves, lag deposits may occur at much greater depths (e.g., lag deposits over clay have been found in water depths of 10 m below datum along the North Sea coast of England). The shelf creates what has been referred to as a convex profile, in contrast to the concave profile associated with situations where lags are not present.

(b) The armored shelf acts to dissipate wave energy, and therefore reduce or even prevent bluff erosion. Boyd (1992) gives several examples where a bluff is protected from erosion by a nearshore shelf and notes that the reduced wave energy may also allow a stable beach to exist at the shore, providing additional protection to the bluff toe. Natural headlands along an eroding cohesive shoreline often owe their existence to the presence of a lag-protected nearshore shelf.

(c) An example of a site where a lag deposit has resulted in an erosion-resistant foreshore and a stable shoreline is located near the town of Goderich on the Canadian shore of Lake Huron. A nearshore profile for this site is shown in Figure III-5-10. The cobble-protected shelf has a depth of 1.75 m and is about 200 m wide. The stratigraphy at the site consists of a stony till unit below the average lake level and a fine-grained till unit above the average lake level. At nearby sites where the fine-grained till unit dips below the average lake level to depths of greater than 2 m, and the nearshore shelf is no longer present, the bluff recession rates range from 0.3 m/year to over 1 m/year.

(2) Different stratigraphic units.

(a) Along most cohesive shores, 3-D variations in contact surfaces between stratigraphic units are common. This results from the complex geomorphologic conditions that formed the underlying geology, which, depending on the location, may include some combination of: glacial, lacustrine, estuarine, or fluvial

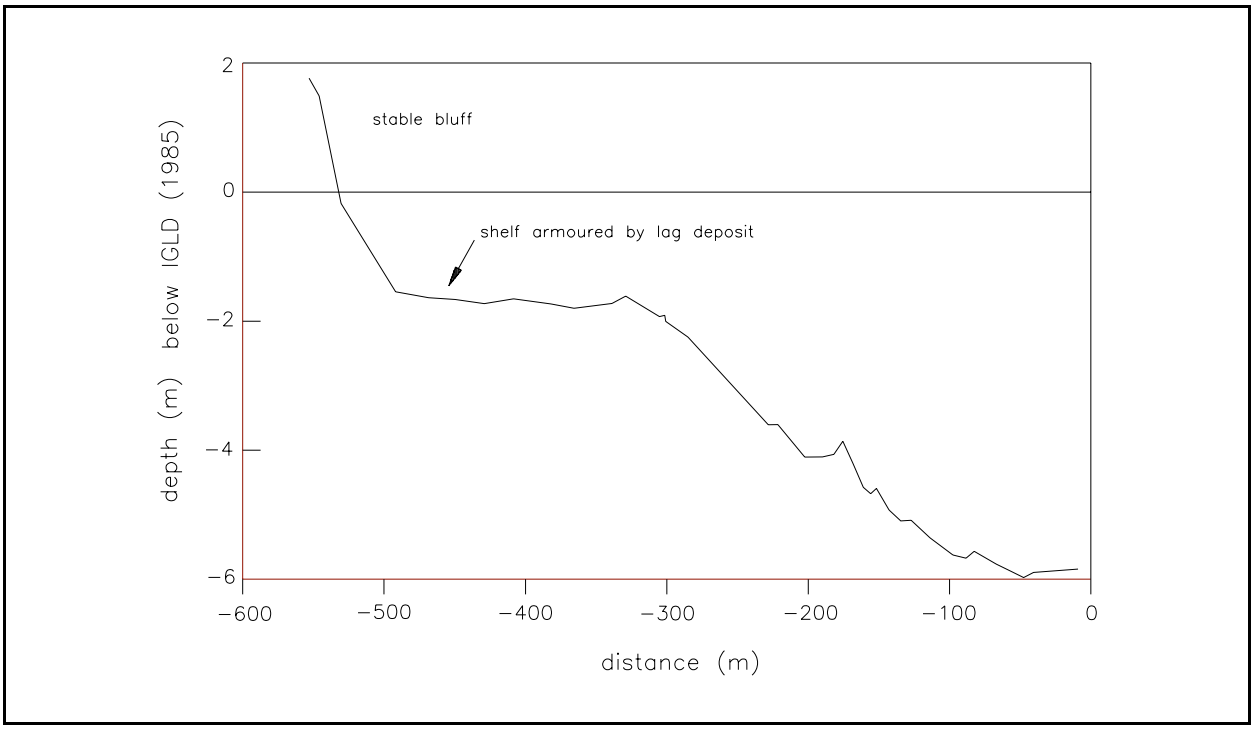

Figure III-5-10. A convex consolidated cohesive profile with a shelf protected by lag deposits located near Goderich, Ontario, on Lake Huron

processes. Therefore, as the shore erodes in time, the recession rates can change, as either more or less erosion resistant, units are encountered further inland. One example of the influence of erosion resistance is East Point located along the Scarborough Bluffs east of Toronto on Lake Ontario. The plan and stratigraphy cross section of this feature are shown in Figure III-5-11. Clearly, East Point is an expression of the more erosion-resistant Leaside (or northern) till unit, which dips below the average lake level at this location. Leaside till is relatively hard and includes boulder pavements (Boyce, Eyles, and Pugin 1995). Along the neighboring shore, the less erosion-resistant Scarborough clay unit exists below the lake level.

(b) Recognition of the variation in erosion resistance of different till units resulted in an unlikely finding during the investigation of the influence of a harbor structure at Port Burwell on downdrift erosion along the north central shore of Lake Erie (Figure III-5-12). A long harbor jetty here intercepts almost all of the sand moving along the shore from west to east, therefore depriving the downdrift shore of sediment. On a sandy shore, this would be a clear case of downdrift erosion due to sediment supply starvation. However, the investigation described by Philpott (1984) revealed that cohesive shores along the north central shore of Lake Erie seldom have (and probably never had) enough sand to halt the downcutting of the underlying till. Updrift of the harbor, the trapping of large quantities of sand eventually halted the nearshore profile downcutting, and the bluff position was stabilized. However, this still did not fully explain why recession rates updrift of the harbor fillet beach were generally lower (about 1 m/year) than those on the downdrift shoreline to the east (in the range of 2 to 4 m/year).

(c) Figure III-5-12 also describes the bluff face stratigraphy at Port Burwell. There is a change in the subaqueous stratigraphic unit at the harbor mouth, where Port Stanley till exists below the lake level on the updrift side and Waterlain till forms the nearshore profile on the downdrift side. Based on a comprehensive investigation, including laboratory testing of the erodibility of the different till units, it was concluded that Waterlain till was less erosion-resistant than the Port Stanley till. It is not coincidental that the change in till

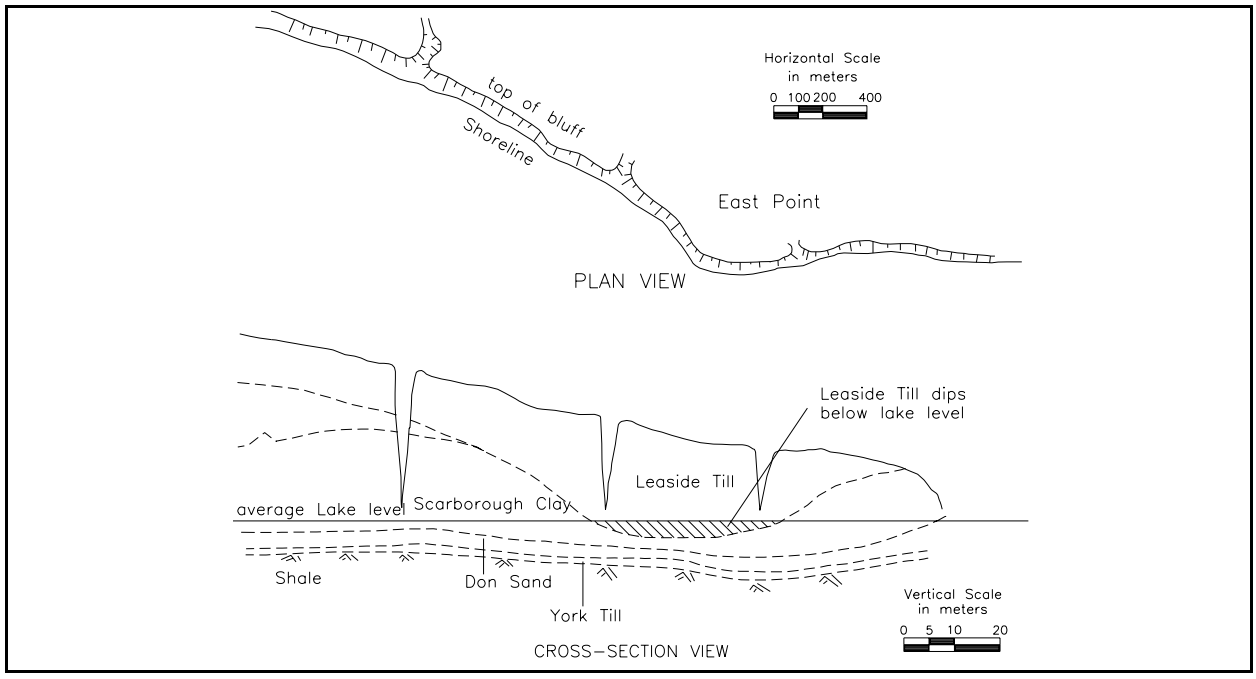

Figure III-5-11. Plan and cross section of East Point along the Scarborough Bluffs (located east of Toronto on Lake Ontario) showing the influence of the erosion-resistant leaside (or northern) till on the local geomorphology

occurred at the harbor mouth, as often creeks or rivers follow the interface between different stratigraphic units.

(d) Riggs, Cleary, and Snyder (1995) provide several examples of both headlands (local areas of slowly retreating or stable shoreline) and local sections of rapidly retreating shoreline, that are a direct result of variability in the erosion resistance of different stratigraphic units that make up the shoreface. They found that headlands result from the presence in the nearshore of more erosion-resistant Pleistocene or older sediments. In contrast, rapidly retreating sections of shore consisted of sand-poor, valley-fill sediment or compact peats and clays deposited in modern estuarine environments.

(3) Quantity and mobility of sand cover.

(a) In natural situations, a protective sand cover can build up over an erodible substrate and protect it from further erosion. Investigations of Great Lakes sites have shown that approximately 200 m^3/m of sand cover (measured from the top of the beach out to the 4-m contour) is required to halt the downcutting process (Nairn 1992). However, even half as much as this quantity can afford at least some protection to the underlying cohesive substratum.

(b) Another important factor is the volatility or mobility of sand cover. If the overlying noncohesive bed forms are rapidly and frequently changing position, the underlying cohesive substratum will be exposed to erosive situations more frequently. Nairn and Parson (1995) have indicated that on the Great Lakes, the shift of bar position in response to changing lake levels has an important influence on the exposure of the underlying till (in the troughs between the bars) to erosion. On an eroding cohesive bluff shore along the North Sea coast of England, Pringle (1985) identified alongshore migrating areas of reduced beach cover and exposed glacial till called 'Ords.' These Ords have an important role in exposing the underlying glacial till to erosion. Figure III-5-13 shows an Ord on the Holderness coast at low tide with glacial till exposed (partly

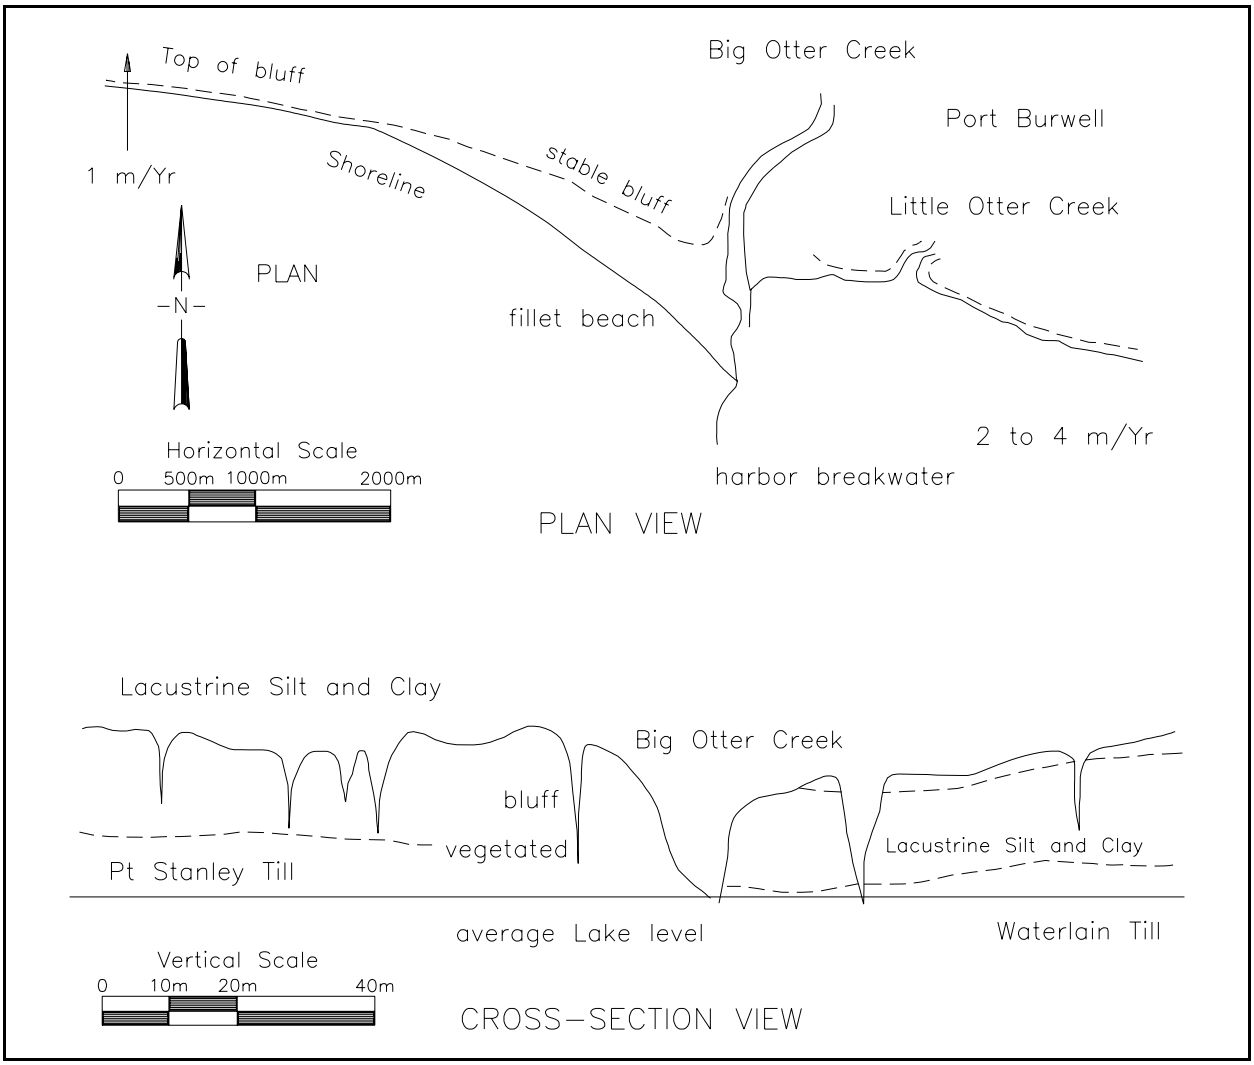

Figure III-5-12. Plan and cross section of the Port Burwell area on the north central shore of Lake Erie showing the influence of a fillet beach and stratigraphy changes on the geomorphology of a cohesive shore

covered with cobbles) between the upper coarse sand beach and a bar consisting of finer sand. The closeup photo of the Ord (Figure III-5-14) shows erosion of the exposed till around a 10-cm-high pedestal protected by a rock cap. Pringle (1985) found that the migration rate for these features was approximately 500 m/year, which is similar to the rate of migration for large sand waves or rhythmic features along Long Island, NY (Thevenot and Kraus 1995). An Ord could be defined as the area between two migrating sand waves. In summary, both cross-shore and alongshore variations in sand cover thickness resulting from migration of bars and sand waves or Ords, respectively, have an important influence on the rate of cohesive sediment erosion in the nearshore zone.

(c) Deposition of large quantities of sand over a cohesive substrate can occur at a change in shoreline orientation where the potential alongshore sediment transport rate rapidly decreases, or at a natural obstruction to alongshore transport, such as at a rock headland. Other instances where sand may eventually build up to protect a profile include sites where the alongshore transport of sediment is intercepted at a harbor jetty. The Port Burwell fillet beach shown in Figure III-5-6, as discussed above, protects the nearshore cohesive substratum and has stopped the bluff recession behind the fillet beach.

Figure III-5-13. Bluff erosion along the Holderness coast of the North Sea. The underlying cohesive profile is exposed at low tide in a trough (referred to as an "Ord") between the upper beach and first bar

Figure III-5-14. Close-up of the exposed cohesive profile on the Holderness coast (Figure III-5-13). A rock-capped pedestal of cohesive sediment, about 10 cm in height, has developed through erosion of the adjacent seabed

(d) Many areas along the Great Lakes shores that once had sufficient sand cover to protect an underlying cohesive substratum from downcutting are now coming under attack as the sediment supply has been reduced through human influences. Reductions to the sediment supply occur through entrapment of sediment at structures which protrude into the lake (including harbor jetties and land reclamation projects that have been created for many purposes, such as power plants, marinas, and docking facilities) as well as through protection of previously eroding sections of shoreline. Shabica and Pranschke (1994) describe one such area north of Chicago on Lake Michigan where the sand cover has decreased from 560 m^3/m in 1975 to 190 m^3/m in 1989. If the depletion of sediment cover continues at this site, the previously very low rates of shoreline recession (less than 0.2 m/year, or 8 in./year) may accelerate.

(4) Local wave and water level conditions. The characteristics of the local wave and water level conditions represent the fourth controlling factor on the geomorphology of consolidated cohesive coasts. Both the intensity and the directionality of the waves can influence the rate of erosion at a particular shore site. Other factors being equal, greater wave energy translates to higher downcutting rates and more rapid shoreline erosion. Directionality of the waves can have a secondary influence on downcutting rates by affecting the mobility of the sand cover over the underlying till. Large swings in wave direction can result in a more dynamic system with respect to the sediment cover. Fluctuations in water level also have an important role in cohesive shore erosion processes as explained by Stewart and Pope (1993) and Fuller (1995). While direct erosion at the bluff toe may be accelerated during high-water conditions, low water leads to acceleration of the nearshore downcutting process (which in turn allows more waves to reach the bluff toe).

b. Profile types. Boyd (1981, 1992) completed an extensive review of nearshore profile shapes for consolidated cohesive shores on the Great Lakes. These essentially fall into two categories: concave profiles and convex profiles. Figure III-5-15 provides a schematic description of these two profile types.

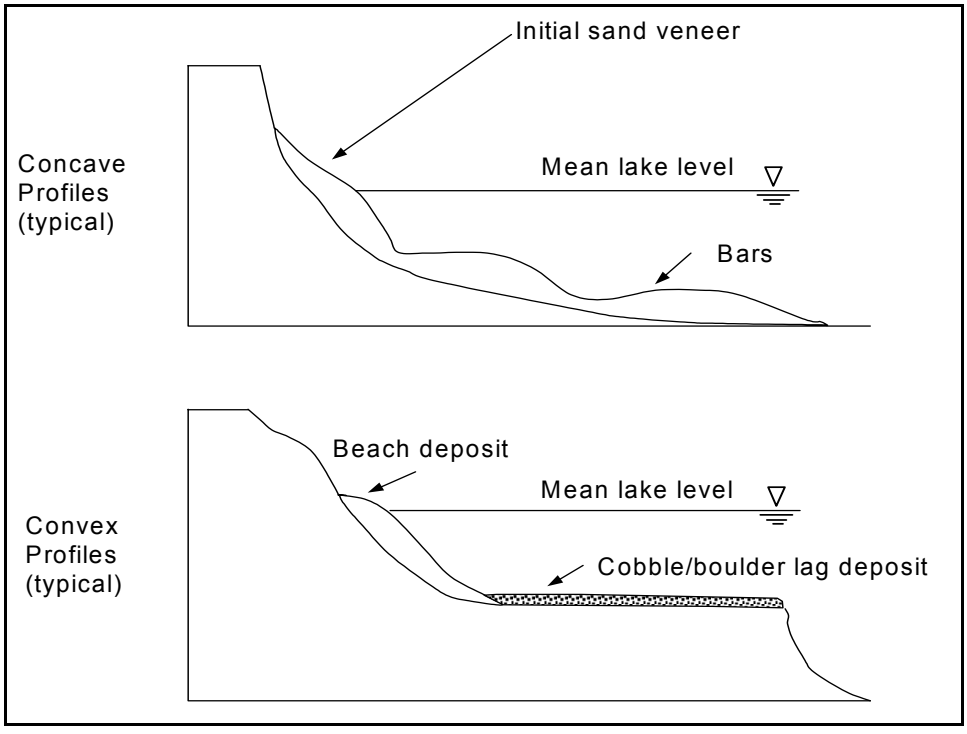

Figure III-5-15. Distinctions between concave and convex consolidated cohesive profiles

(1) Concave profiles. Concave profiles develop in fine-grained sediment with a relatively uniform erosion resistance from the closure point up to the top of the bluff or cliff. These profiles have an exponential form similar to sandy shore profiles described by Dean (1977). Sand cover over these cohesive profiles can range from perhaps as little as 25 to over 200 m^3/m measured between the bluff toe and the 4-m depth contour. The sand cover can be in the form of bars, and, in areas with a sand cover in the high end of the range, a substantial beach at the shore. Stewart and Pope (1993) found that a reduction in the range of water level fluctuations would not reduce the long-term erosion rates for cohesive shores with concave profiles. As explained above, lower water levels result in accelerated lowering of the nearshore profile, which essentially has the same effect as high water levels — allowing waves to reach the bluff toe.

(2) Convex profiles. As noted above, convex profiles develop at locations where potential lag deposits exist within the eroding material. These profiles are characterized by a nearshore shelf, which on the Great Lakes has a depth approximately 2 m below low water datum. At other locations, this depth will be determined by the median grain size of the lag deposit, the wave climate, and the range of water level fluctuations. Long-term erosion rates along these shores are less than rates for concave cohesive shores (having limited sand cover) with the same wave exposure. With the exception of high-water periods, the erosion-resistant nearshore shelf acts to dissipate wave energy before it reaches the shoreline. However, during high water periods, these shorelines are more vulnerable to erosion when waves are able to attack the bluff toe. Therefore, in contrast to cohesive shores with concave profiles, shores with convex profiles would benefit from a reduction in the range of water level fluctuations (Stewart and Pope 1993). Finally, the fish habitat function of cohesive shores with a convex profile shape is much more important owing to the surficial substrate (cobbles and boulders with limited sand cover) and the proximity to a deepwater drop-off at the edge of the shelf.

III-5-6. Sediment Properties and Measurement Techniques

a. Introduction.

(1) In the case of noncohesive sand and gravel, sediment mobility can be estimated just by knowing the grain size and shape, specific gravities of the sediment and water, and the viscosity or temperature of the water (i.e., physical properties). The mobility of cohesive sediment is a more complex phenomenon. Cohesion (particle attraction) is governed by the electrochemistry of the sediment mineral and water; its state of consolidation; and in many cases, by the presence of organisms like diatoms, which can bind the sediment particles together with mucus.

(2) The extent of data requirements will vary depending on the nature of the coastal engineering problem and the nature of the shore. This section presents an overview of the range of possible field and laboratory investigations that can be used to characterize the conditions associated with erosion, transport, deposition, and consolidation on a cohesive shore. This discussion focuses on a characterization of the specific geologic conditions related to the cohesive shore. For the measurement of environmental conditions (e.g., waves and water levels), refer to Part II-3.

b. Consolidated shore erosion. Developing an understanding of consolidated shore erosion requires information on profile shape (beach and nearshore profile techniques are summarized in Part III-3-2), presence or absence of lag deposits, bluff and nearshore stratigraphy, erodibility of the one or more cohesive units in the active nearshore erosion zone (i.e., between high water and the depth of closure), and the sand cover thickness and stability. Available techniques to assess the characteristics listed above are as follows:

(1) Field sampling and geotechnical analyses.

(a) Testing may be performed in situ or in a laboratory on samples extracted from the field. Extraction techniques for seabed or lake bed cohesive sediments include: dredging; coring; box coring; and cutting samples (the latter using a chainsaw with a trenching chain). As noted in Part III-5-6, it is important to retrieve intact samples that, to the extent possible, preserve the natural structure of the cohesive sediment.

(b) None of the available standard geotechnical test procedures provide a direct measure of the erosion resistance of a cohesive sediment in the coastal environment. Nevertheless, the more important characteristics that provide an indirect assessment of erodibility include: grain size analysis (including clay content); liquid and plastic limits; water content; undrained shear strength; bulk density; and consolidation pressure. Techniques for establishing these parameters are presented in the USACE Engineering Manual "Laboratory Soils Testing" (EM 1110-2-1906). Undrained shear strength can be determined in the field using a cone penetrometer or a vane shear apparatus.

(c) Borehole information can be valuable for assessing variations in stratigraphy both above and below the water level.

(2) Laboratory erodibility experiments.

(a) There are no standard and accepted approaches for establishing the erodibility of cohesive sediment in the coastal environment based on geotechnical properties. Therefore, to quantify the relationship between erodibility and shear stress applied under a given flow condition, it is usually necessary to perform laboratory experiments. Experiments may not be required where direct techniques have been applied to determine the erodibility of similar sediment. It is advisable that these experiments be performed with intact, and to the extent possible, undisturbed samples of cohesive sediment in order to preserve the natural structure of the soil.

(b) Four laboratory techniques for assessing erodibility are briefly reviewed in this section. These provide an example of the range of techniques that are available.

(c) Arulanandan, Loganatham, and Krone (1975), and more recently Zeman (1986), describe the use of a rotating cylinder apparatus to assess the erodibility of intact and undisturbed samples of cohesive sediment. This technique is also mentioned for testing the erodibility of mud. In this approach, a long cylindrical sample is mounted inside a larger transparent cell. The cell is then filled with water and rotated. During rotation, the torque transmitted to the inside stationary cylinder is measured to quantify the shear stress applied to the sample. At the end of the test, erosion rates are determined by the loss in mass of the sample. A disadvantage of this approach is the inability to introduce sand to the flow to assess the important influence of sand abrasion.

(d) Another small-scale laboratory technique for testing intact and undisturbed samples is described by Rohan et al. (1986). This procedure is based on an adaptation of the standard pinhole test. Water is circulated through a hole drilled through the axis of a cylindrical sample. The head loss caused by friction in the sample is measured using differential manometers in order to assess the shear stress applied to the soil by the flow. Depending on the size of the hole bored in the sample, it is possible that this technique could be adapted to assess the influence on erosion of sand in the flow.

(e) At a larger scale, intact and undisturbed cohesive sediment samples can be placed in a drop section in the floor of a unidirectional flow flume or tunnel. The sample is then exposed to different flow conditions with and without the presence of sand, and the erosion of the sample surface is surveyed intermittently to determine erosion rates for the different conditions. This technique is also frequently used for mud. Kamphuis (1990) describes the use of a tilting tunnel in which Pitot tubes were used to determine a velocity

profile upstream and downstream of the sample in order to determine the shear stress applied to the sample by the flow. Cornett, Sigouin, and Davies (1994) describe a similar approach using a tilting flume for the analysis of samples extracted from the bed of Lake Michigan near St. Joseph Harbor (Parson, Morang, and Nairn 1996). In this case, a laser doppler velocimeter measured the velocity profile near the bed in order to establish the shear stress applied to the sample by the flow (Figure III-5-16). This figure shows a sand veneer migrating over the till sample in the unidirectional flow flume. In both the Kamphuis (1990) and the Cornett, Sigouin, and Davies (1994) tests, the maximum flows generated were in the range of 3 to 3.5 m/sec (10 to 12 ft/sec). Results from experiments using this technique to estimate erodibility are presented in Part III-5-7b.

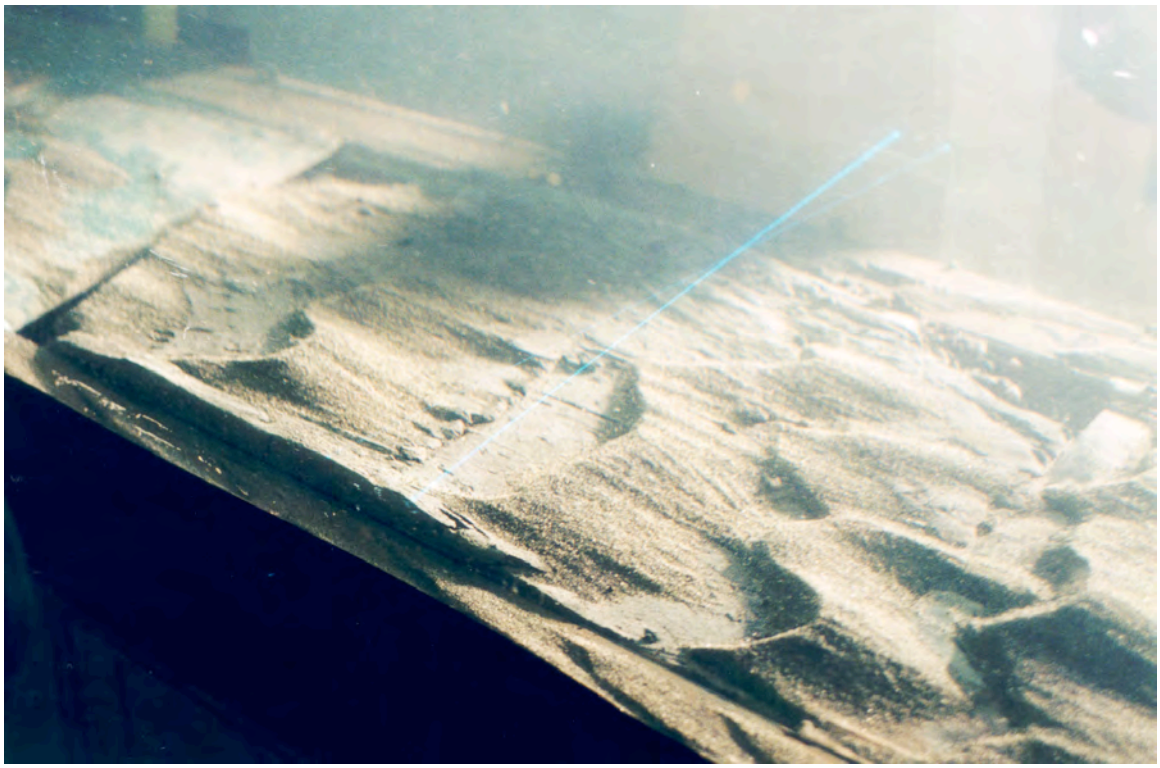

Figure III-5-16. Laser doppler velocimeter (LDV) used to determine shear stress exerted on the till bed in a unidirectional flow flume test. This test features sand in the flow acting as an abrasive

(f) The most realistic approach that can be taken to assess erodibility in a laboratory setting is to create a nearshore profile with intact and undisturbed cohesive sediment samples in a wave flume or basin. This approach was used by Skafel and Bishop (1994) to complete important research into the erosion processes on cohesive shores. Intact samples, measuring 1 m by 0.35 m by 0.45 m, encased in an open-ended steel box were extracted from the top of a bluff on Lake Erie and placed directly in a wave flume. The open-ended steel box was pushed slowly into the till by a 20-ton hydraulic ram and the till at the inner end of the box was cut away using a chainsaw with a trenching chain. The box was then removed with a crane. The till boxes were installed in the flume to create the desired profile shape. In these tests, the effects of sand cover in the form of migrating bars or a patchy veneer were tested. Also, the influence of breaking waves on the erosion of the cohesive sediment was assessed.

(3) Field techniques for assessing surface and subsurface conditions.

(a) One of the most important pieces of information in characterizing a cohesive shore profile is the sand cover thickness across the underlying cohesive profile (i.e., measured from the bluff toe out to a depth of at least 4 m). In addition, where the cohesive profile is exposed, it is also important to determine whether or not a protective lag deposit exists. As with any coastal engineering site investigation, beach and nearshore profiles are essential information. In this section, a variety of techniques for characterizing the surface and subsurface conditions, with particular focus on the sand cover thickness, are presented, ranging from the simplest to the most sophisticated.

(b) The simplest technique of estimating the thickness of the sand cover across the profile involves the following tasks:

- Complete a beach and nearshore profile from the toe of the bluff out to the depth of closure (between the 5- and 10-m water depth).

- Through the use of a steel probe or test pits, attempt to determine the thickness of sand cover near the waterline.

- Estimate the shape of the underlying cohesive profile (as a smooth exponential form) joining points between the toe of the bluff, the position of the till at the waterline (if determinable), and the troughs between the bars on the profile. Typically, the till will be exposed or only thinly covered in the troughs. If repeated profiles are available at a site, these may provide additional information on the position of the underlying till if the position of the troughs between bars shifts between surveys.

(c) In order to complement the simple technique described above, a diving inspection could be completed across the profile. The diver could use an underwater video to document conditions, and a steel probe to estimate sand cover thickness at different locations. Depending on the extent of sand cover, the till may be exposed in some areas. Alternatively, a frame-mounted video camera lowered from a boat or a remotely operated vehicle with video could be used. Video is also valuable in assessing whether or not a lag deposit exists where the cohesive layer is exposed.

(d) In place of a simple steel probe, a jet probe could be used to survey the thickness of the sand cover on the land and underwater. A jet of either water or air can be used to penetrate the sand cover (the latter is only applicable underwater). Shabica and Pranschke (1994) describe the use of a hydraulic probe consisting of an extendible 20 mm diameter pipe through which water is pumped at 2.8 kg/cm^2 (40 psi).

(e) A technique based on electrical resistivity has been used to establish the sand thickness across the subaerial section of beach for sections of the Holderness shoreline. This method is particularly useful at locations with large tidal ranges that allow for significant sections of the profile to be surveyed at low tide.

(f) Ground-penetrating radar was used to survey the thickness of the sand cover for several profiles downdrift of St. Joseph Harbor (Parson, Morang, and Nairn 1996). The limitation of this technique is that it can only be used in a freshwater environment.

(g) Sub-bottom profiling, or high-frequency seismic imaging, is another geophysical technique that is capable of establishing the thickness of sand cover over an underlying cohesive profile. Side-scan sonar is an acoustic technique that provides an image of the seabed or lake bed surficial conditions. While this procedure would not be capable of determining the thickness of sand cover, it could provide useful surficial information such as the extent of exposed gravel and cobble lag deposits. These methods are described in Part IV-5 in greater detail.

c. Erosion, transport, and deposition of mud. In the case of mud, it is useful first to examine the following hydrodynamic sediment properties that will be required by the equations presented later:

(1) Cohesion. The cohesive bond is predominantly electrochemical, increasing with the electrical conductivity of the ambient water and proximity of the particles. Conductivity increases with salinity. The bond between particles may be enhanced, particularly at rest on the bed, by biological 'glues' such as the mucus excreted by diatoms, worm tubes, and feces (Paterson 1994).

(2) Critical shear for erosion.

(a) As water flows over the mud bed, as either steady flow or oscillatory flow under tides and waves, it exerts a shear stress τ on the bed due to viscosity and turbulence (described in greater detail in Part III-6). Not only is shear a real physical stress on the bed sediment, but it also serves as empirical shorthand for the level of turbulence in the flow. Thus, it is a useful parameter in describing suspended load sediment transport; as well as fluid mud (bed load), erosion, and deposition.

(b) At the level of a stationary particle on the bed, shear forces are balanced by the forces of gravity, interparticle friction, and cohesion. Shear is augmented by lift and drag, making the force balance

$$\text{SHEAR} + \text{LIFT} + \text{DRAG} < \text{GRAVITY} + \text{FRICTION} + \text{COHESION}$$

a vector sum, the same as that for noncohesive sand and gravel, but with the addition of cohesion. As flow increases, the left-hand side of this balance increases approximately as the square of velocity, until

$$\text{SHEAR} + \text{LIFT} + \text{DRAG} = \text{GRAVITY} + \text{FRICTION} + \text{COHESION}$$

and the formerly stationary particle leaves the bed and begins to move. The shear stress at which this occurs is known as the *critical shear for erosion* or *erosion threshold* τ_c. τ_c is still shorthand for the entire left-hand side of the balance, not shear alone.

(c) The sediment 'particle' may be an individual grain; but more likely a floc, made up of several grains held together by cohesion. Cohesion plays the major role in the right-hand side of the force balance, and failure (erosion) will occur where cohesion is weakest.

(d) Critical shear τ_c is not a particularly useful concept in fluid mud. At the water/fluid mud interface, the applied shear stress is balanced by a shear strain (flow) of the fluid mud, rather than GRAVITY + FRICTION + COHESION. Also, the fluid mud is essentially a thick, viscous, laminar, boundary layer, protecting the stationary bed from any SHEAR + LIFT + DRAG approaching τ_c. Erosion of fluid mud is better described by densimetric Froude Number entrainment between two fluids (Part III-5-7e).

(3) Erosion rate at twice critical shear. Both the Parthenaides and Krone Equations (Parts III-5-7d and III-5-9c) are 'excess shear' fits to observed erosion and deposition, respectively. For example, the Parthenaides Equation (Part III-5-7d) correlates observed erosion rates with

$$\text{Dimensionless Excess Shear} = (\tau_c - \tau) / \tau_c; \text{ negative } (\tau_c < \tau) \text{ for erosion}$$

The Parthenaides coefficient M_p (in units of kg/m^2/sec) (see Equation III-5-1), is the correlation coefficient between erosion rate and excess shear, when dimensionless excess shear = -1; that is, when $\tau = 2\tau_c$.

(4) Critical shear for deposition.

(a) A critical shear stress for deposition τ_s *Pa* (lbf/ft^2) is not obvious at first glance. In noncohesive sediment, the critical shear for deposition is only slightly less than that for erosion: a noncohesive particle

will come to rest almost as soon as the shear is too small to move it. But the process of deposition of cohesive sediment flocs is quite different; τ_s is generally on the order of one fourth of τ_c.

(b) High shear near the bed breaks up large flocs before they can settle. Then, the resulting smaller flocs and individual particles are resuspended. The critical shear for deposition τ_s is that through which large flocs can pass without being broken up. Note that τ_s is not shorthand for something more; τ_s really is the shear stress in the bottom boundary layer which cannot overcome cohesion in the settling flocs.

(5) Sediment, fluid mud, and water densities.

(a) Important densities and specific gravities:

ρ_w = specific gravity (mass density) of water — 1,000 kg/m^3 (62.4 lb/ft^3) in fresh water, up to 1,030 kg/m^3 (64.3 lb/ft^3) in seawater

ρ_s = specific gravity (mass density) of sediment mineral (no voids): generally 2,000 kg/m^3 (125 lb/ft^3) to 2,700 kg/m^3 (170 lb/ft^3) depending on mineral

(b) Bulk sediment density voids filled with ambient water:

- Of freshly deposited flocs (may be fluid mud if < 1,100 to 1,200 kg/m^3 (70 to 75 lb/ft^3), corresponding to a mass concentration in excess of about 20 kg/m^3 (20 ppt)).
- Of existing bed surface, and layers, e.g., 1,400 kg/m^3 (90 lb/ft^3).
- Of fully consolidated sediment, generally < 2,000 kg/m^3 (125 lb/ft^3).

(6) Grain size and settling velocity.

(a) Settling velocity is a more important hydrodynamic property of cohesive sediment than grain size. Settling velocity is a measure of the sediment's behavior in suspension; grain size only allows us to guess the settling velocity.

(b) The first thing to know about cohesive sediment grain size is that it is *not* a measurable physical constant. True, the size of individual dispersed grains may be inferred from measurements of their settling velocities in distilled (free of dissolved chemicals) water: generally on the order of 10-μ or less. The settling velocity of a 10-μ sphere, 2,500 kg/m^3 (156 lb/ft^3), in water of 20 °C (68 °F) is 0.06 mm/sec (0.002 in./sec).

(c) But cohesive sediment of this size in natural, often salt, water does not stay dispersed for long. Grains stick together when they come close enough for the cohesive forces to overcome the fluid shear and gravity keeping them apart. Aggregations of cohesive sediment grains are called 'flocs.' Flocs are larger than individual grains, of course, but because of water trapped within the floc, they are also less dense than

the pure mineral. Depending on the relationships among floc size, shape, and density, the result is a *floc settling velocity* that may be more or less than that of individual grains. The settling velocity must be determined with the natural sediment in the natural water.

(d) Mud may also be biologically cohesive (Paterson 1994), for example, due to mucus excreted by diatoms. Biological cohesion is even more difficult to predict than electrochemical, providing yet another reason for using natural sediment and natural water in determining floc size and settling velocities.

(7) Degree of consolidation.

(a) The degree of consolidation u is defined as the ratio of the bulk density of the sediment to the bulk density of the 'fully consolidated' sediment, measured under Part III-5-6b(5). Consolidation of cohesive sediment is the compaction of the soil mass accompanied by drainage of the interstitial water, just as with noncohesive sediment. The principal difference is the length and cross-sectional area of the drainage path. In cohesive sediments, the path length is long and the area is small (i.e., low permeability); slowing down drainage and consolidation. Drainage is through the bed surface, into the ambient water, so that a good relative measure of the length of the drainage path P is the depth of burial below the surface. Cross-sectional area of the drainage path must be inferred from measurements of permeability.

(b) Overburden speeds up consolidation but increases the length of the drainage path, especially when the overburden is also cohesive. Nevertheless, consolidation starts at the bottom of a sediment layer and follows the draining water upward, giving even a freshly deposited layer a density gradient, denser at the bottom to less dense at the surface, until the entire layer is fully consolidated. The strength of the sediment represented by the critical shear for erosion τ_c increases with density and consolidation.

(8) Field measurement techniques. Many of the cohesive sediment field and laboratory measurement techniques are the same as those for noncohesive sediment (Part III-1). Nevertheless, some accommodation must be made for mud:

(a) Bed sampling. Much depends on knowledge of the composition and density of surficial sediments, which can be gained from laboratory analysis of surface samples obtained in the field. It is unreasonable to expect that undisturbed mud samples can be collected. In fact, it is difficult to contain most surficial mud in the commonly used Shipek or Ponar grab samplers because the samples leak out. Underwater samples may have to be obtained by divers, and all samples that include entrapped water should be transported in sealed jars and stored at 4 °C (39 °F).

(b) Boreholes and cores. The techniques give information on subsurface sediment layers. Blow counts and cone penetration tests give a relative measure of the strength and density of the layers (but not of the critical shears for erosion and deposition of mud, see below), and cores taken from the layers are as close to undisturbed samples as is possible in cohesive sediment. Boreholes should extend to bedrock or similar hard, impenetrable layers, with cores and cone penetration tests in each major layer.

(c) Suspended sediment sampling. This type of testing is needed to determine composition and quantity of sediment in suspension. Generally, the technique is to pump and filter 4 L of suspension and transport the filter and contents to the laboratory for subsequent analysis. Alternatively, 1 L of suspension may be sealed in jars and transported to the laboratory for filtering and analysis there; this liter may be obtained by pumping or from any of the proprietary suspension samplers. Filters should be no larger than 10 microns. Sampling should be carried out at a minimum of four elevations over the depth, with special attention to the near-bed or fluid mud layer.

(d) Settling tube. Field settling tubes, e.g., the 'Owen Tube' (Eisma, Dyer, and van Leussen 1994) measure the settling velocity of cohesive sediment flocs in 'live' natural water, even in a natural level of turbulence. Typically an undisturbed sample of sediment-water suspension is captured in a horizontal tube. The tube is immediately turned into the vertical position, and the settling velocity of the flocs is determined from density changes that occur in the suspension at various depths in the tube and over various times.

(e) Piezometers. These instruments measure rate of drainage of excess pore pressure from natural muds, and thus permeability and rates of consolidation. Lancelot (Christian, Heffler, and Davis 1993) is a piezometer that first creates excess pore pressure on its insertion in the mud bed, and then measures the rate of decay or drainage.

(f) Optical techniques. These techniques are primarily used as a substitute for suspended sediment sampling. Two basic techniques are used: measuring light transmitted through a known illuminated volume of suspension in a turbidity meter or transmissometer (e.g. Bartz, Zaneveld, and Pak 1978); or measuring light reflected from the suspension by an 'Optical Backscatterance (sic) Sensor' or OBS (e.g. Sternberg, Shi, and Downing 1989). Both require calibration against natural sediment in known concentrations in natural water.

(g) Acoustic techniques. Many novel applications are still under development, mostly in the high-frequency (MHz) range, where for example, suspended sediment concentration and grain size profiles can be measured (e.g. Hay and Sheng 1992). At lower frequencies, echo sounding detects the elevation of the bed and of the surface of fluid mud; and in the side-scan mode, detects bed forms such as ripples and dunes, and their orientation (Hay and Wilson 1994). At still lower (seismic) frequencies, sound penetrates the bed and detects the interfaces between sediment layers of different densities, creating sub-bottom profiles.

(h) Radioactivity techniques. In these techniques, Gamma rays or X-rays are passed through a sediment/water suspension or bed layer (e.g. Sills 1994). The energy passing can be related by calibration to the mass density of the suspension or layer. These techniques are particularly useful in characterizing fluid mud layers, as and where they occur. Radioactivity techniques are also used in laboratory consolidation columns.

(i) Direct shear techniques. There are several field devices that apply a variable shear stress to the surface of a cohesive sediment bed (Gust 1994), and measure the variable rate of erosion (increase in suspended sediment in the water column) and deposition (decrease in suspended sediment in the water column). Results can be used directly in the Parthenaides and Krone equations (Equations 5-1 and 5-4) respectively. The prototype for all such devices is the annular flume, described under Part III-5-6b(9) "Laboratory Measurement Techniques," and sketched in Figure III-5-17. The Sea Carousel described by Amos et al. (1992) is an example of field adaptation of the annular flume.

(j) Correlation with shear strength. Although the critical shear for erosion τ_c would seem to be a function of the shear strength of soft cohesive soil (measured by vane, cone, or penetrometer), the form of that function is not yet known and certainly not linear. Even measuring mechanical surface shear directly on tidal mud flats (Faas et al. 1992) produces mechanical yield stress an order of magnitude larger than the hydrodynamic τ_c.

(9) Laboratory measurement techniques.

(a) Grain size analysis. Standard ASTM D422 laboratory techniques should be applied to determine the physical size of individual grains in bed, core, and suspended sediment samples. Although no ASTM standard has been published, the pipette technique (removing a known volume of suspension from a known

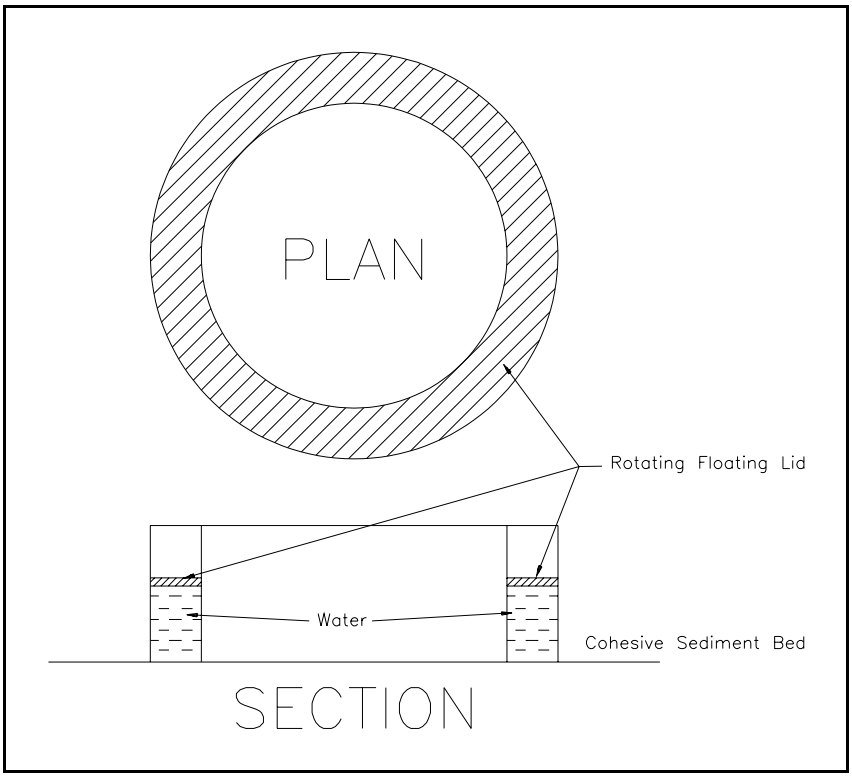

Figure III-5-17. Prototype direct shear device, the annular flume

elevation in the settling column, and filtering or drying to determine sediment concentration), is an alternative to the hydrometer technique. Total dry weight of suspended samples is also required to give field concentration in mg/l (ppm). Both hydrometer and pipette techniques measure settling velocity, and infer grain size from it. The settling column also measures settling velocity in the manner of a large-scale (typically greater than 1 m (40 in.) deep, 0.3 m (12 in.) diameter) hydrometer or pipette test (Gibbs 1972). Sensitive differential pressure transducers record the variations in suspended sediment concentration with depth and time, from which settling velocity distribution in the sample can be computed. Like the consolidation column below, settling columns need to be well-isolated from vibration and temperature changes to prevent artificial flocculation of the settling particles. For clay particules (<4 m), it will be necessary to use a nonstandard particle counter, e.g., Coulter counter. Nonstandard (natural water) hydrometer, pipette, or settling column tests should be used to estimate settling velocity of the flocs and bulk density of deposited sediment.

(b) Consolidation column. A consolidation column is a cylinder containing 2 to 3 m of natural sediment and natural water in a vibration-free environment to ensure natural rates of consolidation (Sills 1994). Variations in pore pressure with time and depth (overburden) are measured with piezometers, and in density, with gamma ray or observed volume. Estimates of permeability (length and diameter of drainage paths, and variation with bulk density) come out of the same measurements, using Equation 5-6, for example.

(c) Direct shear techniques. There are several laboratory devices that apply a variable shear stress to the surface of a cohesive sediment bed and measure the variable rate of erosion (increase in suspended sediment in the water column) and deposition (decrease in suspended sediment in the water column). Results can be used directly in the Parthenaides and Krone Equations of Parts III-5-7d and III-5-9c, respectively. The prototype for all such devices is the annular flume (e.g., Krishnappan 1993), sketched in Figure III-5-17. An annular flume is simply an endless channel in which the shear or velocity of rotation of the lid can be varied

and the changes in the mud bed can be inferred from changes in suspended sediment concentration, measured using one of the techniques described above. The shear force driving the circulation can be measured directly as the force needed to rotate the lid. Laboratory annular flumes generally rotate the flume and the lid in opposite directions, to minimize secondary radial circulation of the water, and to obtain a more uniform distribution of shear on the mud bed. An increase in suspended sediment corresponds to a decrease in the mass of sediment on the bed *m* and a decrease in suspended sediment to an increase in the mass of the bed. It is then possible to extrapolate these measured shear stresses to τ_c and τ_s, at which erosion or deposition ceases; and to interpolate the Parthenaides coefficient M_p and fall velocity *w* (Example Problem III-5-1).

(10) Calibration techniques. Ideally, one should be able to measure all the hydrodynamic properties of a cohesive sediment, and proceed directly to a model of the shore. The model, however, will always need calibration and verification against measurements of erosion and deposition, to fine tune measurements and confirm that the model represents the shore. With some of the hydrodynamic properties unknown, the model can be used to choose between high and low values of the unknown properties, using "design of experiments" techniques (Willis and Crookshank 1994). This still requires intelligent estimates of high and low values of the unknown properties and good field measurements of erosion, deposition, or transport.

III-5-7. Erosion Processes

a. Shear stress.

(1) The formulae for predicting the movement of cohesive sediment predict rates of erosion and deposition, not transport. Try putting a typical cohesive floc size into a noncohesive sediment transport formula (Part III-6) and you will predict virtually infinite transport rates, in which the predicted density of 'sediment in suspension' may exceed its real density on the bed. Noncohesive sediment formulae are generally based on transport limitations: assuming there is a sediment supply to match the transport potential. Cohesive sediment formulae are generally based on supply limitations, and assume the flow can transport all eroded sediment. They define the sediment exchange between the bed and the water column.

(2) The cohesive sediment formulae are also less theoretically based. They form a simple numerical framework for interpolating and extrapolating observed hydrodynamic behavior of cohesive sediment. Generally erosion or deposition is correlated with the excess shear stress.

b. Erodibility of consolidated sediments.

(1) There have been many studies of the erosion resistance of cohesive soils to flowing water. Very few of these investigations have considered the much more complex flow conditions encountered in the coastal zone. Nevertheless, a basic understanding, such as it is, of the complex process of erosion of consolidated cohesive soil provides a basis for assessing the erosion resistance of cohesive soils in the coastal environment.

(2) The erodibility of cohesive soils is controlled by the bonds between cohesive particles. Many tests of remolded cohesive sediments have found that the most important parameters in describing the erodibility of cohesive sediments include consolidation and physio-chemical conditions, both of which influence the degree of bonding between particles. Aside from the difficulty of obtaining intact cohesive samples, the reason for testing remolded and reconsolidated samples is to establish the erodibility of recompacted clays, used as construction materials. Extensive investigations into the relationships between the properties of these 'homogenous' cohesive sediments (e.g., consolidation and other geotechnical parameters), and the physio-chemical properties of the fluid (including temperature, pH, and salt or cation content) have found a direct relationship between these parameters and erodibility (Croad 1981; Arulanandan, Loganatham, and Krone 1975).

(3) More recent investigations of intact consolidated sediment samples have found that the natural structure of the material, including the presence of fissures, fractures, and seams of noncohesive materials such as silt and fine sand, is the most important factor in determining erodibility (Lefebvre, Rohan, and Douville 1985; Hutchinson 1986). The natural structure is uniquely defined by the environmental conditions during the original deposition and subsequent weathering of the sediment (including overconsolidation during glacial periods for some sediments). Conventional geotechnical parameters such as clay content and shear strength do not provide a direct measure of the influence of the natural structure of consolidated sediments as it relates to erodibility. Nevertheless, Kamphuis (1987) suggested that the presence of fissures in samples may be indirectly reflected in the undrained shear strength, consolidation pressure, and clay content.

(4) A technique for assessing the hydraulic erodibility of natural and engineered earth materials including both soil and rock is described by Annandale (1996). This empirical method, which provides a relationship between threshold stream power for erosion and an erodibility index, was developed from field observations of spillway performance downstream of dams. The erodibility index is determined as a scalar product of indices representing the following material properties: (1) mass strength, (2) block/particle size, (3) discontinuity/interparticle bond shear strength, and (4) shape of the material units and their orientation relative to the flow velocity.

(5) For clay materials as for mud, the erodibility index is primarily a function of the shear strength of the soil. Stream power is calculated as the product of near-bed velocity and shear stress. This approach was applied to the scour of weak rock in the presence of waves and currents to investigate scour potential around bridge piers (Anglin et al. 1996).

(6) In summary, in the absence of a reliable and standardized technique for assessing the natural structure of consolidated cohesive sediment, as it relates to erodibility in the coastal environment, more empirical approaches must be followed, such as establishing erodibility coefficients from laboratory tests or field data.

(7) One such example of a direct empirical technique for estimating erodibility is described by Kamphuis (1990) and Parson, Morang, and Nairn (1996). In these tests, intact (undisturbed) samples of consolidated sediment were placed in a drop section of the floor of a high-velocity unidirectional flow flume or tunnel with transparent walls or windows. The shear stress over the samples was determined indirectly by measuring the vertical profile of velocity just above the bed. The average erosion rate was then determined by measuring the volumetric erosion experienced on the surface of a sample within a test period. Rates were determined for velocities in the range of 0.5 to 3 m/sec. Further details on this test procedure are presented in Part III-5-6a. All results determined by using this technique for various types of consolidated sediment (including mudstone, till, and lacustrine clay) are summarized in Figure III-5-18 (from Parson, Morang, and Nairn (1996)). It was found that shear stresses in the range of 0 to 18 Pa resulted in erosion rates in the range of 0 to 8 mm/hr.

(8) In a further extension of this type of testing, Kamphuis (1990) found that the erosion rate increased dramatically when sand was added to the flow. The results of all of the erodibility tests using this technique with sand in flow are presented in Figure III-5-19 (from Parson, Morang, and Nairn (1996)). A comparison of the clear water erosion results of Figure III-5-18 and the sand in flow results of Figure III-5-19, indicates that for the same shear stress and sediment sample, the erosion rate is increased by a factor of 3 to 8 when

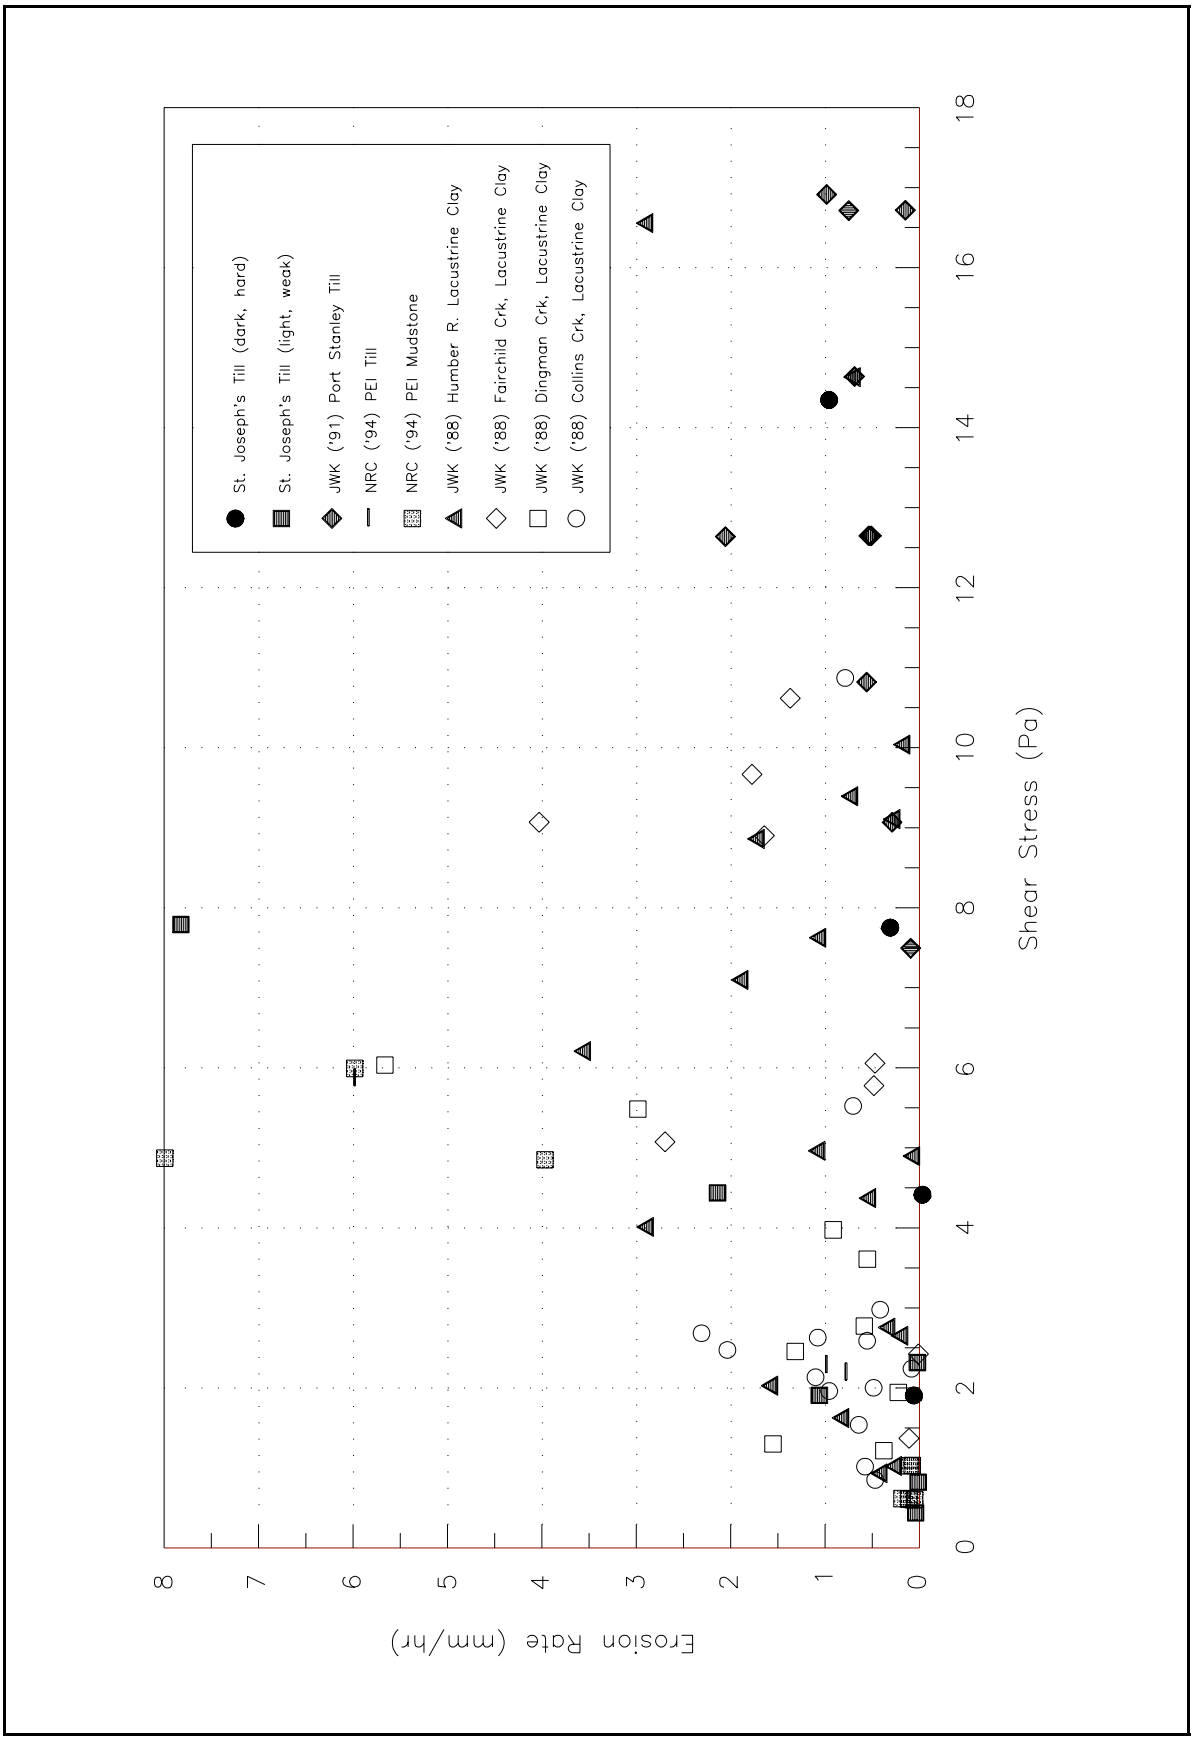

Figure III-5-18. Clear-water erosion rates from unidirectional flow flume and tunnel tests for various materials

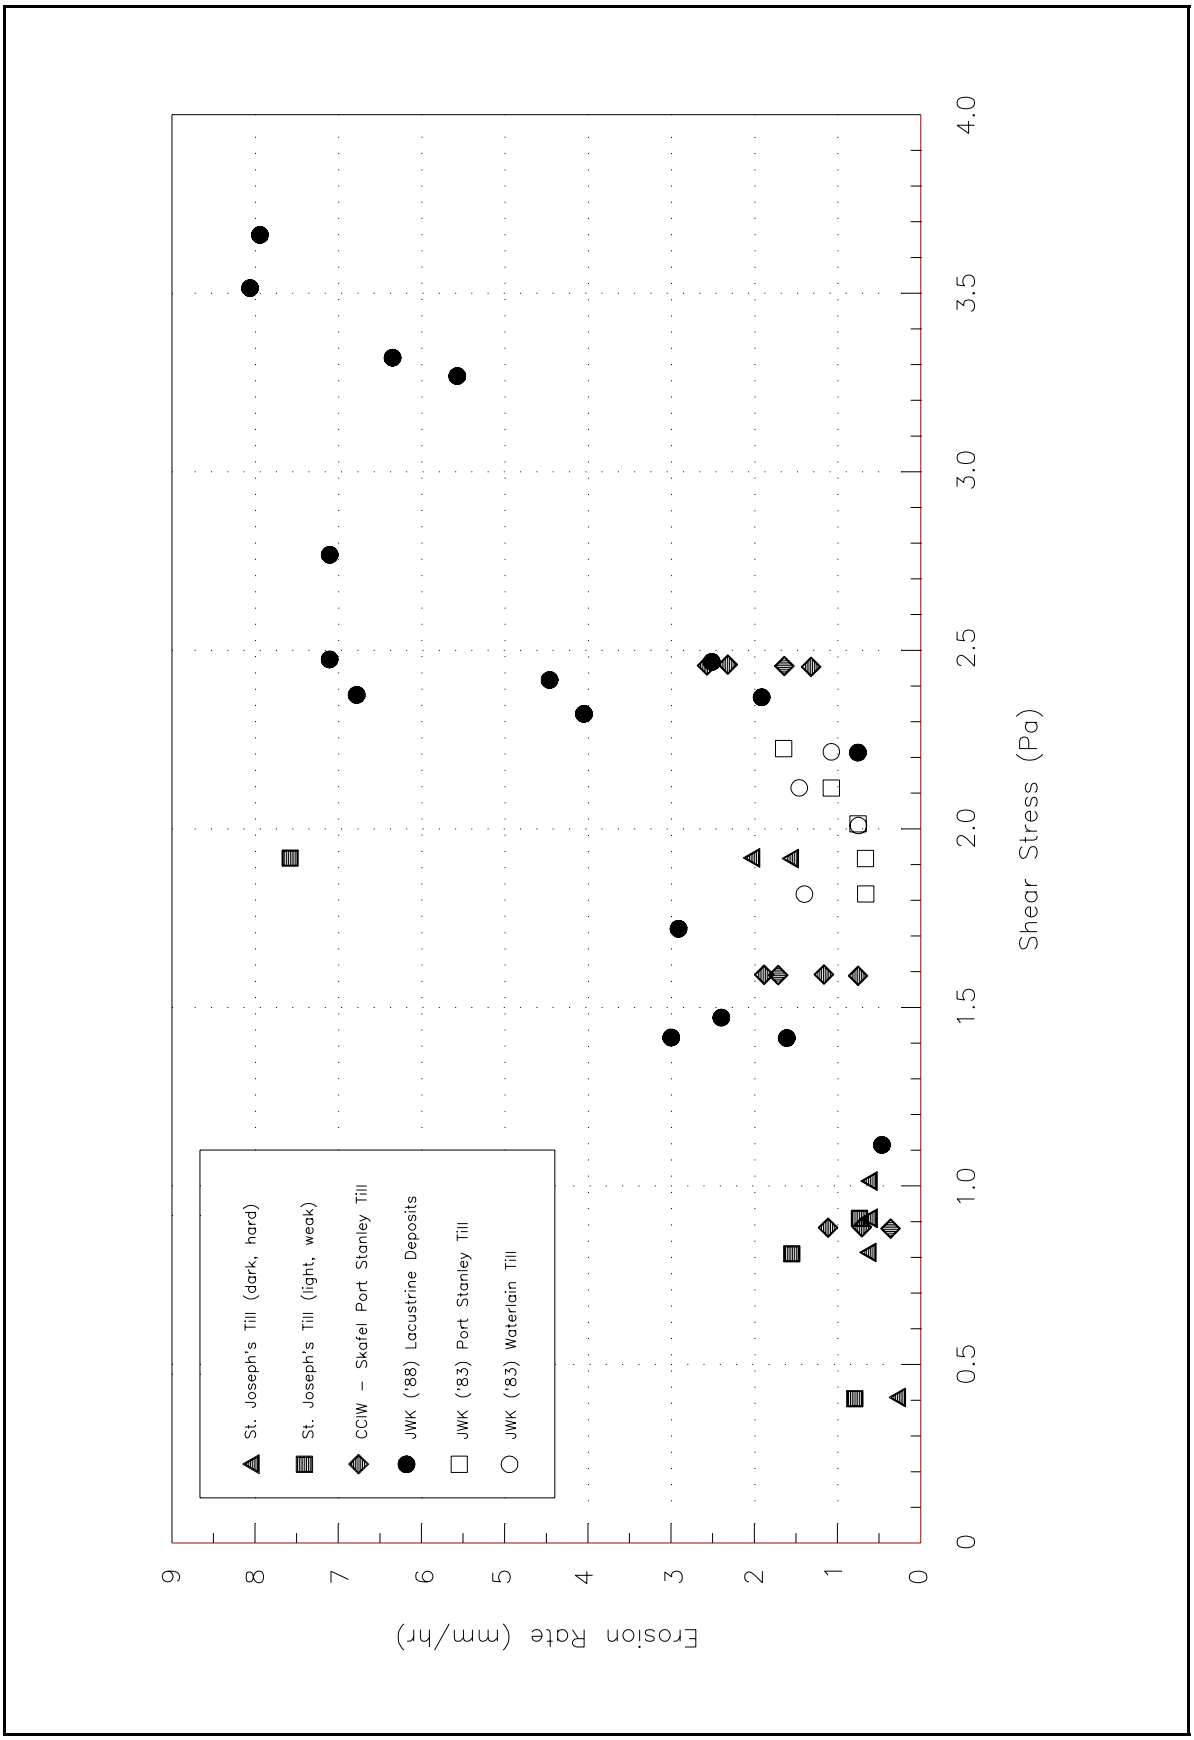

Figure III-5-19. Sand in flow erosion rates from unidirectional flow flume and tunnel tests for various materials

sand is introduced into the flow. It should be noted that the sand-grain size was selected so that sand transport occurred in a saltating (bed load) manner in the tests.

(9) A close review of the results presented in Figure III-5-18 reveals two populations of erosion response. The less erosion-resistant group consists of soft cohesive sediments as well as sediments characterized with a high degree of fracturing and/or the presence of silt seams. In contrast, the more erosion-resistant group consisted of firm, homogenous cohesive sediments. The shear strengths for the material tested ranged from 50 to 200 kPa.

(10) Some of the most recent research into the erodibility of cohesive sediments in the coastal environment has focused on the potential for softening of the exposed surface layer. Davidson-Arnott and Langham (1995) report that at the western end of Lake Ontario, previously overconsolidated till featured shear strengths in the range of 10 to 100 kPa. The softer sediment (10- to 20-kPa shear strength range) was associated with deeper water areas where the till was always exposed (i.e., the noncohesive sediment cover was insignificant) and where the frequency of erosion events was low. In contrast, in shallower areas (depths less than 3 m or 10 ft), the shear strengths were found to be in the range of 30 to 80 kPa. In the shallower depths, the lake bed is exposed to erosion events more frequently and sand cover thicknesses were greater. Using an adapted micro shear vane for a location in a water depth of 3.5 m, they found that the shear strength was lower in the upper 0.1 m of the lake bed and much lower in a 10-mm-thick surface layer. In fresh water, the softening process may be a result of cyclic loading by wave action, whereas in a seawater environment, factors such as salinity and biological activity (such as burrowing organisms) may also be important (Hutchinson 1986).

(11) Finally, an indirect approach to determining the erodibility of consolidated sediment at a specific site is through the use of numerical models to 'back-calculate' the erodibility coefficient through an analysis of environmental conditions (wave action and water levels) and the observed shoreline or lake bed erosion over a given period of time. This approach is discussed in more detail in Part III-5-12.

c. Subaqueous erosion of consolidated sediments.

(1) In this section, the underwater erosion process is described. In the previous section, we explained that the erosion of hard cohesive soils consists of the destruction of bonds between clay particles and the natural structure or framework created through consolidation of the soil matrix. Erosion of consolidated sediment is irreversible. Once the sediment, which often consists of 80 to 90 percent fines, is eroded, it cannot be reconstituted in its consolidated form in the littoral zone. The eroded fines (silt and clay) are winnowed, carried offshore, and deposited in deep water in contrast to the small fraction of sand and gravel, which remains in the littoral zone. Therefore, the erosion of cohesive sediment is fundamentally different from the erosion of noncohesive sediment. In the latter case, for every volume of eroded sand, a large portion of that material will be deposited somewhere in the littoral zone (in some specific instances, onshore or offshore losses of sand from beaches can occur). Therefore, on sandy shores, the process of erosion is reversible.

(2) An extensive study of nearshore profiles on the north central shore of Lake Erie described by Philpott (1984) revealed that the profile shape remained relatively constant over an 80-year interval despite dramatic shore recession. This led Philpott (1984) to conclude that the controlling process in bluff or cliff recession on cohesive shores is not restricted to wave action at the toe (as proposed by Sunamura (1992) for eroding rocky coasts) but by the erosion of the nearshore profile by waves. Boyd (1992) cites many earlier references that also suggest that the nearshore has a controlling influence on shoreline recession. The shoreward shift of the dynamic equilibrium profile implies that erosion or downcutting is proportional to the gradient of the nearshore profile and is, thus, greatest close to shore. Davidson-Arnott (1986) describes field measurements of downcutting for a till profile (through the deployment of micro-erosion meters across a

transect) at a site near Grimsby on Lake Ontario. The results confirm the hypothesis on downcutting, i.e., the rates increase towards the shore in a manner related to the local bed slope, thus allowing for the preservation of the profile shape as it shifts shoreward with time. The downcutting hypothesis has now been confirmed by many other field investigations including 9 years of profile retreat data at Maumee Bay State Park in Ohio (Fuller 1995). Hutchinson (1986) and Sunamura (1992) also note that the rate of lowering or downwasting of the intertidal platform on erodible rocky coasts probably determines the long-term rate of cliff retreat in most instances.

(3) In general, it has also been shown that the underlying cohesive profile, for cases where the properties of the cohesive sediment are uniform along the profile, follows an equilibrium profile shape as defined by Dean (1977). Kamphuis (1990) went on to show that the specific exponential shape of the equilibrium profile at a cohesive shore site was related to the grain size of the overlying noncohesive sediment. In other words, the profile shape could be determined using the grain size of the sand veneer to define the sediment scale parameter A (see Equation 3-15). The shape of the profile can also be influenced by other factors such as variable stratigraphy and the presence of lag deposits as discussed in Part III-5-5. In these cases, a smooth equilibrium profile with an exponential shape will not exist, at least not over the full profile. Riggs, Cleary, and Snyder (1995) note that in most instances along the North Carolina coasts, the complexity of the underlying stratigraphy is such that the profile rarely resembles the equilibrium form found on truly sandy shores.

(4) The downcutting process is illustrated in Figure III-5-20 for a cohesive shore site located east of Toronto along the Scarborough Bluffs. The bluff face has retreated approximately 30 m (100 ft) in a 37-year period. The underlying cohesive profile shape in 1952 is very similar to that in 1989; it has simply shifted shoreward by 30 m. Therefore, the long-term bluff or cliff retreat rate is equivalent to the profile retreat rate. This figure also shows that there can be a significant quantity of sand covering an underlying cohesive profile. The position of the underlying cohesive profile shown in Figure III-5-20 was estimated based on observations that the cohesive sediment is usually exposed or very thinly covered in the troughs between the bars. Also, it is known that the till is exposed at the toe of the bluff (i.e., at the back of the beach).

(5) Figure III-5-20 demonstrates that there is not a cross-shore balance of erosion and deposition. All of the eroded material from the cohesive profile and the bluff is either winnowed offshore (clay and silt fractions) or transported alongshore (sand and gravel fractions).

(6) The profile retreat model for cohesive shores implies that: the amount that the driving forces for erosion exceed the resisting forces is inversely proportional to the water depth. In other words, the most active subaqueous erosion occurs at the shoreline. In general, it may be assumed that the erosion resistance of the cohesive sediment is consistent across the profile (if anything, the sediment may be less erosion-resistant in deeper water due to the increased role of softening). Therefore, the driving force for erosion must increase in the shoreward direction. These observations provide important evidence on the nature of the driving forces for cohesive profile erosion.

(7) Coakley, Rukavina, and Zeman (1986) proposed that outside the surf zone, the downcutting process is driven by shear stresses generated by the orbital motion under waves. Outside the surf zone, this driving force is inversely proportional to water depth. However, considering that wave heights and the related orbital velocity decreases in the surf zone, this mechanism cannot explain the inverse relationship between depth and driving force in this zone. Nairn, Pinchin, and Philpott (1986) proposed that the complex combination of driving forces in the surf zone may be represented by the rate of energy dissipation (described by the rate of wave height decay). Using a model of wave energy dissipation for random waves, it was shown that the rate of energy dissipation was directly proportional to the rate of downcutting in the surf zone. In the surf

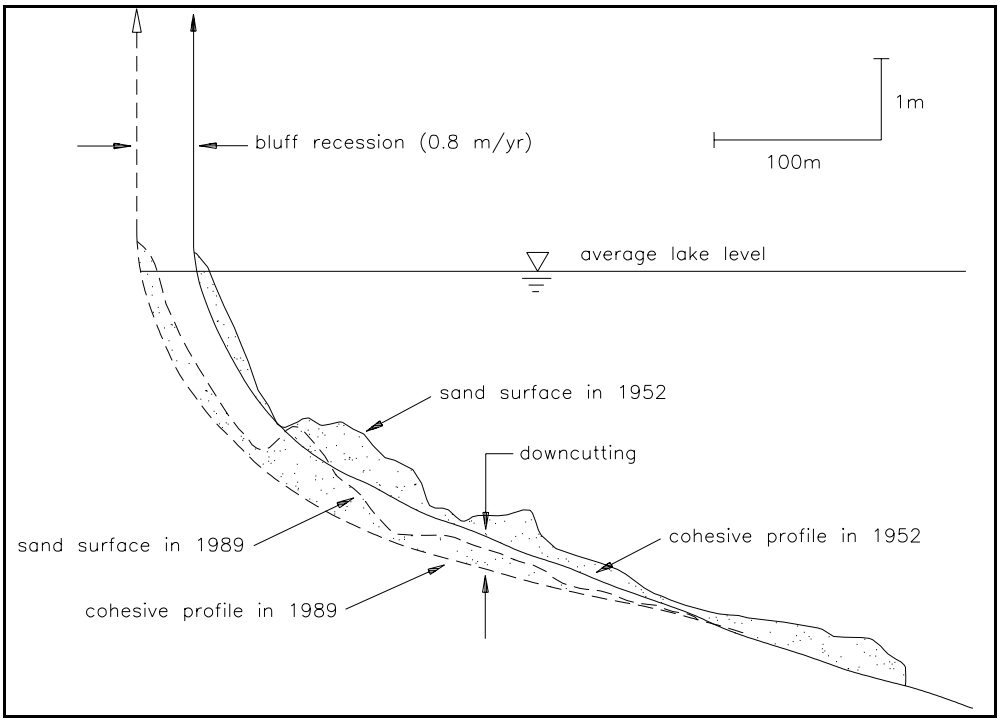

Figure III-5-20. Bluff retreat and profile downcutting over a 37-year period at Scarborough Bluffs, located east of Toronto on Lake Ontario

zone, the rate of energy dissipation provides a good indicator of the possible driving forces such as intensity of flows (e.g., undertow and alongshore currents) as well as the intensity of near-bed turbulence (i.e., plunging breakers, which generate high near-bed turbulence, are associated with rapid wave decay). The erosive nature of plunging breakers (and the associated near-bed turbulence) on cohesive profile erosion was demonstrated through laboratory experiments performed in a wave flume with intact cohesive samples (Skafel 1995).

(8) Sand acts as an abrasive agent in the erosion of consolidated shores. Referring to Figure III-5-20, it is also likely that the presence of alongshore bars can have the opposite effect of protecting the underlying cohesive sediment from exposure and subsequent downcutting. As these bars migrate with changing wave and water level conditions, different areas of the underlying cohesive profile become exposed in the troughs between the bars. The influence of the quantity and mobility of sand cover over a cohesive profile is explored in greater detail in Part III-5-2.

(9) At the boundary between the action of subaqueous and subaerial erosion processes, the bluff or cliff toe can in some instances experience notching. This notching typically occurs in more competent materials such as rock, frozen sediments, and harder cohesive sediments, (i.e., in materials that are capable of withstanding failure when undercut).

(10) In summary, the fundamental principles of consolidated cohesive shore erosion are:

(a) The erosion of consolidated cohesive sediment is irreversible.

(b) The long-term rate of shoreline retreat is directly related to the rate of nearshore downcutting and the associated profile retreat.

(c) The local rate of downcutting is proportional to the gradient of the nearshore slope at any location across the profile.

(d) In addition to acting as an abrasive agent that accelerates consolidated cohesive sediment erosion, sand can also serve to protect an underlying cohesive profile from erosion.

d. Subaqueous erosion of mud. The Parthenaides Equation for mud erosion (Parthenaides 1962, Mehta et al. 1989) is an excess shear equation describing the erosion rate of a cohesive sediment:

$$\frac{dm}{dt} = M_p \frac{(\tau_c - \tau)}{\tau_c} \tag{III-5-1}$$

where

m = mass of sediment on the bed, kg/m^2 (lb/ft^2)

t = time, sec

τ = bed shear, Pa (lbf/ft^2)

τ_c = critical shear for erosion, Pa (psf) (lbf/ft^2)

M_p = 'Parthenaides Coefficient,' erosion rate at twice τ_c, kg/m^2/sec (lb/ft^2/sec)

e. Fluid mud.

(1) This assumes a well-defined interface between bed and water column: sediment on the bed remains at rest; while that in the water column moves with the water. Often, cohesive sediment forms an intermediate layer of fluid mud (denser than water; less dense than the bed; still capable of motion, but slower than the ambient flow). Fluid mud layers are frequently found near the shoreline, where wave activity can 'pump up' excess pore pressures within the fluid mud mass, slowing down drainage and consolidation. Hydrographers generally define fluid mud as having a density of less than 1,100 to 1,200 kg/m^3 (70 to 75 lb/ft^3).

(2) Erosion processes in fluid mud are similar to mixing processes at a salt-wedge interface. A layer of lighter fluid (water with suspended sediment) flowing above the denser fluid mud eventually induces waves in the interface when a critical Richardson Number or densimetric Froude Number is exceeded. Wind-wave activity in the upper layer increases the interfacial waves, diverting energy from the surface waves. As the difference in flow rates increases, the interfacial wave energy increases until breaking occurs, putting some fluid mud back in suspension and entraining clearer water in the fluid mud.

(3) The densimetric Froude Number is defined as:

$$F_r = \sqrt{\frac{(V_w - V_{fm})^2 \rho_{fm}}{g h_{fm} (\rho_{fm} - \rho_w)}} \tag{III-5-2}$$

where

V_w = mean velocity in the water layer, m/sec (fps), above

V_{fm} = mean velocity in the fluid mud layer, m/sec (fps)

ρ_w = density of the water layer, kg/m^3 (lb/ft^3)

ρ_{fm} = density of the fluid mud layer, kg/m^3 (lb/ft^3)

g = acceleration due to gravity, m/sec^2 (ft/sec^2)

h_{fm} = thickness (depth) of fluid mud layer, m (ft)

(4) This reduces to the more familiar Froude Number at the water surface, where the upper layer is air of relatively negligible density and the lower fluid mud layer is the water. It defines the ratio of the velocity differential at the interface (V_w - V_{fm}) to the celerity of a small gravity wave in the interface. When that ratio is unity, the equivalent of a hydraulic jump (breaking wave) may be expected in the interface, with resultant entrainment of fluid mud in the water (erosion of the fluid mud) balanced by entrainment of water in the fluid mud.

(5) At the interface between the fluid mud and the bed, the fluid mud protects the bed from erosion. Shear that develops between the mud and the bed is generally too low to entrain stationary particles. The processes at this interface are entirely deposition, as water drains from the fluid mud.

f. Subaerial erosion processes.

(1) Subaerial erosion processes on cohesive shores do not necessarily have anything to do with the air or wind, although strengthening of mud flats has been noted by Amos et al. (1992) due to evaporation at low water in the macrotidal Bay of Fundy. On consolidated shores, the primary subaerial erosion process is slumping of oversteep bluffs or cliffs.

(2) As stated earlier, the long-term bluff or cliff retreat rate is determined by the rate of profile downcutting. In a review of shoreline erosion data from the Lake Erie shoreline, Kamphuis (1987) points out that cliff height does not exert much influence on the process (in fact, a distinct lack of correlation was noted) because erosional debris from a shore cliff is quickly swept away, winnowed offshore, and deposited in deep water. Exceptions to this generalization include locations where the debris is not easily removed from the toe of the cliff (e.g., in the case of eroded rock cliffs or blocks of frozen sediment along Arctic shores). The primary reason for slope failures along a cohesive shore is the oversteepened nature of the slope owing to the ongoing profile and toe erosion. Nevertheless, even though subaerial processes do not determine the long-term rate of shoreline recession on cohesive shores (i.e., the frequency of slope failures), these processes are critical in determining when and where a failure will occur.

(3) Slope stability is a function of the balance between the downward force of gravity and the strength of the geologic materials in a bluff or cliff. The strength of the geologic materials depends on the cohesion of particles and the presence or absence of groundwater. The stratigraphy of a bluff or cliff can have a significant influence on slope stability. Weak clay layers can provide slip planes for slope failures or serve to confine groundwater flows, which may appear as springs at the bluff face. Where groundwater exits the bluff face, seepage erosion can occur. Also, depending on the sequence of layering, groundwater flows can act to increase pressures within the slope and contribute to instability. This will often occur when seepage pathways at the bluff face are blocked by talus from a slide further up the slope. In some instances, the

combination of surface runoff and seepage can lead to the development of large gullies. Slope failures may be classified as: falls and topples; rotational (i.e., circular) and translational slides; and, spreads and flows. The type of failure is a function of the geologic conditions at the site. There are a variety of methods for assessing slope stability.

(4) Figures III-5-21 to III-5-23 show some examples of eroding bluffs along the Great Lakes. Recent rotational failures are evident in Figure III-5-21 along the north central shore of Lake Erie. The development of a gulley is shown in Figure III-5-22 from another location on the north central shore of Lake Erie. Figure III-5-23 shows an eroding shale bluff along the western Lake Ontario shoreline.

Figure III-5-21. A rotational bluff failure along the north central shore of Lake Erie

(5) In addition to slope stability, surface erosion of the cliff or bluff face can have a secondary influence on the overall erosion of the feature. Surface erosion results from runoff, seepage, rain, and spray from wave action. This would be one of the key processes leading to the erosion of the shale bluff shown in Figure III-5-23.

(6) Edil and Bosscher (1988) present a Great Lakes perspective overview of forces and resistance influencing cohesive shore slope erosion which result in mass movement (including sliding, flow, and creep) and particle movement (including wave, wind, ice, rill and sheet erosion and sapping through seepage flow).

(7) Kuhn and Osborne (1987) investigated the recession of cohesive cliffs on the California coast. The short-term cliff recession is partly related to subaerial processes such as drainage of precipitation and the effects of urbanization at the cliff top. At these locations the cliff base is well protected by a substantial beach deposit which restricts the downcutting of the subaqueous profile. Notably, almost all of the sand at these sites is supplied by nearby rivers and not by cliff recession. This is in contrast to the Great Lakes and barrier islands on the U.S. east coast, where very little sand is supplied by rivers in most areas.

Figure III-5-22. Gully erosion of a bluff along the north central shore of Lake Erie

Figure III-5-23. An eroding shale bluff along the west Lake Ontario shoreline

(8) A cliff stabilization project for the Scarborough Bluffs (east of Toronto on Lake Ontario) is discussed by Parker, Matich, and Denney (1986) (Figure III-5-24). It has been recognized that arresting the foreshore downcutting at the base of the bluffs is not sufficient on its own to control the erosion of an oversteep slope; proper drainage systems must be implemented to prevent gullies from developing and to address the problem of piping through sand and silt lenses. Parker, Matich, and Denney (1986) also note that the toe of the bluff must be surcharged in some locations to prevent large slip failures from occurring. One function of the land base created at the toe of the slope in Figure III-5-24 is to provide sufficient area to construct a surcharge berm. The surcharge provided by extensive shingle beaches along the south coast of England is known to contribute to the stability of cliffs that rise behind the beaches (Fleming and Summers 1986).

Figure III-5-24. Shore protection consisting of a wide berm protected by a revetment along the base of the Scarborough Bluffs located east of Toronto on Lake Ontario

Bioegineering, which consists of promoting the growth of vegetation (e.g., through the placement of mats consisting of bundled twigs to enhance rooting), may also help to stabilize an oversteep slope.

(9) Another extensive review of subaerial processes was made by Hutchinson (1986); other processes that he identified included: freeze/thaw cycles; alternate wetting and drying; and mechanical and hydrodynamic effects of micro-geological features such as erratic cobbles and boring organisms. Hutchinson (1986) provides sample test results indicating that seawater penetrated the pores of glacial tills from the Holderness coast of England (along the North Sea) to depths of at least 0.85 m. He goes on to suggest that an increase in the concentration of NaCl in the pore water from the intrusion of the seawater may increase the net attractive forces between clay particles and increase the degree of aggregation. The degree to which this effect will occur will depend on the clay content and the chemical properties of the cohesive sediment. Hutchinson (1986) concludes that the opposite effect may occur along freshwater shores, where the intrusion of fresh water may dilute the salt or cation content, thus decreasing the net attractive forces between clay particles, and increasing the susceptibility to erosion.

III-5-8. Transport Processes

a. Advection and dispersion.

(1) Cohesive sediments are not transported as bed load, except in the form of fluid mud (see Part III-5-8b below). They almost always are transported in suspension: advected (carried with the ambient water at the flow velocity) and dispersed (moved from areas of high sediment concentration to low by mixing, such as turbulence). Advection and dispersion are described in Part II-6-2.

(2) But sediment, even a floc, is denser than the ambient water and hence settles as it is being advected and dispersed. This results in a downward bias of the vertical dispersion relation

$$S - Cw = -D_z \frac{dC}{dz} \tag{III-5-3}$$

where

S = vertical (upward) dispersion of sediment, kg/m^2/sec (lb/ft^2/sec)

w = settling velocity of floc, m/sec (ft/sec)

D_z = vertical dispersion coefficient, m^2/s (ft^2/sec)

C = suspended sediment concentration, kg/m^3 (lb/ft^3)

z = vertical dimension, m (ft)

b. Fluid mud. Fluid mud, as its name suggests, flows and is a mechanism for transport of cohesive sediment. It flows down slopes by gravity, sometimes referred to as a 'turbidity current,' which is why fluid mud is often found in the bottoms of dredged cuts. Fluid mud is also dragged along by the shear of the water flowing above it. How it flows is determined by its rheology; which in turn, must be measured for each fluid mud combination of sediment and water. Fluid mud may have an apparent yield point, remaining stable until a critical slope or shear is exceeded. More likely, its flow velocity will vary in a nonlinear way with slope or shear, from stiffest at lowest shear to most fluid at highest shear.

III-5-9. Deposition Processes

a. Flocculation.

(1) Cohesive sediments rarely settle as individual grains in nature. Collisions between sediment grains are encouraged by differences in settling velocity, turbulence, Brownian motion, and electrochemical attraction or cohesion.

(2) When cohesive grains collide they tend to stick together, or cohere. To determine settling velocity in the laboratory, cohesive grains can be kept apart in distilled water containing a dispersing agent to neutralize the electrochemical bond.

(3) The process by which individual cohesive particles agglomerate while settling is called *flocculation*; and the resulting large particles with entrapped water, *flocs*. The settling velocity of a floc is a function of its size, shape, and relative density. A floc usually settles faster than its constituent particles; but because of

the entrapped water, its density is less than that of the sediment mineral, and the settling velocity of the floc may actually be slower than that of an individual clay particle. The size and shape of flocs, and their settling velocity, are hydrodynamic sediment properties which must be measured or determined by model calibration as described in Part III-5-3.

b. Shear stress. The principle of excess shear is also used for correlating observed rates of cohesive sediment deposition with flow. But for deposition, 'excess' is the amount by which the shear τ is less than a critical shear for deposition τ_s.

c. Krone Equation. The Krone Equation for mud deposition (Krone 1962, Mehta et al. 1989) is as follows:

$$\frac{dm}{dt} = Cw\frac{(\tau_s - \tau)}{\tau_s} \tag{III-5-4}$$

where

m = mass of sediment on the bed, kg/m^2 (lb/ft^2)

t = time, sec

τ = bed shear, Pa (lbf/ft^2)

τ_s = critical shear for deposition, Pa (lbf/ft^2)

C = suspended sediment concentration above the bed, kg/m^3 (lb/ft^3)

w = settling velocity of sediment floc, m/sec (ft/sec)

Comparison of the Krone and Parthenaides Equations (Part III-5-4d) suggests that the Krone Equation may be less empirical, more theoretical. There is no obvious empirical coefficient to match the Parthenaides coefficient M_p, but the unknown coefficient hidden in the Krone Equation is w, the settling velocity of the flocs.

d. Fluid mud. Deposition takes place at both interfaces: that between water and fluid mud; and also that between fluid mud and the stationary bed. At the water/fluid mud interface, the process can still be predicted by the Krone Equation, except the density of the deposited sediment is less than 1,100 to 1,200 kg/m^3 (70 to 75 lb/ft^3). At the fluid mud/bed interface, the deposition process is one of consolidation: as the fluid mud drains, it consolidates to the point where it is too dense to remain fluid.

III-5-10. Consolidation

a. Strength versus consolidation.

(1) The critical shear for erosion τ_c is a function of the consolidation or density of the bed. Think of the cohesion between sediment particles varying inversely, like the force of gravity, with distance between particles. The closer the particles are to each other, the stronger the cohesive bond and the greater the shear force needed to separate them.

(2) The Migniot Equation expresses the exponential relationship between mud density and critical shear for erosion as:

$$\tau_c = N\rho_s^M \tag{III-5-5}$$

where

ρ_s = bulk density of sediment on the surface of the bed, kg/m^3 (lb/ft^3)

M, N = constants to be determined for the sediment and water.
M is dimensionless and tends to be less than 1; *N* equals 10^{-1} or 10^{-2} in the SI system of units.

b. Degree of consolidation. The Terzaghi consolidation relation, developed for building settlement calculations, also serves to illustrate the consolidation of coastal cohesive sediment.

$$u = 0.964\left(\frac{tC_v}{P^2}\right)^{0.415} \tag{III-5-6}$$

where

u = degree of consolidation, dimensionless ratio

C_v = a consolidation coefficient to be determined, m^2/sec (ft^2/sec) (values on the order of 1 x 10-5 m^2/sec are not uncommon)

P = length of the drainage path, m (ft) (generally depth of burial)

III-5-11. Wave Propagation

a. Roughness and shear.

(1) The predominant nearshore wave transformation associated with muddy beds is wave energy dissipation or attenuation. Refraction, diffraction, and reflection all pretty much obey the rules set out in Part II-3-3, but wave attenuation is generally much greater over mud beaches than over sand and gravel. As more wave energy is absorbed by the mud, less reaches the breaker line.

(2) This energy dissipation can only partially be accounted for through the traditional mechanisms of bed roughness and friction. In fact, a mud bed is usually smoother (less rough) than sand.

b. Fluid mud.

(1) The predominant mechanism of wave attenuation is in the thick, viscous boundary layer of fluid mud (Lee 1995, Lee and Mehta 1994). Part of the wave energy goes to ‘pumping up’ excess pore pressures maintaining the mud in a fluid state. But more is converted to work done in moving the fluid mud against viscous shear.

Example Problem III-5-1

FIND:

Apply the Parthenaides and Krone Equations to the annular flume test results in the table, to determine values of:

M_p = Parthenaides coefficient for this combination of sediment and water

τ_c = Critical shear for erosion at this sediment density

w = Settling velocity of sediment flocs for this combination of sediment and water

τ_s = Critical shear for deposition for this combination of sediment and water

For the purposes of this example, ignore changes in bed elevation and water depth due to erosion and deposition.

GIVEN:

Table III-5-2
Example Problem III-5-1, "Annular Flume Test Results"

Applied Shear (Pa)	Duration (sec)	Starting Concentration (kg/m^3)	End Concentration (kg/m^3)
0	600	0	0
0.2	600	0	0
0.4	600	0	0
0.6	600	0	1
0.8	600	1	3.33
1.0	600	3.33	7
0.8	600	7	7
0.6	600	7	7
0.4	600	7	7
0.2	600	7	1
0	50	1	0

Bulk (dry) density of sediment on the bed = 1,500 kg/m^3

Water density = 1,020 kg/m^3

Area of annular flume bed = 1 m^2

Water depth = 0.2 m

Total water volume, therefore = 0.2 m^3

(Sheet 1 of 3)

Example Problem III-5-1 (Continued)

SOLUTION:

Since the bed area of the annular flume has been carefully chosen to be 1 m^2, the rate of change of total sediment suspension will directly give us the quantity dm_b/dt. Otherwise, we would have had to multiply both sides of both equations by the area of the bed.

Our results are not given as total sediment in suspension, but as concentration in kg/m^3. We need to multiply them by the volume of water in the annular flume, 0.2 m^3, to get total sediment numbers equivalent to dm/dt on the bed.

So, for example, when the applied shear was 0.6 Pa

$$dm/dt = (V \times \Delta C) / (A \times \Delta T) = (0.2\ m^3 \times -1\ kg/m^3) / (1\ m^2 \times 600\ sec)$$
$$= -3.33 \times 10^{-4}\ kg/m^2\text{-sec}$$

Similarly for 0.8 Pa, -7.77×10^{-4} kg/m^2/sec, and for 1.0 Pa, -1.22×10^{-3} kg/m^2-sec.

This concludes the erosion data for the Parthenaides Equation. By plotting erosion rate versus shear (Figure III-5-25), we can extrapolate back to the shear at which the erosion rate is zero, τ_c = 0.45 Pa. From the same plot we can read M_p, the erosion rate at $2\tau_c$ = 0.9 Pa, = 10^{-3} kg/m^2-sec.

In the same way, the deposition results can be used as shear is reduced, with the Krone Equation for

0.2 Pa and C_{avg} = 4.0 kg/m^3, dm/dt = 2×10^{-3} kg/m^2-sec

and for

0.0 Pa and 0.5 kg/m^3, dm/dt = 4×10^{-3} kg/m^2-sec

Note that we can use the mean sediment concentration C_{avg}, since deposition rate is a linear function of concentration. In high concentration, settling velocity also becomes an inverse function of concentration.

The result at 0.0 Pa gives the floc settling velocity directly

$$w = (dm/dt) / (C_{avg} \times \tau_s / \tau_s) = (4 \times 10^{-3}\ kg/m^2\text{-sec}) / (0.5\ kg/m^3) = 8 \times 10^{-3}\ m/sec$$

Substituting this in the Krone Equation at 0.2 Pa, yields

$$\tau_s = (\tau \times C_{avg} \times w) / (C_{avg} \times w - dm/dt)$$
$$= (0.2\ Pa \times 4.0\ kg/m^3 \times 8 \times 10^{-3}\ m/sec) / (4.0\ kg/m^3 \times 8 \times 10^{-3}\ m/sec - 2 \times 10^{-3}\ kg/m^2\text{-sec})$$
$$= 0.21\ Pa$$

A real set of data, whether from field or laboratory annular flume, will be more difficult to work with. Complications to be expected are:

The variation of erosion rate with bed shear will not be linear, but will require some judgment and nonlinear regression to determine τ_c.

(Sheet 2 of 3)

Example Problem III-5-1 (Concluded)

You will never again have the luxury of somebody timing the settlement of the last floc, giving *w* directly. Instead, you will have to solve two or more equations with two or more unknowns, one of which is *w*.

Bed sediment density, and hence τ_c, varies with depth of erosion due to consolidation.

A natural bed will be layered, with discontinuities in consolidation and sedimentology over depth.

Water volume and depth vary with depth of erosion.

Direct measurement of bed shear is often difficult, particularly in the field laboratory where rotation of the lid of the annular flume is resisted by fluid shear, both in the flume and on the upper surface.

The area of the bed in the direct shear device (annular flume in this example) is seldom a convenient 1 m^2 or 1 ft^2.

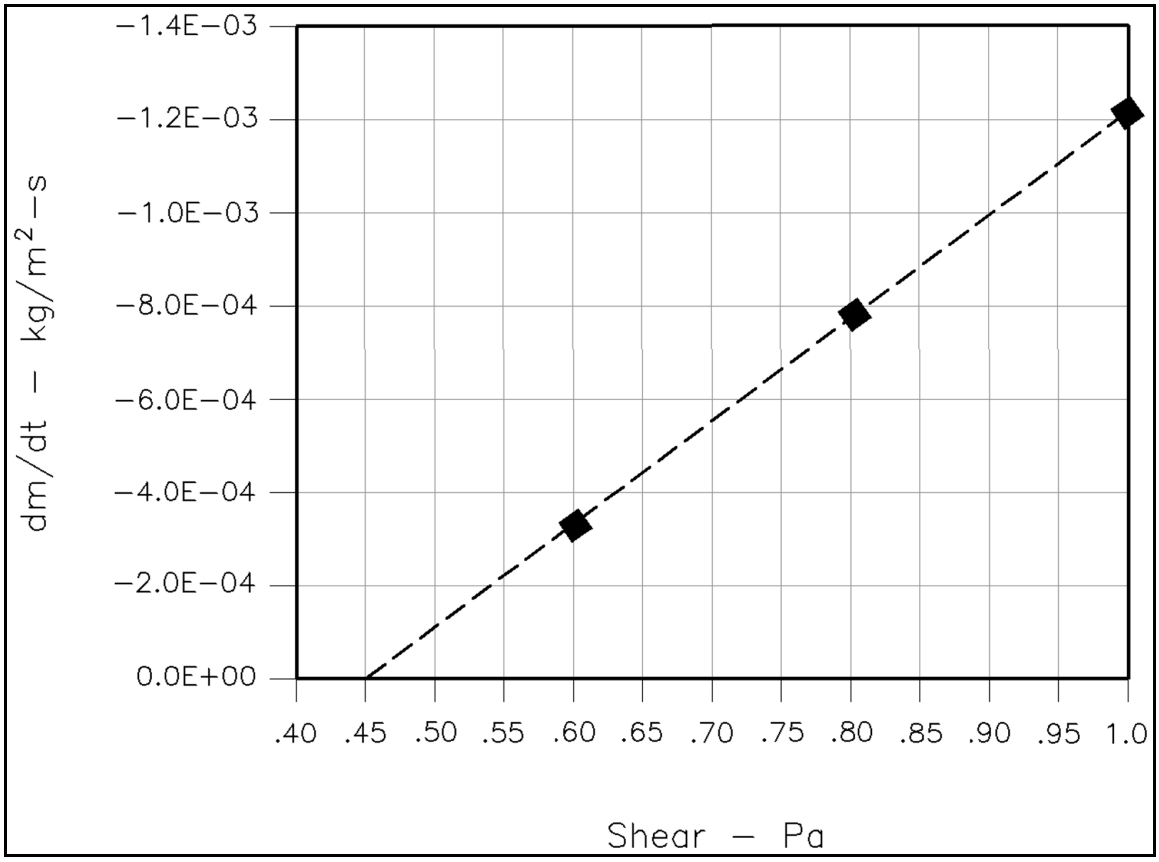

Figure III-5-25. Plot of erosion rate versus shear for example problem

(Sheet 3 of 3)

Figure III-5-26 (Lee 1995) summarizes the interactions between a mud shore and waves:

(a) At low water or under calm seas, the profile formed by the previous wave condition consolidates.

(b) Breaking waves result in mass erosion at the breaker line, with high turbidity in the surf zone; lower turbidity and surface erosion occur seaward of the breaker line, to the point where bed shear is less than the critical shear for erosion.

(c) Turbidity in the surf zone reaches that of fluid mud, flowing generally downhill offshore and collecting in troughs, under the influence of the wave orbital motion within the fluid mud.

(d) Return to (1), consolidation of the new profile under calm seas or at low water.

(3) Lee (1995) and Lee and Mehta (1994) found that wave height decays exponentially across the profile, i.e.

$$H_y = H_0 e^{-k_i y} \tag{III-5-7}$$

where

y = distance along wave ray, m (ft), positive towards shore

H_0 = incident wave height at $y = 0$, m (ft)

H_y = wave height at y, m (ft)

k_i = wave height attenuation coefficient, m^{-1} (ft^{-1})

(4) The wave height attenuation coefficient k_i characterizes the fluidization potential of the mud. It is obviously a function of the rheology of the bed; and also probably of the wave period T and incident wave height H_0. Lee (1995) and Lee and Mehta (1994) believe k_i to be a function of the local wave height, and talk of a spatial mean $\overline{k_i}$ across the profile. In practice, $\overline{k_i}$ is another calibration coefficient, like the Parthenaides coefficient, to be determined by fitting to observations of wave attenuation and profile development. A high $\overline{k_i}$ indicates a thick fluid mud layer, which Lee (1995) and Lee and Mehta (1994) associate with offshore flow on an eroding profile; a low $\overline{k_i}$, with an accreting profile. Lee (1995) quotes values of $\overline{k_i}$ in the range $0.0001 \le k_i \le 0.05$.

III-5-12. Numerical Modeling

a. Introduction.

(1) In this section, the role of numerical modeling is discussed both as an engineering tool and a planning tool. The development of numerical modeling of cohesive shore erosion is not far advanced. Nevertheless, approaches that have been utilized are briefly summarized. Numerical models are generally applied to simulate a future outcome given a known set of input conditions. For cohesive shore applications, there are at least four possibilities where numerical models can provide valuable information as follows:

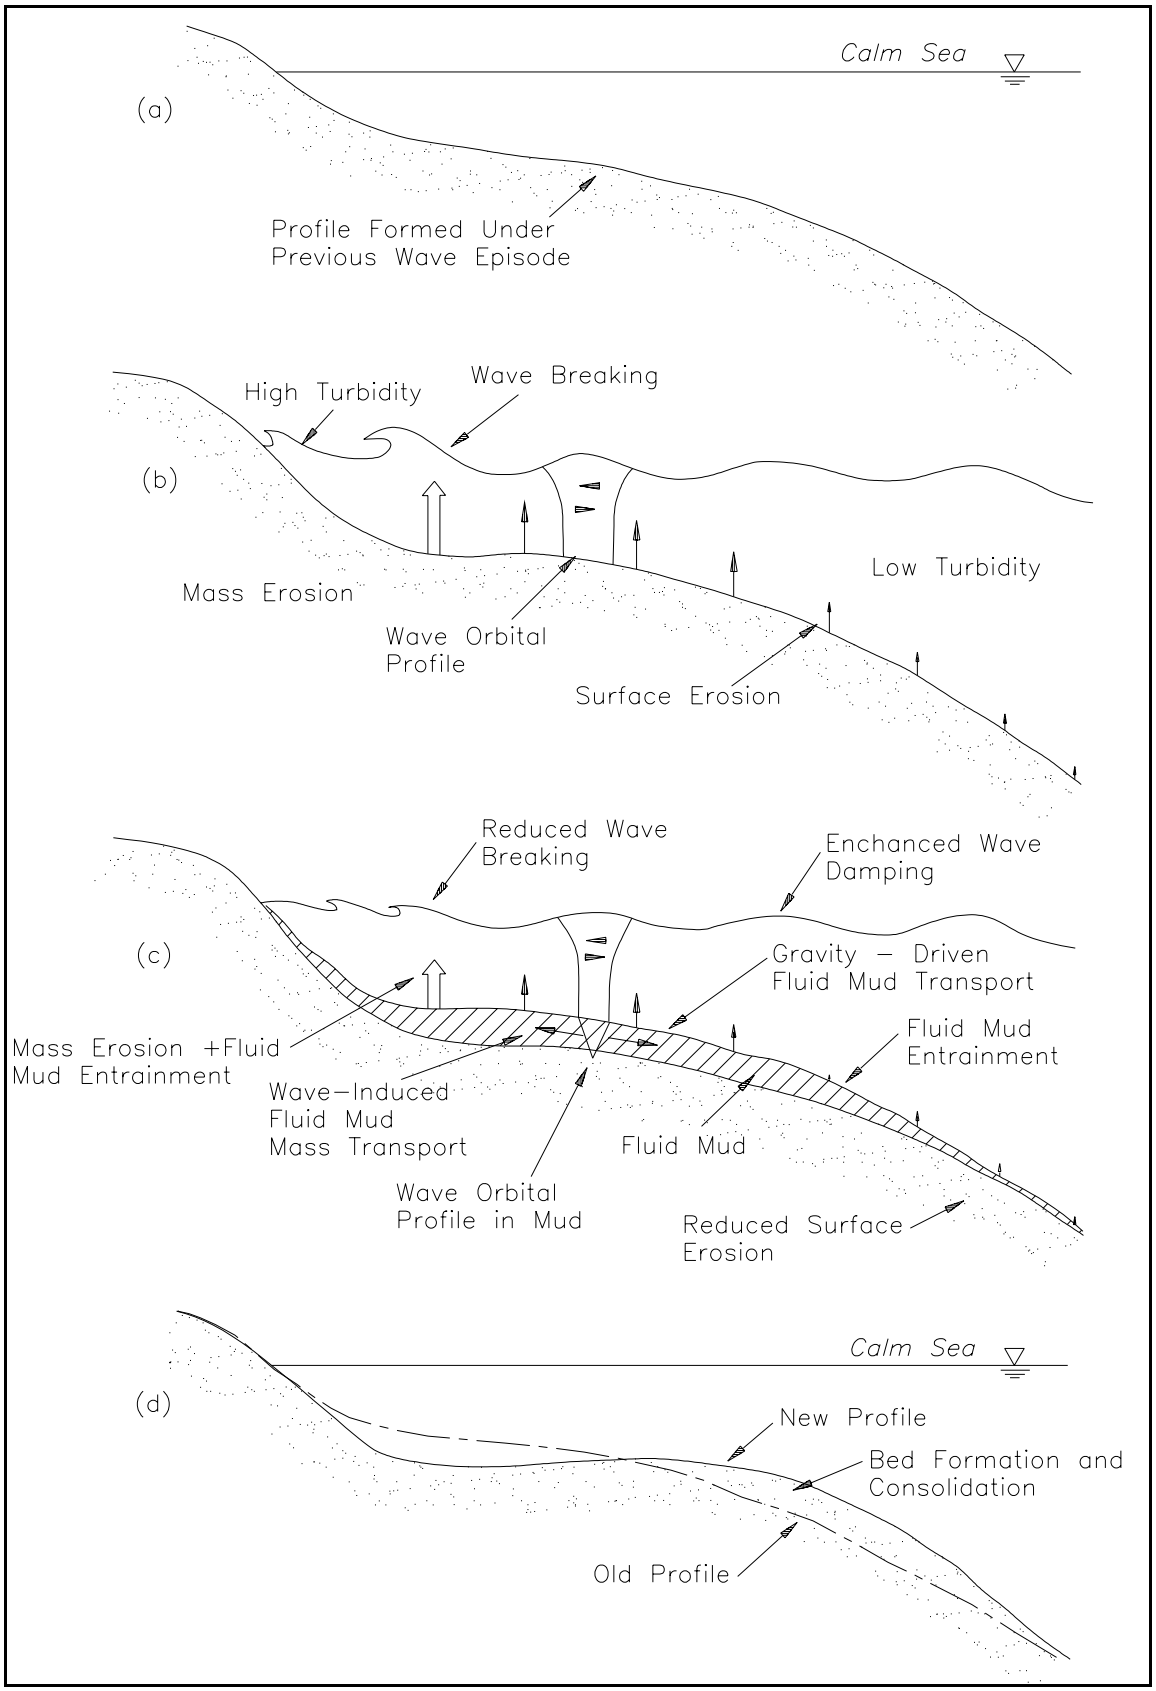

Figure III-5-26. Mud beach processes (after Lee (1995))

(a) To forecast long-term erosion rates (i.e., on the order of 50 years for developing shorelines). 'Developing shorelines' refer to areas where the evolution of a shore profile is at an early stage (e.g., newly created reservoirs). In these cases, the future rate of shoreline recession will probably differ from that experienced in the past owing to the evolving shape of the nearshore profile. Future erosion rates are required to plan setbacks and development around the new water bodies. In addition, the changing nature of the littoral zone (slopes and surficial substrate) may be important to the management of fish habitat.

(b) To forecast long-term erosion rates where either the environmental or the geologic conditions are changing due to natural or human causes. Natural influences that may change include increased storminess, sea level rise, changes to sand supply, or the changing geology encountered as the shoreline erodes. Human influences may include changes to water level fluctuations by water level regulation and reduction in the sand cover over the cohesive profile due to interruptions or reduction in sand supply to the littoral zone.

(c) To forecast the performance and potential impacts of coastal engineering works. For example, downcutting will continue offshore of the toe of a revetment constructed on a cohesive shore, and this outcome must be forecast and addressed in the design of the structure.

(d) Based on known historic recession rates and environmental conditions, numerical models can be applied to 'back-calculate' erodibility coefficients to describe the erosion resistance of a particular type of cohesive sediment. In turn, this can be used to assess future erosion rates at another site with the same sediment type but with different environmental conditions (i.e., the wave and water level climate).

(2) Therefore, there are many situations where numerical modeling would serve as an important tool for coastal engineering and coastal zone planning in cohesive shore environments.

b. Simulating erosion of consolidated sediment.

(1) Two approaches to modeling consolidated cohesive shore erosion are described in this section. Both rely on a significant degree of empiricism.

(2) The first approach is described by Penner (1993) for estimating future bank recession rates on Western Canadian lakes and reservoirs. This procedure consists of using a wave hindcast to determine the amount of wave energy that reaches a bluff face (accounting for losses over the nearshore profile). From this information and a knowledge of an erodibility coefficient, the future rate of shore recession can be determined. The erodibility coefficient relates volumetric erosion to the wave energy that reaches the bluff toe. This coefficient may be determined through back-calculation, or model calibration, for a location with known history of erosion (with the wave climate calculated by a wind-wave hindcast) or it may be estimated based on published values by others who have used this technique in the past (e.g., Penner 1993, Mollard 1986; Kachugin 1970; Newbury and McCullough 1984).

(3) Since this method essentially ignores the role of profile downcutting, it is primarily applicable to profiles that are at an early stage of development (i.e., with a very steep profile and narrow nearshore zone). In these cases, most of the wave energy is dissipated at the bluff face, in contrast to the more developed shoreline profiles on the Great Lakes and ocean coasts where the majority of wave energy is dissipated across the profile.

(4) This method has been applied to estimate the future shoreline position around new reservoirs in order to establish setback and ownership requirements. It has been refined to consider variations in erodibility of the materials encountered through time as the shoreline recedes. A table of erodibility coefficients from Penner (1993) is reproduced in Table III-5-3 below. The empirical coefficients relate wave energy that reaches the bluff toe to the weight of eroded sediment.

(5) Table III-5-3 reveals some interesting comparisons to the previous discussions of erosion processes. The high erodibility coefficient for the case of sand cover over the till confirms the importance of sand as an abrasive agent. For cases with a sand or gravel overlay, the erodibility coefficient is 2-10 times higher than the coefficients for soft and hard till. This compares well with the results of the laboratory experiments where erosion rates were increased by a factor of 3 to 8 with the introduction of sand to the flow for a range of hard and soft consolidated cohesive sediments (Part III-5-4b). Also, the category of a till bluff with a lag-protected nearshore corresponds to the slowly eroding convex profile type discussed above.

Table III-5-3
Erodibility Coefficients (from Penner (1993))

Material Type	Erodibility Coefficient (m^2/tonne)
Till with sand or gravel surficial overlay	0.0004
Soft till	0.0002
Hard till	0.00004
Till with a dense cover of surficial boulders	0.00002
Sandstone, siltstone, or shale covered with till	0.00005 to 0.0002

(6) A second approach to the numerical modeling of cohesive shore erosion is based on the conceptual model proposed by Nairn, Pinekin, and Philpott (1986). This approach relates downcutting to the shear stress generated by orbital velocities under unbroken waves and to the rate of wave energy dissipation for broken waves. The predicted downcutting determines the profile retreat rate which is assumed to determine the bluff or cliff retreat rate above water. A numerical model of coastal processes (Nairn and Southgate 1993) is used to determine the orbital velocity, the rate of wave energy dissipation, and the fraction of broken waves at locations across a nearshore profile. Erodibility coefficients relating downcutting rates to the conditions associated with broken and unbroken waves are determined in one of two ways. First, these coefficients can be back-calculated or calibrated based on a known profile retreat rate and the associated environmental conditions (i.e., the wave and water level conditions corresponding to the period of known profile retreat).

(7) Alternatively, intact cohesive sediment samples can be extracted from the study site and tested in a unidirectional flow flume as discussed in Part III-5-6a. The erodibility coefficients can then be determined based on known coefficients for sediments with a similar laboratory response. However, the latter approach is only valid for locations with similar sand cover conditions. The reason for this is that in long-term applications, the model ignores the presence of sand cover, and therefore the erodibility coefficient also accounts for the mobility and quantity of sand cover.

(8) A more detailed version of the model described in Nairn and Southgate (1993) has been developed to assess short-term erosion on cohesive profiles (i.e., over a period of weeks). This model accounts for the movement of limited quantities of sand over a hard surface. Erosion is activated in the model only where sediment transport occurs over an exposed segment of cohesive sediment. This model has been successfully tested against the laboratory wave flume data of Skafel and Bishop (1994) on cohesive profile erosion (Nairn and Southgate 1993).

(9) The numerical model described in Nairn and Southgate (1993) has been applied to assess the influence on erosion of modifications to the water level regulation on the Great Lakes. Stewart and Pope (1993) determined the potential future long-term (i.e., 50 to 100 years) profile retreat (and the associated shoreline erosion) rates for several different test sites. At each of these sites, the model was calibrated against a known profile retreat rate to determine the erodibility coefficients. These test sites featured a variety of wave exposures and profile types. For a potential lake level regulation scenario with a reduced range of water

level fluctuations (i.e., lower highs and higher lows), the long-term erosion on cohesive shores with convex profiles was found to be reduced, but the long-term erosion on concave profiles was unchanged.

c. Simulating erosion and deposition of mud.

(1) The numerical models described in *a.* above may also be used for erosion of mud shore, given a suitable choice of erodibility coefficient or critical shear for erosion. Nevertheless, these do not handle the other cohesive shore processes (transport, deposition, and consolidation), for which a full hydrodynamic model is required.

(2) Willis and Crookshank (1994) describe a bed sediment 'module' designed to be called as a subroutine to a full 1-, 2-, or 3-D model of wave and current hydrodynamics on the shore. This module applies the equations presented in this chapter to compute the exchange of sediment between the bed and the water column, at each grid point in the model, at each time-step. Because of its 'add-on' nature, it cannot deal with the intermediate state of fluid mud, for which an integrated water-sediment 3-D model is required (e.g. Le Hir 1994).

III-5-13. Engineering and Management Implications

The differences between processes on sandy and cohesive shores are fundamental to successful planning and engineering on cohesive shores. This section provides a discussion of some of the important issues.

a. Setbacks and cliff stablilization.

(1) The two most important issues in the planning and management of cohesive shores relate to implementing setbacks for development and to managing human influences on the sediment supply. Successful coastal management can sometimes avoid the need for costly shore protection structures.

(2) Many jurisdictions along U.S. shorelines impose a setback for new development consisting of some multiple of the average annual recession rate (e.g., 30 to 100 times the average annual recession rate). The purpose of the setback is to avoid the need for shore protection within the life of the new development, recognizing the irreversible and inevitable erosion that occurs along cohesive shores (and some sandy shores as well). However, this procedure may not be fully reliable, for several reasons. Most importantly, the environmental and geologic conditions that determine the recession rate can change through time both naturally (e.g., increased storminess, higher water levels, changes in erodibility as the shore erodes) and through human influences (e.g., by reducing the sand supply to the littoral zone).

b. Vegetation.

(1) Where possible, every effort should be made to replace vegetation (salt marsh, grass, mangrove) whose loss might have triggered or allowed mud shore instability (Part III-5-1b). The root system provides fiber reinforcement to the soil. Above the bed, the body of the vegetation protects the mud from shear due to currents and waves and creates a calm layer close to the bed to encourage deposition and settlement.

(2) Vegetation is required to halt mud erosion, but most vegetation cannot germinate and establish itself on an eroding or unstable shore. Some less natural form of shore protection is needed to create the conditions necessary for the vegetation to establish. This may be as simple as geotextile or willow mats imitating the root system until the natural roots can develop. But (temporary) bunds may be required to protect an area of germinating vegetation, at least until the plants can withstand currents and waves.

(3) Vegetation is also useful on consolidated cohesive shores. Brambles, for example, can help stabilize an eroding bluff or cliff against subaerial erosion while discouraging at least human traffic. However, this type of solution will only be effective in the long term if seabed or lake bed downcutting is halted.

c. Interruption to sediment supply and downdrift impacts.

(1) Another important planning requirement on cohesive shores is the management of sediment budget; specifically, human influences on sand supply. The erosion of cohesive shores results in a contribution of noncohesive sediment to the littoral sediment budget. This contribution consists of the sand and gravel-size fraction of the bluff and nearshore bottom material. There are three human influences that can reduce the sand supply:

(a) The construction of shore protection eliminates the contribution of the noncohesive fraction from the erosion of the bluff (and possibly part of the nearshore) for the protected reach of shore. On an individual-project basis, this reduction in the total supply to the littoral sediment budget may be small. However, the cumulative impact of many shore protection projects along many kilometers may be significant (as explained below).

(b) The construction of harbors, lakefills, or other projects which protrude into the lake result in large quantities of sand being trapped (in fillet beaches) and diverted offshore (once the fillet beaches have reached full capacity). Often, this sand is permanently lost from the active littoral system.

(c) Dredging or sand mining. Dredging is often required at harbor structures where sediment has been diverted offshore and deposited in navigation channels. The sand-sized portion of the dredged sediment is lost from the littoral system if it is placed outside the littoral zone (i.e., offshore, on land, or in a confined disposal facility).

It is also important to note here that sand supply can be reduced or increased through natural changes. For example, as the shore retreats, stratigraphic units containing more or less sand may be exposed to erosion.

(2) The impact of reducing the sand supply depends on the type and characteristics of the downdrift shore. Depending on the quantity of the natural sand cover along the downdrift cohesive shore, the reduction in sand supply may or may not increase the erosion rate. If the sand quantity is high (greater than approximately 150 m^3/m), the erosion rate will be increased. On the other hand, if the sand cover is already low (less than approximately 50 m^3/m), the erosion rate will probably be unaffected. Invariably, at the downdrift end of a reach of eroding consolidated shore, there is an accreting or stable sand beach deposit that receives the noncohesive fraction eroded from the bluffs. The cutoff or reduction in sand supply to this beach may trigger the onset of its erosion.

d. Remedial measures for cohesive shore erosion.

(1) In order to arrest shoreline recession on a consolidated cohesive shore, it is necessary to stop the downcutting across the profile out to a depth where the future rate of downcutting will not adversely affect the coastal protection system. Three examples of how this can be achieved are as follows:

(a) Through beach nourishment (possibly in conjunction with retaining structures such as detached breakwaters) to increase the sand cover volume to a level sufficient to protect the underlying cohesive profile under most conditions (this volume is approximately 200 m^3/m for Great Lakes shorelines).

(b) Through the construction of offshore breakwaters.

(c) Through the construction of revetment with the toe excavated a sufficient distance into the lake bed or seabed. As an alternative to excavating the toe, a toe protection berm could be placed with sufficient thickness and width to accommodate settling through erosion offshore of the toe of the berm. In most cases, this approach will lead to the eventual disappearance of beaches due to ongoing downcutting offshore of the toe of the revetment and the related steepening of the profile to an extent where sand beaches cannot be maintained naturally. Another critical issue affecting the future performance of revetments on consolidated cohesive shores is the flanking erosion of adjacent unprotected shores. The ends of the revetment may have to be periodically extended back to the shore to address flanking.

(2) One key constraint that must be considered in the design of coastal structures on consolidated cohesive shores is that the nearshore profile will continue to erode offshore of the structure. This has two potentially adverse implications for the stability and performance of the structure:

(a) The toe of the structure may be destabilized if it has not been designed to accommodate ongoing downcutting.

(b) With the deepening of the nearshore profile, the structure will be exposed to larger waves in the future. Both of these outcomes should be considered in design.

(3) Figures III-5-27 and III-5-28 demonstrate the consequences of inappropriate shore protection structures along consolidated shores. The cohesive foundations of the gravity seawall in Figure III-5-27 were undermined, causing the wall to topple. Figure III-5-28 shows that the sheet-pile wall and groin system were ineffective at preventing downcutting and arresting bluff retreat.

(4) For design purposes, the rate of foreshore lowering at any point on the profile can be determined using the profile retreat model. The required information is the approximate shape of the underlying cohesive profile and the shoreline retreat rate. Caution should be applied in using this technique since both the profile shape and the retreat rate could change in the future due to: changing stratigraphy in the foreshore, increased storminess, changes in water levels, and changes to the overlying sand cover.

e. Foundations.

(1) The foundation of structures on cohesive coasts should be assessed with respect to the stability of the underlying cohesive sediment. For locations with high bluffs or cliffs, presumably the loading associated with the structure will be much less than that associated with the bluff itself (i.e., prior to erosion).

(2) Protection of the toe of the bluff and the nearshore profile, on its own, may not be sufficient to stabilize an oversteepened bluff face. The bluff or cliff will usually be in an oversteepened condition prior to the implementation of protection (except in the case where a slope failure has recently occurred). One or more of the following three actions could be taken to address this problem:

(a) Allow the slope to naturally stabilize through surface erosion and failures, and to eventually be colonized by natural vegetation.

Figure III-5-27. A toppled concrete seawall along the Lake Michigan coast of Berrien County. Failure probably resulted from undermining of the underlying glacial till foundation, April 1991

Figure III-5-28. A steel sheet-pile wall and groin field has been ineffective at protecting this section of cohesive shore along the Berrien County shore of Lake Michigan, south of the town of St. Joseph, April 1994

Example Problem III-5-2

FIND:

A revetment is being designed to protect an eroding bluff. Find the total downcutting expected over a period of 25 years at the toe of a shore protection structure placed at a water depth of 2 m below low water on a cohesive profile.

Given:

The following information is available:

(1) The long-term bluff retreat rate is 1.0 m/year.

(2) The median grain size of the sand overlying the till is 0.2 mm, 200 μ.

Procedure:

The following steps are taken to develop a solution:

(1) Determine the shape of the underlying cohesive profile. In the absence of direct field information, the cohesive profile shape may be assumed to follow the equilibrium profile for the overlying sand as suggested by Kamphuis (1990) (Part III-5-5a).

(2) Determine the distance offshore to the toe of the revetment (i.e., at the 2-m depth contour) based on the equilibrium profile.

(3) Considering that the bluff retreat rate is equivalent to the profile retreat rate, find the depth of water for the distance determined in step 2 plus 25 m (i.e., 25 years at 1 m/year).

(4) Expected downcutting is the difference between the initial 2-m depth and the depth determined in step 3 above.

Solution:

(1) Using the information provided in Part III-3-3 and Figure III-3-17, the relationship between distance offshore (y) and depth of water (h) for a grain size of 0.2 mm is described by:

$$h = A\, y^{2/3}$$

(2) Therefore, $y = (h/A)^{1.5} = (2/0.1)^{1.5} = 89$ m

The toe of the revetment is located 89 m seaward of the shoreline after construction.

(3) After 25 years, the profile will have shifted inshore by a distance of 25 m. Of course, the erosion inshore of the revetment associated with this shift will be prevented by the presence of the revetment. However, offshore of the toe, the downcutting will continue at the historic rate. Therefore, the new depth at the toe will be the depth associated with a distance of 89 + 25 m from the shoreline (i.e., the distance from shore to the toe of the revetment had the revetment not been constructed). The new depth is calculated as follows:

$$h = A\, y^{0.67} = (0.1)\ 114^{0.67} = 2.39 \text{ m}$$

(Continued)

Example Problem III-5-2 (Concluded)

(4) Therefore, the expected downcutting over a 25-year period at the toe of the revetment in a water depth of 2 m is 0.39 m (i.e., 2.39 - 2.0).

In reality there are factors that may make this either a conservative (high) or nonconservative (low) estimate. If the revetment is located along a shore with steady sand transport, it is possible that the revetment toe may be protected from downcutting most of the time by the presence of a bar at the base of the revetment (this outcome depends very much on the site conditions, including: grain size, profile shape, and wave climate). If this is the case, the 0.39 m of lowering over 25 years may be an overestimate. On the other hand, if the cohesive sediment at the toe of the revetment is not protected by a sandbar, local scour could occur in addition to the erosion associated with profile lowering. Local scour could easily exceed 0.39 m. It is important to note that with the lowering of the offshore profile through the downcutting process, the local scour will increase with time as larger waves are able to reach the revetment. Also, this solution assumed that the nearshore profile was well described by an equilibrium profile shape. This may not be the case if the nearshore stratigraphy consists of geologic units with different erosion resistances.

The lowering at the toe of a shore protection structure built on a cohesive shore should also be considered in the design of the structure. Specifically, armor unit stability and overtopping potential should be estimated for the expected future depths associated with the design life of the structure.

(b) Accelerate the stabilization process by constructing a drainage system and through bioengineering to encourage and promote colonization of the slope by native vegetation.

(c) Control the local groundwater flows to minimize destabilizing factors at the bluff face.

(3) In some cases, the natural stable slope, with its toe at the back of the shore protection, may not be acceptable due to the proximity of development to the top of the bluff or cliff. In these cases, additional measures may be taken to achieve a steeper stable slope either through buttressing at the toe, through the implementation of drainage systems in the slope, or other measures to address the potential causes of slope failures at the site.

(4) What size of seawall can soft mud support? Even an earth dike a couple of meters high can result in an overnight slip circle failure through the 'beach' foundation, and longer-term subsidence will need to be compensated for in the design. Geotechnical considerations are of prime importance in the design of shore protection on soft shores; not just bearing (compressive) strength, but shear strength and consolidation rates as well (Part VI-5). Mud might not be able even to support heavy, land-based construction equipment. On many soft shores, mud has built up over centuries to thicknesses in excess of 30 m (100 ft), so that trenching to firm foundation may be uneconomical.

III-5-15. Definition of Symbols

ρ_{fm}	Density of the fluid mud layer [force/length^3]
ρ_s	Mass density of sediment grains [force-time^2/length^4]
ρ_w	Mass density of water (salt water = 1,025 kg/m^3 or 2.0 slugs/ft^3; fresh water = 1,000kg/m^3 or 1.94 slugs/ft^3) [force-time^2/length^4]
τ	Bed shear [force/length^2]
τ_c	Critical shear for erosion or erosion threshold [force/length^2]
τ_s	Critical shear stress for deposition [force/length^2]
C	Suspended sediment concentration [force/length^3]
C_v	Consolidation coefficient [length^2/time]
D_z	Vertical dispersion coefficient [length^2/sec]
F_r	Densimetric Froude number (Equation III-5-2)
g	Gravitational acceleration (32.17 ft/sec^2, 9.807m/sec^2) [length/time^2]
h	Equilibrium beach profile depth (Equation III-3-13) [length]
H_0	Incident wave height [length]
h_{fm}	Thickness of fluid mud layer [length]
H_y	Wave height at location y [length]
$\overline{k_i}$	Spatial mean wave attenuation coefficient [length^{-1}]
k_i	Wave height attenuation coefficient [length^{-1}]
m	Mass of sediment on the bed [force/length^2]
M	Constant in the Mignoit equation (Equation III-5-5) which expresses the exponential relationship between mud density and critical shear for erosion [dimensionless]
M_p	Parthenaides coefficient [force/length^2/time]
N	Constant in the Mignoit equation (Equation III-5-5) which expresses the exponential relationship between mud density and critical shear for erosion [dimensionless]
P	Length of the drainage path [length]
S	Vertical (upward) dispersion of sediment (Equation III-5-3) [force/length^2/time]
t	Time
T	Wave period [time]

u	Degree of consolidation, ratio of bulk density of a sediment to bulk density of a fully consolidated sediment [dimensionless]
V_{fm}	Mean velocity in the fluid mud layer [length/time]
V_w	Mean velocity in the water layer [length/time]
w	Sediment fall velocity [length/time]
y	Distance along wave ray [length]
y	Equilibrium beach profile distance offshore (Equation III-3-13) [length]
z	Vertical dimension [length]

Chapter III-6
Sediment Transport Outside the Surf Zone

III-6-1. Introduction

a. Coastal engineers often regard the seaward boundary of the surf zone as the deepwater limit of significant wave and current effect. From the outer break point shoreward to the beach, waves and their associated currents are recognized as major sources of sediment resuspension and transport. Seaward of this point there is a region from roughly 2 to 3 m depth to approximately 20 to 30 m depth within which the importance of waves and currents on sediment transport processes is not well understood. Sediment transport within this region, usually referred to as the inner shelf, is the central focus of this chapter.

b. During severe coastal storms some material removed from the beach is carried offshore and deposited on the inner shelf in depths at which, under normal wave conditions, it is not resuspended. The fate of this material has, for some time, provided a troublesome set of questions for coastal engineers. Will this sediment be returned to the surf zone and perhaps even the beach or will it be carried further offshore to the deeper waters of the continental shelf? Furthermore, what are the time scales of these sediment motions, regardless of their directionality? Similar questions are relevant for sediment deposited on the inner shelf from human activities e.g., "what is the fate and transport of dredged material from inlets or navigation channels as well as contaminated sediment resulting from discharge of sewage?"). In order to answer these and similar questions related to sedimentary processes in inner shelf waters, it is necessary to establish a quantitative framework for the analysis and prediction of sediment transport processes outside the surf zone.

c. To fully appreciate the complexity of this problem it is necessary to recognize that sediment transport has been extensively studied for decades and yet it is still not possible to predict transport rates with any degree of certainty. A majority of these studies have been carried out in laboratory flumes under highly idealized conditions of steady two-dimensional flow over uniform noncohesive sand. Few studies have addressed the added complications of bed form drag, sediment concentration influence on flow, and cohesive sediment movement. On the inner shelf, as on most of the active seabed, sediment transport is a nonlinear, turbulent, two-phase flow problem complicated by bed forms, bottom material characteristics, current variability, and by the superposition of waves. In addition, transport can be comprised of bed load as well as suspended load, the quantitative separation of which is of considerable complexity.

d. The fundamental approach to predicting sediment transport is to relate the frictional force exerted by the fluid and consequent bed shear stress τ_b to the sediment transport rate q. There are two ways to address prediction of sediment transport. Empirical approaches use measurements of fluid velocity and depth as well as bottom roughness and grain size to determine proportionality relationships over a wide variety of conditions. Theoretical approaches attempt to use turbulent flow dynamics to determine the proportionality values directly. A predictive theory of turbulent flow does not exist and stochastic analysis, though useful, cannot provide an understanding of sediment transport mechanics in turbulent flows. Validating experiments must therefore be used to determine coefficients arising from assumptions incorporated into any theoretical prediction formulations. A major difficulty encountered by either the empirical or theoretical approach is the inability to adequately measure sediment transport rates. Consequently, existing formulations for predicting sediment transport rates show large discrepancies, even when they are applied to the same data (White, Milli, and Crabbe 1975; Heathershaw 1981; Dyer and Soulsby 1988).

e. The purpose of this chapter is to present an approach to the quantitative analysis and prediction of sediment transport outside the surf zone. This approach will incorporate hydrodynamics of wave-current boundary layer flow, fluid-sediment interaction near the bottom, and sediment transport mechanics.

III-6-2. Combined Wave and Current Bottom Boundary Layer Flow

a. Introduction.

(1) In inner shelf waters and over the entire continental shelf during extreme storm events, near-bottom flow will be determined by the nonlinear interaction of waves and slowly varying currents. This superposition of flows of different time scales and hence different boundary layer scales results in the wave bottom boundary layer being nested within the current boundary layer. The high turbulence intensities within the thin wave bottom boundary layer cause the current to experience a higher bottom resistance in the presence of waves than it would if waves were absent. Conversely, the wave bottom boundary layer flow will also be affected by the presence of currents, although far less so than the current is affected by the presence of waves.

(2) A 10-s wave 1 m in height produces a near-bottom orbital velocity exceeding 0.15 m/s in depths less than 30 m. Due to the oscillatory nature of the wave orbital velocity, the bottom boundary layer has only a limited time, approximately half a wave period, to grow. This results in the development of a thin layer, a few centimeters in thickness, immediately above the bottom, called the wave bottom boundary layer, within which the fluid velocity changes from its free stream value to zero at the bottom boundary. The high-velocity shear within the wave bottom boundary layer produces high levels of turbulence intensities and large bottom shear stresses.

(3) In contrast to the wave motion, a current, wind-driven or tidal, will vary over a much longer time scale, on the order of several hours. Hence, even if the current is slowly varying, the current bottom boundary layer will have a far greater vertical scale, on the order of several meters, than the wave bottom boundary layer. Consequently the velocity shear, turbulence intensities, and bottom shear stress will be much lower for a current than for wave motion of comparable velocity.

(4) The simple eddy viscosity model proposed by Grant and Madsen (1986) is adopted throughout most of this chapter in order to obtain simple closed-form, analytical expressions for combined wave-current bottom boundary layer flows and associated sediment transport. A review of alternative models, employing more sophisticated turbulence closure schemes is given in Madsen and Wikramanayake (1991). Alternative wave-current interaction theories applicable to sediment transport are: prescribed mixing length distribution (Bijker 1967), momentum deficit integral (Fredsoe 1984), and turbulent kinetic energy closure (Davies et al. 1988). All four theories are compared in Dyer and Soulsby (1988). A detailed discussion of the eddy viscosity model approach is given in Madsen (1993).

(5) Although limitations of analyses will be pointed out in each section, some major limitations applicable throughout this chapter are stated here. (a) The hydrodynamic environment is limited to *nonbreaking* wave conditions described by *linear wave theory* and near-bottom *unidirectional* steady currents. The former limitation places the applicability of results derived in this chapter well outside the surf zone, whereas the latter precludes the use of formulas presented here for flows exhibiting appreciable turning of the current velocity vector with height above the bottom. (b) Only sediment that can be characterized as *cohesionless* is considered.

(6) Most flows that transport sediment are turbulent boundary layer shear flows and the forces exerted on the sediment bed are governed by the turbulence characteristics. Over a horizontal bottom, these flows are characterized by their large scale of variation in the horizontal plane relative to the scale of variation in the vertical plane. This disparity in length scales makes it possible to neglect vertical acceleration within the boundary layer (Schlichting 1960). Figure III-6-1 shows the turbulent boundary layer structure and mean velocity profile for a two-dimensional horizontal flow in the xz-plane, x being horizontal and z vertical. The turbulent boundary layer is made up of three sublayers; the viscous sublayer, the turbulence generation layer,

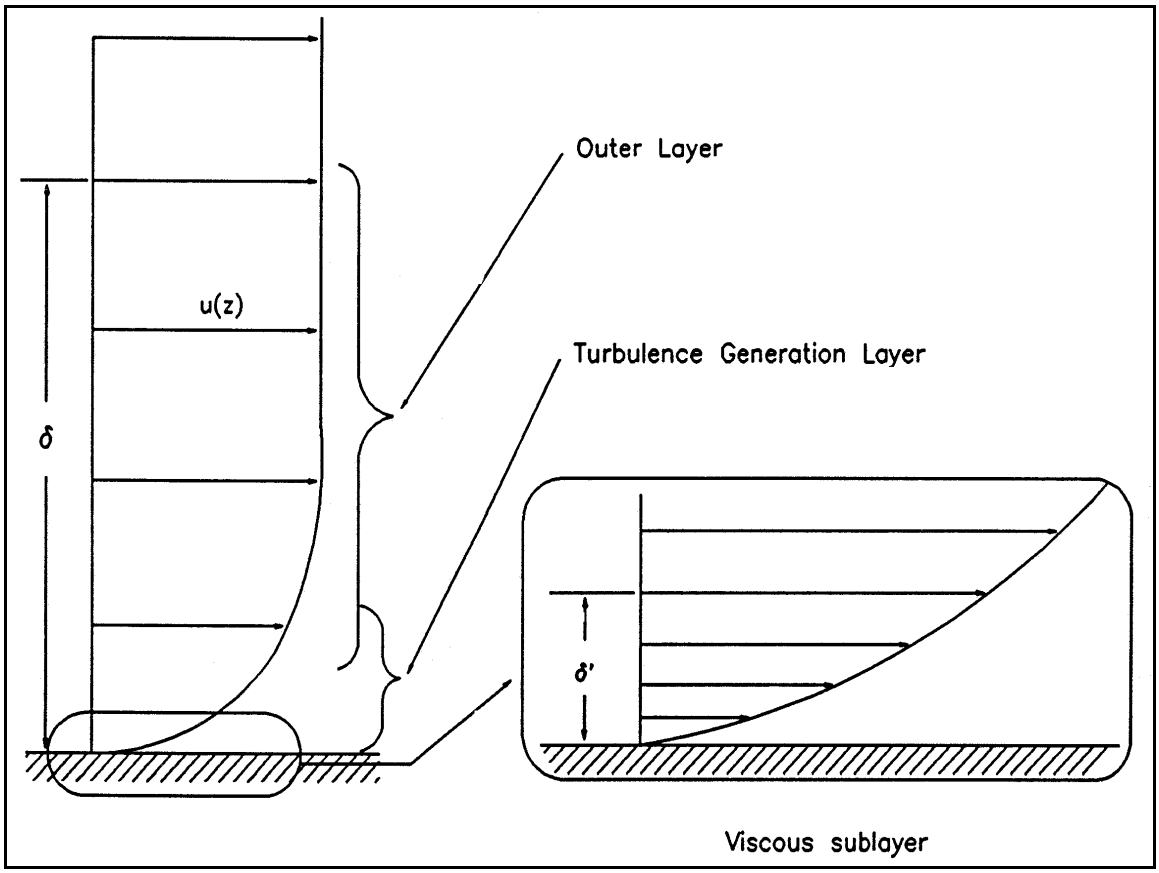

Figure III-6-1. Turbulent boundary layer structure and mean velocity profile

and the outer layer. In the viscous sublayer, turbulent fluctuations in velocity are present, but velocity fluctuations normal to the boundary must tend towards zero as the bottom is approached. Consequently, molecular transport of fluid momentum dominates turbulent transport very near the bottom and the shear stress τ can be modeled approximately by the laminar boundary layer relationship

$$\tau = \rho \nu \frac{\partial u}{\partial z} \tag{III-6-1}$$

where ρ is fluid density, ν the kinematic viscosity of the fluid, and u is horizontal velocity.

(7) The turbulence generation layer is characterized by very energetic small-scale turbulence and high fluid shear. Turbulent eddies produced in this region are carried outward and inward toward the viscous sublayer. If the bottom roughness elements (sediment grains and/or bed forms) have a height greater than the viscous sublayer, the turbulence generation layer extends all the way to the bottom.

(8) The outer layer makes up most of the turbulent boundary layer and is characterized by much larger eddies, which are more efficient at transporting momentum. This high efficiency of momentum transport produces a mean velocity profile that is much gentler than in the turbulence generation layer, Figure III-6-1.

(9) Turbulent boundary layer shear flow models can be simply developed by artificially choosing a constant ν_T (called the eddy viscosity), which is much larger than its laminar (molecular) value and that reflects the size of the eddy structure associated with the turbulent flow. This assumption results in a simple conceptual eddy viscosity model for turbulent shear stress that may be expressed as

$$\tau = \rho \nu_T \frac{\partial u}{\partial z} \tag{III-6-2a}$$

with the turbulent eddy viscosity

$$\nu_T = \kappa u_* z \tag{III-6-2b}$$

where κ is known as von Karman's constant and $u_* = (\tau_b/\rho)^{1/2}$ is called the shear velocity, where τ_b is the shear stress at the bed (z = 0). A complete derivation of this model is given in Madsen (1993).

(10) Experimental determinations have shown relatively little variation of κ, leading to von Karman's "universal" constant assumed to have the value 0.4.

b. Current boundary layer.

(1) Currents on the inner shelf can be considered to flow at a steady velocity compared to the orbital velocity of waves. Defining the shear stress due to currents τ_c, the current velocity profile can be expressed as

$$u_c = \frac{u_{*c}}{\kappa} \ln\frac{z}{z_o} \tag{III-6-3}$$

where $u_{*c} = (\tau_c/\rho)^{1/2}$ denotes the current shear velocity. Equation 6-3 is the classic logarithmic velocity profile expressed in terms of z_o, the value of z at which the logarithmic velocity profile predicts a velocity of zero. For a smooth bottom z_o = z = 0, but for a rough bottom, the actual location of the boundary is not a single value of z. Hence $z = 0$ becomes a somewhat ambiguous definition of the "theoretical" location of the bottom with some portions of the boundary actually located at $z > 0$ and others at $z < 0$. Therefore, application of Equation 6-3 in the immediate vicinity of a solid bottom is purely formal and its prediction of $u_c = 0$ at $z = z_o$ is of no physical significance.

(2) From the extensive experiments by Nikuradse (1933), the value of z_o is obtained as

$$z_0 = \begin{cases} \dfrac{\nu}{9u_*} & \text{for smooth turbulent flow} \\ \dfrac{k_n}{30} & \text{for fully rough turbulent flow} \end{cases} \tag{III-6-4}$$

in which k_n is the equivalent Nikuradse sand grain roughness, so called because Nikuradse in his experiments used smooth pipes with uniform sand grains glued to the walls, and therefore found it natural to specify the wall roughness as the sand grain diameter. Smooth or fully rough turbulent flow are delineated by Madsen (1993).

$$\frac{k_n u_*}{\nu} \geq 3.3 \quad \text{for fully rough turbulent flow}$$
$$\frac{k_n u_*}{\nu} \leq 3.3 \quad \text{for fully smooth turbulent flow} \tag{III-6-5}$$

(3) For turbulent flows over a plane bed consisting of granular material it is natural to take $k_n = D$ = diameter of the grains composing the bed. For flow over a bottom covered by distributed roughness elements (e.g., resembling a rippled bottom), the value $k_n = 30\, z_0$ is referred to as the equivalent Nikuradse sand grain roughness, with z_0 obtained by extrapolation of the logarithmic velocity distribution above the bed, to the value $z = z_0$ where u_c vanishes.

(4) Figure III-6-2 is a semilogarithmic plot of a current velocity profile obtained over a bottom consisting of 1.5-cm-high triangular bars at 10-cm spacing (Mathisen 1993). It is noticed that velocity measurements over crests and midway between crests (troughs) of the roughness elements deviate from the expected straight line within the lower 2.5 to 3 cm and further than ≈10 cm above the bottom. The near-bottom deviations reflect the proximity of the actual bottom roughness elements, which make the velocity a function of location, i.e., the flow is nonuniform immediately above the bottom roughness features. The nonlogarithmic velocity profile far from the boundary is associated with the flow being that of a developing boundary layer flow in a laboratory flume, i.e., the flow above $z \approx 10$ cm is essentially a potential flow unaffected by boundary resistance and wall turbulence.

(5) The well-defined variation of u_c versus log z (Figure III-6-2) can be applied to the case 3 cm < z < 10 cm. By extrapolation to $u_c = 0$, one obtains the value $z = z_0 \approx 0.7$ cm or $k_n = 30\, z_0 \approx 21$ cm, since the flow is rough turbulent. This example clearly illustrates that k_n, the equivalent Nikuradse sand grain roughness, is a function of bottom roughness configuration and does not necessarily reflect the physical scale of the roughness protrusions. Thus, the data shown in Figure III-6-2 were obtained for a physical roughness scale of 1.5 cm, the height of the triangular bars, and result in an equivalent Nikuradse roughness of 21 cm. This large value of k_n is, of course, associated with the much larger flow resistance produced by the triangular bars.

(6) It is often convenient to express the bottom shear stress associated with a boundary layer flow in terms of a current friction factor f_c defined by

$$\tau_c = \frac{1}{2} f_c \rho (u_c\ (z_r))^2 \tag{III-6-6}$$

(7) The somewhat cumbersome notation used in Equation 6-6 is chosen deliberately to emphasize the fact that the value of the current friction factor is a function of the reference level, $z = z_r$, at which the current velocity is specified. From Equation 6-6, the current shear velocity is obtained

$$u_{*c} = \sqrt{\frac{\tau_c}{\rho}} = \sqrt{\frac{f_c}{2}}\ u_c(z_r) \tag{III-6-7}$$

and introducing this expression in Equation 6-3, with $z = z_r$ and $\kappa = 0.4$ leads to an equation for the current friction factor

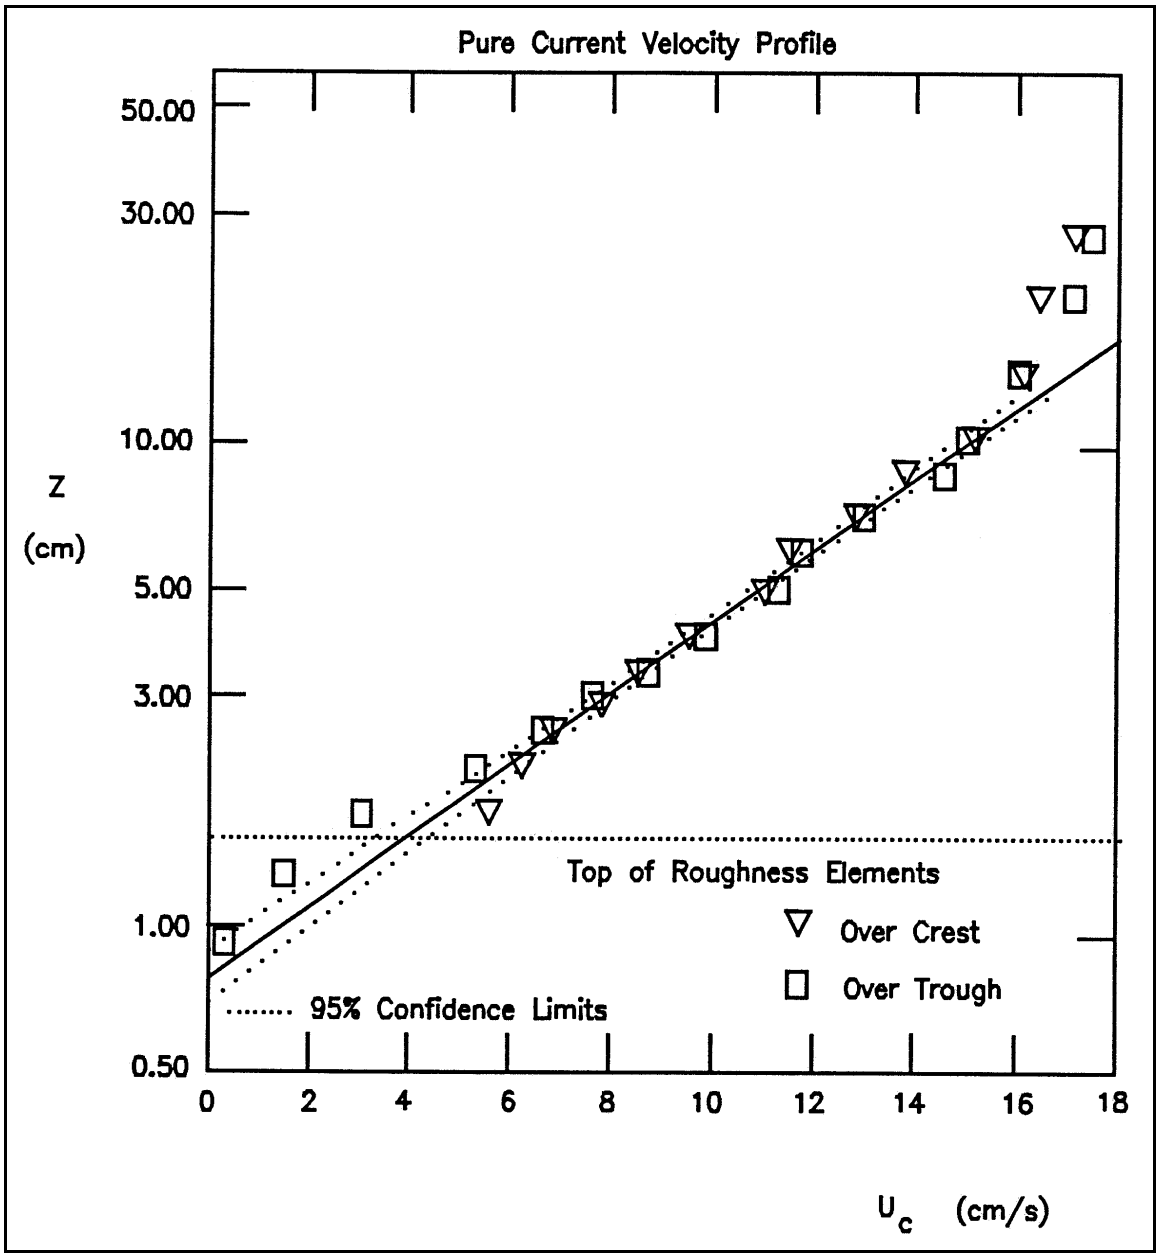

Figure III-6-2. Measured turbulent velocity profile for flow over artificial two-dimensional roughness elements (Mathisen 1993)

$$\frac{1}{4\sqrt{f_c}} \approx \log_{10} \frac{z_r}{z_0} \tag{III-6-8}$$

in terms of the reference elevation and the boundary roughness scale.

(8) For rough turbulent flows $z_0 = k_n/30$ and Equation 6-8 is an explicit equation for f_c in terms of the relative roughness z_r/k_n. For smooth turbulent flows $z_0 = \nu/(9u_{*c})$ and Equation 6-8 leads to an implicit equation for f_c (Madsen 1993)

EXAMPLE PROBLEM III-6-1

FIND:

The current friction factor f_c, the shear velocity u_{*c}, and the bottom shear stress τ_c, for a current over a flat bed.

GIVEN:

The current is specified by its velocity $u_c(z_r) = 0.35$ m/s at $z_r = 1.00$ m. The bottom is flat and consists of uniform sediment of diameter $D = 0.2$ mm. The fluid is seawater ($\rho \approx 1{,}025$ kg/m^3, $\nu \approx 1.0\times10^{-6}$ m^2/s).

PROCEDURE:

1) Start with Equation 6-4 *assuming* rough turbulent flow: $z_0 = k_n/30$.

2) Solve Equation 6-8 for f_c.

3) Obtain u_{*c} from Equation 6-7.

4) Check rough turbulent flow assumption by evaluating $k_n u_{*c}/\nu$ and using Equation 6-5.

5) *If* $k_n u_{*c}/\nu \geq 3.3$, flow *is* rough turbulent. Results (f_c and u_{*c}) obtained in steps 2 and 3 constitute the solution and τ_c is obtained from Equation 6-6 or from the definition $\tau_c = \rho u_{*c}^2$.

6) *If* $k_n u_{*c}/\nu < 3.3$, flow *is smooth turbulent* and the solution is obtained by the following iterative procedure (steps 7 and 8).

7) Obtain $z_0 = \nu/(9u_{*c})$ using u_{*c} from step 3.

8) With z_0 from step 7 return to step 2 to obtain a new f_c, and a new u_{*c} from step 3 and reenter (step 7).

9) When consecutive values of u_{*c} agree to two significant digits, iteration is complete. The last values of f_c and u_{*c} constitute the solution and τ_c is obtained from Equation 6-6 or from the definition $\tau_c = \rho u_{*c}^2$

(Continued)

Example Problem III-6-1 (Concluded)

SOLUTION:

It is first *assumed* that the flow will turn out to be classified as rough turbulent, in which case Equation 6-4 gives

$$z_0 = \frac{k_n}{30} = \frac{D}{30} = 6.67\times10^{-6} \text{ m} = 6.67\times10^{-4} \text{ cm}$$

where $k_n = D$ is chosen, since the bed is flat. With this z_0 value, Equation 6-8 is solved for f_c with $z_r = 1.00$ m, giving

$$f_c = 2.33\times10^{-3}$$

and the corresponding shear velocity is obtained from Equation 6-7 with $u_c(z_r) = 0.35$ m/s

$$u_{*c} = 1.19\times10^{-2} \text{ m/s} = 1.19 \text{ cm/s}$$

But is the flow really rough turbulent as *assumed*? To check this assumption, the boundary Reynolds number is computed using the rough turbulent estimate of u_{*c}

$$\frac{k_n u_{*c}}{\nu} = \frac{D u_{*c}}{\nu} = 2.38 < 3.3$$

From Equation 6-5 it is seen that the flow should be classified as smooth turbulent. (If $k_n u_{*c}/\nu$ had been greater than 3.3, the problem would have been solved.) Therefore, an estimate

$$z_0 = \frac{\nu}{9u_{*c}} \approx 9.3\times10^{-6} \text{ m}$$

is obtained from Equation 6-4 using the rough turbulent u_{*c}. With this value of z_0, Equation 6-8 gives the *current friction factor*

$$f_c = 2.47\times10^{-3}$$

and, from Equation 6-7, the *shear velocity* and the *bottom shear stress*

$$u_{*c} = 1.23\times10^{-2} \text{ m/s} = 1.23 \text{ cm/s and } \tau_c = \rho u_{*c}^2 = 0.155 \text{ N/m}^2 \approx 0.16 \text{ Pa}$$

Since the smooth turbulent u_{*c} obtained here is close to the rough turbulent estimate, returning with it to update $z_0 = \nu/(9u_{*c})$ and repeating the procedure does not change f_c and u_{*c} given above, so they do indeed represent the solution. An alternative solution strategy would be to compute f_c from the implicit Equation 6-9 once it was recognized that the flow was smooth turbulent.

$$\frac{1}{4\sqrt{f_c}} + \log_{10}\frac{1}{4\sqrt{f_c}} = \log_{10}\frac{z_r u_c(z_r)}{\nu} + 0.20 \qquad \text{(III-6-9)}$$

which shows f_c's dependency on a Reynolds number, $\frac{z_r u_c(z_r)}{\nu}$, when the flow is classified as smooth turbulent.

c. Wave boundary layers.

(1) Introduction. Wave boundary layers on the inner shelf are inherently unsteady due to the oscillatory nature of near-bottom wave orbital velocity. However, for typical gravity wave periods on the inner shelf, it is assumed that the boundary layer thickness, here denoted by δ_w, will be sufficiently small so that flow at the outer edge of the boundary layer may be predicted directly from linear wave theory. An extreme complication of the unsteady nature of waves arises in the application of the simple turbulent eddy viscosity model. Specifically, wave turbulent eddy viscosity becomes a time-dependent variable $u_* = (|\tau_b|/\rho)^{1/2} = u_*(t)$. However, the effect of a time-varying eddy viscosity is surprisingly small when compared with results obtained from a simple time-invariant eddy viscosity model in which $u_* = u_{*wm} = (|\tau_{wm}|/\rho)^{1/2}$ is determined from the maximum bottom wave shear stress τ_{wm}, during one wave cycle (Trowbridge and Madsen 1984). Therefore, the eddy viscosity model gives a wave shear stress

$$\tau_w = \rho \nu_t \frac{\partial u_w}{\partial z} = \rho\, \kappa\, u_{*wm}\, z \frac{\partial u_w}{\partial z} \qquad \text{(III-6-10)}$$

where u_w is the wave orbital velocity (Grant and Madsen 1979, 1986). Using Equation 6-10, applying simple linear periodic wave theory to the boundary conditions, and simplifying by taking the limiting form of the solution for the velocity profile gives

$$u_w = \frac{2}{\pi} \sin\varphi\, u_{bm} \ln\frac{z}{z_o} \cos(\omega t + \varphi) \qquad \text{(III-6-11)}$$

in which u_{bm} is the maximum near-bottom wave orbital velocity, ω is $2\pi/T$, and φ, the phase lead of near-bottom wave orbital velocity, is given by

$$\tan\varphi = \frac{\frac{\pi}{2}}{\ln\frac{\kappa u_{*wm}}{z_o \omega} - 1.15} \qquad \text{(III-6-12)}$$

From the near-bottom velocity profile, the bottom shear stress may be obtained from

$$\tau_w = \tau_{\omega m} \cos(\omega t + \varphi) \qquad \text{(III-6-13)}$$

Expressing the maximum bottom shear stress in terms of a *wave friction factor* f_w defined by Jonsson (1966)

$$\tau_{wm} = \frac{1}{2} f_w \rho u_{bm}^2 \qquad \text{(III-6-14)}$$

or equivalently

$$u_{*wm} = \sqrt{\frac{\tau_{wm}}{\rho}} = \sqrt{\frac{f_w}{2}}\, u_{bm} \tag{III-6-15}$$

Using Equations 6-10 to 6-15 and simplifying (Madsen 1993) results in an implicit equation for the wave friction factor

$$\kappa \sqrt{\frac{2}{f_w}} = \sqrt{\left(\ln \frac{\kappa \sqrt{\frac{f_w}{2}}\, u_{bm}}{z_0 \omega} - 1.15 \right)^2 + \left(\frac{\pi}{2} \right)^2} \tag{III-6-16}$$

With $\kappa = 0.4$ and recognizing that

$$A_{bm} = \frac{u_{bm}}{\omega} \tag{III-6-17}$$

is the bottom excursion amplitude predicted by linear wave theory, Equation 6-16 may be approximated by the following implicit wave friction factor relationship (Grant and Madsen 1986)

$$\frac{1}{4\sqrt{f_w}} + \log_{10} \frac{1}{4\sqrt{f_w}} = \log_{10} \frac{A_{bm}}{k_n} - 0.17 + 0.24 \left(4\sqrt{f_w} \right) \tag{III-6-18}$$

for rough turbulent flow when $k_n = 30 z_0$.

For smooth turbulent flow, $30 z_0 = 3.3\nu / u_{*wm}$ replaces k_n in Equation 6-18, which may then be written

$$\frac{1}{4\sqrt{4f_w}} + \log_{10} \frac{1}{4\sqrt{4f_w}} = \log_{10} \sqrt{\frac{\mathrm{RE}}{50}} - 0.17 + 0.06 \left(4\sqrt{4f_w} \right) \tag{III-6-19}$$

in which

$$\mathrm{RE} = \frac{u_{bm} A_{bm}}{\nu} \tag{III-6-20}$$

is a wave Reynolds number. For completeness, the wave friction factor for a *laminar wave boundary layer* is given by (Jonsson 1966)

$$f_w = \frac{2}{\sqrt{\mathrm{RE}}} \tag{III-6-21}$$

(2) Evaluation of the wave friction factor.

(a) From knowledge of the equivalent roughness k_n and wave condition A_{bm} and u_{bm}, three formulas for f_w have been presented. The choice of which f_w to select is quite simply *the largest* of the three values. In this context it is mentioned that the wave friction factors predicted for smooth turbulent and laminar flow,

Equations 6-19 and 6-21, are identical for RE $\approx 3\times10^4$, which may be taken as a reasonable value for the transition from laminar (RE $< 3\times10^4$) to turbulent flow.

(b) The evaluation of wave friction factors from Equations 6-18 and 6-19 can proceed by iteration. The iterative procedure is illustrated for Equation 6-18 by writing it in the following form

$$\frac{1}{x^{(n+1)}} = \left(\log_{10} \frac{A_{bm}}{k_n} - 0.17 \right) - \log_{10} \frac{1}{x^{(n)}} + 0.24 x^{(n)} \qquad \text{(III-6-22)}$$

with the superscript denoting the iteration step $\left(x = 4\sqrt{f_w} \right)$ and iteration started by choosing $x^{(0)} = 0.4$.

(c) It was assumed, in conjunction with the presentation of Equation 6-11 for the orbital velocity profile within the wave boundary layer, that this expression represented an approximation valid only for small values of $z_0\omega/(\kappa u_{*wm}) = (0.12/\sqrt{f_w})(k_n/A_{bm})$, i.e., for relatively large values of A_{bm}/k_n. For this reason and also because the iterative solution of the wave friction factor Equation 6-18 is rather slowly converging for $A_{bm}/k_n < 100$, Figure III-6-3 gives the exact solution for f_w and φ for $A_{bm}/k_n < 100$.

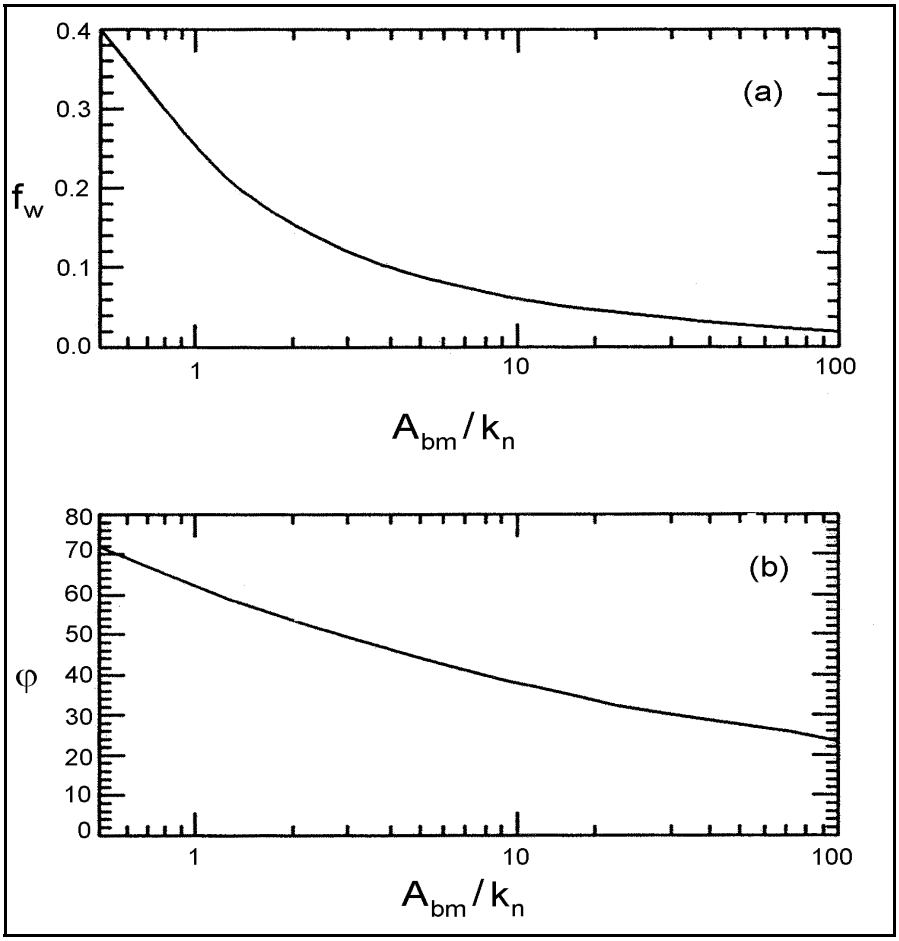

Figure III-6-3. Wave friction factor diagram (a) and bottom friction phase angle (b)

(d) For smooth turbulent boundary layer flows, Equation 6-19 may be arranged in a fashion similar to Equation 6-22, and the iterative solution proceeds as outlined above with $x = 4\sqrt{4f_w}$.

(3) Wave boundary layer thickness. From the logarithmic approximation given by Equation 6-11, which is valid only near the bottom and for large values of $\kappa u_{*wm}/(z_0\omega)$, the location for which $|u_w| = u_{bm}$ is obtained as $z \approx \kappa u_{*wm}/(\pi\omega)$. Although use of Equation 6-11 for the prediction of boundary layer thickness exceeds its validity, the results suggest

$$\delta_w = \frac{\kappa u_{*wm}}{\omega} = \kappa \sqrt{\frac{f_w}{2}}\ A_{bm} \tag{III-6-23}$$

in agreement with conclusions reached based on the complete solution to the boundary layer problem (Grant and Madsen 1986).

(4) The velocity profile.

(a) With the limitation of the validity of the velocity profile given by Equation 6-11 in mind, it is seen from Equation 6-16 that the velocity profile within the wave boundary layer may be expressed in the following extremely simple form, with an upper limit of validity given by the z value for which $|u_w| = u_{bm}$, or approximately $z = \delta_w/\pi$, i.e.,

$$u_w = \frac{\sqrt{\frac{f_w}{2}}\ u_{bm}}{\kappa} \ln \frac{z}{z_0} \cos(\omega t + \varphi) = \frac{u_{*wm}}{\kappa} \ln \frac{z}{z_0} \cos(\omega t + \varphi) \tag{III-6-24}$$

(b) Figure III-6-4 compares the experimentally obtained periodic orbital velocity amplitude within the wave boundary layer (Jonsson and Carlson 1976, Test No. 1) with the prediction afforded by the exact solution obtained from the theory presented here and the approximate solution given by Equation 6-24. Clearly, the approximate velocity profile compares favorably with both the exact and the experimental profiles near the bottom, as it should. Although some differences become apparent further from the boundary, the approximate solution provides an adequate representation of the measured profile, particularly when its intended use for the prediction of sediment transport rates is kept in mind.

(5) Extension to spectral waves.

(a) The preceding analysis of wave bottom boundary layer mechanics was based on the assumption of simple periodic waves. In reality, wind waves are more realistically represented by the superposition of several individual wave components of different frequencies and directions of propagation, i.e., by a directional wave spectrum, rather than by a single periodic component. Madsen, Poon, and Graber (1988) presented a bottom boundary layer model for waves described by their near-bottom wave orbital velocity spectrum. This reference provides the details of an analysis, the basis of which is an assumed time-invariant eddy viscosity similar to the one discussed earlier for a simple periodic wave. The analysis utilizes the near-bottom maximum orbital velocity $u_{bm,i}$ and radian frequency ω_i of the individual i^{th} wave components of the wave spectrum to calculate a single set of representative periodic wave characteristics (see Madsen (1993) for details).

(b) Given the widespread use of the significant wave concept in coastal engineering practice it is important to emphasize that the representative periodic wave characteristics defined by Madsen (1993) are not those of the significant wave, but rather those of a wave with the significant period and the

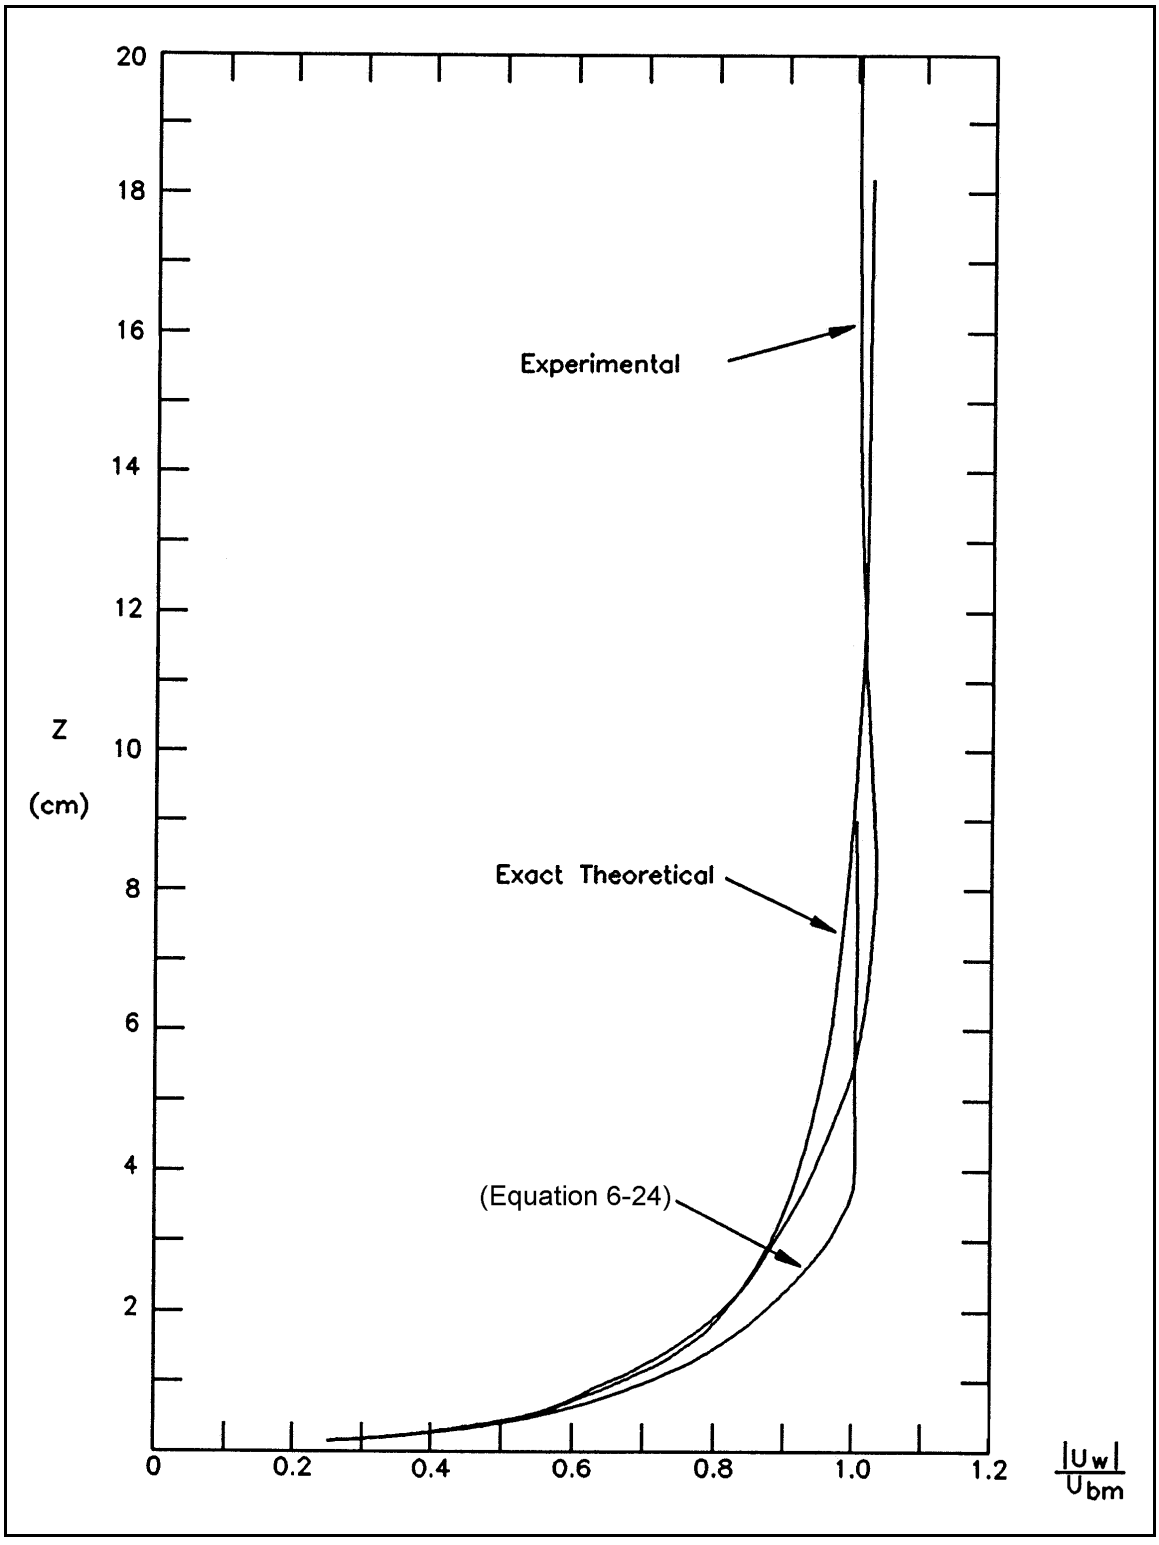

Figure III-6-4. Comparison of present model's prediction of wave orbital velocity within the wave boundary layer with measurements by Jonsson and Carlson (1976, Test No. 1)

EXAMPLE PROBLEM III-6-2

FIND:

The wave friction factor f_w, the maximum shear velocity u_{*wm}, the maximum bottom shear stress τ_{wm}, and the bottom shear stress phase angle φ, for a pure wave motion over a flat bed.

GIVEN:

The wave is specified by its near-bottom maximum orbital velocity u_{bm} = 0.35 m/s and period T = 8.0 s. The bottom is flat and consists of uniform sediment of diameter D = 0.1 mm. The fluid is seawater ($\rho \approx 1{,}025$ kg/m^3, $\nu \approx 1.0\times10^{-6}$ m^2/s).

PROCEDURE:

1) Compute bottom orbital excursion amplitude from linear wave theory: $A_{bm} = (H/2)/\sinh(2\pi h/L) = u_{bm}/\omega$, using $H = H_{rms}$ = root-mean-square wave height = $H_s/\sqrt{2}$, $\omega = 2\pi/T$ with T = significant wave period, and h = water depth. (This step is not needed here, since u_{bm} and T are specified)

2) *Assume* rough turbulent flow and solve Equation 6-18 using the iterative procedure illustrated by Equation 6-22 for f_w.

3) Obtain u_{*wm} from Equation 6-15.

4) Check rough turbulent flow assumption by evaluating $k_n u_{*wm}/\nu$ and using Equation 6-15.

5) *If* $k_n u_{*wm}/\nu \geq 3.3$, flow *is* rough turbulent. Results (f_w and u_{*cw}) obtained in steps 2 and 3 constitute the solution. τ_{wm} is obtained from Equation 6-14 or 6-15 and φ is obtained by solving Equation 6-12 with $z_0 = k_n/30$.

6) *If* $k_n u_{*wm}/\nu < 3.3$ flow *is smooth turbulent* and f_w is obtained by solving Equation 6-19 using the iterative procedure illustrated by Equation 6-22 with A_{bm}/k_n replaced by $\sqrt{RE/50}$ and $x = 4\sqrt{4f_w}$.

7) With f_w from step 6, Equation 6-15 gives u_{*wm} and τ_{wm} is obtained from Equation 6-14 or Equation 6-15.

8) With u_{*wm} from step 7, the value of $z_0 = \nu/(9u_{*wm})$ is obtained from Equation 6-15 for smooth turbulent flow.

9) The phase angle φ is calculated from Equation 6-12 using z_0 from step 8.

(Sheet 1 of 3)

Example Problem III-6-2 (Continued)

SOLUTION:

From the given wave characteristics, it follows that

$$\omega = 2\pi/T = 0.785 \text{ s}^{-1} \; ; \; A_{bm} = u_{bm}/\omega = 0.446 \text{ m} = 44.6 \text{ cm}$$

Assuming the wave boundary layer to be rough turbulent, $k_n = D = 30z_0$, and the wave friction factor is obtained by solving Equation 6-18 using the iterative procedure illustrated by Equation 6-22. For $k_n = D = 0.1$, one obtains

$$\log_{10} \frac{A_{bm}}{k_n} - 0.17 = 3.48$$

and starting with $x^{(0)} = 0.4$, Equation 6-22 gives $x^{(1)} = 0.315$ followed by $x^{(2)} = 0.327$, $x^{(3)} = 0.325$, and finally $x^{(4)} = 0.326 = 4\sqrt{f_w}$. Thus,

$$f_w = (0.326/4)^2 = 6.64 \times 10^{-3}$$

and from Equation 6-15

$$u_{*wm} = \sqrt{\frac{f_w}{2}}\, u_{bm} = 2.02 \times 10^{-2} \text{ m/s} = 2.02 \text{ cm/s}$$

This is the true solution only if the flow is rough turbulent as *assumed*, i.e., only if $k_n u_{*wm}/\nu > 3.3$. Here, $k_n = 0.1$ mm and the u_{*wm} obtained above gives

$$\frac{k_n u_{*wm}}{\nu} = 2.02 < 3.3$$

so the flow is *not rough* but smooth turbulent, i.e., f_w should be obtained from Equation 6-19 and not from Equation 6-18. Equation 6-19 may be rearranged to take the form analogous to Equation 6-22

$$\frac{1}{x^{(n+1)}} = \left(\log_{10} \sqrt{\frac{\text{RE}}{50}} - 0.17 \right) - \log_{10} \frac{1}{x^{(n)}} + 0.06 x^{(n)}$$

(Sheet 2 of 3)

Example Problem III-6-2 (Concluded)

with $x = 4\sqrt{4f_w}$ and

$$\mathrm{RE} = \frac{u_{bm}A_{bm}}{\nu} = 1.56\times10^{5}$$

Therefore

$$\left(\log_{10}\sqrt{\frac{\mathrm{RE}}{50}} - 0.17\right) = 1.58$$

and starting iteration with $x^{(0)} = 0.0$ gives $x^{(1)} = 08.29$, $x^{(2)} = 0.646$, $x^{(3)} = 0.7$,... and finally $x^{(6)} = 0.686 =$

$4\sqrt{4f_w} = 8\sqrt{f_w}$, or the *wave friction factor*

$$f_w = 7.35\times10^{-3}$$

which results in the *maximum shear velocity*

$$u_{*wm} = \sqrt{\frac{f_w}{2}}\,u_{bm} = 2.12\times10^{-2}\ \mathrm{m/s} = 2.12\ \mathrm{cm/s}$$

and a *maximum bottom shear stress*, Equation 6-32,

$$\tau_{wm} = \rho\left(u_{*wm}\right)^2 = 0.461\ \mathrm{N/m^2} = 0.46\ \mathrm{Pa}$$

The *phase angle* φ of the bottom shear stress is obtained from Equation 6-12 with

$$z_0 = \frac{\nu}{9u_{*wm}} = 5.24\times10^{-6}\ \mathrm{m}$$

obtained from Equation 6-4 for smooth turbulent flow

$$\tan\varphi = 0.242 \rightarrow \varphi = 13.6^\circ \approx 14^\circ$$

(Sheet 3 of 3)

root-mean-square wave height. Thus, for surface waves specified in terms of their significant height H_s and period T_s, the near-bottom representative periodic orbital velocity is obtained from a wave with root mean square height $H_{rms} = H_s/\sqrt{2}$, and wave period T = T_s .

(6) Dissipation. Time-averaged rate of energy dissipation in the wave bottom boundary layer is obtained from Kajiura (1968) as

$$D_p = \frac{1}{4} \rho (f_w \cos\varphi) u_{bm}^3 \tag{III-6-25}$$

for periodic waves and can be extended to spectral waves using the representative periodic wave properties as given above (Madsen, Poon, and Graber 1988).

d. Combined wave-current boundary layers.

(1) Introduction.

(a) The simple conceptual model of near-bottom turbulence suggests that the eddy viscosity immediately above the bottom is a function of time whenever the flow is unsteady. In the context of a pure wave motion, it was, however, found that assuming a time-invariant eddy viscosity, based on the maximum shear velocity, resulted in a greatly simplified analysis without sacrificing accuracy appreciably (Trowbridge and Madsen 1984). In the case of combined wave-current bottom boundary layer flows, the eddy viscosity immediately above the bottom is therefore scaled by the maximum combined wave-current shear velocity. Since the vertical extent of wave-associated turbulence is limited by the wave bottom boundary layer thickness, the wave contribution to the turbulent mixing must vanish at some level above which only the current shear velocity contributes to turbulent mixing.

(b) For the general case of combined wave-current flows with the current at an angle φ_{wc} to the direction of wave propagation, the maximum combined bottom shear stress τ_m may be obtained from

$$\begin{aligned} \tau_m &= |\boldsymbol{\tau}_{wm} + \boldsymbol{\tau}_c| \\ &= \sqrt{(\tau_{wm} + \tau_c |\cos \varphi_{wc}|)^2 + (\tau_c \sin \varphi_{wc})^2} \\ &= \tau_{wm} \sqrt{1 + 2\frac{\tau_c}{\tau_{wm}} |\cos \varphi_{wc}| + \left(\frac{\tau_c}{\tau_{wm}}\right)^2} \end{aligned} \tag{III-6-26}$$

(c) Since the boundary layer flow for combined waves and currents at an angle is three-dimensional, one should in principle solve for the horizontal velocity vector's two components. However, when the *x*-direction is chosen as the wave direction, unsteady flow will exist only in this direction. In this case it can be shown that all formulas derived for the pure wave case in Part III-6(2)c are valid also for waves in the presence of a current when u_{*wm} is replaced by u_{*m} obtained from Equation 6-26 with $u_{*m} = (\tau_m/\rho)^{1/2}$. For

example, the velocity profile is given by Equation 6-11 with u_{*wm} replaced by u_{*m}. As mentioned previously, $u_{*wm} \approx u_{*m}$, which shows that the wave motion is only weakly influenced by the presence of a current.

(d) The steady flow is entirely in the direction of the current, i.e., at an angle φ_{wc} to the wave direction. Invoking the "law of the wall," the current velocity is (for $z < \delta_{cw}$ where δ_{cw} is defined in Equation 6-38)

$$u_c = \frac{u_{*c}}{\kappa} \frac{u_{*c}}{u_{*m}} \ln \frac{z}{z_0} \tag{III-6-27}$$

and z_0 is given by Equation 6-4 with u_{*m} replacing u_*.

(e) For $z > \delta_{cw}$ the solution is

$$u_c = \frac{u_{*c}}{\kappa} \ln \frac{z}{z_{0a}} \tag{III-6-28}$$

where z_{0a} denotes an arbitrary constant of integration, referred to as the *apparent bottom roughness*. Matching the two solutions at $z = \delta_{cw}$ and introducing the expression for z_{0a} in Equation 6-28 gives an alternative form of the solution for $z > \delta_{cw}$

$$u_c = \frac{u_{*c}}{\kappa} \left(\ln \frac{z}{\delta_{cw}} + \frac{u_{*c}}{u_{*m}} \ln \frac{\delta_{cw}}{z_0} \right) \tag{III-6-29}$$

(f) These expressions clearly reveal the pronounced effect that waves may have on current velocity profiles. First of all, the velocity gradient inside the wave-current boundary layer is reduced by a factor u_{*c}/u_{*m} relative to its value in absence of waves. This, of course, is a consequence of the increased turbulence intensity within the wave boundary layer arising from the waves. In the extreme case of $u_{*c}/u_{*m} \approx 0$, u_c remains nearly zero throughout the wave boundary layer. Thus, currents in the presence of waves experience an enhanced bottom roughness (i.e., for the same current velocity at a specified level above the bottom the 0current shear velocity and shear stress will increase with wave activity).

(g) Figure III-6-5 compares a current velocity profile in the presence of waves predicted by the present wave-current interaction theory with the measured current profile (Bakker and van Doorn 1978). Two theoretical predictions are shown, one in which δ_{cw} is based on Equation 6-23 with $u_{*wm} = u_{*m}$ and another in which δ_{cw} was increased by a factor of 1.5. From the comparison, it is concluded that the definition of δ_{cw} given by Equation 6-23 may be adopted for the wave-current interaction theory presented here. This wave-current interaction theory may be applied to a wave described by its near-bottom orbital velocity spectrum by using the representative periodic wave with the direction of wave propagation chosen as the peak direction (Madsen 1993).

(2) Combined wave-current velocity profile. Having chosen the x-axis as the direction of wave propagation, the wave orbital velocity profile immediately above the bottom is given by Equation 6-11 where the phase angle φ defined by Equation 6-12 is evaluated with $u_{*wm} = u_{*m}$.

The current velocity vector is given by

$$\boldsymbol{u}_c = u_c(z) \{\cos \varphi_{wc}, \sin \varphi_{wc}\} \tag{III-6-30}$$

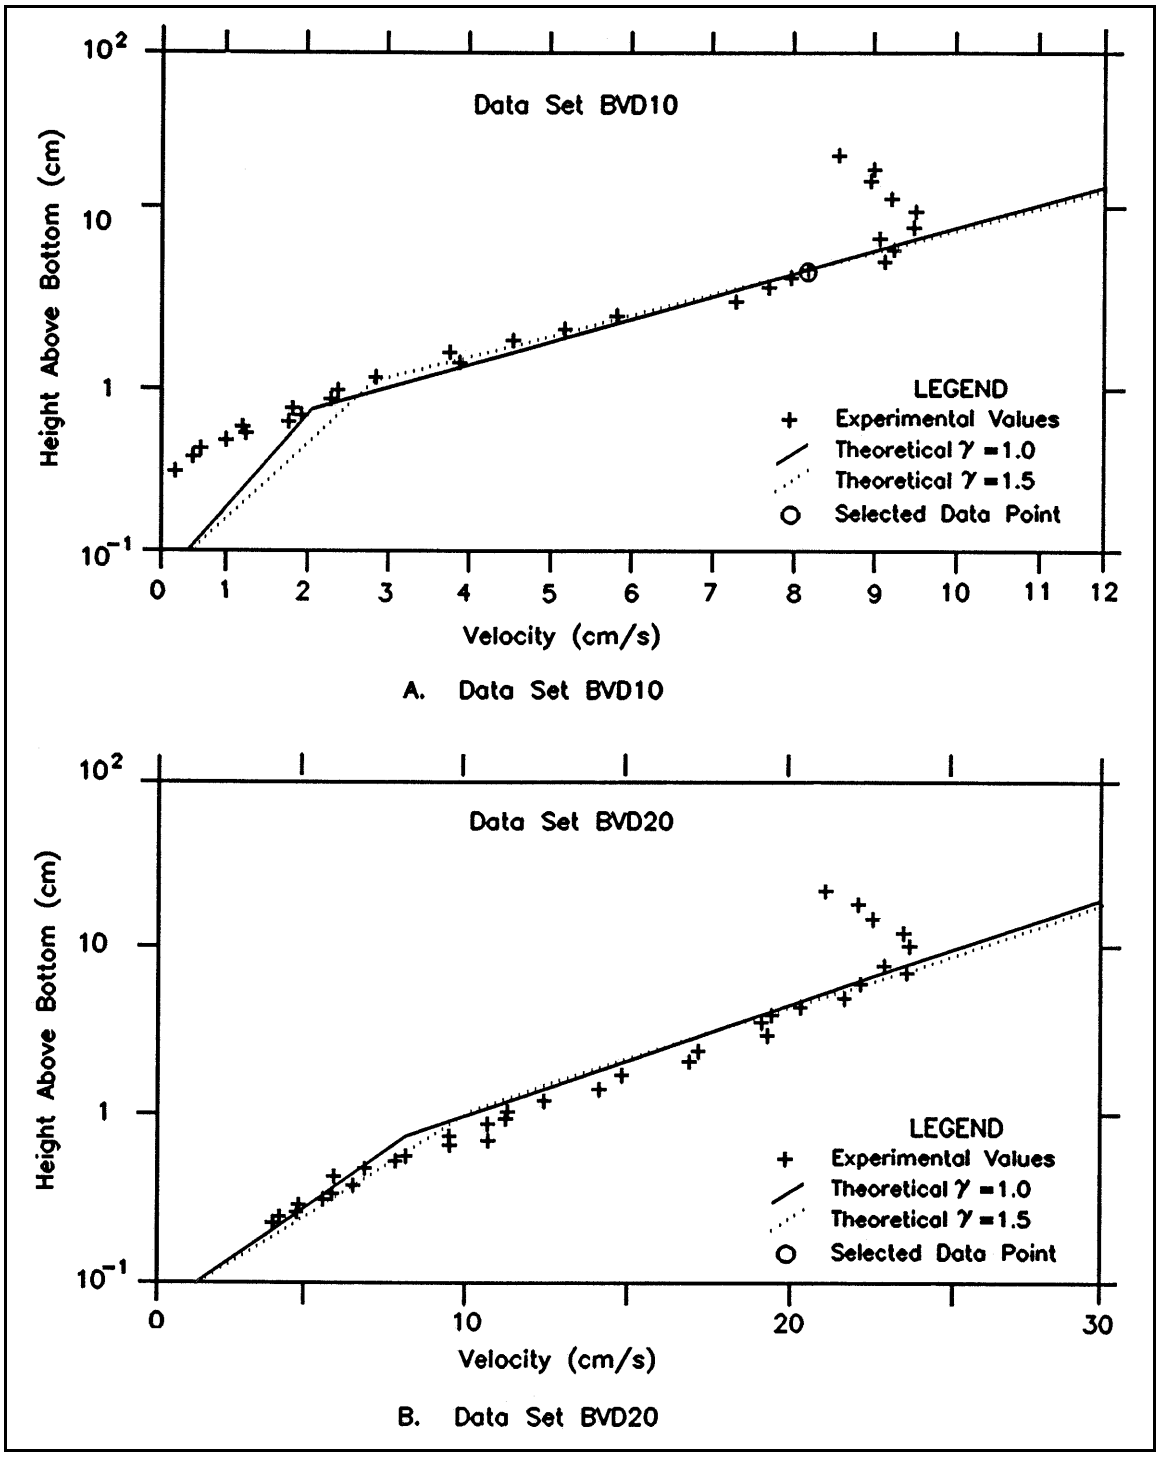

Figure III-6-5. Comparison of current profile in the presence of waves predicted by present model with measured current profile

where $u_c(z)$ is given by Equations 6-27 and 6-29.

(3) Combined wave-current bottom shear stress. Similarly, the time-varying bottom shear stress associated with combined wave-current flows may be obtained from

$$\tau_b(t) = \{\tau_{wm} \cos(\omega t + \varphi) + \tau_c \cos \varphi_{wc}, \tau_c \sin \varphi_{wc}\} \tag{III-6-31}$$

(4) Methodology for the solution of a combined wave-current problem.

(a) For a wave motion specified by u_{bm} and ω ($A_{bm} = u_{bm}/\omega$) and a bottom roughness specified by its equivalent Nikuradse roughness k_n, the pertinent formulas for the solution of a combined wave-current bottom boundary layer flow problem are the relative strengths of currents and waves

$$\mu = \frac{\tau_c}{\tau_{wm}} = \frac{u_{*c}^2}{u_{*wm}^2} \tag{III-6-32}$$

which appears in the factor relating maximum wave and maximum combined bottom shear stresses (Equation 6-26)

$$C_\mu = \sqrt{1 + 2\mu \cos \varphi_{wc} + \mu^2} \tag{III-6-33}$$

and wave friction factor formulas, given by Equations 6-18 and 6-19 for pure waves, become for combined wave-current flows (for derivation see Grant and Madsen (1986))

$$\frac{1}{4\sqrt{\frac{f_{cw}}{C_\mu}}} + \log_{10} \frac{1}{4\sqrt{\frac{f_{cw}}{C_\mu}}} = \log_{10} \frac{C_\mu A_{bm}}{k_n} - 0.17 + 0.24 \left(4\sqrt{\frac{f_{cw}}{C_\mu}} \right) \tag{III-6-34}$$

for rough turbulent flow, i.e., $k_n > 3.3\nu/u_{*m}$, and

$$\frac{1}{4\sqrt{\frac{4f_{cw}}{C_\mu}}} + \log_{10} \frac{1}{4\sqrt{\frac{4f_{cw}}{C_\mu}}} = \log_{10} \sqrt{\frac{C_\mu^2 \, \mathrm{RE}}{50}} - 0.17 + 0.06 \left(4\sqrt{\frac{4f_{cw}}{C_\mu}} \right) \tag{III-6-35}$$

for smooth turbulent flow, i.e., $k_n < 3.3\nu/u_{*m}$.

(b) The solution of Equation 6-34 or Equation 6-35 proceeds in the iterative manner illustrated by Equation 6-22 except $x = 4\sqrt{f_{cw}/C_\mu}$ replaces $x = 4\sqrt{f_w}$. Also, Figure III-6-3 may be used with $C_\mu A_{bm}/k_n$ replacing A_{bm}/k_n as entry, and the value of f_w obtained from the ordinate being interpreted as the value of f_{cw}/C_μ.

(c) The wave friction factor in the presence of currents f_{cw} is defined by

$$\frac{\tau_{wm}}{\rho} = u_{*wm}^2 = \frac{1}{2} f_{cw} u_{bm}^2 \quad \text{(III-6-36)}$$

and when Equation 6-33 is introduced in Equation 6-26, the maximum combined shear stress reads

$$\frac{\tau_m}{\rho} = u_{*m}^2 = C_\mu u_{*wm}^2 \quad \text{(III-6-37)}$$

(d) Finally, the wave boundary layer thickness is given by the modified form of Equation 6-23, i.e.,

$$\delta_{cw} = \frac{\kappa u_{*m}}{\omega} \quad \text{(III-6-38)}$$

(e) Current specified by $\boldsymbol{\tau}_c$, i.e., $\frac{\tau_c}{\rho} = u_{*c}^2$ and φ_{wc} are known.

(f) Starting with $\mu = 0, C_\mu = 1$, the wave friction factor is obtained from Equation 6-34. The values of u_{*wm}^2 and u_{*m}^2 are obtained from Equations 6-36 and 6-37. Rough turbulent flow is checked by calculating $k_n u_{*m}/\nu$. If not greater than 3.3, flow is smooth turbulent and the wave friction factor is recalculated from Equation 6-35, followed by evaluation of u_{*m}^2 and u_{*wm}^2 as before. In most cases, flow is rough turbulent and the check of rough or smooth turbulent flow is only necessary during the first iteration.

(g) With the pure wave estimate of $u_{*wm}^2 = u_{*m}^2$ in hand, one obtains updated values of μ and C_μ from Equations 6-32 and 6-33. The wave friction factor is obtained from the appropriate relationship, Equation 6-34 or Equation 6-35, by solving for f_{cw}/C_μ followed by multiplication with C_μ. Values of u_{*wm}^2 and u_{*m}^2 are obtained from Equations 6-36 and 6-37. Upon return to Equation 6-32 with the latest value of u_{*wm}^2 the procedure may be repeated until f_{cw} remains essentially unchanged from one iteration to the next. As a reasonable convergence criterion, it is recommended to calculate f_{cw} with no more than three significant figures.

(h) The wave-current interaction problem is now solved and, following evaluation of the wave boundary layer thickness δ_{cw} from Equation 6-38, the current velocity profile may be obtained from Equation 6-27 for $z \le \delta_{cw}$ and from Equation 6-29 for $z \ge \delta_{cw}$.

(i) Current specified by $\boldsymbol{u}_c$ at $z = z_r$ (i.e., $u_c(z = z_r)$) and φ_{wc} are known.

(j) Again $\mu = 0$ and $C_\mu = 1$ are used for the first iteration which proceeds as outlined under step e above. For this case, however, the first iteration is carried through determination of δ_{cw} from Equation 6-38. At this point, Equation 6-29, assuming $z_r > \delta_{cw}$, may be regarded as a quadratic equation in the unknown current shear velocity

$$\kappa u_c(z_r) = \ln \frac{z_r}{\delta_{cw}} u_{*c} + \frac{\ln \frac{\delta_{cw}}{z_0}}{u_{*m}} u_{*c}^2 \quad \text{(III-6-39)}$$

with the solution

EXAMPLE PROBLEM III-6-3

FIND:

The current shear velocity and bottom shear stress, u_{*c} and τ_c, the maximum wave shear velocity and bottom shear stress, u_{*wm} and τ_{wm}, as well as the maximum combined shear velocity and bottom shear stress, u_{*m} and τ_m, for a combined wave-current flow over a flat bed.

GIVEN:

The wave is specified by its near-bottom maximum orbital velocity u_{bm} = 0.35 m/s and period T = 8 s. The current is specified by its magnitude $u_c(z_r)$ = 0.35 m/s at z_r = 1.00 m and direction $\varphi_{wc} = 45°$ relative to the direction of wave propagation. The bottom is flat and consists of uniform sediment of diameter D = 0.2 mm. The fluid is seawater (ρ = 1,025 kg/m^3, $\nu \approx 1.0\times10^{-6}$ m^2/s).

PROCEDURE:

1) Compute wave characteristics as in step 1 of Example Problem III-6-2.

2) *Assume* rough turbulent flow and solve the wave-current interaction following the iterative procedure described in subsection III-6(2)d(4)i.

3) Check if flow is rough turbulent by evaluating $k_n u_{*m}/\nu$ with u_{*m} obtained in step 2.

4) *If* $k_n u_{*m}/\nu \geq 3.3$, flow *is* rough turbulent and values of u_{*c}, u_{*wm}, and u_{*m} obtained in step 2 constitute the solution. Bottom shear stresses are obtained from the definition of shear velocities: $\tau = \rho u_*^2$.

5) *If* $k_n u_{*m}/\nu < 3.3$ flow *is smooth turbulent* and the combined wave-current flow is solved as in step 2 except for Equation 6-35 replacing Equation 6-34 when the wave friction factor in the presence of a current is evaluated.

6) With u_{*c}, u_{*wm}, and u_{*m} from step 5, $\tau = \rho u_*^2$ is used to obtain bottom shear stresses.

SOLUTION:

For the given wave parameters, $\omega = 2\pi/T = 0.785$ s^{-1}, $A_{bm} = u_{bm}/\omega = 0.446$ m, and $k_n = D = 2\times10^{-4}$ m since the bottom is flat. Proceeding as outlined in Part III-6(2)d subsection (4)a, starting with $\mu = 0$, Equation 6-33 gives $C_\mu = 1$. *Assuming rough* turbulent flow, Equation 6-34 reduces to the exact form of the pure wave friction factor Equation 6-18 whose solution is obtained iteratively using Equation 6-22 (see Example Problem III-6-2) as

$$f_{cw} = f_w = 7.86\times10^{-3}$$

The maximum shear velocity is given by Equation 6-37, i.e.,

$$u_{*m} = \sqrt{C_\mu}\, u_{*wm} = u_{*wm} = \sqrt{\frac{f_{cw}}{2}}\, u_{bm} = 2.19\times10^{-2} \text{ m/s} = 2.19 \text{ cm/s}$$

(Continued)

Example Problem III-6-3 (Concluded)

since C_μ is currently assumed to be 1. From $k_n u_{*m}/\nu = 4.38$ it follows that the flow indeed is *rough* turbulent *as assumed*. (If $k_n u_{*m}/\nu < 3.3$, one would have to return and compute f_{cw} from Equation 6-35.) It therefore follows from Equation 6-38 that

$$\delta_{cw} = 1.12\times10^{-2} \text{ m} = 1.12 \text{ cm}$$

With these values and $z_0 = k_n/30 = D/30 = 6.67\times10^{-6}$ m, Equation 6-40 is solved to give a first estimate of the current shear velocity

$$u_{*c} = 1.47\times10^{-2} \text{ m/s} = 1.47 \text{ cm/s}$$

Using the first estimates of $u_{*c} = 1.47$ cm/s and $u_{*wm} = 2.19$ cm/s, Equation 6-32 gives

$$\mu = \left(\frac{u_{*c}}{u_{*wm}} \right)^2 = 0.45$$

and with $\varphi_{wc} = 45°$, Equation 6-33 gives $C_\mu = 1.36$.

To solve Equation 6-34 for the wave friction factor in the presence of a current f_{cw}, it is rearranged in a manner identical to Equation 6-22, i.e.,

$$\frac{1}{x^{(n+1)}} = \left(\log_{10} \frac{C_\mu A_{bm}}{k_n} - 0.17 \right) - \log_{10} \frac{1}{x^{(n)}} + 0.24 x^{(n)}$$

with $x = 4\sqrt{f_w/C_\mu}$. Solving iteratively starting with $x^{(0)} = 0.4$ gives $x^{(4)} = 0.342 = 4\sqrt{f_w/C_\mu}$, or

$$f_{cw} = (x/4)^2 C_\mu = 9.94\times10^{-3}$$

The value of the wave shear velocity is now obtained from Equation 6-36

$$u_{*wm} = \sqrt{\frac{f_{cw}}{2}}\, u_{bm} = 2.47\times10^{-2} \text{ m/s} = 2.47 \text{ cm/s} \quad \text{and} \quad \tau_{wm} = \rho u_{*wm}^2 = 0.624 \text{ Pa}$$

followed by

$$u_{*m} = \sqrt{C_\mu}\, u_{*wm} = 2.88\times10^{-2} \text{ m/s} = 2.88 \text{ cm/s} \quad \text{and} \quad \tau_m = \rho u_{*m}^2 = 0.850 \text{ Pa}$$

from Equation 6-37 and

$$\delta_{cw} = \frac{\kappa u_{*m}}{\omega} = 1.47\times10^{-2} \text{ m} = 1.47 \text{ cm}$$

With these values in hand, Equation 6-40 gives a second estimate of the current shear velocity

$$u_{*c} = 1.63\times10^{-2} \text{ m/s} = 1.63 \text{ cm/s} \quad \text{and} \quad \tau_c = \rho u_{*c}^2 = 0.272 \text{ Pa}$$

EXAMPLE PROBLEM III-6-4

FIND:

The current shear velocity u_{*c}, the maximum wave shear velocity u_{*wm}, the maximum combined shear velocity u_{*m}, and the wave boundary layer thickness δ_{cw} for a combined wave-current turbulent boundary layer flow.

GIVEN:

The wave is specified by its near-bottom maximum orbital velocity u_{bm} = 0.35 m/s and period T = 8.0 s. The current is specified by its magnitude u_c = 0.35 m/s at z_r = 1.00 m and direction $\varphi_{wc} = 45°$ relative to the direction of wave propagation. The equivalent Nikuradse roughness of the bottom is k_n = 4.4 cm. The fluid is seawater (ρ = 1,025 kg/m^3, $\nu \approx 10^{-6}$ m^2/s).

PROCEDURE:

Identical to Example Problem III-6-3. However, the iterative solution of the wave friction factor in Equation 6-34 is started with an initial value obtained from Figure III-6-3 to speed up convergence.

SOLUTION:

For the given wave parameters $\omega = 2\pi/T = 0.785$ s^{-1} and $A_{bm} = u_{bm}/\omega = 0.446$ m, the procedure to follow is identical to that used in Example Problem III-6-3, except that here

$$\frac{A_{bm}}{k_n} = \frac{0.446}{0.044} \approx 10$$

is much smaller. Therefore, during the first iteration (with $\mu = 0$ and $C_\mu = 1$) the wave friction factor is obtained from Figure III-6-3

$$f_w = f_{cw} \approx 0.058$$

instead of solving Equation 6-34. The pure wave approximation therefore gives

$$u_{*wm} = u_{*m} = \sqrt{\frac{f_w}{2}}\, u_{bm} = 5.96 \text{ cm/s}$$

and

$$\delta_{cw} = \frac{\kappa u_{*wm}}{\omega} = 3.04 \text{ cm}$$

With these values, the first estimate of the current shear velocity is obtained from Equation 6-40

$$u_{*c} = 2.84 \text{ cm/s}$$

(Continued)

Example Problem III-6-4 (Concluded)

An updated value of μ is then

$$\mu = \left(\frac{u_{*c}}{u_{*wm}} \right)^2 = 0.23$$

and from Equation 6-33

$$C_\mu = 1.17$$

Recognizing that Equation 6-34 is identical to the pure wave friction factor (Equation 6-18) if $C_\mu A_{bm}/k_n$ replaces A_{bm}/k_n and f_{cw}/C_μ replaces f_w, the value of f_{cw}/C_μ may be read off Figure III-6-3 when $C_\mu A_{bm}/k_n = 11.7$ is used as an entry. In this manner

$$f_{cw}/C_\mu \approx 0.053 \rightarrow f_{cw} \approx 0.062$$

is obtained. Clearly, the accuracy of the reading obtained from Figure III-6-3 is not impressive, so the value is regarded only as a rough estimate. From Equation 6-36, Equation 6-37, and Equation 6-38, it follows that

$$u_{*wm} = 6.16 \text{ cm/s}, \; u_{*m} = 6.67 \text{ cm/s}, \; \delta_{cw} = 3.40 \text{ cm}$$

and from Equation 6-40

$$u_{*c} = 2.94 \text{ cm/s}$$

With these values $\mu = (u_{*c}/u_{*wm})^2 = 0.23$, i.e., the iteration is complete.

So the solution is $u_{*c} = 2.94$ cm/s, $\tau_c = \rho u_{*c}^2 = 0.89$ Pa, $u_{*wm} = 6.16$ cm/s, $\tau_{wm} = \rho u_{*wm}^2 = 3.89$ Pa, $u_{*m} = 6.67$ cm/s, $\tau_m = \rho u_{*m}^2 = 4.56$ Pa, and $\delta_{cw} = 3.40$ cm.

EXAMPLE PROBLEM III-6-5

FIND:

The current velocity $u_c(\delta_{cw})$ at $z = \delta_{cw}$, the apparent roughness z_{0a}, and the phase angle of the wave-associated bottom shear stress for a combined wave-current bottom boundary layer flow.

GIVEN:

Wave, current, and bottom roughness are as specified in Example Problem III-6-4.

PROCEDURE:

1) Solve the wave-current interaction problem following the procedure described for Example Problem III-6-4.

2) With u_{*m}, from step 1 δ_{cw} is obtained from Equation 6-38.

3) $u_c\,(z = \delta_{cw})$ is obtained from Equation 6-27 with $z = \delta_{cw}$ obtained in step 2 and $z_0 = k_n/30$ since flow is rough turbulent. If flow had been smooth turbulent, i.e., $k_n u_{*m}/\nu < 3.3$, Equation 6-27 is used with $z_0 = \nu/(9u_{*m})$ as given by Equation 6-5.

4) Equation 6-28 is solved for z_{0a} using u_{*c} from step 1, $z = \delta_{cw}$ from step 2, and $u_c = u_c(z = \delta_{cw})$ from step 3.

5) The phase angle φ is obtained from Equation 6-12 with u_{*wm} replaced by u_{*m} from step 1 and $z_0 = k_n/30$.

SOLUTION:

With u_{*c} = 2.94 cm/s, u_{*m} = 6.67 cm/s, and δ_{cw} = 3.40 cm from Example Problem III-6-4, Equation 6-27 gives (with $z_0 = k_n/30$ = 4.4/30 cm)

$$u_c(\delta_{cw}) = \frac{u_{*c}}{\kappa}\,\frac{u_{*c}}{u_{*m}}\,\ln\frac{\delta_{cw}}{z_0} = 10.2 \text{ cm/s}$$

By matching this with the expression for the current velocity profile outside the boundary layer (Equation 6-28) one obtains

$$u_c(\delta_{cw}) = \frac{u_{*c}}{\kappa}\,\ln\frac{\delta_{cw}}{z_{0a}} \quad \text{and solving for } z_{0a} \text{ gives} \quad z_{0a} = 0.85 \text{ cm/s}$$

The phase of the wave-associated bottom shear stress is obtained from Equation 6-12 with u_{*wm} replaced by u_{*m}, i.e.,

$$\tan\varphi = 0.79 \rightarrow \varphi = 38^\circ$$

$$u_{*c} = u_{*m} \frac{\ln \dfrac{z_r}{\delta_{cw}}}{\ln \dfrac{\delta_{cw}}{z_0}} \left[-\frac{1}{2} + \sqrt{\frac{1}{4} + \kappa \frac{u_c(z_r)}{u_{*m}} \frac{\ln \dfrac{\delta_{cw}}{z_0}}{\left(\ln \dfrac{z_r}{\delta_{cw}} \right)^2}} \right] \tag{III-6-40}$$

(k) Having now obtained an estimate of u_{*_c}, returning to Equation 6-32 with $u_{*_{wm}}$ known from the first iteration, the value of μ is updated. With this updated value of μ, the entire procedure is repeated until a new value of u_{*_c} is obtained. For this iteration, convergence of μ to no more than two significant digits is recommended.

(l) The theoretical predictions shown in Figure III-6-5 were obtained in this manner using the indicated data point to specify the current.

III-6-3. Fluid-Sediment Interaction

a. Introduction.

(1) In Part III-6-2, the purely hydrodynamic problem of turbulent bottom boundary layer flows was treated. There it was found that the fluid-bottom interaction could be represented by a bottom shear stress $\boldsymbol{\tau}_b$, which, for the general case of combined wave-current flows, is given by Equation 6-31. Since the wave component $\tau_{wm}\cos(\omega t + \varphi)$ and the current component τ_c are both associated with logarithmic velocity profiles immediately above the bottom, Equations 6-24 and 6-27, respectively, the combined velocity immediately above the bottom is logarithmic.

(2) For a bottom consisting of a granular material, the physical flow condition in the vicinity of the individual grains is sketched in Figure III-6-6. Recalling that the logarithmic velocity profile in this region is merely an extrapolation from flow conditions obtained further from the boundary, it is evident that the actual resistance experienced by the flow is not a uniformly distributed force per unit horizontal area, but rather a sum of drag forces on individual grains (roughness elements). Thus, in reality

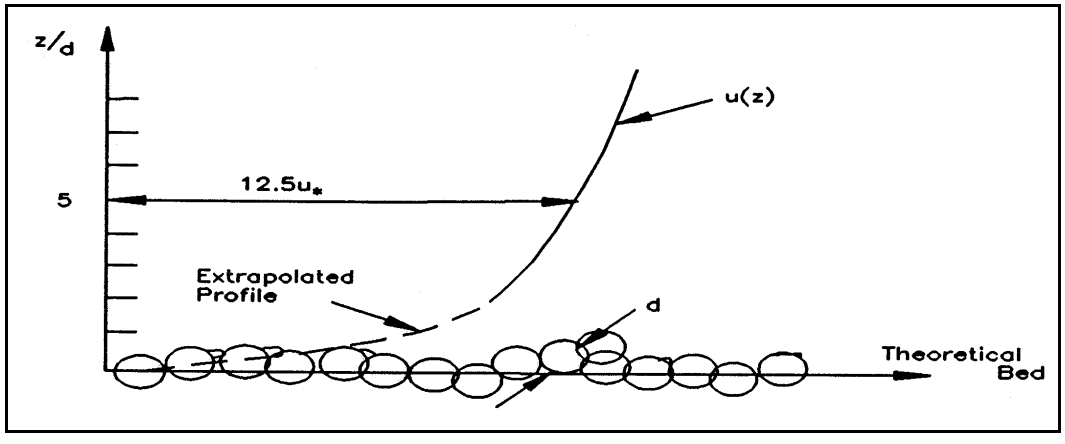

Figure III-6-6. Sketch of turbulent flows with logarithmic profile over granular bed

$$\tau_b = \sum_{\substack{\text{unit} \\ \text{area}}} \bar{F}_{D,\text{grain}}$$

(3) Not until a level somewhat above the individual roughness elements is it reasonable to assume that eddies, forming around individual grains and ejected into the flow, have merged to produce a turbulent shear flow of the type considered in the conceptual model of turbulent shear stresses presented in Part III-6-2.

(4) In addition to the spatial variation of the actual interaction between a turbulent flow and a granular bottom, it should also be kept in mind that a turbulent flow, even for a *steady* current, is inherently *unsteady*. The logarithmic velocity profile represents the time-averaged velocity profile with high-frequency turbulent fluctuations being removed by the averaging process. The drag force on individual grains is therefore not constant but varies with time due to turbulent fluctuations. The drag forces on individual grains are therefore average values as suggested by the overbar notation.

(5) It is evident from the description above that the complex nature of interaction between a flowing fluid and the individual grains on the fluid-sediment interface defies rigorous mathematical treatment unless a hydrodynamic model is employed which resolves the flow structure around individual grains including temporal variation associated with turbulent fluctuations. Since such a detailed hydrodynamic model is not available at present, we are forced to adopt heuristic, physically based conceptual models consistent with the level of our flow description to "derive" quantitative relationships for fluid-sediment interaction, and rely on empirical evidence to determine "constants" that are necessary to render the relationships predictive.

b. The Shields parameter.

(1) From the preceding discussion of the nature of near-bottom turbulent flows, it follows that the bottom shear stress may be taken as an expression for the drag force, i.e., the mobilizing force, acting on individual sediment grains on the bed surface. For a sediment of diameter D there are approximately $1/D^2$ grains per unit area, so

$$\bar{\bar{F}}_{D,grain} \propto \tau_b D^2 \tag{III-6-41}$$

where the double overbar indicates a temporal, as well as a spatial, average.

(2) For a *cohesionless sediment* the individual sediment grains rest and stay on the bottom due to their submerged weight and resist horizontal motion due to the presence of neighboring grains. Thus, for a cohesionless sediment, the stabilizing force is associated with the submerged weight of the individual grains

$$W_{grain} \propto (\rho_s - \rho) g D^3 \tag{III-6-42}$$

where ρ_s denotes the density of the sediment material ($\rho_s \approx 2{,}650$ kg/m^3 for quartz).

(3) The ratio of mobilizing (drag) and stabilizing (submerged weight) forces is of fundamental physical significance in fluid-sediment interaction for *cohesionless sediment*. This ratio is known as the *Shields parameter* (Shields 1936)

$$\psi = \frac{\tau_b}{(\rho_s - \rho) g D} = \frac{\tau_b}{(s - 1) \rho g D} = \frac{u_*^2}{(s - 1) g D} \tag{III-6-43}$$

in which $s = \rho_s/\rho$ is the density of the sediment relative to that of the fluid.

c. Initiation of motion.

(1) Introduction.

(a) For a turbulent flow over a flat bed consisting of cohesionless sediment of diameter D the equivalent Nikuradse sand grain roughness is $k_n = D$. From the discussion of turbulent boundary layer flows it was found that the roughness scale experienced by the flow, z_0 as given by Equation 6-5, depends on whether the flow is characterized as smooth or rough turbulent. The parameter determining the characteristics of the near-bottom flow and hence the mobilizing force acting on individual sediment grains is the *boundary Reynolds number*

$$\mathrm{Re}_* = \frac{u_* k_n}{\nu} = \frac{u_* D}{\nu} \tag{III-6-44}$$

(b) From simple physical considerations it therefore follows that the conditions of neutral stability of a sediment grain on the fluid-sediment interface may be expressed as a *critical value of the Shields parameter*

$$\psi_{cr} = \frac{\tau_{cr}}{(s - 1)\rho g D} = \frac{u_{*cr}^2}{(s - 1) g D} = f(\mathrm{Re}_*) \tag{III-6-45}$$

where $f(\mathrm{Re}_*)$, which is obtained from models or from experimental data, denotes some function of Re_*. Figure III-6-7 shows the traditional Shields diagram given by Equation 6-45 with supporting data obtained from uniform steady flow experiments (Raudkivi 1976). It shows that $\psi_{cr} \approx 0.06$ is approximately constant for $\mathrm{Re}_* > 100$, i.e., for fully rough turbulent flow, whereas the critical Shields parameter increases steadily from a minimum of 0.035 for values of $\mathrm{Re}_* < 10$, i.e., essentially corresponding to smooth turbulent flow conditions.

(c) In establishing the critical condition for initiation of motion, also referred to as threshold or incipient motion condition (expressed formally by Equation 6-45), it is important to keep in mind the nature of fluid-sediment interaction. For values of $\psi > \psi_{cr}$, mobilizing forces exceed stabilizing forces and sediment motion occurs. This does not mean that for $\psi < \psi_{cr}$ by a small amount, sediment does not move at all. For turbulent flow conditions in the vicinity of $\psi \approx \psi_{cr}$, the arrival of particularly strong turbulent eddies from the turbulence generation layer may momentarily increase the drag on one or a few sediment grains and, if the response time of the individual grains is shorter than the duration of this pulse, a few grains may be dislodged (i.e., a movement of the sediment may occur).The empirical curve on a ψ versus Re_* diagram that expresses the critical condition (i.e., the Shields curve or the Shields criterion) should therefore be interpreted as representing a "gray area" around the curve itself. For flow conditions within this gray area, sediment movement may take place but it becomes increasingly sporadic as ψ drops below the curve defining ψ_{cr}.

(2) Modified Shields diagram.

(a) In order to predict the flow condition that will cause sediment motion for a given sediment (i.e., s and D known) the traditional Shields curve given by Equation 6-45 or Figure III-6-7 is somewhat cumbersome to use, since the flow characteristic of interest (u_{*cr}) is involved in both parameters. This problem can be circumvented by recognizing that the Shields curve defines a unique relationship between ψ_{cr} and Re_*. Thus, from the definition of ψ_{cr} (Equation 6-45), one obtains

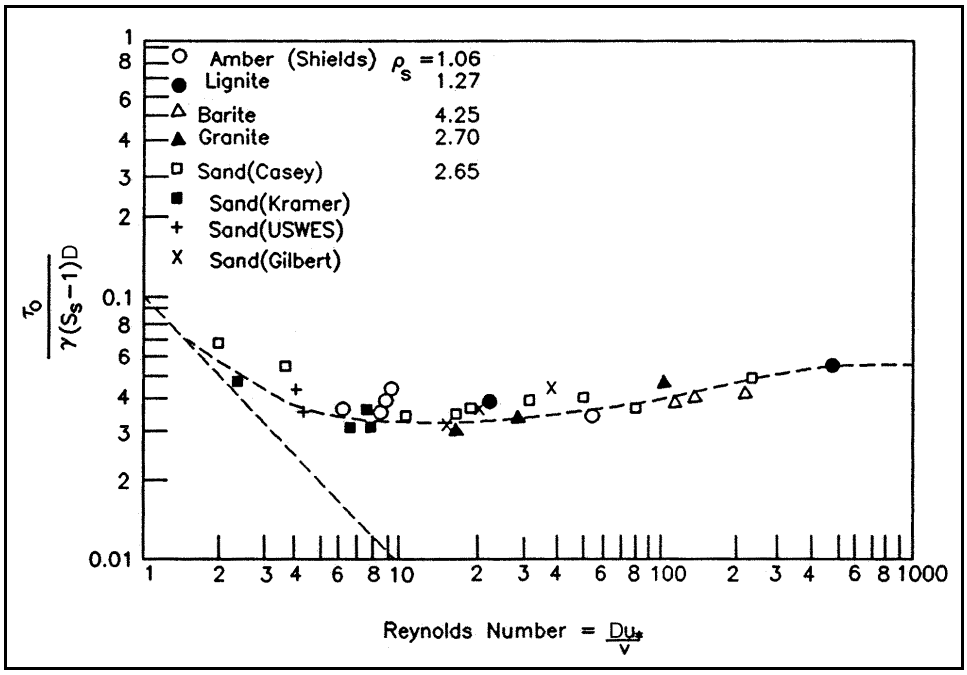

Figure III-6-7. Shields diagram for initiation of motion in steady turbulent flow (from Raudkivi (1967))

$$u_{*cr} = \sqrt{(s - 1) g D}\ \sqrt{\psi_{cr}} \tag{III-6-46}$$

which can be introduced in the definition of Re_* to obtain a parameter (Madsen and Grant 1976)

$$S_* = \frac{D}{4\nu}\sqrt{(s - 1) g D} = \frac{\mathrm{Re}_*}{4\sqrt{\psi_{cr}}} \tag{III-6-47}$$

(b) The factor of 4 appears in the definition of S_* to render the numerical values of S_* comparable with the Re_* values in the traditional Shields diagram. This is done merely for convenience and has no physical significance.

(c) By taking corresponding values of Re_* and ψ_{cr} from the traditional Shields diagram, one can obtain the value of the sediment-fluid parameter S_*, which in turn can be used to replace Re_* in the Shields diagram. In this manner the *modified Shields diagram* (Madsen and Grant 1976) shown in Figure III-6-8 can be constructed.

(d) The modified Shields diagram terminates at the lower end of S_* at a value of 1 which, for quartz sediments in seawater, corresponds to a sediment diameter of $D \approx 0.1$ mm, i.e., a very fine sand. Although cohesion may become important for diameters below 0.1 mm, clean silty sediments, i.e., without too much organic material and/or clay, can be considered cohesionless and therefore governed by a Shields-type initiation of motion criteria. Raudkivi (1976) presents limited experimental data on threshold conditions obtained for low values of Re_* (in the range 0.03 to 1). A best-fit line to the portion of these data obtained for grain-shaped sediments gives the following criterion

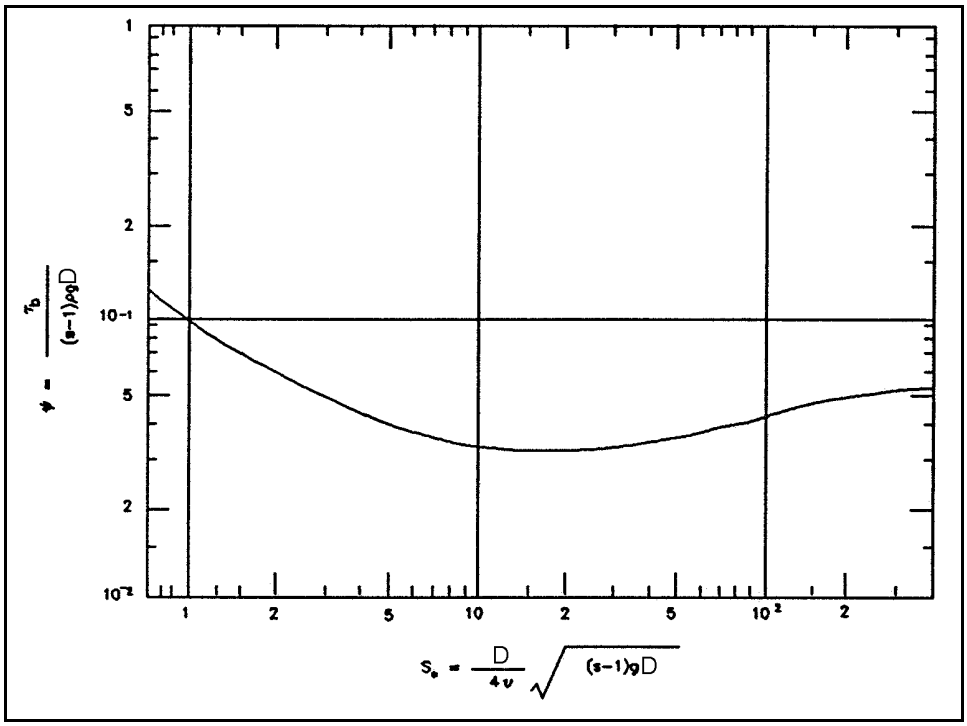

Figure III-6-8. Modified Shields diagram (Madsen and Grant 1976)

$$\psi_{cr} = 0.1 \mathrm{Re}_*^{-1/3} \quad \text{for} \quad \mathrm{Re}_* < 1 \tag{III-6-48}$$

which upon the modification, i.e., using Equation 6-47, may be written as

$$\psi_{cr} = 0.1 S_*^{-2/7} \quad \text{for} \quad S_* < 0.8 \tag{III-6-49}$$

(e) For large values of S_*, the flow corresponding to initiation of motion is fully rough turbulent, $\mathrm{Re}_* > 100$, and the value of $\psi_{cr} \approx 0.06$ may be used for S_* values larger than the range covered in Figure III-6-9.

(3) Modified Shields criterion.

(a) The modified Shields criterion for initiation of motion of a cohesionless sediment shown in Figure III-6-8 was obtained from steady turbulent flow experiments. The fact that this criterion is applicable also for unsteady turbulent boundary layer flows, as demonstrated by the results presented in Figure III-6-9 (Madsen and Grant 1976), is not surprising when the nature of the onset of sediment movement is considered. For flow conditions in the vicinity of $\psi \approx \psi_{cr}$ the sporadic movement of a few grains is, as discussed above, associated with high-frequency turbulent fluctuations in the mobilizing force acting on a grain. Since the near-bottom mean velocity profile is logarithmic for waves as well as for currents, it is physically reasonable to expect the near-bottom turbulence to be similar, i.e., scaled by the instantaneous value of the bottom shear velocity. Provided therefore that the response time of the individual sediment grains is short relative to the time scale of turbulent fluctuations, which are expected to be the same for waves and currents if the shear velocities are the same, initiation of motion will be affected by unsteadiness only if the wave period is on the order of the time scale of the turbulent fluctuations. This not being the case, the effects of unsteadiness

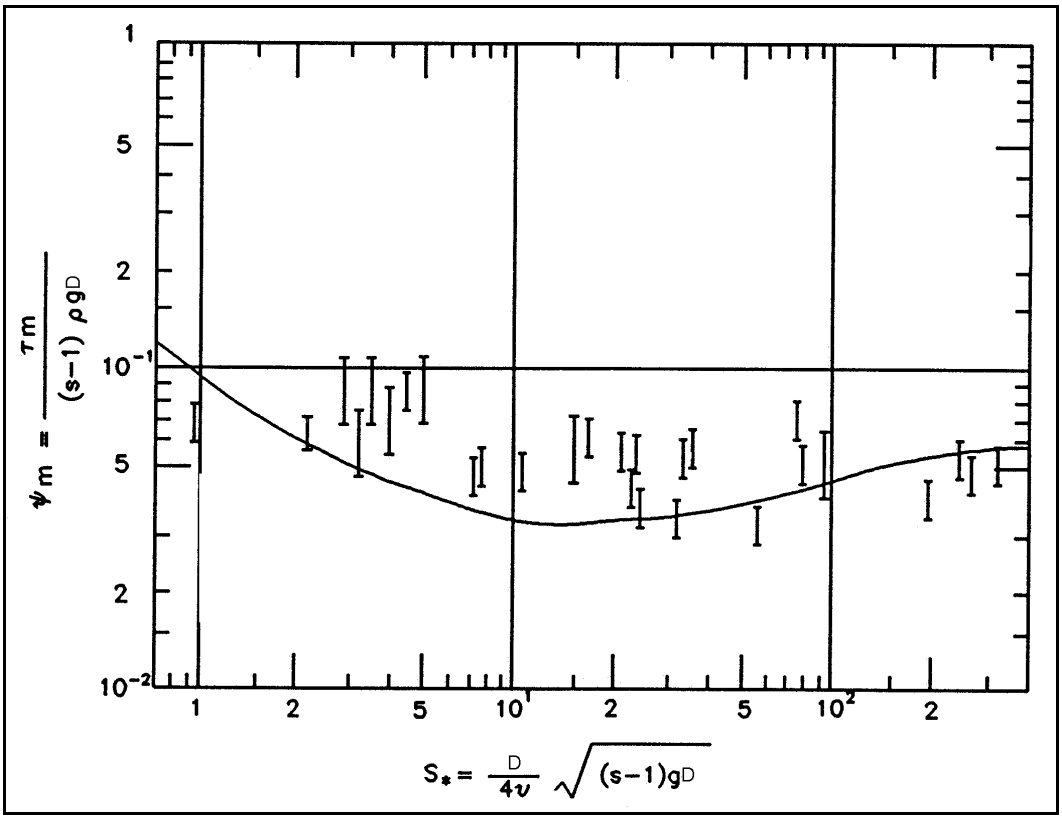

Figure III-6-9. Comparison of Shields curve with data on initiation of motion in oscillatory turbulent flows (after Madsen and Grant ((1976))

of the mean flow are negligible and sediment grains react essentially instantaneously to the applied shear stress, i.e., initiation of motion is obtained from

$$\psi_m = \frac{u_{*m}^2}{(s-1)gD} = \psi_{cr} \tag{III-6-50}$$

in which u_{*m} denotes the maximum shear velocity, i.e., $u_{*m} = u_{*c}$, u_{*wm}, and u_{*m} for pure current, pure wave, and combined wave-current flows, respectively.

(b) The effect of bottom slope on the initiation of motion of sediment grains on the fluid-sediment interface may be accounted for by considering a modification of the simple force balance (Madsen 1991) between fluid drag, gravity, and frictional resistance against movement along a plane bottom inclined at an angle β to horizontal in the direction of flow, where β is taken positive if the bottom is sloping upward in the direction of flow. The resulting force balance suggests that the critical Shields parameter for flow over a sloping bottom may be expressed as

$$\psi_{cr,\beta} = \psi_{cr}\left\{\cos\beta\left(1 + \frac{\tan\beta}{\tan\varphi_s}\right)\right\} \tag{III-6-51}$$

where φ_s is the friction angle for a stationary spherical interfacial grain.

EXAMPLE PROBLEM III-6-6

FIND:

The critical shear velocity u_{*cr} and critical bottom shear stress τ_{cr} for initiation of motion.

GIVEN:

Sediment is quartz sand, ρ_s = 2,650 kg/m^3, of diameter D = 0.2 mm. Fluid is seawater (ρ = 1,025 kg-/m^3, $\nu \approx 1.0\times10^{-6}$ m^2/s).

PROCEDURE:

1) Compute value of the sediment-fluid parameter S_* defined by Equation 6-47.

2) *If* $S_* < 0.8$ obtain ψ_{cr} from Equation 6-49 (be concerned about sediment being cohesive since formula is limited to cohesionless sediments).

3) If $S_* > 300$, $\psi_{cr} \approx 0.06$.

4) If $0.8 < S_* < 300$ obtain ψ_{cr} from Figure III-6-8.

5) Solve Equation 6-45 for u_{*cr} with ψ_{cr} obtained in step 2, 3, or 4.

6) Obtain $\tau_{cr} = z\rho\, u_{*cr}^2$ from definition of shear velocity.

SOLUTION:

The sediment-fluid parameter defined by Equation 6-47 is first computed with $s = \rho_s/\rho = 2.59$ and $g = 9.80$ m/s^2

$$S_* = \frac{D}{4\nu}\sqrt{(s-1)gD} = 2.79$$

With this value of S_* the critical Shields parameter is obtained from Figure III-6-8

$$\psi_{cr} \approx 0.052$$

and using the definition of the Shields parameter given by Equation 6-45

$$u_{*cr} = \sqrt{(s-1)gD\ \psi_{cr}} = 1.27\times10^{-2} \text{ m/s} = 1.27 \text{ cm/s}$$

or $\tau_{cr} = \rho(u_{*cr})^2 = 0.165$ N/m$^2 \approx 0.17$ Pa

If $S_* < 0.8$ had been obtained, Equation 6-49 and *not* Figure III-6-8 should be used to find ψ_{cr}.

d. Bottom roughness and ripple generation. When the flow intensity (expressed in terms of the Shields parameter ψ) exceeds the critical condition for initiation of motion ψ_{cr}, sediment grains will start to move virtually instantaneously (Madsen 1991). However, for ψ exceeding ψ_{cr} by a modest amount (ψ > (1.1 to 1.2)ψ_{cr}), the plane bottom will no longer remain plane. It becomes unstable, deforms, and exhibits bed forms and ripples.

(1) The skin friction concept.

(a) The appearance of bed forms on the sediment-fluid interface changes the appearance of the bottom to the flow above. Rather than giving rise to a flow resistance associated with drag forces on individual sediment grains, i.e., a roughness scaled by the sediment diameter, the flow will separate at the crest of the bed forms and flow resistance will primarily be composed of pressure drag forces on bottom bed forms, i.e., a roughness scaled by the bed form geometry. The appearance of ripples on the bottom changes the physical bottom roughness by orders of magnitude.

(b) Despite the increased bottom roughness associated with a rippled bed, the *drag force acting on individual sediment grains and not the drag force on the bed forms* is responsible for the sediment motion caused by the flow. In the terminology of bottom shear stresses, it is the average shear stress acting on the sediment grains, *the skin friction*, that moves sediment and not the total shear stress comprising skin friction and form drag. The concept of partitioning bottom shear stress into a skin friction and a form drag component, i.e., taking

$$\tau_b = \tau_b^{/} + \tau_b^{//} \tag{III-6-52}$$

in which $\tau_b^{/}$ denotes the skin friction component and $\tau_b^{//}$ the form drag component, illustrated in Figure III-6-10, has received considerable attention in the context of sediment transport mechanics in steady turbulent flows (Raudkivi 1976).

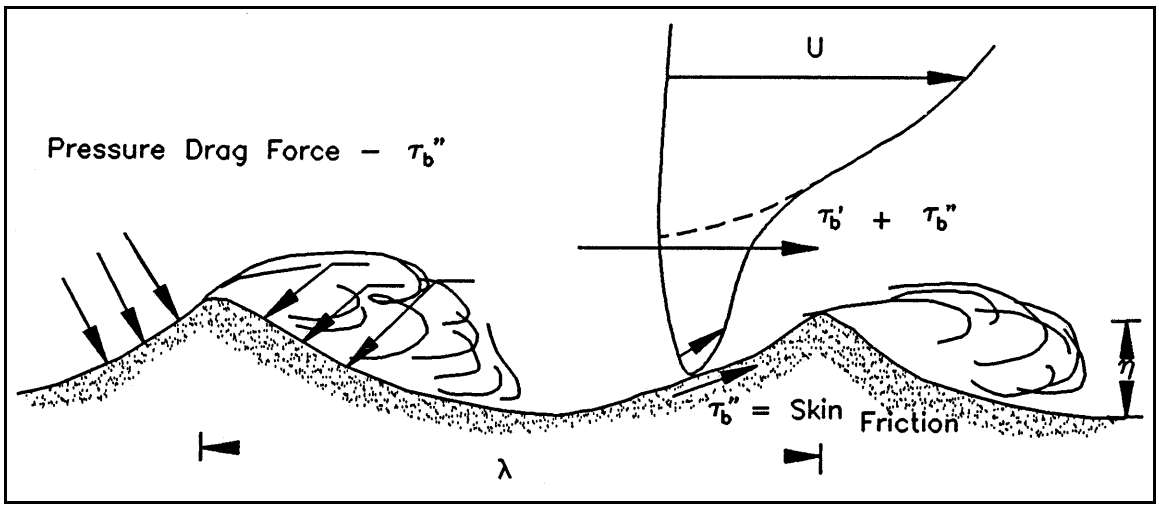

Figure III-6-10. Conceptualization of pressure drag τ_b'', skin friction τ_b', total shear stress $\tau_b'+\tau_b''$, for turbulent flow over a rippled bed

(c) For a pure wave motion, it is assumed that the skin friction bottom shear stress is obtained quite simply (Madsen and Grant 1976) by evaluating the bottom shear stress from the given wave condition, u_{bm} and ω, as if the bottom roughness scale were the sediment grain diameter D. Thus, for a wave motion, the skin friction bottom shear stress is obtained from

$$\tau'_{wm} = \frac{1}{2}\rho f'_w u_{bm}^2 \tag{III-6-53}$$

where f'_w is the wave friction factor obtained from Equation 6-18, Equation 6-19, or Equation 6-21 for a roughness

$$k_n = k'_n = D \tag{III-6-54}$$

Laboratory data on wave-generated ripples as well as ripple geometry for spectral waves is discussed (Madsen 1993) in some detail.

(d) For combined wave-current flows it has been proposed (Glenn and Grant 1987) to evaluate the skin friction bottom shear stress in a similar manner, i.e., using the wave-current interaction model presented in Part III-b(2)d with a roughness specified by Equation 6-54. However, if a combined wave-current boundary layer flow is specified by a current velocity outside the wave boundary layer, i.e., $u_c(z_r)$ with $z_r > \delta_{cw}$, the direct use of this information in the formulas given in Part III-6(2)d with $k_n = k'_n = D$ would lead to an ambiguous determination of the skin friction, since this approach presumes the variation of the current velocity outside the wave boundary layer to be governed by the grain size roughness, which is true only for a flat bed, i.e., in the absence of form drag.

(e) To overcome this problem, the combined wave-current theory presented in Part III-6(2)d is first used with k_n = total equivalent Nikuradse sand grain roughness, accounting for the presence of bed forms, to predict the current velocity at the outer edge of the wave boundary layer, i.e.,

$$u_c(z_r) \quad \text{with} \quad z_r = \delta_{cw} \tag{III-6-55}$$

is obtained from a model considering total bottom shear stresses.

(f) With the current specified by Equation 6-55, the skin friction shear stress is now computed from the general wave-current interaction theory using the grain size roughness $k_n = k'_n = D$. In this manner (Wikramanayake and Madsen 1994a), the ambiguity of the prediction of combined wave-current skin friction shear stresses is avoided.

(2) Field data on geometry of wave-generated ripples.

(a) When field data on ripple geometry are plotted against the skin friction Shields parameter,

$$\psi'_m = \frac{\tau'_{wm}}{(s-1)\rho g D} = \frac{(u'_{*wm})^2}{(s-1)gD} \tag{III-6-56}$$

they exhibit an extensive scatter. By trial and error it was found (Wikramanayake and Madsen 1994a) that the parameter providing the best correlation of field data on ripple geometry was

$$Z = \frac{\psi_m'}{S_*} \tag{III-6-57}$$

in which S_* is the sediment-fluid parameter defined by Equation 6-47.

(b) The equations for the empirical relationships for ripple geometry in the field are (Madsen 1993).

$$\frac{\eta}{A_{bm}} = \begin{cases} 1.8\times10^{-2}\ Z^{-0.5} & 0.0016 < Z < 0.012 \\ 7.0\times10^{-4}\ Z^{-1.23} & 0.012 < Z < 0.18 \end{cases} \tag{III-6-58}$$

and

$$\frac{\eta}{\lambda} = \begin{cases} 1.5\times10^{-1}\ Z^{-0.009} & 0.0016 < Z < 0.012 \\ 1.05\times10^{-2}\ Z^{-0.65} & 0.012 < Z < 0.18 \end{cases} \tag{III-6-59}$$

where A_{bm} is defined by Equation 6-17, η is ripple height, λ is ripple length, and the lowest and highest range of validity indicate the range covered by the experimental data.

(3) Prediction of ripple geometry under field conditions.

(a) From knowledge of the representative periodic wave (recall that this is defined here as the rms wave and not the significant wave) and sediment characteristics, the skin friction shear stress τ_{wm}' is obtained from Equation 6-53.

(b) With τ_{wm}' known, the value of ψ_m' is obtained from Equation 6-56 and if $2\psi_m' > \psi_{cr}$, obtained from the modified Shields curve in Figure III-6-8, sediment motion is assumed to take place and the parameter Z is obtained from Equation 6-57.

With Z known, the empirical relationship given by Equations 6-58 and 6-59 is used to obtain the ripple geometry. If ψ_m' exceeds a value of 0.35 or if $Z > 0.18$, the bed is assumed flat corresponding to sheet flow conditions.

e. Moveable bed roughness.

(1) The determination of moveable bed roughness over naturally rippled beds is limited by the lack of reliable field measurements over a range of wave conditions. The limited amount of available data on wave-generated ripple geometry and the associated rate of energy dissipation in the wave bottom boundary layer above the rippled bed have been analyzed (Wikramanayake and Madsen 1994a). Their analysis results suggest the adoption of the following simple relationship for moveable bed roughness associated with rippled beds

$$k_n = 4\eta \tag{III-6-60}$$

where η is the ripple height. However, the translation of ripple geometry to equivalent roughness, Equation 6-60, is based entirely on laboratory data for periodic waves and is of dubious value for field roughness determinations. Therefore, the following procedure is suggested (Madsen 1993).

(2) For a wave condition specified in terms of the representative periodic wave, the ripple height is obtained from Equation 6-58, and the movable bed roughness k_n is obtained from Equation 6-60.

(3) If ψ_m' suggests no sediment motion, $2\psi_m' < \psi_{cr}$, the movable bed roughness is taken as $k_n = k_n' = D$ unless information on bottom roughness associated with bioturbation of the bottom sediments is available.

(4) If $\psi_m' > \approx 0.35$ or if $Z > 0.18$, the bed is expected to be flat, i.e., corresponding to sheet flow conditions. Recent results from field experiments (Madsen et al. 1993) suggest a value of $k_n = 15D$ to be appropriate for sheet flow conditions. Since the conditions from which this result was obtained correspond to values of $\psi_m' \approx 1$ and since it is physically reasonable to assume the movable bed roughness for sheet flow conditions depends on the intensity of sediment transport over the flat bed, which in turn is related to the magnitude of ψ_m', it is *tentatively proposed* that

$$k_n = 15\psi_m' D \tag{III-6-61}$$

be adopted for sheet flow conditions. This expression agrees in form with an expression proposed for steady flow (Wilson 1989) although the coefficients differ.

III-6-4. Bed-load Transport

a. Introduction.

(1) When flow and sediment characteristics combine to produce a Shields parameter greater than the critical value, sediment is set in motion. One result of this is the generation of bed forms, discussed in Part III-6-3; another is, of course, the initiation of a non-zero transport of sediment.

(2) For values of the Shields parameter slightly above critical or, more specifically, for low transport rates, the predominant mode of sediment transport takes place as individual grains rolling, sliding, and/or jumping (saltating) along the bed. This mode of sediment transport is referred to as *bed load* and, since it takes place in close proximity of the bed, it is dependent on *skin friction*.

(3) Several empirical bed-load transport formulas have been proposed for steady turbulent boundary layer flows (Raudkivi 1976). One of these, the Meyer-Peter and Müller formula (Meyer-Peter and Müller 1948), enjoys particular popularity in the engineering literature. However, since it was originally developed from data obtained for steady flows in rivers and channels of negligible slope, its adoption for unsteady wave or combined wave-current turbulent boundary layer flows over an inclined bed is not straightforward. A conceptual model for bed-load transport of sediment grains rolling or sliding along an inclined bottom has been proposed (Madsen 1993) as a physical interpretation of the purely empirical Meyer-Peter and Müller formula. The resulting formulation is time-averaged and solved under the assumptions that: waves dominate

EXAMPLE PROBLEM III-6-7

FIND:

The height η, length λ, and movable bed roughness k_n, of wave-generated ripples in the field.

GIVEN:

The representative periodic wave motion is specified as in Example Problem III-6-3. Bottom sediment is quartz, ρ_s = 2,650 kg/m^3, of diameter D = 0.2 mm. Fluid is seawater (ρ = 1,025 kg/m^3, $\nu \approx 1.0\times10^{-6}$ m^2/s).

PROCEDURE:

1) Obtain the wave shear velocity u'_{*wm} assuming grain size roughness k'_n = d = median sediment diameter, following the procedure described in Example Problem III-6-2. (Result is denoted here by *prime* to signify *skin friction* shear velocity.)

2) With u'_{*wm} from step 1 compute ψ'_m from Equation 6-56.

3) Evaluate S_* as defined by Equation 6-47.

4) Determine ψ_{cr} following procedure of Example Problem III-6-6.

5) If $\psi'_m < \frac{1}{2}\psi_{cr}$ there will be no sediment motion and no ripples, i.e., $\eta = \lambda = 0$. Bottom roughness *is* the sediment grain diameter ($k_n = k'_n = D$) unless other information is available, e.g., photos showing relict ripples or other roughness features.

6) If $\psi'_m > 0.35$, sheet flow is assumed. The bed is flat, i.e., $\eta = \lambda = 0$, and the movable bed roughness k_n is obtained from Equation 6-61.

7) If $\frac{1}{2}\psi_{cr} < \psi'_m < 0.35$, the parameter Z defined by Equation 6-57 is computed.

8) If Z falls within the range indicated for Equations 6-58 and 6-59, these are used to compute η and λ. The movable bed roughness k_n is obtained from Equation 6-60.

9) If $Z < 0.0016$ and $D < 0.6$ mm, it is *recommended* that η, λ, and k_n be obtained as if $Z = 0.0016$.

10) If $Z > 0.18$ and $D > 0.08$ mm, sheet flow is assumed (i.e., $\eta = \lambda = 0$), and Equation 6-61 is used to obtain k_n.

(Continued)

Example Problem III-6-7 (Concluded)

SOLUTION:

In Example Problem III-6-3, the initial solution for the wave friction factor neglected the presence of a current ($\mu = 0$, $C_\mu = 1$) and gave $f_w = 7.86\times10^{-3}$. Since the wave motion and the bottom roughness ($k_n = k_n' = D = 0.2$ mm) are the same here, the maximum skin friction shear velocity is given by

$$u'_{*wm} = \sqrt{f_w'/2}\; u_{bm} = 2.19\times10^{-2} \text{ m/s} = 2.19 \text{ cm/s}$$

From the definition of the Shields parameter, Equation 6-56, it follows that

$$\psi'_m = \frac{\left(u'_{*wm}\right)^2}{(s-1)gD} = 0.154$$

The sediment being the same as specified in Example Problem III-6-5 where $\psi_{cr} = 0.052$ was obtained, it is seen that the sediment will be moving, since $\psi'_m > \psi_{cr}$. Since $\psi'_m < 0.35$, flat bed (sheet flow) is not predicted and bed forms are therefore expected. The geometry of these bed forms is obtained from the field relationships, Equations 6-58 and 6-59. With the parameter

$$Z = \frac{\psi'_m}{S_*} = 0.055$$

since $S_* = 2.79$ in Example Problem III-6-6, which is within the range $0.012 < Z < 0.18$, one therefore obtains from Equation 6-58

$$\frac{\eta}{A_{bm}} = 7\times10^{-4}\, Z^{-1.23} = 2.47\times10^{-2}$$

or, with $A_{bm} = 44.6$ cm (Example Problem III-6-3)

$$\eta = \frac{\eta}{A_{bm}} A_{bm} = 1.1 \text{ cm}$$

The ripple steepness is obtained from Equation 6-59

$$\frac{\eta}{\lambda} = 1.05\times10^{-2}\, Z^{-0.65} = 6.91\times10^{-2} \rightarrow \lambda = \eta/(\eta/\lambda) = 15.9 \text{ cm} \approx 16 \text{ cm}$$

From Equation 6-60, one obtains the movable bed roughness

$$k_n = 4\eta = 4.4 \text{ cm}$$

EXAMPLE PROBLEM III-6-8

FIND:

The skin friction shear velocities associated with the current $u_{*c}^{/}$, the wave $u_{*wm}^{/}$, and the maximum combined $u_{*m}^{/}$, as well as the phase angle of the wave-associated shear stress φ', for a combined wave-current flow over a movable bed in the field.

GIVEN:

The representative periodic wave is specified by its near-bottom maximum orbital velocity $u_{bm} = u_{br} = 0.35$ m/s and period $T = 8.0$ s. The current is specified by its magnitude $u_c(z_r) = 0.35$ m/s at $z_r = 1.00$ m and direction $\varphi_{wc} = 45°$ relative to the direction of wave propagation. The bed consists of uniform quartz sand, $\rho_s = 2{,}650$ kg/m^3, of diameter $D = 0.2$ mm. The fluid is seawater ($\rho = 1{,}025$ kg/m^3, $\nu \approx 1.0\times10^{-6}$ m^2/s).

PROCEDURE:

1) Considering *only* the wave motion, the movable bed roughness k_n is obtained following the procedure given in Example Problem III-6-7.

2) With k_n from step 1, the combined wave-current problem is solved following the procedure described in Example Problem III-6-4.

3) From the combined wave-current flow solution obtained in step 2, the current velocity $u_c(z = \delta_{cw})$ is computed by the procedure of Example Problem III-6-5.

4) With the current specification $u_c = u_c(\delta_{cr})$ at $z = \delta_{cw}$ from step 3, the wave-current interaction problem is solved for $k_n^{/} = D$ following the procedure described in Example Problem III-6-3.

5) The skin friction phase angle φ' is obtained from Equation 6-12 with $u_{*wm} = u_{*m}^{/}$.

SOLUTION:

The *first step* to follow in determining the skin friction components for a combined wave-current boundary layer flow is to determine the movable bed roughness. Since the presence of a current is neglected in performing this step, this was done in Example Problem III-6-7 for the wave and sediment characteristics considered here and resulted in $k_n = 4.4$ cm.

The *second step* is to determine the current velocity at the edge of the boundary layer, $u_c(\delta_{cw})$ from the wave-current interaction model using the movable bed roughness obtained in step 1. This was done in Example Problems III-6-4 and III-6-5 where the bottom roughness was specified as $k_n = 4.4$ cm, i.e., exactly the movable bed roughness determined in step 1 for the given wave and sediment characteristics.

(Continued)

Example Problem III-6-8 (Concluded)

The *third step* is to determine the shear velocities and stresses associated with the combined wave-current boundary layer flow over a bottom of roughness $k_n = k_n' = D$ = sediment diameter with the current specified as obtained in step 2. From Example Problem III-6-5, the current specification is therefore

$$u_c(z_r) = 10.2 \text{ cm/s} \quad \text{at} \quad z_r = \delta_{cw} = 3.40 \text{ cm}$$

at an angle $\varphi_{wc} = 45$ deg to the direction of wave propagation. With this current specification, $k_n = k_n' = D = 0.2$ mm, and wave characteristics $u_{bm} = 35$ cm/s and $\omega = 2\pi/T = 0.785$ s^{-1} ($A_{bm} = u_{bm}/\omega = 44.6$ cm) solution of the wave-current interaction problem follows Example Problem III-6-3.

For $\mu = 0$ and $C_\mu = 1$, the first iteration is identical to that in Example Problem III-6-3, resulting in $u_{*wm}' = u_{*m}' = 2.19$ cm/s and $\delta_{cw}' = 1.12$ cm. With these values and using the current specifications given above, Equation 6-40 gives

$$u_{*c}' = 0.96 \text{ cm/s}$$

Second iteration is therefore based on $\mu = \left(u_{*c}'/u_{*wm}'\right)^2 = 0.194$ and, from Equation 6-33, $C_\mu = 1.15$. For this value of C_μ solving iteratively for $x = 4\sqrt{f_{cw}/C_\mu}$ in the manner outlined in Example Problem III-6-3 results in $x^{(3)} = 0.349$, or

$$f_{cw}' = 8.73 \times 10^{-3}$$

and therefore

$$u_{*wm}' = 2.31 \text{ cm/s} \; ; \quad u_{*m}' = 2.48 \text{ cm/s} \quad \text{and} \quad \delta_{cw}' = 1.26 \text{ cm}$$

with which Equation 6-40 gives

$$u_{*c}' = 1.01 \text{ cm/s}$$

The next value of $\mu = \left(u_{*w}/u_{*wm}'\right)^2 = 0.191$ is virtually identical to the previous value, so no further iteration is necessary.

The solution is therefore

$$u_{*c}' = 1.01 \text{ cm/s} \; , \quad u_{*wm}' = 2.31 \text{ cm/s} \; , \quad u_{*m}' = 2.48 \text{ cm/s}$$

and the phase angle of the wave-associated skin friction bottom shear stress is obtained from Equation 6-12 with $u_{*wm} = u_{*m}'$ and $z_0 = d/30$

$$\tan \varphi' = 0.25 \rightarrow \varphi' = 13.8° \approx 14°$$

currents $\mu = \tau_c'/\tau_{wm}' << 1$; maximum shear stress is much larger than critical $\mu_{CR} = \tau_{CR}/\tau_{wm}' << 1$; and bottom slope is relatively small

$$\mu_b = \frac{\tan\beta}{\tan\varphi_m} << 1 \tag{III-6-62}$$

where $\beta > 0$ is bottom slope upward relative to direction of flow and φ_m is friction angle (Madsen 1993). Results of this analysis provide the following formulations for the time-averaged bed-load transport $\overline{q_{SB}}$.

b. Pure waves on sloping bottom. For a non-zero bottom slope, i.e., $\mu_b \neq 0$, but still without any current, the time-averaged net bed-load transport is

$$\left(\frac{\bar{q}_{sB}}{\sqrt{(s-1)gD}\,D}\right)_\beta = 8\left(\psi_{wm}'\right)^{\frac{3}{2}}\overline{|\cos\theta|^{\frac{3}{2}}}\{-\mu_b,0\} = 4.5\left(\psi_{wm}'\right)^{\frac{3}{2}}\{-\mu_b,0\} \tag{III-6-63}$$

in the direction of the wave propagation, $+x$, if $-\mu_b > 0$ and opposite the wave direction if $-\mu_b < 0$. Since $\mu_b > 0$ if the wave propagates up a slope, $\beta_w > 0$, and $\mu_b < 0$ if the wave is directed towards deeper water ($\beta_w < 0$), this simply states that the net transport is down-slope as expected.

c. Combined wave-current flows. Since the approximate bed-load transport formula is linear in the small parameters, the net bed-load transport associated with combined wave-current flows can be evaluated by time averaging for $\mu_b = 0$. The resulting net bed-load transport is given by

$$\left(\frac{\bar{q}_{sB}}{\sqrt{(s-1)gD}\,D}\right)_{wc} = 6\left(\psi_c'\right)^{\frac{3}{2}}\frac{u_{*wm}'}{u_{*c}'}\left\{\frac{3}{2}\cos\varphi_{wc},\ \sin\varphi_{wc}\right\} \tag{III-6-64}$$

where ψ_c' denotes the Shields parameter based on the current skin friction shear stress. It should be noted that the direction of sediment transport is *not* in the direction of the current but is obtained from

$$\tan\varphi_{ws} = \frac{2}{3}\tan\varphi_{wc} \tag{III-6-65}$$

This expression shows that φ_{ws}, the direction of the net bed-load transport measured counterclockwise from the x-axis, deviates from the current direction towards the direction of wave orbital velocities.

d. Combined current and bottom slope effect. It is interesting to note that the superposition of a current in the direction of wave propagation, i.e., $\varphi_{wc} = 0$, up a slope may lead to zero net transport. Thus, the sum of transport given by Equations 6-63 and 6-64 is zero if

$$\mu_b = 2\mu \tag{III-6-66}$$

Although the upslope transport here is associated with an assumed current, it is reasonable to anticipate a similar upslope effect associated with nonlinear wave effects, i.e., a larger upslope shear stress under the crest

than the downslope stress under the trough. The balance expressed in Equation 6-66 may therefore be thought of as a simulation of an equilibrium profile condition for inner shelf waters.

e. Extension to spectral waves. To compute the bed load for spectral wave conditions, the procedures outlined in the foregoing sections are followed using the representative periodic wave characteristics defined in Part III 6-2-*b* (4).

f. Extension to sediment mixtures.

(1) For a sediment mixture consisting of several distinct size classes of diameter D_n with the volume fraction of the nth size class being f_n in the bottom sediments, the total bed-load transport of the sediment mixture is given by

$$\bar{q}_{sB} = \sum f_n \bar{q}_{sB,n} \tag{III-6-67}$$

(2) This extension to sediment mixtures follows directly from the conceptual bed-load transport model (Madsen 1993) when it is assumed that the fraction of excess skin friction shear stress carried by moving grains of the nth size class is $f_n\left(\tau_b' - \tau_{cr,n}\right)$.

(3) For each size class, the procedure is therefore exactly as outlined in the preceding section with D replaced by D_n, the diameter of the nth size class. The skin friction bottom shear stress is, however, the same for all size classes and is computed for a single representative grain diameter ($D = D_r = D_{50}$ = the median diameter of the sediment mixture in the bed).

III-6-5. Suspended Load Transport

a. Introduction.

(1) For low transport rates, the predominant mode of transport is sediment grains moving along the bottom, i.e., in the form of bed load. As the flow intensity and, hence, the bed-load transport, is increased individual grains moving along the bottom take off from the bottom with increasing frequency, e.g., due to impact with stationary grains protruding above their neighbors. Thus, as the flow intensity increases, the mode of transport changes from one of rolling and sliding along the bottom to one of jumping along the bottom. For this mode of transport, moving grains are in direct contact with immobile bottom grains only for a fraction of the time they spend in transport, and the basic assumptions behind the conceptual transport model presented in the preceding section are no longer valid.

(2) Sediment transport associated with individual sediment grains making isolated or a series of jumps along the bottom, referred to as saltation, provides a transition from bed-load transport that takes place immediately above the bottom to suspended load transport that takes place in the overlying water column. From this distinction between the bed-load and suspended load transport modes, it follows that suspended load is governed by the turbulence associated with the *total bottom shear stress*, i.e., the shear stress predicted from the movable bed roughness estimate obtained from Part III-6-3, whereas the bed load is governed by the *skin friction shear stress*.

EXAMPLE PROBLEM III-6-9

FIND:

The bed-load transport rate for a combined wave-current flow over a sloping bottom.

GIVEN:

The wave is specified by its maximum near-bottom orbital velocity u_{bm} = 0.35 m/s, period T = 8.0 s, and angle of incidence α = 45 deg. The current is at an angle of φ_{wc} = 45 deg to the wave direction and has a magnitude of $u_c(z_r)$ = 0.35 m/s at z_r = 1.00 m. The bottom has a uniform slope of β = 1 deg and consists of uniform quartz sand ρ_s = 2,650 kg/m^3, with diameter D = 0.2 mm. The fluid is seawater (ρ = 1,025 kg/m^3, $\nu \approx 1.0\times10^{-6}$ m^2/s).

PROCEDURE:

1) The skin friction shear velocities and stresses are computed using the procedure of Example Problem III-6-8.

2) The skin friction Shields parameters, ψ_c' and ψ_{wm}', are obtained from Equation 6-43 with $u_* = u_{*c}'$ and u_{*wm}', respectively, as obtained in step 1.

3) The time-averaged combined wave-current bed-load transport vector is obtained from Equation 6-64 using u_{*c}' and u_{*wm}' from step 1 and ψ_c' from step 2.

4) The bottom slope parameter μ_b is calculated from Equation 6-62, where β is bottom slope in the direction of wave propagation (positive if wave is traveling towards shallower waters) and φ_m = 30 deg.

5) The time-averaged bottom slope bed-load transport vector is obtained from Equation 6-63 with ψ_{wm}' from step 2.

6) The total time-averaged bed-load transport vector is obtained by vector addition of the wave-current and slope bed-load transport vectors obtained in step 3 and step 5, respectively. (The x component denotes the transport in the direction of wave propagation, the y component is transport 90 deg counterclockwise to the direction of wave propagation.)

(Continued)

Example Problem III-6-9 (Concluded)

SOLUTION:

To calculate bed-load transport, one needs to use skin friction shear stresses. The problem specification is here identical to that of Example Problem III-6-8, so the skin friction problem was solved there, i.e., $u'_{*c} = 1.01$ cm/s and $u'_{*wm} = 2.31$ cm/s. The corresponding skin friction Shields parameters are obtained from Equation 6-56 with $s = \rho_s/\rho = 2.59$ and $D = 0.2$ mm

$$\psi'_c = 0.033 \quad \text{and} \quad \psi'_{wm} = 0.17$$

With these values, the bed-load transport associated with the combined wave-current flow is obtained in nondimensional form from Equation 6-64

$$\left(\frac{\bar{q}_{sB}}{\sqrt{(s-1)gD}D} \right)_{wc} = 0.082 \left\{ \frac{3}{2} \cos \varphi_{wc} \, , \quad \sin \varphi_{wc} \right\}$$

or in dimensional form with $\varphi_{wc} = 45$ deg

$$\left(\bar{q}_{sB}\right)_{wc} = \{9.7, 6.5\} \times 10^{-3} \text{ cm}^3/(\text{cm s})$$

To obtain the contribution due to bottom slope, the slope β_w in the direction of wave propagation is needed. Since the bottom slope is $\beta = 1$ deg and the angle of incidence is $\alpha = 45$ deg, the bottom slope in the direction of wave propagation is $\tan \beta_w = \tan \beta \cos \alpha = 0.012$. Equation 6-62 therefore gives, with $\varphi_m = 30$ deg, $\mu_b = \tan \beta_w / \tan \varphi_m = 0.021$. Bed-load transport due to bottom slope is obtained from Equation 6-63 in nondimensional form

$$\left(\frac{\bar{q}_{sB}}{\sqrt{(s-1)gD}D} \right)_{\beta} = 0.32\{-\mu_b, 0\}$$

or in dimensional form

$$\left(\bar{q}_{sB}\right)_{\beta} = \{-7.5, 0\} \times 10^{-4} \text{ cm}^3/(\text{cm s})$$

The total bed-load transport rate is obtained as the sum of the wave-current and bottom slope contributions, i.e.,

$$\bar{q}_{sB} = \left(\bar{q}_{sB}\right)_{wc} + \left(\bar{q}_{sB}\right)_{\beta} \approx \{9.0, 6.5\} \times 10^{-3} \text{ cm}^3/(\text{cm s})$$

with the x component being in the direction of wave propagation and the y component being at 90 deg counterclockwise from the wave direction.

(3) Distribution of suspended sediment in the water column is governed by the fall velocity of the sediment w_f, the sediment diffusion coefficient v_s, and the volume concentration of sediment in suspension c. Assuming the sediment-fluid mixture behaves as a clear fluid, a close analogy can be drawn between the turbulent diffusion of momentum and sediment diffusion such that

$$v_s = v_t = k u_* z \tag{III-6-68}$$

For combined wave-current bottom boundary layer flows, the concentration of suspended sediments c may be resolved into its mean $\bar{c}$ and time-varying wave-associated c_w components.

b. Sediment fall velocity.

(1) In order to solve the equations governing the distribution of suspended sediment concentration in the vertical, it is necessary to obtain the value of the sediment fall velocity w_f.

(2) Assuming a spherical sediment grain, the force balance of submerged weight and fluid drag on a grain falling through an otherwise quiescent fluid gives

$$(\rho_s - \rho)\, g \left(\frac{\pi}{6} D^3 \right) = \frac{1}{2} \rho\, C_D \left(\frac{\pi}{4} D^2 \right) w_f^2 \tag{III-6-69}$$

or

$$\frac{w_f}{\sqrt{(s-1)\, g\, D}} = \sqrt{\frac{4}{3\, C_D}} \tag{III-6-70}$$

(3) The drag coefficient C_D is a function of the Reynolds number $Re_D = D\, w_f / \nu$, which is a function of S_*, the sediment-fluid parameter defined by Equation 6-47.

(4) From the empirical relationship of C_D versus Re_D (Schlichting 1960), C_D is obtained for a specified value of Re_d. With this value of C_D the nondimensional fall velocity is obtained from Equation 6-70, and this value is used with the specified value of Re_D to obtain the corresponding value of S_*. In this manner (Madsen and Grant 1976), the graph of nondimensional fall velocity as a function of the sediment fluid parameter, shown in Figure III-6-11, is obtained.

(5) Extending the graph to values of S_* above the upper limit of Figure III-6-11 is accomplished by using

$$\frac{w_f}{\sqrt{(s-1)\, g\, D}} = 1.82 \quad \text{for} \quad S_* > 300 \tag{III-6-71}$$

(6) For values of S_* below unity, i.e., for quartz grains of $d < 0.1$ mm in seawater, the fall velocity is obtained from Stokes Law, which in the present notation may be written

$$\frac{w_f}{\sqrt{(s-1)\, g\, D}} = \frac{2}{9} S_* \quad \text{for} \quad S_* < 0.8 \tag{III-6-72}$$

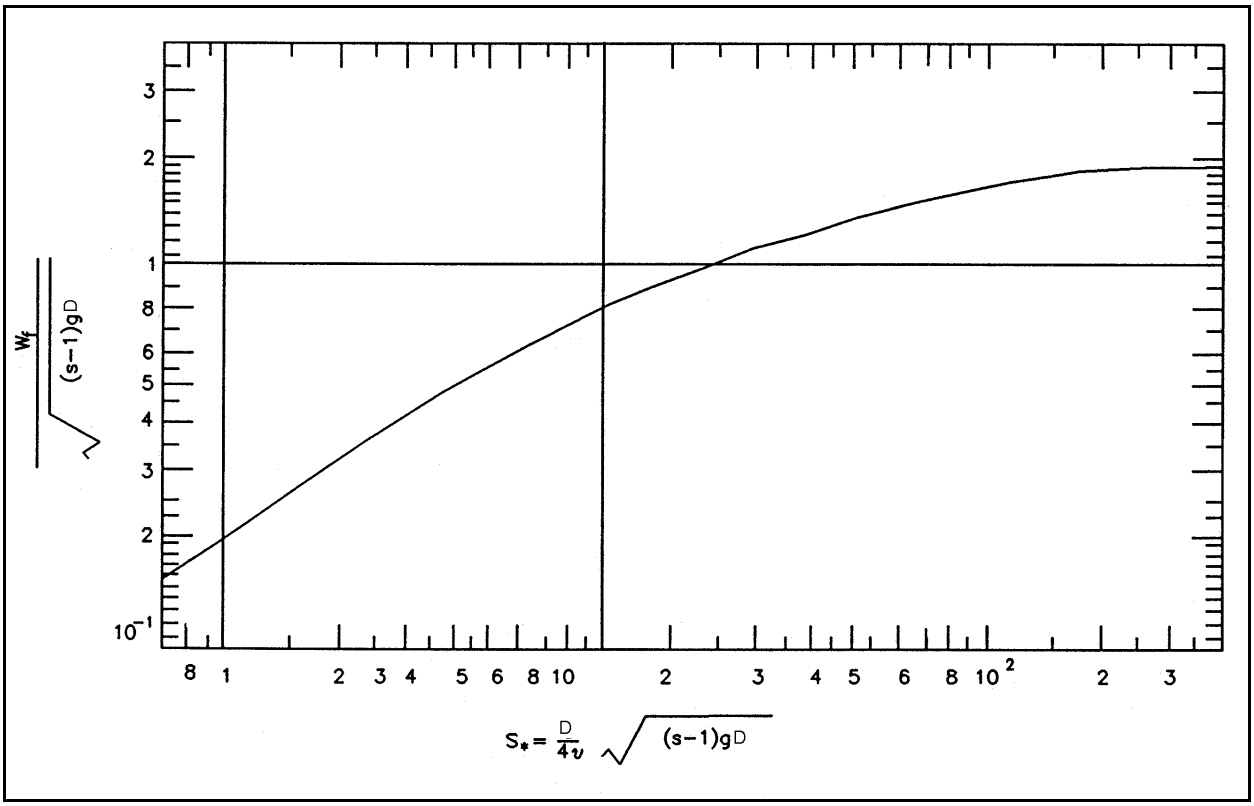

Figure III-6-11. Nondimensional fall velocity for spherical particles versus the sediment fluid parameter (Madsen and Grant 1976)

(7) Although Figure III-6-11 is obtained for sediment assumed to be spherical, it yields reasonably accurate fall velocities for natural cohesionless granular sediments (Dietrich 1982).

c. Reference concentration for suspended sediments.

(1) Introduction.

(a) With the fall velocity determined, all parameters in the equation governing the suspended sediment concentration distribution are in principle known. To solve the equation it is, however, necessary to specify boundary conditions. One boundary condition is simply that no sediment is transported through the water surface or that the suspended sediment concentration vanishes at large distances above the bottom, if the water depth is sufficiently large. Another is the boundary condition that expresses the amount of sediment available for entrainment immediately above the bottom. Whereas the former is universally agreed upon the latter boundary condition is the subject of considerable controversy. It is beyond the scope of this presentation to get into the subtleties of this controversy, so the most commonly accepted form of the bottom boundary condition for suspended sediment concentration, the *specification of a reference concentration*, is adopted here.

(b) The *reference concentration* is given as (Madsen 1993)

$$c_R = \gamma C_b \left(\frac{|\tau_b'(t)|}{\tau_{cr,\beta}} - 1 \right) \tag{III-6-73}$$

EXAMPLE PROBLEM III-6-10

FIND:
Find the sediment fall velocity

GIVEN:
Sediment is quartz sand, ρ_s = 2,650 kg/m^3, of diameter D = 0.2 mm.
Fluid is seawater (ρ = 1,025 kg/m^3, $\upsilon \approx 1.0\times10^{-6}$ m^2/s).

PROCEDURE:
1) The sediment-fluid parameter S_*, defined by Equation 6-47, is calculated.

2) If $S_* > 300$, the sediment fall velocity w_f is obtained from Equation 6-71.

3) If $S_* < 0.8$, the sediment fall velocity w_f is obtained from Equation 6-72.

4) If $0.8 < S_* < 300$, w_f is obtained from Figure III-6-11 using S_* from step 1 as entry.

SOLUTION:
The sediment-fluid parameter is calculated from

$$S_* = \frac{D}{4\nu}\sqrt{(s-1)\,g\,D} = 2.79$$

with $s = \rho_s/\rho = 2.59$.

Figure III-6-11 then gives the nondimensional fall velocity

$$\frac{w_f}{\sqrt{(s-1)\,g\,D}} \approx 0.40$$

and therefore

$$w_f = 2.23 \text{ cm/s}$$

in which γ is the so-called resuspension parameter and C_b is the volume concentration of sediment in the bed, generally taken as 0.65 (Smith and McLean 1977) for a bed consisting of cohesionless sediment.

(c) It is emphasized that the resuspension parameter γ in Equation 6-73 is intimately related to the choice of reference elevation z_r, which explains at least part of the considerable variability of γ values reported in the literature. Similarly, γ values reported in the literature can be used only in conjunction with their particular z_r values. This being said, the numerical values

$$\gamma = \begin{cases} 2\times10^{-3} & \text{for rippled bed} \\ 2\times10^{-4} & \text{for flat bed} \end{cases} \tag{III-6-74}$$

EXAMPLE PROBLEM III-6-11

FIND:

The reference concentration for suspended sediment computations for combined wave-current boundary layer flows.

GIVEN:

Wave, current, sediment, and bottom slope specifications are identical to those of Example Problem III-6-9.

PROCEDURE:

1) Skin friction shear velocities and stresses are computed following the procedure of Example Problem III-6-8.

2) The time-averaged (mean) reference concentration $\bar{c}_R$ is obtained from Equation 6-75 with C_b = 0.65, τ'_{wm}, and τ_{cr} as obtained in step 1, and the appropriate choice of γ from Equation 6-74.

3) The periodic (wave) reference concentration c_{Rw} is obtained from Equation 6-76 using γ and C_b as in step 2 and shear velocities obtained in step 1. The bottom slope in the direction of wave propagation β_w is positive if the wave is traveling up-slope, and φ_m = 30 deg.

SOLUTION:

The reference concentration for suspended load computations depends on skin friction shear velocities, obtained in Example Problem III-6-8 for the same problem specification as here, and may be separated into a mean and a periodic component.

The mean reference concentration is given by Equation 6-75, which may alternatively be written

$$\bar{c}_R = \gamma\ C_b \left\{ \frac{2}{\pi} \left(\frac{u'_{*wm}}{u_{*cr}} \right)^2 - 1 \right\}$$

where u'_{*wm} = 2.31 cm/s (Example Problem III-6-8) and u_{*cr} = 1.27 cm/s (Example Problem III-6-6). The resuspension parameter is given by Equation 6-74. Since the bed is rippled for these problem specifications, cf. Example Problem III-6-7, $\gamma = 2\times10^{-3}$ is chosen here. With C_b = 0.65 the *mean reference concentration* is

$$\bar{c}_R = 1.44\times10^{-3}\ (\mathrm{cm}^3/\mathrm{cm}^3)$$

(Continued)

Example Problem III-6-11 (Concluded)

The periodic reference concentration is given by Equation 6-76. The maximum value may be written

$$c_{Rwm} = \gamma\ C_b \left\{ \frac{4}{\pi} \left(\frac{u'_{*c}}{u_{*cr}} \right)^2 \cos\ \varphi_{wc} - \left(\frac{u'_{*wm}}{u_{*cr}} \right)^2 \frac{\tan\ \beta_w}{\tan\ \varphi_m} \right\}$$

which is evaluated using u'_{*c} = 1.01 cm/s (Example Problem III-6-8), φ_{wc} = 45 deg, and $\tan \beta_w / \tan \varphi_m = \mu_b = 0.021$ (Example Problem III-6-9) to give the *wave-associated maximum reference concentration*

$$c_{Rwm} = 0.65 \times 10^{-3}\ (\mathrm{cm}^3/\mathrm{cm}^3)$$

with a temporal variation $\cos(\omega t + \varphi')$ with φ' = 14 deg (Example Problem III-6-8). Both mean and periodic reference concentrations are specified at

$$z_R = 7D = 0.14\ \mathrm{cm}$$

obtained for and from a model closely resembling the present model, with reference elevation $z_R = 7D$, are adopted here (Wikramanayake and Madsen 1994b). It should, however, be emphasized that there is considerable uncertainty associated with the adoption of these γ values, or any other values for that matter.

(d) To evaluate the general expression for the reference concentration given by Equation 6-73 for combined wave-current flows, the assumption of wave dominance is introduced in the context of evaluation of bed-load transport as previously done in Part III-6-4. Subject to the limitations stated there, the reference concentration is valid for dominant wave conditions ($\tau'_c << \tau'_{wm}$) exceeding critical conditions ($\tau_{cr} << \tau'_{wm}$) over a gently sloping bottom ($\tan\beta_w \ll \tan\varphi_m$).

(2) Mean reference concentration. From the general expression for the reference concentration (Madsen 1993), the time-invariant, mean reference concentration is obtained as

$$\bar{c}_R = \gamma\ C_b \left(\frac{2}{\pi} \frac{\tau'_{wm}}{\tau_{cr}} - 1 \right) \qquad \text{(III-6-75)}$$

and is applied at $z = z_r = 7D$.

(3) Wave reference concentration. The periodic component of the reference concentration (Madsen 1993), the wave reference concentration, is given by

$$c_{Rw} = \gamma\ C_b \left(\frac{4}{\pi}\ \frac{\tau_c^{/}}{\tau_{cr}}\ \cos\ \varphi_{wc} - \frac{\tau_{wm}^{/}}{\tau_{cr}}\ \frac{\tan\ \beta_w}{\tan\ \varphi_m} \right)\ \cos\ \theta = c_{Rwm}\ \cos\ \theta \tag{III-6-76}$$

at $z = z_r = 7D$. In this expression it is recalled that the wave phase is given by

$$\theta = \omega t + \varphi^{/} \tag{III-6-77}$$

where φ' is the phase angle given by Equation 6-14 for skin friction conditions, i.e., with $u_{*wm} = u_{*m}^{/}$.

d. Concentration distribution of suspended sediment. For a combined wave-current flow, the eddy viscosity or eddy diffusivity is given by

$$\nu_s = \begin{cases} \kappa u_{*m} z & z < \delta_{cw} \\ \kappa u_{*c} z & z > \delta_{cw} \end{cases} \tag{III-6-78}$$

with

$$\delta_{cw} = \frac{\kappa u_{*m}}{\omega} \tag{III-6-79}$$

and the shear velocities being those determined from the wave-current interaction model described in Part III-6-2-c using the equivalent Nikruradse roughness corresponding to the movable bed roughness obtained by the procedures outlined in Part III-6(3)e.

(1) Mean concentration distribution. Using the equation governing the distribution of mean concentration (Madsen 1993), and introducing the eddy diffusivity from Equation 6-78 yields

$$\overline{c} = \overline{c}_R \left(\frac{z}{z_r} \right)^{\left(-\frac{w_f}{\kappa u_{*m}} \right)} \qquad \text{for} \quad z < \delta_{cw} \tag{III-6-80}$$

and

$$\overline{c} = \overline{c}_R \left(\frac{\delta_{cw}}{z_r} \right)^{\left(-\frac{w_f}{\kappa u_{*m}} \right)} \left(\frac{z}{\delta_{cw}} \right)^{\left(-\frac{w_f}{\kappa u_{*c}} \right)} \qquad \text{for} \quad z > \delta_{cw} \tag{III-6-81}$$

where $\overline{c}_R$ is given by Equation 6-75, and the mean concentrations are matched at $z = \delta_{cw}$.

(2) Wave-associated concentration distribution. The wave-generated suspended sediment concentration can be approximated as (Madsen 1993)

$$c_w \approx c_{Rwm}\ \cos(\omega\ t + \varphi^{/}) - c_{Rwm}\ \frac{2}{\pi}\ \sin \varphi_s\ \ln \frac{z}{z_r}\ \cos\ (\omega\ t + \varphi^{/} + \varphi_s) \tag{III-6-82}$$

where

$$\tan \varphi_s = \frac{\frac{\pi}{2}}{\ln \frac{\kappa u_{*m}}{z_r \omega} - 1.15} \tag{III-6-83}$$

This is a highly simplified solution for the wave-associated suspended sediment concentration within the wave boundary layer, i.e., for $z < \delta_{cw}$. For a more accurate representation of the wave-associated concentration profile, reference is made to Wikramanayake and Madsen (1994b).

e. Suspended load transport. The suspended load transport is obtained from the product of the velocity vector, and the concentration of suspended sediment followed by integration over depth is denoted by *h*. Time averaging the instantaneous transport rate produces a net transport rate, which is the quantity of interest. Indicating time-averaging by an overbar, the total net suspended load transport rate is obtained from

$$\overline{\boldsymbol{q}}_{sS,T} = \int_{z_r}^{h} \boldsymbol{u}_c \, \overline{c} \, dz + \int_{z_r}^{h} \overline{\boldsymbol{u}_w \, c_w} \, dz \tag{III-6-84}$$

This equation identifies the contribution to the total net suspended load transport as one associated entirely with *mean suspended load transport*

$$\overline{q}_{sS} = \int_{z_r}^{h} u_c \, \overline{c} \, dz \tag{III-6-85}$$

which takes place in the direction of the current ,i.e., at an angle φ_{wc} to the direction of wave propagation, and *mean wave-associated suspended load transport*

$$\overline{q}_{sSw} = \int_{z_r}^{h} \overline{u_w \, c_w} \, dz \tag{III-6-86}$$

which is in the direction of wave propagation when positive.

(1) Mean suspended load transport. The mean suspended load transport, given by Equation 6-85, must be considered for two specific conditions.

(a) When $z_r > z_0$, the current velocity profile is valid for $z \geq z_r$ and the mean suspended load transport is obtained from

$$\overline{q}_{sS} = \frac{u_{*c}}{\kappa} \, \overline{c}_R \left(\frac{\delta_{cw}}{z_r} \right)^{\left(\frac{-w_f}{\kappa u_{*m}} \right)} \delta_{cw} \, (I_1 + I_2) \quad \text{for} \quad z_r > z_0 \tag{III-6-87}$$

where

$$I_1 = \frac{\kappa u_{*c}}{\kappa u_{*m} - w_f}\left\{\ln\frac{\delta_{cw}}{z_0} - \frac{\kappa u_{*m}}{\kappa u_{*m} - w_f} - \left(\frac{z_r}{\delta_{cw}}\right)^{\frac{\kappa u_{*m} - w_f}{\kappa u_{*m}}}\left(\ln\frac{z_r}{z_0} - \frac{\kappa u_{*m}}{\kappa u_{*m} - w_f}\right)\right\} \tag{III-6-88}$$

represents the contribution from inside the wave boundary layer; and

$$I_2 = \frac{\kappa u_{*c}}{\kappa u_{*c} - w_f}\left\{\left(\frac{h}{\delta_{cw}}\right)^{\frac{\kappa u_{*c} - w_f}{\kappa u_{*c}}}\left(\ln\frac{h}{z_{0a}} - \frac{\kappa u_{*c}}{\kappa u_{*c} - w_f}\right) - \left(\ln\frac{\delta_{cw}}{z_{0a}} - \frac{\kappa u_{*c}}{\kappa u_{*c} - w_f}\right)\right\} \tag{III-6-89}$$

expresses the transport above the wave boundary layer.

(b) When $z_r < z_0$, the current velocity profile is not defined for $z_r < z < z_0$. To remedy this physically unrealistic situation, the current velocity profile given by Equation 6-27 is modified to read

$$u_c = \frac{u_{*c}}{\kappa}\,\frac{u_{*c}}{u_{*m}}\,\frac{\ln\frac{\delta_{cw}}{z_0}}{\ln\frac{\delta_{cw}}{z_r}}\,\ln\frac{z}{z_r} \quad \text{for} \quad z < \delta_{cw} \tag{III-6-90}$$

for the purpose of evaluating the transport within the wave boundary layer. The modification retains the matching condition with the outer solution at $z = \delta_{cw}$ and extends the velocity profile down to $z = z_R$.

(c) Introducing Equation 6-90 in the integration leads to

$$\bar{q}_{sS} = \frac{u_{*c}}{\kappa}\,\bar{c}_R\left(\frac{\delta_{cw}}{z_r}\right)^{-\frac{w_f}{\kappa u_{*m}}}\delta_{cw}\,(I_3 + I_2) \quad \text{for} \quad z_r < z_0 \tag{III-6-91}$$

where

$$I_3 = \frac{\ln\frac{\delta_{cw}}{z_0}}{\ln\frac{\delta_{cw}}{z_r}}\,\frac{\kappa u_{*c}}{\kappa u_{*m} - w_f}\left\{\ln\frac{\delta_{cw}}{z_r} - \frac{\kappa u_{*m}}{\kappa u_{*m} - w_f}\left[1 - \left(\frac{z_r}{\delta_{cw}}\right)^{\frac{\kappa u_{*m} - w_f}{\kappa u_{*m}}}\right]\right\} \tag{III-6-92}$$

and I_2 is given by Equation 6-89.

(2) Mean wave-associated suspended load transport. The mean wave-associated suspended load transport is obtained from Equation 6-86. Since u_w and c_w, given by Equations 6-11 and 6-82, respectively, are approximations valid only for $z < \delta_{cw}/\pi$, the integration is extended only to this upper limit. Similar to the computation of the mean suspended load transport, it is necessary here to distinguish between the two cases of $z_0 < z_r$ and $z_r < z_0$. If $z_r > \delta_{cw}/\pi$, wave-associated transport is considered negligibly small.

EXAMPLE PROBLEM III-6-12

FIND:

The mean suspended load transport rate for a combined wave-current boundary layer flow.

GIVEN:

Wave, current, sediment, and bottom slope as given in Example Problem III-6-9. Water depth h = 5.0 m.

PROCEDURE:

1) Movable bed roughness k_n is determined as described in Example Problem III-6-7.

2) Total shear velocities u_{*c}, u_{*wm}, and u_{*m}, and wave boundary layer thickness δ_{cw} are obtained by solving the wave-current interaction following the procedure of Example Problem III-6-4 with k_n from step 1.

3) Apparent bottom roughness z_{0a} and shear stress phase angle φ are obtained as described in Example Problem III-6-5.

4) Skin friction shear velocities u'_{*c}, u'_{*wm}, and u'_{*m}, and phase angle φ′ are obtained as in Example Problem III-6-8.

5) Example Problem III-6-10 is followed to obtain the fall velocity w_f.

6) Mean reference concentration $\overline{c}_R$ is obtained as in Example Problem III-6-11.

7) If $z_r = 7D > z_0 = k_n/30$, the mean suspended sediment transport $\overline{q}_{sS}$ is obtained from Equations 6-87 through 6-89.

8) If $z_r = 7D < z_0 = k_n/30$, the mean suspended sediment transport $\overline{q}_{sS}$ is obtained from Equations 6-91, III-6-92, and 6-89.

9) The mean suspended sediment transport obtained in step 7 or step 8 is in the direction of the current, which in turn is at an angle of φ_{wc} to the direction of wave propagation. In a coordinate system with x in the direction of wave propagation, the mean suspended sediment transport vector is $\overline{\boldsymbol{q}}_{\boldsymbol{sS}} = \overline{q}_{sS}\{\cos\varphi_{wc}, \sin\varphi_{wc}\}$.

(Continued)

Example Problem III-6-12 (Concluded)

SOLUTION:

Since quantities needed for the computation of suspended load transport have been obtained in previous example problems, these are summarized here.

Reference concentration (Example Problem III-6-11): $\bar{c}_R = 1.44\times10^{-3}$ at $z_r = 0.14$

Fall velocity (Example Problem III-6-10): $w_f = 2.23$ cm/s

Shear velocities and *wave boundary layer thickness* based on total movable bed roughness (Example Problem III-6-4): $u_{*c} = 2.94$ cm/s, $u_{*m} = 6.67$ cm/s, and $\delta_{cw} = 3.40$ cm

The *movable bed roughness* and the *apparent bottom roughness* (Example Problems III-6-7 and III-6-5): $z_0 = k_n/30 = 0.15$ cm and $z_{0a} = 0.85$ cm

From the input values summarized above it is seen that $z_r = 0.14$ cm $\approx z_0 = 0.15$ cm. One could therefore choose either Equation 6-87 or Equation 6-91 to obtain the mean suspended load transport. Since $z_r < z_0$, Equation 6-91 is chosen here.

The leading term in Equation 6-91 is computed first

$$\frac{u_{*c}}{\kappa}\,\bar{c}_R\left(\frac{\delta_{cw}}{z_r}\right)^{-\frac{w_f}{\kappa u_{*m}}}\delta_{cw} = 2.5\times10^{-3}\ \text{cm}^3/(\text{cm s})$$

The integral I_3 is evaluated from Equation 6-92

$$I_3 = \frac{3.12}{3.19}\times 2.68\{3.19 - 6.08[1 - 0.59]\} = 1.83$$

and I_2 is obtained from Equation 6-89

$$I_2 = -1.12[0.012(6.38 + 1.12) - (1.39 + 1.12)] = 2.71$$

The mean suspended load transport is therefore obtained from Equation 6-91 as

$$\bar{q}_{sS} = 2.5\times10^{-3}(I_3 + I_2) = 1.1\times10^{-2}\ \text{cm}^3/(\text{cm s})$$

and is in the direction of the current, i.e., at an angle $\varphi_{wc} = 45$ deg to the direction of wave propagation.

(a) For $z_0 < z_r < \delta_{cw}/\pi$, Equations 6-11 and 6-82 may be introduced directly into Equation 6-86 to give

$$\bar{q}_{sSw} = \frac{1}{\pi^2} \sin\varphi \; u_{bm} \, c_{Rwm} \, \delta_{cw} \times \left(\cos(\varphi - \varphi') I_4 - \frac{2}{\pi} \sin\varphi_s \cos(\varphi - \varphi' - \varphi_s) I_5 \right) \quad \text{for} \quad z_0 < z_r \tag{III-6-93}$$

in which

$$I_4 = \ln \frac{\delta_{cw}}{\pi z_0} - 1 - \frac{\pi z_r}{\delta_{cw}} \left(\ln \frac{z_r}{z_0} - 1 \right) \tag{III-6-94}$$

and

$$I_5 = \ln \frac{z_r}{z_0} \left(\ln \frac{\delta_{cw}}{\pi z_r} - 1 + \frac{\pi z_r}{\delta_{cw}} \right) + \left(\ln \frac{\delta_{cw}}{\pi z_r} \right)^2 - 2 \ln \frac{\delta_{cw}}{\pi z_r} + 2 \left(1 - \frac{\pi z_r}{\delta_{cw}} \right) \tag{III-6-95}$$

(b) For $z_r < z_0$ the same modification of the logarithmic velocity profile introduced in the context of mean suspended load transport yields, for $z_r < z_0$

$$\bar{q}_{sSw} = \frac{1}{\pi^2} \sin\varphi \; u_{bm} \; c_{Rwm} \; \delta_{cw} \frac{\ln \frac{\delta_{cw}}{\pi z_0}}{\ln \frac{\delta_{cw}}{\pi z_r}} \times \left(\cos(\varphi - \varphi') I_6 - \frac{2}{\pi} \sin\varphi_s \cos(\varphi - \varphi' - \varphi_s) I_7 \right) \tag{III-6-96}$$

where

$$I_6 = \ln \frac{\delta_{cw}}{\pi z_r} - 1 + \frac{\pi z_r}{\delta_{cw}} \tag{III-6-97}$$

and

$$I_7 = \left(\ln \frac{\delta_{cw}}{\pi z_r} \right)^2 - 2 \ln \frac{\delta_{cw}}{\pi z_r} + 2 \left(1 - \frac{\pi z_r}{\delta_{cw}} \right) \tag{III-6-98}$$

EXAMPLE PROBLEM III-6-13

FIND:

The mean wave-associated suspended load transport rate for a combined wave-current boundary layer flow.

GIVEN:

Same problem specifications as in Example Problem III-6-12.

PROCEDURE:

1) First steps are identical to steps 1 and 2 in Example Problem III-6-12.

2) If $z_r = 7D > \delta_{cw}/\pi$, wave-associated suspended sediment transport is negligibly small.

3) If $z_r = 7D < \delta_{cw}/\pi$, steps 3 through 5 of Example Problem III-6-12 are followed.

4) The wave-associated reference concentration c_{Rw} is obtained as in Example Problem III-6-11.

5) The sediment suspension phase angle φ_s is obtained from Equation 6-83 with $z_r = 7D$.

6) If $z_r = 7D > z_0 = k_n/30$, the mean wave-associated suspended sediment transport $\overline{q}_{sSw}$ is obtained from Equations 6-93 through 6-95.

7) If $z_r = 7D < z_0 = k_n/30$, the mean wave-associated suspended sediment transport $\overline{q}_{sSw}$ is obtained from Equations 6-96 through 6-98.

8) The suspended sediment transport obtained in step 6 or step 7 is in the direction of wave propagation, i.e., $\text{uu}\,\overline{\boldsymbol{q}}_{sSw} = \overline{q}_{sSw}\{1,\ 0\}$ with x in the direction of wave propagation.

(Continued)

Example Problem III-6-13 (Concluded)

SOLUTION:

In addition to the quantities given in Example Problem III-6-12, the computation of the mean wave-associated suspended load transport requires knowledge of *phase angles*

$$\varphi = 38° \quad \text{and} \quad \varphi' = 14°$$

obtained from Example Problems III-6-5 and 8. The sediment suspension phase angle φ_s is obtained from Equation 6-83 with $z_r = 7D = 0.14$ cm

$$\tan \varphi_s = 0.77 \rightarrow \varphi_s = 37.6° \approx 38°$$

and the *maximum wave-associated reference concentration* (Example Problem III-6-11) is

$$c_{Rwm} = 0.65 \times 10^{-3}$$

Since $z_r = 0.14$ cm $< z_0 = 0.15$ cm, the wave-associated mean transport is obtained from Equation 6-96.

The leading term of this equation becomes

$$\frac{1}{\pi^2} \sin \varphi \quad u_{bm} \; c_{Rwm} \; \delta_{cw} \; \frac{\ln \dfrac{\delta_{cw}}{\pi z_0}}{\ln \dfrac{\delta_{cw}}{\pi z_r}} = 5.0 \times 10^{-3} \text{ cm}^3/(\text{cm s})$$

and the integral I_6 is obtained from Equation 6-97

$$I_6 = 2.05 - 1 + 0.13 = 1.18$$

and I_7 is given by Equation 6-98

$$I_7 = 4.18 - 4.09 + 2(1 - 0.13) = 1.83$$

Introducing these quantities in Equation 6-96, the *mean wave-associated suspended load transport* is obtained as

$$\bar{q}_{sSw} = 5.0 \times 10^{-3} \left(1.18 \cos (38° - 14°) - 1.83 \frac{2}{\pi} \sin 38° \cos (38° - 14° - 38°) \right) = 1.9 \times 10^{-3} \text{ cm}^3/(\text{cm s})$$

The direction of this transport is in the direction of wave propagation.

(3) Computation of total suspended load transport for combined wave-current flows.

(a) With the wave and current components of the skin friction bottom shear stress including the phase angle φ' obtained following the procedures given in Part III-6-3-*c*, the mean $\bar{c}_R$ and wave-associated c_{Rwm} reference concentrations are obtained from Equations 6-75 and 6-76, respectively, and the phase angle for the wave-associated concentration φ_s is obtained from Equation 6-83.

(b) From the hydrodynamic wave-current interaction model corresponding to movable bed roughness, u_{*c}, u_{*wm}, u_{*m}, and φ are known and w_f is obtained from Part III-6-5-*a*. Thus, with δ_{cw} given by Equation 6-79, all quantities necessary to evaluate Equations 6-87 and 6-93, for $z_0 < z_r = 7D$, or Equations 6-91 and 6-96, for $z_r = 7D < z_0$, are available.

f. Extensions of methodology for the computation of suspended load.

(1) Extension to spectral waves. For a wave motion described by its near-bottom orbital velocity spectrum, the representative periodic wave characteristics discussed in Part III-6-2-b (4) are used. Once again it is emphasized that this representative wave corresponds to the use of the rms wave height and *not* the significant wave height.

(2) Extension to sediment mixtures. For a sediment mixture, the suspended load transport may be calculated as described above for a single grain size of diameter D.

(a) The skin friction $\tau_b'(t)$ and movable bed roughness k_n are computed using the median grain size $D = D_{50}$.

(b) For each grain size class of diameter D_n, the reference concentration is obtained from the formulas given in Part III-6(5)*c* with τ_{cr}, the critical shear stress, replaced by $\tau_{cr,n}$, the critical shear stress for the nth size class, and C_b, the sediment concentration in the bed, being replaced by $f_n C_b$ where f_n, is the volume fraction in the bed of sediment of diameter D_n. This reference concentration is assumed to be specified at $z = z_r = 7D_{50}$ for all size classes.

(c) For each size class, the suspended load transport is now computed as detailed in Part III-6(5)e using the fall velocity $w_{f,n}$ appropriate for the nth size class.

(d) When suspended load transport has been obtained for each size class, the total suspended load transport for the sediment mixture is obtained by adding the contribution of individual size classes.

III-6-6. Summary of Computational Procedures

a. Problem specification. A properly posed problem requires the following specifications:

(1) *The waves* are specified by near-bottom orbital velocity u_{bm}, radian frequency ω ($A_{bm} = u_{bm}/\omega$), and their angle of incidence α ($|\alpha| < \pi/2$) if waves are traveling towards shallower water). For spectral waves, a representative periodic wave is defined in Part III-6(2)c(5). If the significant wave characteristics H_s and T_s are given, the equivalent periodic wave has a height $H_{rms} = h_s/\sqrt{2}$ and period $T = T_s$.

(2) *The current* is specified by a reference current $u_c(z_r)$ at $z = z_r$ above the bottom and its direction φ_{wc} measured counterclockwise from the direction of wave propagation; or by the average bottom shear stress τ_c and its direction φ_{wc}.

(3) *The fluid* is specified by its density, $\rho \approx 1{,}025$ km/m^3 for seawater, and kinematic viscosity, $\nu \approx 10^{-6}$ m^2/s for seawater.

(4) *The sediment* is specified by its diameter D and density ρ_s ($s = \rho_s/\rho$). The sediment must be characterized as cohesionless.

(5) *The bottom slope* is specified normal to depth contours by $\tan\beta$ ($\beta > 0$). The slope in direction of wave propagation is then $\tan\beta_w = \tan\beta\cos\alpha > 0$ if bottom is sloping upwards in wave direction ($|\alpha| < \pi/2$).

b. Model parameters.

(1) A number of model parameters and constants have been introduced and must be specified to proceed towards a solution

κ = von Karman's constant = 0.4

φ_s = static friction angle of sediment = 50°

φ_m = moving friction angle of sediment = 30°

C_b = volume concentration of sediment in the bed = 0.65

γ = resuspension parameter = 2×10^{-3} for rippled beds, 2×10^{-4} for flat beds (sheet flow)

(2) Figure III-6-12 specifies coordinate, angle, and bottom slope definitions used in this chapter.

c. Computational procedures. The following steps should be followed to obtain the total sediment transport rate at a point:

(1) Movable bottom roughness is determined from the wave and sediment characteristics. The maximum wave skin friction shear stress τ'_{wm} is obtained following the procedures described in Part III-6(2)*c* using $k_n = k_n' = D$. Sediment motion is checked using the modified Shields diagram, Part III-6(3)*c*. If sediment *is not* moving, $k_n = D$ *is* the movable bed roughness. If sediment is found to move, the movable bed roughness k_n is obtained following the procedures outlined in Part III-6(3)*e* using $\tau'_{wm} = \tau'_m$.

(2) With the movable bed roughness k_n known, the wave-current interaction model (Part III-6(2)*d*) is used to obtain total bottom shear stresses, shear velocities, and phase angles so that wave orbital and current velocity profiles may be evaluated.

(3) Using the current at the edge of the wave boundary layer obtained from the movable bed roughness model as the current specification, the wave-current interaction model (Part III-6(2)*d*) is used with $k_n' = D$ to obtain the combined wave-current skin friction shear stress $\tau'_b(t)$.

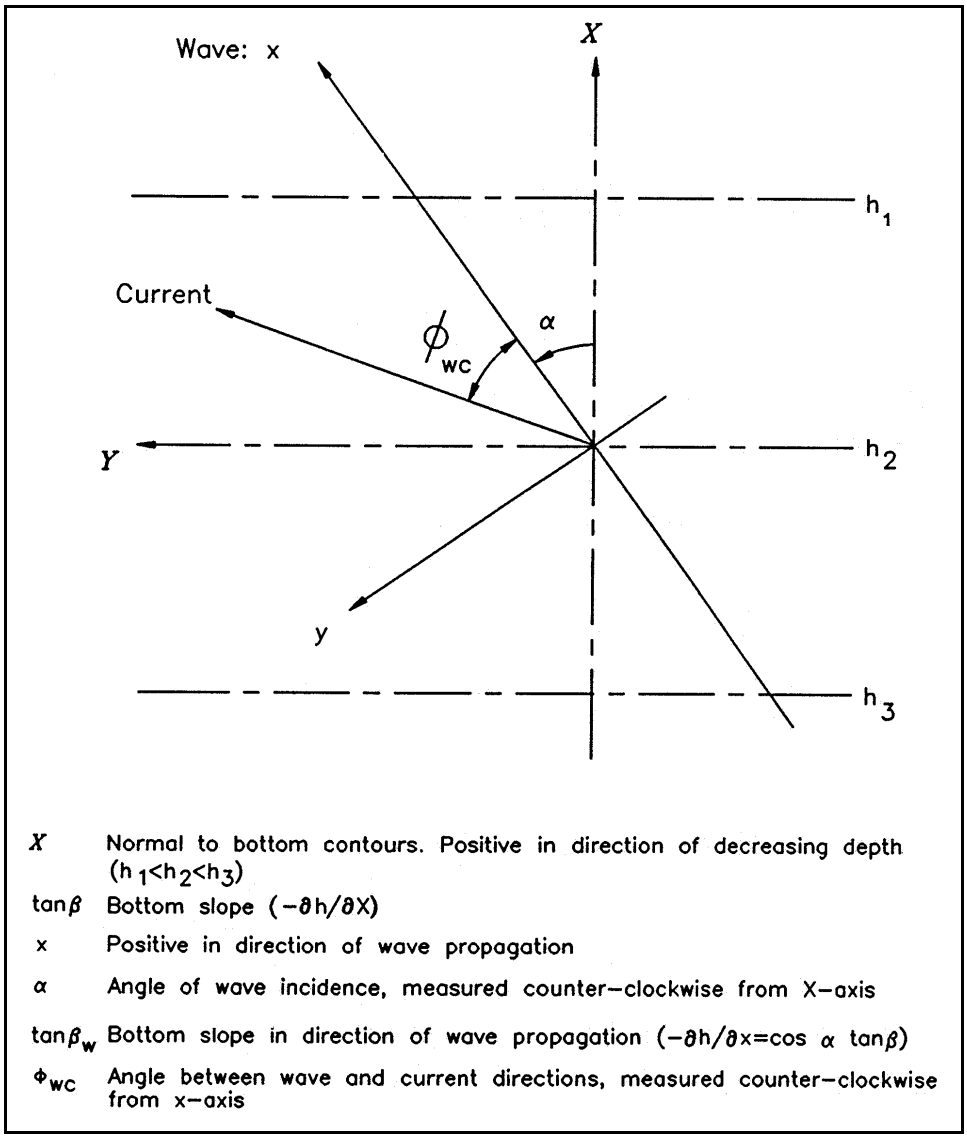

Figure III-6-12. Definition sketch of coordinates, angles, and bottom slope

(4) Bed-load transport can now be computed following the methodology presented in Part III-6(4).

(5) The reference concentration for suspended sediment is next obtained from Part III-6(5)*c*, and the total suspended load transport is obtained by vector addition of the mean and the mean wave-associated contributions that are obtained from Part III-6(5)*e*. The former is in the direction of the current, whereas the latter is in the wave direction.

(6) Adding bed-load and suspended load transport provides a prediction of the total sediment transport rate, expressed as a vector.

EXAMPLE PROBLEM III-6-14

FIND:

The total sediment transport vector for a combined wave-current boundary layer flow.

GIVEN:

All problem specifications are identical to those given in Example Problems III-6-9, 12, and 13.

PROCEDURE:

1) Bed-load sediment transport vector is computed following Example Problem III-6-9.

2) Mean suspended sediment transport vector is obtained following the procedure of Example Problem III-6-12.

3) Mean wave-associated suspended sediment transport vector is obtained from Example Problem III-6-13.

4) Total sediment transport vector is obtained as the vector sum of steps 1, 2, and 3.

SOLUTION:

With x being in the direction of wave propagation and y perpendicular to x, the total sediment transport in the x direction is obtained from Example Problems III-6-9, 12, and 13.

x-component of bed load = 9.0×10^{-3} cm^3/(cm s)
x-component of mean suspended load = $1.1\times10^{-2} \cos \varphi_{wc} = 7.8\times10^{-3}$ cm^3/(cm s)
x-component of mean wave-associated transport = 1.9×10^{-3} cm^3/(cm s)
Total transport in wave direction = $\overline{q}_{sT,x} = 1.9\times10^{-2}$ cm^3/(cm s)

y-component of bed load = 6.5×10^{-3} cm^3/(cm s)
y-component of mean suspended load = $1.1\times10^{-2} \sin \varphi_{wc} = 7.8\times10^{-3}$ cm^3/(cm s)
y-component of mean wave-associated transport = 0 cm^3/(cm s)
Total transport perpendicular to wave direction = $\overline{q}_{sT,y} = 1.4\times10^{-2}$ cm^3/(cm s)

Thus, the magnitude of the total sediment transport vector is

$$|\overline{\boldsymbol{q}}_{sT}| = \sqrt{\overline{q}_{sT,x}^2 + \overline{q}_{sT,y}^2} = 2.4\times10^{-2} \text{ cm}^3/(\text{cm s})$$

directed at an angle $\varphi_{wT} \approx 37°$ to the wave direction.

III-6-8. Definition of Symbols

β	Bottom slope [deg]
β_w	Bottom slope in the direction of wave propagation [deg]
γ	Resuspension parameter [dimensionless]
δ_{cw}	Boundary layer thickness for a combined wave-current turbulent boundary layer [length]
δ_w	Boundary layer thickness [length]
η	Ripple height [length]
κ	von Karman's constant (= 0.4)
λ	Ripple length [length]
μ	Ratio of Shear stress due to currents (τ_c) to Maximum bottom shear stress (τ_{wm})
μ_b	Bottom slope parameter
ν	Kinematic viscosity [length^2/time]
ν_s	Sediment diffusion coefficient
ν_T	Turbulent eddy viscosity [length^2/time]
ρ	Mass density of water (salt water = 1,025 kg/m^3 or 2.0 slugs/ft^3; fresh water = 1,000kg/m^3 or 1.94 slugs/ft^3) [force-time^2/length^4]
ρ_s	Mass density of sediment grains [force-time^2/length^4]
τ_b	Bottom shear stress [force/length^2]
τ_c	Shear stress due to currents [force/length^2]
τ_{cr}	Critical bottom shear stress for initiation of motion [force/length^2]
τ_m	Maximum combined bottom shear stress [force/length^2]
τ_w	Bottom shear stress [force/length^2]
τ_{wm}	Maximum bottom shear stress [force/length^2]
τ'_b	Bottom skin friction shear stress [force/length^2]
τ'_{wm}	Skin friction bottom shear stress for wave motion [force/length^2]
τ''_b	Bottom drag shear stress [force/length^2]
φ	Phase lead of near-bottom wave orbital velocity (bottom shear stress phase angle) [deg]
φ_m	Friction angle [deg]
φ_s	Friction angle for a stationary interfacial sediment grain [deg]

Ψ	Shields parameter (Equation III-6-43) [dimensionless]
Ψ_{cr}	Critical Shields parameter (Equation III-6-45) [dimensionless]
$\Psi_{cr,\beta}$	Critical Shields parameter for flow over a sloping bottom (Equation III-6-51) [dimensionless]
Ψ'_C	Shields parameter based on the current skin friction shear stress [dimensionless]
Ψ'_m	Skin friction Shields parameter [dimensionless]
ω	Wave angular or radian frequency (= $2\pi/T$) [time^{-1}]
A_{bm}	Bottom excursion amplitude predicted by linear wave theory [length]
c	Volume concentration of sediment in suspension [length^3/length^3]
$\overline{c}$	Mean volume concentration of sediment in suspension [length^3/length^3]
$\overline{c}_R$	Mean reference concentration [length^3/length^3]
C_μ	Factor relating maximum wave and maximum combined bottom shear stresses (equation III-6-33)
C_b	Volume concentration of sediment in the bed
c_R	Reference concentration [length^3/length^3]
c_{Rwm}	Wave-associated maximum reference concentration [length^3/length^3]
c_w	Wave-associated volume concentration of sediment in suspension [length^3/length^3]
D	Sediment grain diameter [length - generally millimeters]
D_p	Time-averaged rate of energy dissipation in the wave bottom boundary layer (Equation III-6-25)
f_c	Current friction factor [dimensionless]
f_{cw}	Wave friction factor in the presence of currents [dimensionless]
f_w	Wave friction factor [dimensionless]
f'_w	Wave friction factor [dimensionless]
g	Gravitational acceleration (32.17 ft/sec^2, 9.807m/sec^2) [length/time^2]
h	Water depth [length]
H_{rms}	Root-mean-square wave height [length]
H_s	Significant wave height [length]
k_n	Equivalent Nikuradse sand grain roughness [length]
k_n	Movable bed roughness [length]
q	Sediment transport rate [length^3/time]

$\overline{q_{sB}}$	Total bed-load transport of a sediment mixture [length^3/length-time]
RE	Wave Reynolds number [dimensionless]
Re_*	Boundary Reynolds number [dimensionless]
S_*	Sediment-fluid parameter (Equation III-6-47) [dimensionless]
T	Significant wave period [time]
T_s	Significant wave period [time]
u	Horizontal particle velocity [length/time]
u_*	Shear velocity [length/time]
u_{*c}	Current shear velocity [length/time]
u_{*cr}	Critical shear velocity [length/time]
u_{*m}	Maximum combined shear velocity [length/time]
u_{*wm}	Maximum wave shear velocity [length/time]
u_{bm}	Maximum near-bottom wave orbital velocity [length/time]
u_w	Wave orbital velocity [length/time]
w_f	Sediment fall velocity [length/time]
W_{grain}	Submerged weight of individual sediment grains
z	Elevation from bottom [length]
Z	Parameter providing a correlation of field data on ripple geometry [dimensionless]
z_{0a}	Arbitrary constant of integration (apparent bottom roughness)

Chapter IV-1
Coastal Terminology and Geologic Environments

IV-1-1. Background

a. Since man has ventured to the sea, he has been fascinated by the endless variety of landforms and biological habitats that occur at the coast. With the exception of high altitude alpine, a full spectrum of environments is found around the world's coastlines. These range from icy arctic shores to rocky faulted coasts to temperate sandy barriers to tropical mangrove thickets, with a myriad of intermediate and mixed forms. This part of the *Coastal Engineering Manual* (CEM) concentrates on the geology of the coastal zone. This broad subject encompasses both the geomorphology (the shape and form) of the landforms and the nature of the ancient strata that underlie or outcrop in the region. The forces that shape, and are shaped by, the coast are part of the overall picture, although here geology merges with the other earth sciences of meteorology and oceanography.

b. This and the two chapters that follow have ambitious goals:

(1) To review overall geological, environmental, and climatological settings of the world's coasts.

(2) To describe particular shore types in detail and provide examples.

(3) To explain how shore types are created by and interact with the forces of waves, currents, and weather (sometimes known as “morphodynamics”).

The emphasis here is on features and landforms that range in size from centimeters to kilometers and are formed or modified over time scales of minutes to millennia (Figure IV-1-1).

c. Another subject of crucial importance to coastal researchers is biology. The biological environment is partly established by the geological setting. Conversely, biology affects coastal geology in many ways:

(1) Coral reefs and mangroves have created large stretches of coastline.

(2) Cliff erosion is accelerated by the chemical solution and mechanical abrasion caused by some organisms.

(3) Lagoons and estuaries slowly fill with the by-products of plants and the sediment they trap, forming wetlands.

These topics are briefly reviewed in this text, but details of the flora and fauna that inhabit the coast are not covered here.

d. Field methods and data analysis procedures applicable to geological field studies at the coast are not reviewed in this part of the CEM. Field methods are constantly evolving and changing as new instruments and technology are developed. Coastal monitoring methods were reviewed in Gorman, Morang, and Larson (1998); Larson, Morang, and Gorman (1997); and Morang, Larson, and Gorman (1997a,b). Readers who plan to conduct field studies should contact surveyors or contractors familiar with the latest technology and should review trade journals that discuss oceanographic, geographic information systems (GIS), remote sensing, and surveying advances.

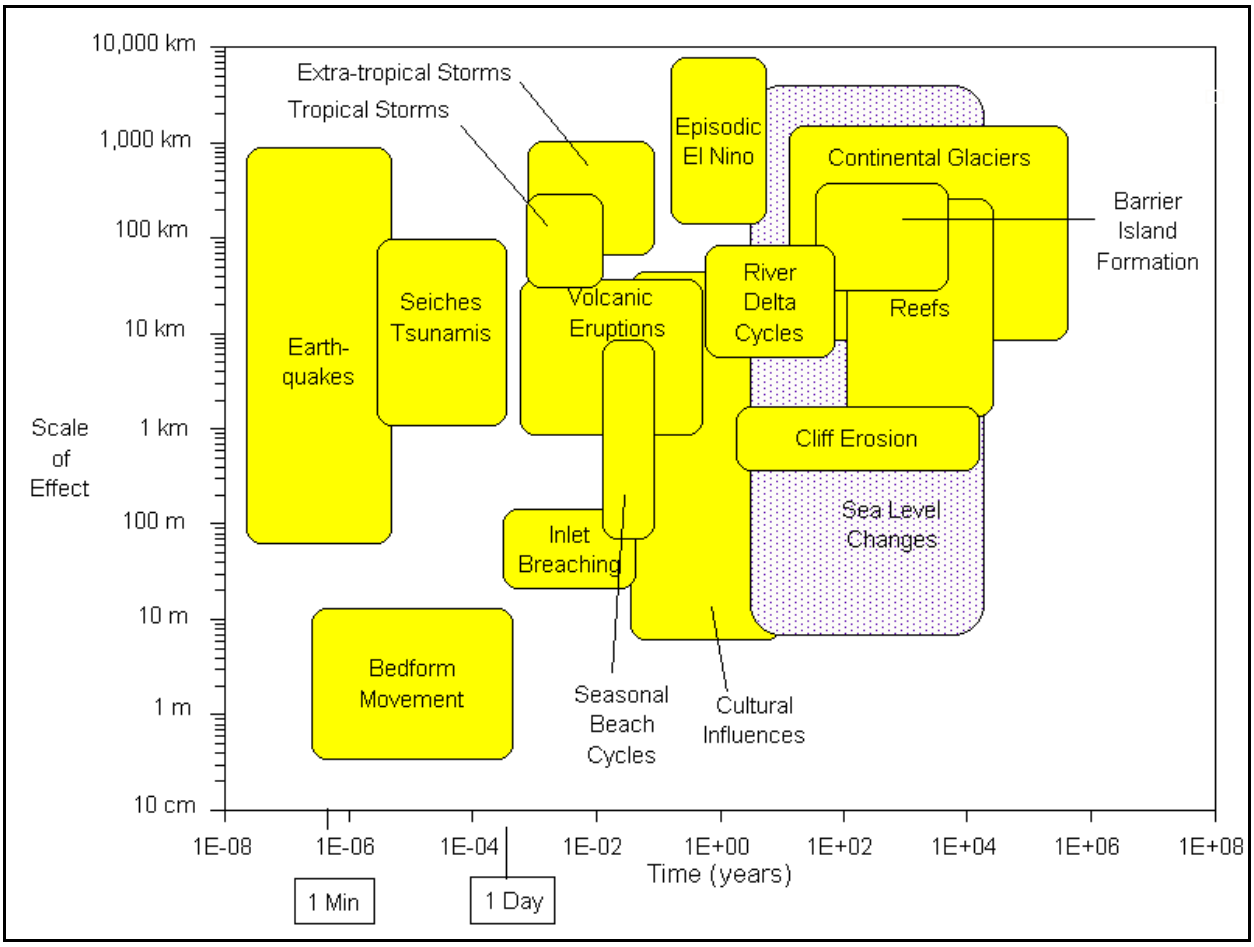

Figure IV-1-1. Temporal and spatial scales of geologic and oceanographic phenomena

IV-1-2. Coastal Zone Definitions and Subdivisions

a. Introduction.

(1) Many coastal zone features and subdivisions are difficult to define because temporal variability or gradational changes between features obscure precise boundaries. In addition, nomenclature is not standardized, and various authors describe the same features using different names. If the same name is used, the intended boundaries may differ greatly. This ambiguity is especially evident in the terminology and zonation of shore and littoral areas. In the absence of a widely accepted standard nomenclature, coastal researchers would do well to accompany reports and publications with diagrams and definitions to ensure that readers will fully understand the authors' use of terms.

(2) The following subparagraphs present coastal zone definitions and subdivisions based largely, but not exclusively, on geological criteria. They do not necessarily coincide with other geological-based zonations or those established by other disciplines. It should be borne in mind that coastal zone geology varies greatly from place to place, and the zonations discussed below do not fit all regions of the world. For example, coral atolls are without a coast, shoreface, or continental shelf in the sense defined here. The Great Lakes and other inland water bodies have coasts and shorefaces but no continental shelves. Thus, while divisions and categories are helpful in describing coastal geology, flexibility and good descriptive text and illustrations are always necessary for adequate description of a given region or study site.

b. Coastal zone. In this manual, *coastal zone* is defined as the transition zone where the land meets water, the region that is directly influenced by marine or lacustrine hydrodynamic processes. The coastal zone extends offshore to the continental shelf break and onshore to the first major change in topography above the reach of major storm waves. Although this discussion excludes upland rivers, river mouth deltas, where morphology and structure are a result of the dynamic interplay of marine and riverine forces, are included. The coastal zone is divided into four subzones (Figures IV-1-2 and IV-1-3):

(1) Coast.

(2) Shore.

(3) Shoreface.

(4) Continental shelf.

c. Coast. The *coast* is a strip of land of indefinite width that extends from the coastline inland as far as the first major change in topography. Cliffs, frontal dunes, or a line of permanent vegetation usually mark this inland boundary. On barrier coasts, the distinctive back-barrier lagoon/marsh/tidal creek complex is considered part of the coast. It is difficult to define the landward limit of the coast on large deltas like the Mississippi, but the area experiencing regular tidal exchange can serve as a practical limit (in this context, New Orleans would be considered "coastal"). The seaward boundary of the coast, the *coastline*, is the maximum reach of storm waves. On shorelines with plunging cliffs, the coast and coastline are one and the same. It is difficult to decide if a seawall constitutes a coast; the inland limit might better be defined at a natural topographic change.

d. Shore. The *shore* extends from the low-water line to the normal landward limit of storm wave effects, i.e., the coastline. Where beaches occur, the shore can be divided into two zones: *backshore* (or berm) and *foreshore* (or beach face). The foreshore extends from the low-water line to the limit of wave uprush at high tide. The backshore is horizontal while the foreshore slopes seaward. This distinctive change in slope, which marks the juncture of the foreshore and backshore, is called the beach or berm crest.

e. Shoreface. The *shoreface* is the seaward-dipping zone that extends from the low-water line offshore to a gradual change to a flatter slope denoting the beginning of the continental shelf. The continental shelf transition is the *toe of the shoreface*. Its location can only be approximately marked due to the gradual slope change. Although the shoreface is a common feature, it is not found in all coastal zones, especially along low-energy coasts or those consisting of consolidated material. The shoreface can be delineated from shore-perpendicular profile surveys or from bathymetric charts (if they contain sufficient soundings in shallow water). The shoreface, especially the upper part, is the zone of most frequent and vigorous sediment transport.

f. Continental shelf. The *continental shelf* is the shallow seafloor that borders most continents (Figure IV-1-3). The shelf floor extends from the toe of the shoreface to the shelf break where the steeply inclined continental slope begins. It has been common practice to subdivide the shelf into inner-, mid-, and outer zones, although there are no regularly occurring geomorphic features on most shelves that suggest a basis for these subdivisions. Although the term *inner shelf* has been widely used, it is seldom qualified beyond arbitrary depth or distance boundaries. Site-specific shelf zonation can be based on project

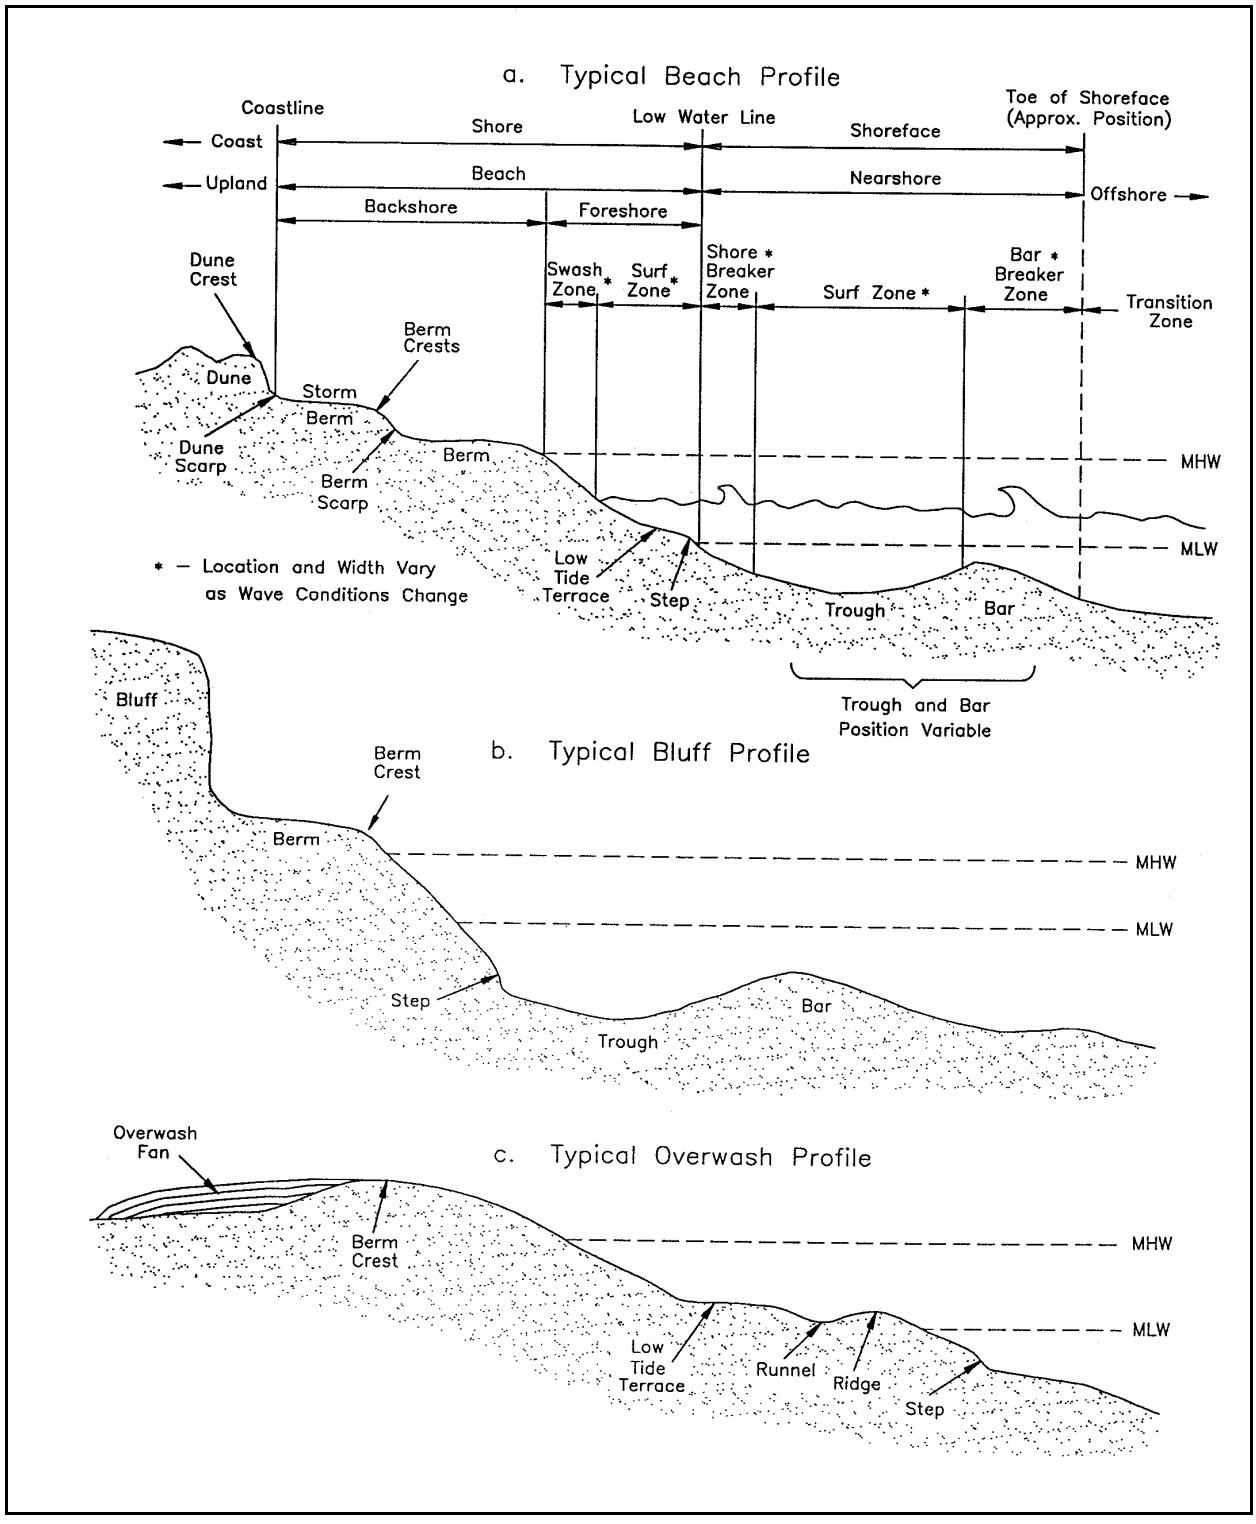

Figure IV-1-2. Definition of terms and features describing the coastal zone

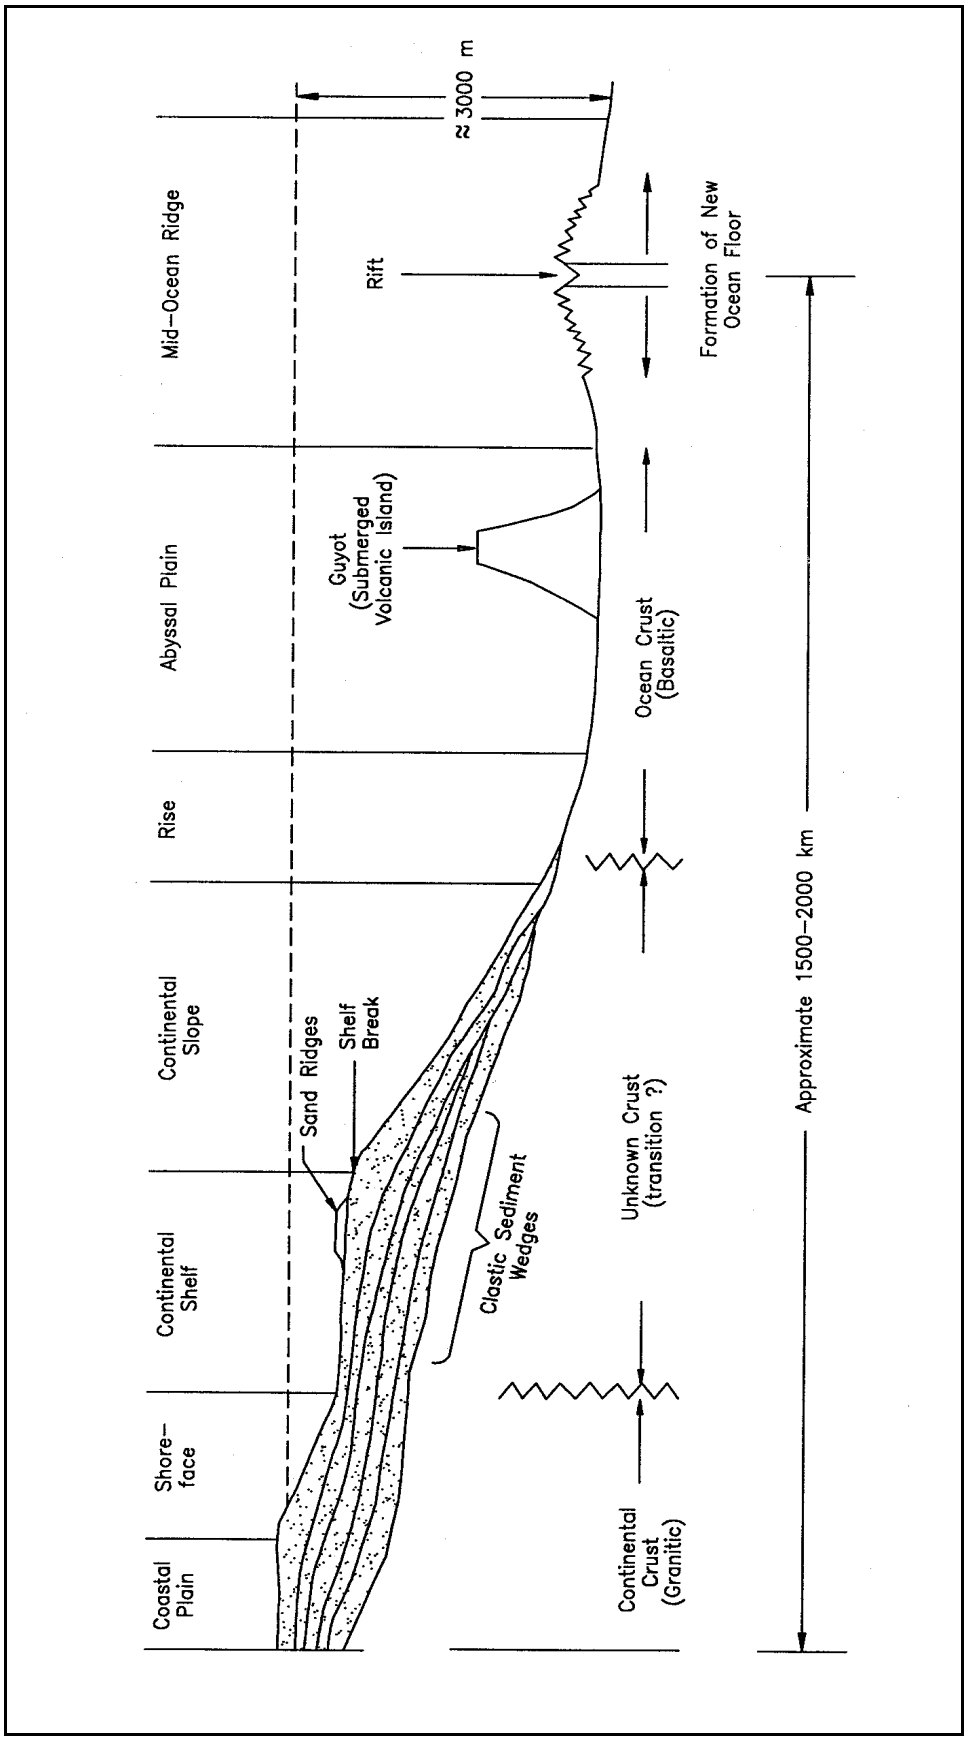

Figure IV-1-3. Continental shelf and ocean floor along the trailing-edge of a continent (i.e., representative of the U.S. Atlantic Ocean coast). Figure not to scale, great vertical exaggeration)

requirements and local geologic conditions. Some coastal areas (e.g., bays and the Great Lakes) do not extend out to a continental shelf.

g. Shoreline definitions. Common coastal geomorphic features are defined in Table IV-1-1 below. These have been adapted from the *National Shoreline Data Standard,* a draft standard prepared by the National Oceanic and Atmospheric Administration (NOAA).

Table IV-1-1
Definitions of Common Coastal Geomorphic Features

Apparent shoreline Line drawn on a map or chart in lieu of a mean high-water line or the mean water level line in areas where either may be obscured by marsh, mangrove, cypress, or other type of marine vegetation. This line represents the intersection of the appropriate datum on the outer limits of vegetation and appears to the navigator as the shoreline (Ellis 1978).

Backshore That part of the beach that is usually dry, being reached only by the highest tides, and by extension, a narrow strip of relatively flat coast bordering the sea (Ellis 1978).

Bank Edge of a cut or fill; the margin of the watercourse; an elevation of the seafloor located on a continental shelf or an island shelf and over which the depth of water is relatively shallow but sufficient for safe surface navigation (reefs or shoals, dangerous to surface navigation may arise above the general depths of a bank) (Ellis 1978).

Beach (or seabeach) Zone of unconsolidated material that extends landward from the low-water line to the place where there are marked changes in material or physiographic form, or to the line of permanent vegetation (usually the effective limit of storm waves). A beach includes foreshore and backshore (Ellis 1978).

Beach berm Nearly horizontal portion of the beach or backshore formed by the deposit of materials by wave action. Some beaches have no berms, others have one or several (Ellis 1978).

Berm Nearly horizontal portion of a beach or backshore having an abrupt fall and formed by wave deposition of material and marking the limit of ordinary high tides (Ellis 1978).

Berm crest Seaward limit of a berm (Ellis 1978).

Bluff A cliff or headland with an almost perpendicular face (International Hydrographic Bureau 1990).

Bottom lands Land below navigable freshwater bodies (Coastal States Organization 1997).

Cliff Land rising abruptly for a considerable distance above the water or surrounding land (Hydrographic Dictionary 1990).

Coast General region of indefinite width that extends from the sea inland to the first major change in terrain features (Ellis 1978).

Coastal zone (legal definition for coastal zone management) The term coastal zone means the coastal waters (including the lands therein and thereunder) and the adjacent shorelands (including the waters therein and thereunder), strongly influenced by each and in proximity to the shorelines of the several coastal states, and includes islands, transitional and inter-tidal areas, salt marshes, wetlands, and beaches. The zone extends, in Great Lakes waters, to the international boundary between the Unites States and Canada and in other areas seaward to the outer limit of the United States territorial sea. The zone extends inland from the shorelines only to the extent necessary to control shorelands, the uses of which have a direct and significant impact on the coastal waters. Excluded from the coastal zone are lands the use of which is by law subject solely to the discretion of or which is held in trust by the Federal Government, its officers, or agents (Hicks 1984).

Coast line (According to Public Law 31) Defined as the line of ordinary low water along that portion of the coast that is in direct contact with the open sea and the line marking the seaward limit of inland waters (Shalowitz 1964).

Coastline Same as shoreline (see coast line) (Hicks 1984).

Dry sand beach Sandy area between the mean high tide line and the vegetation line (Coastal States Organization 1997).

Estuary An embayment of the coast in which fresh river water entering at its head mixes with the relatively saline ocean water. When tidal action is the dominant mixing agent it is usually termed a tidal estuary. Also, the lower reaches and mouth of a river emptying directly into the sea where tidal mixing takes place. The latter is sometimes called a river estuary (Hicks 1984).

Foreshore That part of shore which lies between high and low water mark at ordinary tide (International Hydrographic Bureau 1990).

Freshwaters Waters that do not ebb and flow with the tide. The determinative factor is that the water body does not ebb and flow with the tide, not the salt content of the water (Coastal States Organization 1997).

High-water line A generalized term associated with the tidal plane of high water but not with a specific phase of high water (for example, higher high water, lower high water) (Shalowitz 1964).

High-water mark A line or mark left upon tide flats, beach, or alongshore objects indicating the elevation of the intrusion of high water. The mark may be a line of oil or scum along shore objects, or a more or less continuous deposit of fine shell or debris on the foreshore or berm. This mark is physical evidence of the general height reached by wave runup at recent high waters. It should not be confused with the mean high water line or mean higher high water line (Hicks 1984).

Inshore In beach terminology, the zone of variable width between the shoreface and the seaward limit of the breaker zone (Ellis 1978).

Intertidal zone (technical definition) The zone between the mean higher high water and mean lower low water lines (Hicks 1984).

Island A piece of land completely surrounded by water (International Hydrographic Bureau 1990).

Ledge A shelf -like projection, on the side of a rock or mountain. A rocky formation continuous with and fringing the shore (International Hydrographic Bureau 1990).

Levee Artificial bank confining a stream channel or limiting adjacent areas subject to flooding; an embankment bordering a submarine canyon or channel, usually occurring along the outer edge of a curve (Ellis 1978).

Littoral Pertaining to the shore, especially of the sea; a coastal region. Used extensively with “riparian” (Shalowitz 1964).

Shorelands General term including tidelands and navigable freshwater shores below the ordinary high-water mark (Coastal States Organization 1997).

Shoreline The line of contact between the land and a body of water. On Coast and Geodetic Survey nautical charts and surveys, the shoreline approximates the mean high-water line. In Coast Survey usage, the term is considered synonymous with coastline (Shalowitz 1962).

Submerged lands Lands covered by water at any stage of the tide, as distinguished from tidelands, which are attached to the mainland or an island and cover and uncover with the tide. Tidelands presuppose a high-water line as the upper boundary; submerged lands do not (Shalowitz 1962).

Tidal estuary See estuary (Hicks 1984).

Tidelands The land that is covered and uncovered by the daily rise and fall of the tide. More specifically, it is the zone between the mean high waterline and the mean low waterline along the coast, and is commonly known as the “shore” or “beach.” Referred to in legal decisions as between the ordinary high-water mark and ordinary low-water mark. Tidelands presuppose a high-water line as the upper boundary (Shalowitz 1964).

Tidewaters Waters subject to the rise and fall of the tide. Sometimes used synonymously with tidelands, but tidewaters are better limited to areas always covered with water. The amount of tide is immaterial (Shalowitz 1964).

Upland Land above mean high water mark and subject to private ownership, as distinguished from tidelands, ownership of which is prima facie in the state but also subject to divestment under state statutes (Shalowitz 1964).

Waterline Juncture of land and sea. This line fluctuates, changing with the tide or other fluctuations in the water (Ellis 1978).

Wet sand beach Area between the ordinary high tide and the ordinary low tide lines (Coastal States Organization 1997).

IV-1-3. Geologic Time and Definitions

a. Geologic fossil record. Geologists have subdivided geologic time into *eras, periods,* and *epochs* (Figure IV-1-4). Pioneering geologists of the 1800's based the zonations on the fossil record when they discovered that fossils in various rock formations appeared and disappeared at distinct horizons, thus providing a means of comparing and correlating the relative age of rock bodies from widely separated

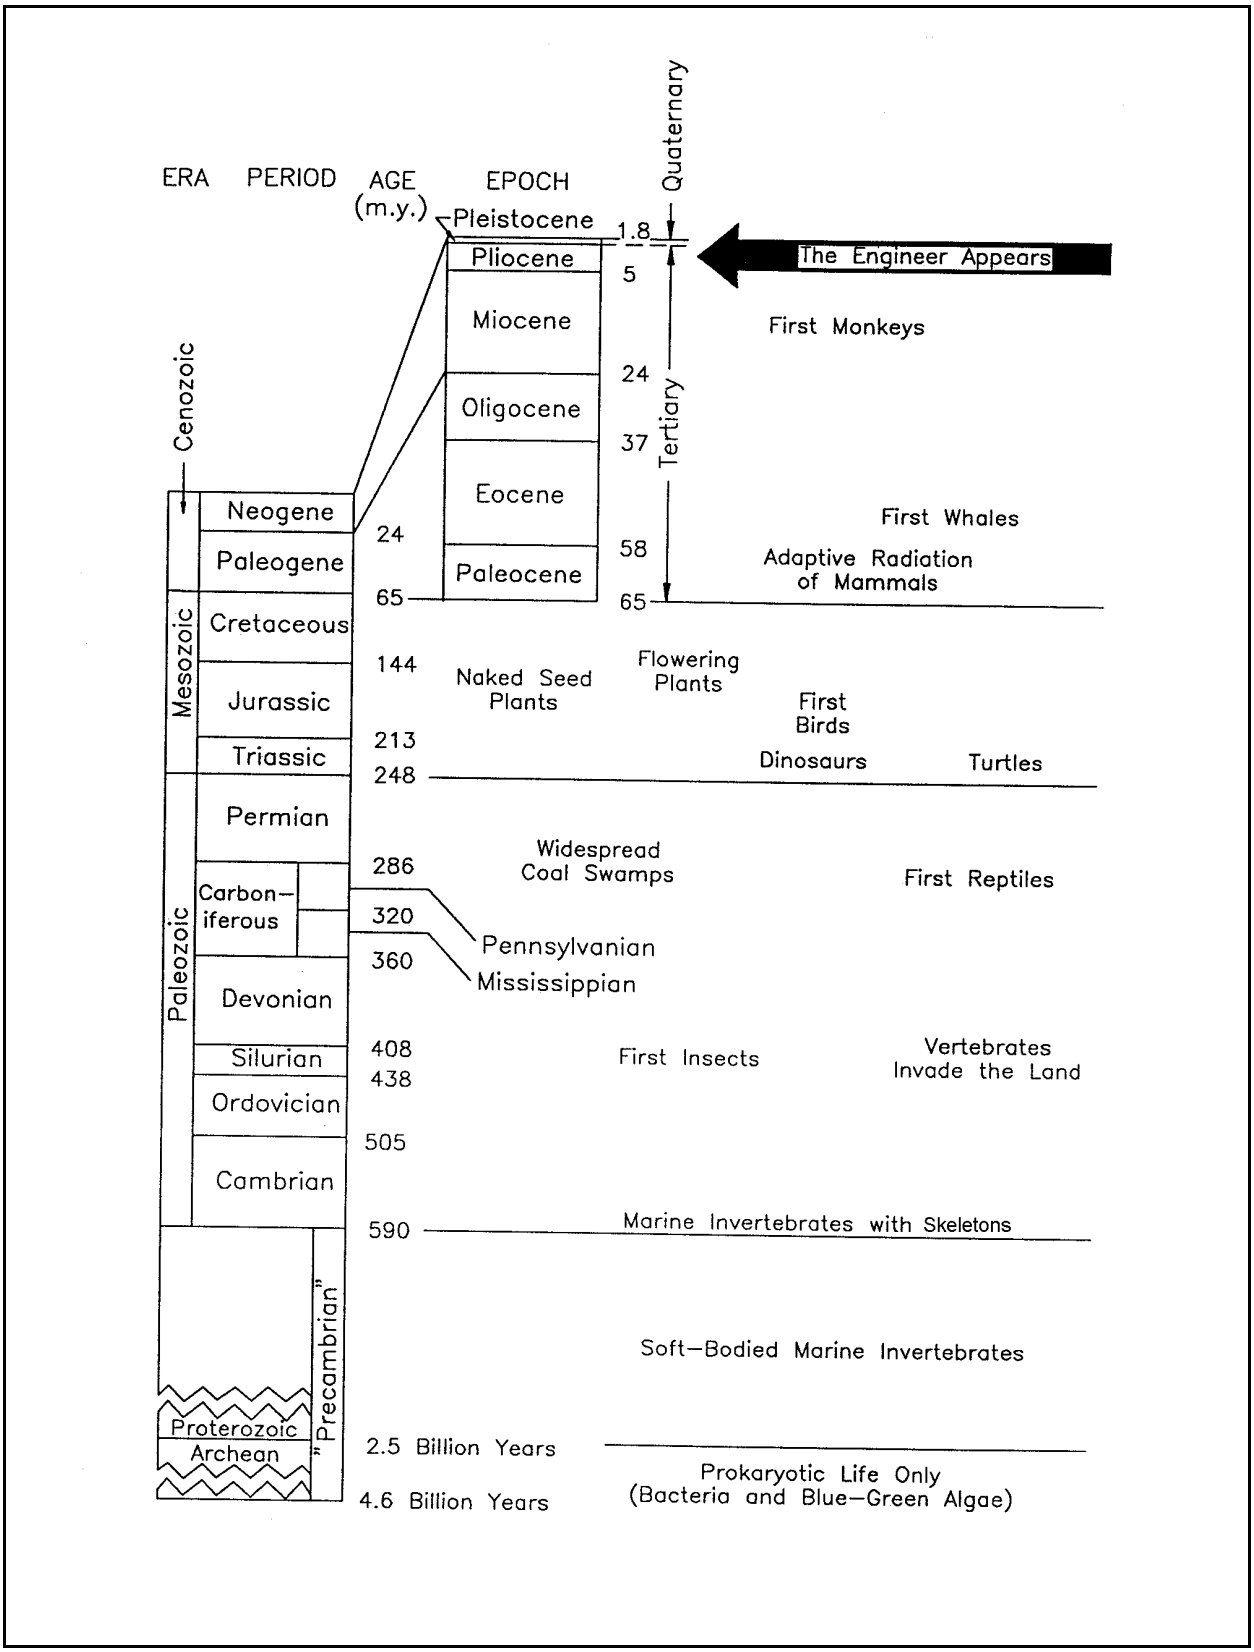

Figure IV-1-4. Geologic time scale. Chronological ages are based on radiometric dating methods (figure adapted from Stanley (1986))

locations. For example, the boundary between the *Mesozoic* ("interval of middle life") and the *Cenozoic* ("interval of modern life") eras is marked by the disappearance of hundreds of species, including the dinosaurs, and the appearance or sudden proliferation of many new species (Stanley 1986). The fossil time scale was relative, meaning that geologists could compare rock units but could not assign absolute ages in years. It was not until the mid-20th century that scientists could measure the absolute age of units by radiometric dating. The geologic times listed in Figure IV-1-4, in millions of years, are best estimates based on radiometric dates.

b. Geologic time considerations for coastal engineering. The epochs of most concern to coastal engineers and geologists are the *Pleistocene* and *Recent* (also commonly known as the *Holocene*), extending back a total of 1.8 million years before present. *Quaternary* is often used to designate the period comprising the Pleistocene and Recent Epochs.

(1) The Pleistocene Epoch was marked by pronounced climatic fluctuations in the Northern Hemisphere - changes that marked the modern Ice Age. The continental glaciers that periodically covered vast areas of the northern continents during this time had profound influence on the surficial geology. Many geomorphic features in North America were shaped or deposited by the ice sheets. Flint's (1971) *Glacial and Quaternary Geology* is an exhaustive study of the effects of Pleistocene ice sheets on North American geology.

(2) The Holocene Transgression started approximately 15,000 to 18,000 years ago with the beginning of global sea level rise. Presumably, a concurrent event was the waning of the continental glaciers possibly caused by a warming climate around the world. Most of the dynamic, morphological features that we associate with the active coastal environment are Holocene in age, but the preexisting geology is often visible, as well. For example, the drumlins of Boston Harbor and the end moraine islands of southern New England (Long Island, Martha's Vineyard, and Block and Nantucket Islands) are deposits left by the Wisconsin stage glaciers (Woodsworth and Wigglesworth 1934), but barrier spits and beaches found along these shores are more recent (Holocene) features.

(3) North American glacial stages.[1] Worldwide climatic fluctuations and multiple glacial and interglacial stages were the overwhelming Quaternary processes that shaped the surficial geomorphology and biological diversity of our world. Major fluctuations in eustatic, or worldwide, sea level accompanied the waxing and waning of the continental glaciers. Oxygen isotope analysis of deep sea sediments suggests that there were as many as nine glacial and ten interglacial events in the last 700,000 years (Kraft and Chrzastowski 1985). North American stages and approximate ages are listed in Table IV-1-2. The most recent glacial stage was the Wisconsin in North America and the Würm in Europe, during which sea level was more than 100 m below present. In northern latitude coasts, the coastal worker will often encounter geologic and geomorphic evidence of the Wisconsin glacial stage. Less evidence remains of the earlier North American stages except raised shore terraces along parts of the U.S. Atlantic and Gulf coasts (e.g., see Winkler (1977); Winkler and Howard (1977)).

IV-1-4. Water Level Datums and Definitions

Critical in evaluating sea level information or in constructing shoreline change maps are the level and type of datum used. Because water levels are not constant over space and time, depths and elevations must be

[1] Stage is a time term for a major subdivision of a glacial epoch, including the glacial and interglacial events (Bates and Jackson 1984).

Table IV-1-2
North American Pleistocene Glacial and Interglacial Stages

Age (approx. years)[1]	Glacial and Interglacial Stages	Age (approx. years)[2]
12,000-Present	Recent (Holocene)	10,000-Present
150,000-12,000	Wisconsin	100,000-10,000
350,000-150,000	Sangamon Interglacial	300,000-100,000
550,000-350,000	Illinoisan	450,000-300,000
900,000-550,000	Yarmouth Interglacial	1,100,000-450,000
1,400,000-900,000	Kansan	1,300,000-1,100,000
1,750,000-1,400,000	Aftonian Interglacial	1,750,000-1,300,000
> 2,000,000-1,750,000	Nebraskan	2,000,000-1,750,000
> 2,000,000(?)	Older glaciations	

[1] Dates based on generalized curve of ocean-water temperatures interpreted from foraminifera in deep sea cores (curve reproduced in Strahler (1981)).
[2] Dates from Young (1975) (original sources not listed).

referenced to established datums. In marine coastal areas, datums are typically based on tide elevation measurements. A glossary of tide elevation terms is presented in Part II-5-3, and water surface elevation datums are discussed in Part II-5-4.

IV-1-5. Factors Influencing Coastal Geology

The coast is probably the most diverse and dynamic environment found anywhere on earth. Many geologic, physical, biologic, and anthropomorphic (human) factors are responsible for shaping the coast and keeping it in constant flux. Ancient geological events created, modified, and molded the rock and sediment that form the foundation of the modern coastal zone. Over time, various physical processes have acted on this preexisting geology, subsequently eroding, shaping, and modifying the landscape. These processes can be divided into two broad classes: active forces, like waves and tides, which occur constantly, and long-term forces and global changes that affect the coast over time scales of years.

a. Underlying geology and geomorphology.[1] The geologic setting of a coastal site controls surficial geomorphology, sediment type and availability, and overall gradient. The geology is modified by physical processes (e.g., waves and climate), biology, and man-made activities, but the overall "look" of the coast is primarily a function of the regional lithology and tectonics. These topics are discussed in the following paragraphs.

(1) Lithology. *Lithology* concerns the general character of rock or sediment deposits. The most critical lithologic parameters responsible for a rock's susceptibility to erosion or dissolution are the mineral composition and the degree of consolidation. Striking contrasts often occur between coasts underlain by consolidated rock and those underlain by unconsolidated material. Marine processes are most effective when acting on uncemented material, which is readily sorted, redistributed, and sculpted into forms that are in a state of dynamic equilibrium with incident energy.

[1] *Geomorphology* is a study of natural topographic features and patterns forming the earth's surface, including both terrestrial and subaqueous environments.

(a) Consolidated coasts. Consolidated rock consists of firm and coherent material. Coastal areas consisting of consolidated rock are typically found in hilly or mountainous terrain. Here, erosional processes are usually dominant. The degree of consolidation greatly influences the ability of a rocky coastline to resist weathering and erosion. Resistance depends on susceptibility to mechanical and chemical weathering, hardness and solubility of constituent minerals and cementation, nature and density of voids, and climatic conditions. Rock type, bedding, jointing, and orientation of the strata greatly influence the geomorphic variability of the shoreline (Figures IV-1-5, IV-2-20, and IV-2-31). For example, large portions of the shorelines of Lakes Superior, Huron, and Ontario are rocky and prominently display the structure of the underlying geology.

- *Mechanical weathering* is the disintegration of rock without alteration of its chemical nature. Examples of mechanical weathering include fluctuations in temperature (causing repetitive thermal expansion and contraction), expansion due to crystallization from salt or ice, wetting and drying, overburden fluctuations, and biological activity.

- *Chemical weathering* is the decomposition of rock material by changes in its chemical composition. This process includes hydration and hydrolysis, oxidation and reduction, solution and carbonation, chelation, and various biochemical reactions.

(b) Unconsolidated coasts. In contrast to consolidated coasts, depositional and erosional processes dominate unconsolidated coasts, which are normally found on low relief coastal plains or river deltas. Commonly, shorelines have been smoothed by erosion of protruding headlands and by the deposition of barrier islands, spits, and bay mouth barriers. Along unconsolidated coasts, large amounts of sediment are usually available, and morphological changes occur rapidly. Waves and currents readily alter relict geomorphic features in this environment. Figure IV-1-6 illustrates features associated with unconsolidated depositional environments. The Atlantic and Gulf of Mexico coasts of the United States are mostly unconsolidated, depositional environments (except select locations like the rocky shores in New England).

(2) Tectonics. Forces within the earth's crust and mantle deform, destroy, and create crustal material. These tectonic activities produce structural features such as faults and folds (anticlines and synclines) (Figure IV-1-7). Tectonic movements produce large-scale uplift and subsidence of land masses. The west coast of the United States is an example of a tectonically dominated coast, in sharp contrast to the east coast, which is mostly depositional. According to Shepard's (1973) coastal classification, a fault coast is characterized by a steep land slope that continues beneath the sea surface. The most prominent feature exhibited by a fault coast is a scarp where normal faulting has recently occurred, dropping a crustal block so that it is completely submerged, leaving a higher block standing above sea level (Figure IV-1-8). Examples of fault-block coasts are found in California. Active faults such as the Inglewood-Rose Canyon structural zone outline the coast between Newport Bay and San Diego, and raised terraces backed by fossil cliffs attest to continuing tectonism (Orme 1985).

(3) Volcanic coasts. The eruption of lava and the growth of volcanoes may result in large masses of new crustal material. Conversely, volcanic explosions or collapses of existing volcanic cones can leave huge voids in the earth's surface known as calderas. When calderas and cones occur in coastal areas, the result is a coastline dominated by circular convex and concave contours (Shepard 1973). Coastlines of this sort are common on volcanic islands such as the Aleutians (Figure IV-1-9). The morphology of volcanic shores is discussed in more detail in Part IV-2.

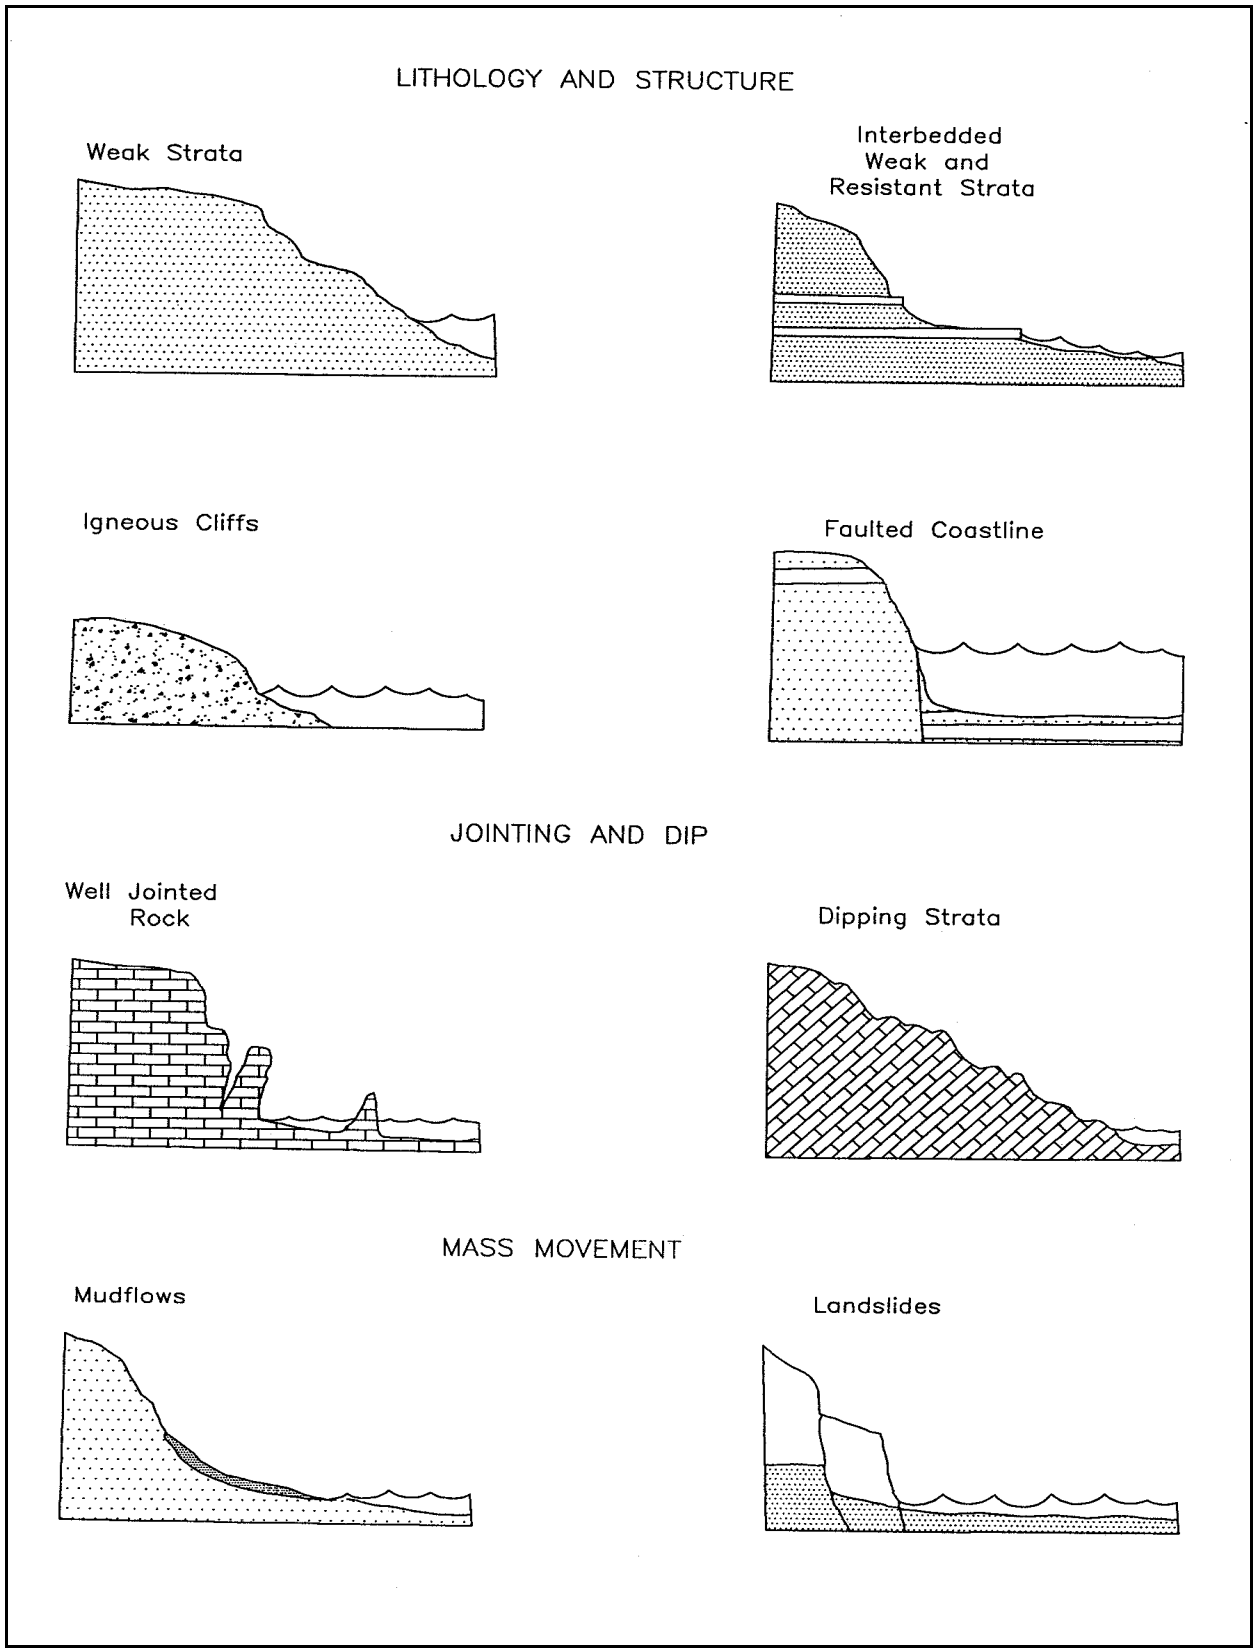

Figure IV-1-5. Cross-section views of aspects of geomorphic variability attributable to lighology, structure, and mass movement along semi-consolidated coasts (from Mossa, Meisberger, and Morang (1992))

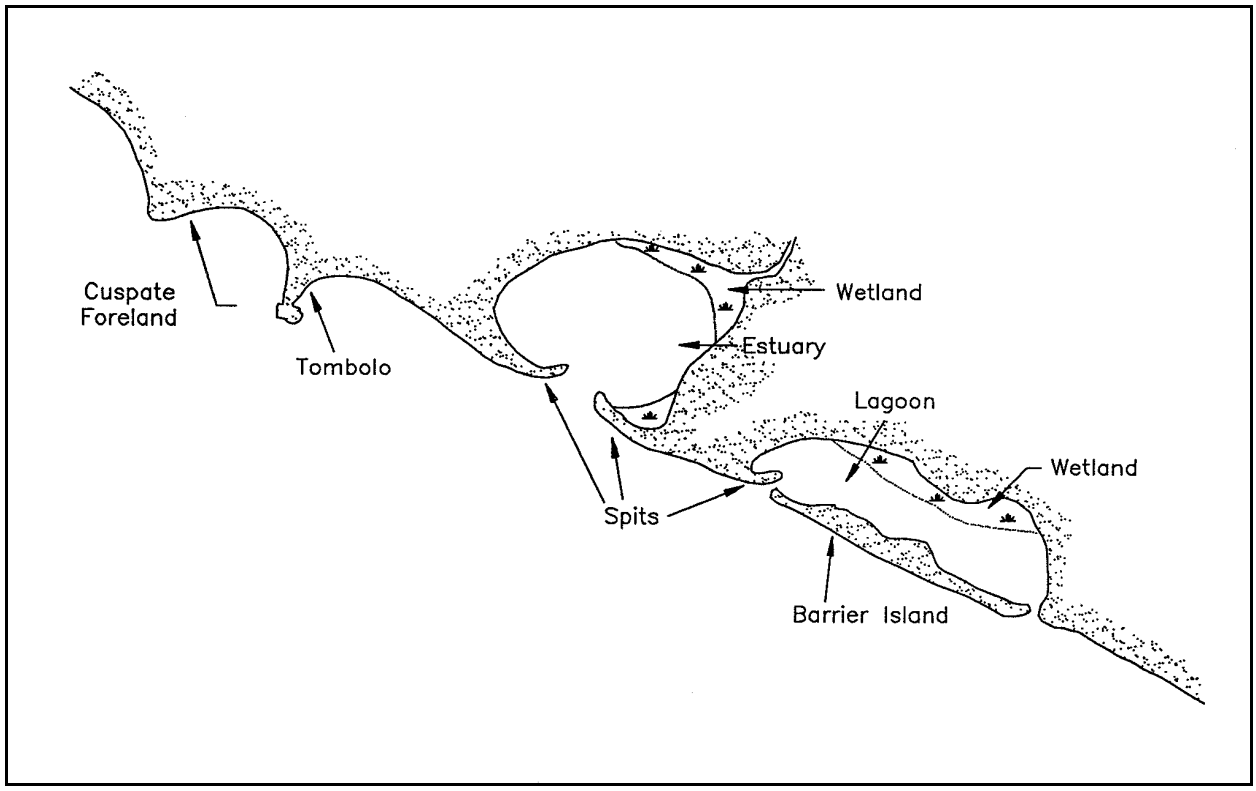

Figure IV-1-6. Examples of features associated with depositional coastal environments. These features consist mostly of unconsolidated sediments (after Komar 1976))

b. High-frequency dynamic processes. The following paragraphs briefly list processes that impart energy to the coastal zone on a continuous or, as with storms, repetitive basis. Any geological or engineering investigation of the coastal zone must consider the sources of energy that cause erosion, move sediment, deposit sediment, and rearrange or shape the preexisting topography. These processes also result in temporary changes in water levels along the coast. Long-term sea level changes are discussed in paragraph IV-1-6.

(1) Waves.

(a) Water waves (sometimes called *gravity waves*) are the dominant force driving littoral processes on open coasts. The following quotes from the *Shore Protection Manual* (1984) underscore the significance of waves in shaping coastal zone geomorphology:

> Waves are the major factor in determining the geometry and composition of beaches and significantly influence the planning and design of harbors, waterways, shore protection measures, coastal structures, and other coastal works. Surface waves generally derive their energy from the winds. A significant amount of this wave energy is finally dissipated in the nearshore region and on the beaches.
>
> Waves provide an important energy source for forming beaches; sorting bottom sediments on the shoreface; transporting bottom materials onshore, offshore, and alongshore; and for causing many of the forces to which coastal structures are subjected. An adequate understanding of the fundamental physical processes in surface wave generation and propagation must precede any attempt to

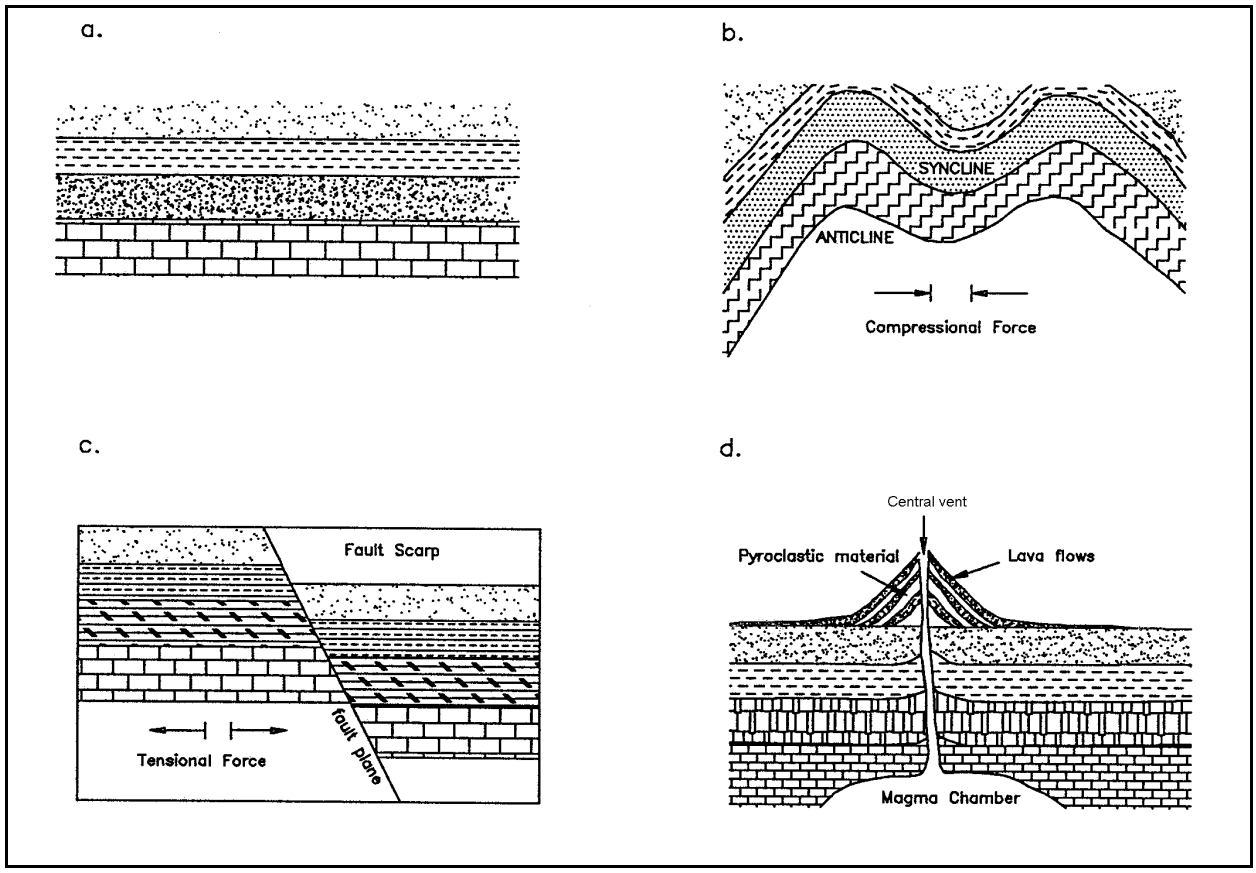

Figure IV-1-7. Examples of tectonically produced features: (a) stable undeformed block; (b) symmetrical folding resulting from compressional forces; (c) normal faulting resulting from tensional forces; (d) composed of alternating layers of pyroclastic material (ash) and lava flows

understand complex water motion in the nearshore areas of large bodies of water. Consequently, an understanding of the mechanics of wave motion is essential in the planning and design of coastal works.

(b) A detailed discussion of water wave mechanics is presented in Parts II-1, II-2, and II-3. Bascom's (1964) *Waves and Beaches* is a general introduction to the subject for the nonspecialist.

(2) Tides.

(a) The most familiar sea level changes are those produced by astronomical tides. *Tides* are a periodic rise and fall of water level caused by the gravitational interaction among the earth, moon, and sun. Because the earth is not covered by a uniform body of water, tidal ranges and periods vary from place to place and are dependent upon the natural period of oscillation for each water basin (Komar 1998). Tidal periods are characterized as diurnal (one high and one low per day), semidiurnal (two highs and two lows per day), and mixed (two highs and two lows with unequal heights) (Figure II-5-16). In the coastal zone, variations in topography, depth, seafloor sediment type, and lateral boundaries also affect the tide. For more background information and theory, refer to Part II-4.

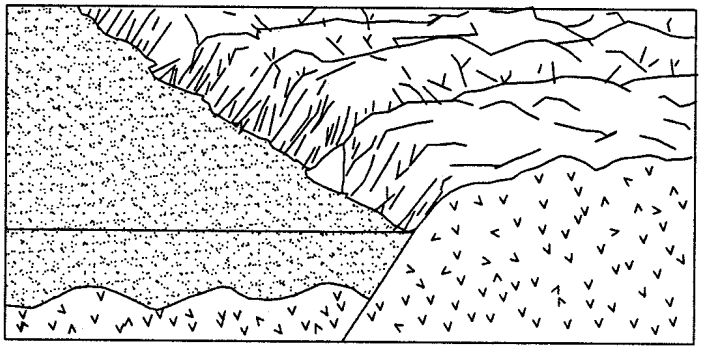

Figure IV-1-8. Example of a fault coast exhibiting a prominent fault scarp

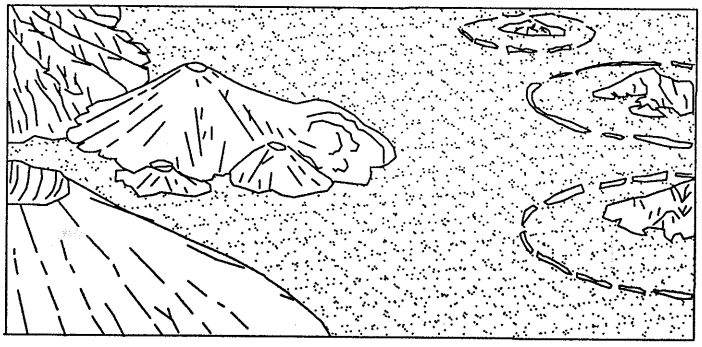

Figure IV-1-9. Example of a volcanic coast with numerous circular islands

(b) The importance of tides to coastal geological processes is threefold. First, the periodic change in water level results in different parts of the foreshore being exposed to wave energy throughout the day. In regions with large tidal ranges, the water may rise and fall 10 m, and the shoreline may move laterally several kilometers between high and low water. This phenomenon is very important biologically because the ecology of tidal flats depends on their being alternately flooded and exposed. The geological significance is that various parts of the intertidal zone are exposed to erosion and deposition.

(c) Second, tidal currents themselves can erode and transport sediment. Generally, tidal currents become stronger near the coast and play an increasingly important role in local circulation (Knauss 1978). Because of the rotating nature of the tidal wave in many locations (especially inland seas and enclosed basins), ebb and flood currents follow different paths. As a result, residual motions can be highly important in terms of transport and sedimentation (Carter 1988). In inlets and estuaries, spatially asymmetric patterns of ebb and flood may cause mass transport of both water and sediment.

(d) Third, tides cause the draining and filling of tidal bays. These bays are found even in low-tide coasts such as the Gulf of Mexico. This process is important because it is related to the cutting and migration of tidal inlets and the formation of flood- and ebb-tidal shoals in barrier coasts. The exchange of seawater in and out of tidal bays is essential to the life cycle of many marine species.

(3) Energy-based classification of shorelines.

(a) Davies (1964) applied an energy-based classification to coastal morphology by subdividing the world's shores according to tide range. Hayes (1979) expanded this classification, defining five tidal categories for coastlines:

- Microtidal, < 1 m.
- Low-mesotidal, 1-2 m.
- High-mesotidal, 2-3.5 m.
- Low-macrotidal, 3.5-5 m.
- Macrotidal, > 5 m.

The Hayes (1979) classification was based primarily on shores with low to moderate wave power and was intended to be applied to trailing edge, depositional coasts.

(b) In the attempt to incorporate wave energy as a significant factor modifying shoreline morphology, five shoreline categories were identified based on the relative influence of tide range versus mean wave height (Figure IV-1-10) (Nummedal and Fischer 1978; Hayes 1979; Davis and Hayes 1984):

- Tide-dominated (high).
- Tide-dominated (low).
- Mixed-energy (tide-dominated).
- Mixed energy (wave-dominated).
- Wave-dominated.

(c) The approximate limit of barrier island development is in the field labeled "mixed energy (tide-dominated)." Notice that these fields cover a range of tide and wave heights. It is the relative effects of these processes that are important, not the absolute values. Also, at the lower end of the energy scales, there is a delicate balance between the forces; where tide-dominated, wave-dominated, or mixed-energy morphologies may develop with very little difference in wave or tide parameters. By extension, tidal inlets have sometimes been classified using this nomenclature.

(d) Continuing research has shown, however, that earlier approaches to classifying the coast on the basis of tidal and wave characteristics have been oversimplified because many other factors can play critical roles in determining shoreline morphology and inlet characteristics (Davis and Hayes 1984; Nummedal and Fischer 1978). Among these factors are:

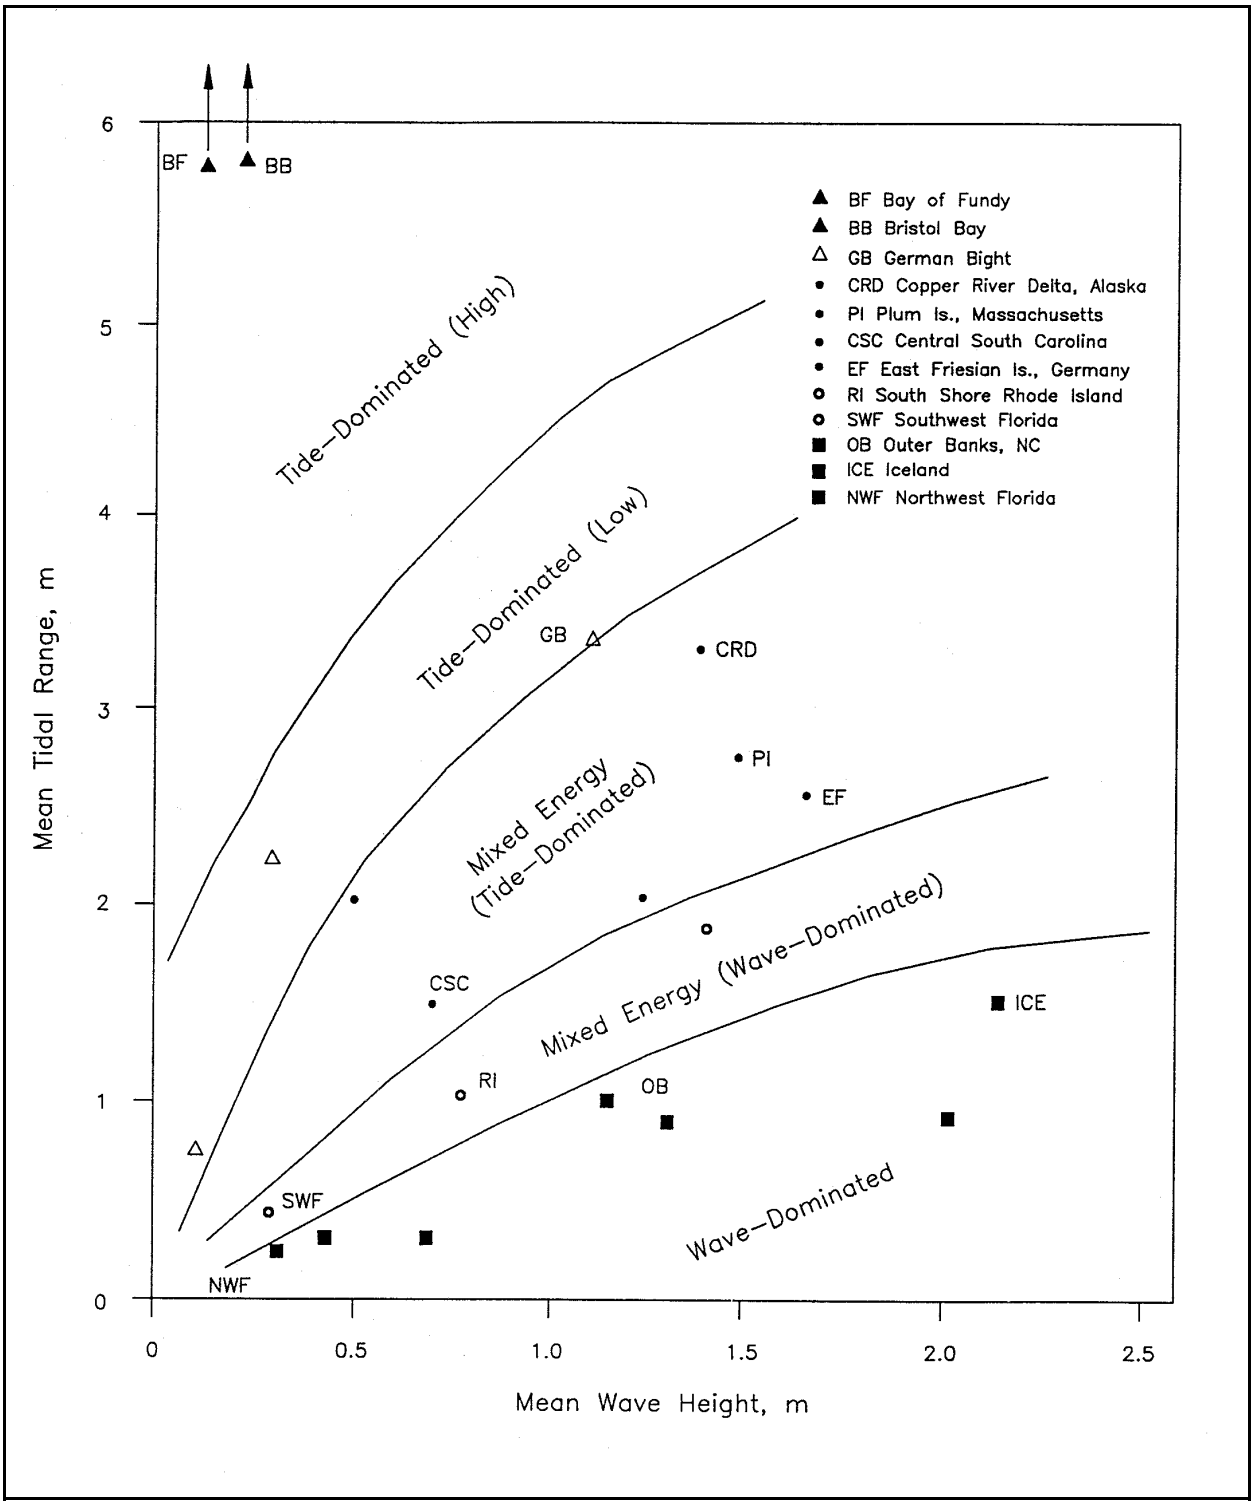

Figure IV-1-10. Energy-based classification of shorelines (from Hayes (1979))

- Physiographic setting and geology.
- Tidal prism.
- Sediment availability.
- Influence of riverine input.
- Bathymetry of the back-barrier bays.
- Meteorology and the influence of storm fronts.

(4) Meteorology. *Meteorology* is the study of the spatial and temporal behavior of atmospheric phenomena. *Climate* characterizes the long-term meteorologic conditions of an area, using averages and various statistics. Factors directly associated with climate such as wind, temperature, precipitation, evaporation, chemical weathering, and seawater properties all affect coastal geology. The shore is also affected by wave patterns that may be due to local winds or may have been generated by storms thousands of kilometers away. Fox and Davis (1976) is an introduction to weather patterns and coastal processes, and Hsu (1988) reviews coastal meteorology fundamentals.

(a) Wind. Wind is caused by pressure gradients, horizontal differences in pressure across an area. Wind patterns range in scale from global, which are generally persistent, to local and short duration, such as thunderstorms.

(b) Direct influence of wind. Wind has a great influence on coastline geomorphology, both directly and indirectly. The direct influence includes wind as an agent of erosion and transportation. It affects the coastal zone by eroding, transporting, and subsequently depositing sediment. Bagnold (1954) found that a proportional relationship exists between wind speed and rate of sand movement. The primary method of sediment transport by wind is through saltation, or the bouncing of sediment grains across a surface. Two coastal geomorphic features that are a direct result of wind are dunes and related blowouts (Pethick 1984). *Dunes* are depositional features whose form and size are a result of sediment type, underlying topography, wind direction, duration, and strength. *Blowouts* form when wind erodes an unvegetated area, thus removing the sand and leaving a depression or trough. These features are discussed in more detail in Parts III-4 and IV-2.

(c) Indirect effect. Wind indirectly affects coastal geomorphology as wind stress upon a water body causes the formation of waves and oceanic circulation.

(d) Land/sea breeze. Diurnal variations in the wind result from differential heating of the ocean and land surfaces. During the day, especially in summer, heating of the land causes the air to expand and rise, thus forming an area of low pressure. The pressure gradient between the water and the land surfaces causes a landward-directed breeze. At night, the ocean cools less rapidly than does the land, thus resulting in air rising over the ocean and subsequently seaward-directed breezes. These breezes are rarely greater than 8 m/sec (18 mph) and therefore do not have a great effect upon coastline geomorphology, although there may be some offshore-onshore transport of sediment on beaches (Komar 1998).

(e) Water level setup and setdown. Onshore winds cause a landward movement of the surface layers of the water and thus a seaward movement of deeper waters. Strong onshore winds, if sustained, may also cause increased water levels or setup. The opposite occurs during offshore winds.

(f) Seiches. *Seiches* are phenomena of standing oscillation that occur in large lakes, estuaries, and small seas in response to sudden changes in barometric pressure, violent storms, and tides. This condition causes the water within the basin to oscillate much like water sloshing in a bowl.

(5) Tropical storms. A *cyclone* is a system of winds that rotates about a center of low atmospheric pressure clockwise in the Southern Hemisphere and anti-clockwise in the Northern Hemisphere (Gove 1986). *Tropical storm* is a general term for a low-pressure, synoptic-scale[1] cyclone that originates in a tropical area. At maturity, tropical cyclones are the most intense and feared storms in the world; winds exceeding 90 m/sec (175 knots or 200 mph) have been measured, accompanied by torrential rain (Huschke 1959). By convention, once winds exceed 33 m/sec (74 mph), tropical storms are known as *hurricanes* in the Atlantic and eastern Pacific, *typhoons* in the western Pacific (Philippines and China Sea), and *cyclones* in the Indian Ocean.

(a) Tropical storms can cause severe beach erosion and destruction of shore-front property because elevated sea level, high wind, and depressed atmospheric pressure can extend over hundreds of kilometers. Tropical storms can produce awesome property damage (Table IV-1-3) and move vast quantities of sediment.

- The great Gulf of Mexico hurricane of 1900 inundated Galveston Island, killing over 6,000 residents (NOAA 1977-estimates range from 8-12,000 dead).

- During the September 1919 hurricane that struck the Florida Keys, 300 lives were lost in Key West, where winds were reported at 50 m/sec (110 mph). The final death toll of over 600, mostly in ships at sea, made this the third deadliest U.S. hurricane on record.

- The Great New England Hurricane that devastated Long Island and southern New England in September of 1938 killed 600 people and eliminated beach-front communities along the southern Rhode Island shore (Minsinger 1988). Survivors reported 15-m (50-ft) breakers sweeping over the Rhode Island barriers (Allen 1976). Shinnecock Inlet was cut through the Long Island barrier (Morang 1999).

- Hurricane Hugo hit the U.S. mainland near Charleston, South Carolina, on September 21, 1989, causing over $4 billion in damage, eroding the barriers, and producing other geologic changes up to 180 km north and 50 km south of Charleston (Davidson, Dean, and Edge 1990; Finkl and Pilkey 1991).

- A cyclone on June 9, 1998, inundated low-lying coastal plains and salt pans in northwest India. Over 14,000 people vanished into the Arabian Sea.

Simpson and Riehl (1981) have examined the effects of hurricanes in the United States. This work and Neumann et al. (1987) list landfall probabilities for the U.S. coastline. Tropical storms from 1871 to 1986 are plotted in Neumann et al. (1987). Tannehill (1956) identified all known Western Hemisphere hurricanes before the 1950's. Worldwide representative tropical storm tracks are shown in Figure IV-1-11 and Atlantic tracks in Figure II-5-29.

(b) The Saffir-Simpson Scale has been used for over 20 years by the U.S. National Weather Service to compare the intensity of tropical cyclones (Table IV-1-4). Cyclones are ranked into five categories based on maximum wind speed and the amount of damage that they cause (Figure IV-1-12), with 5 representing

[1] Synoptic-scale refers to large-scale weather systems as distinguished from local patterns such as thunderstorms.

Table IV-1-3
Damage Estimates and Payouts by Insurance Companies for U.S. Catastrophes

Date	Event (Region of Greatest Influence)	Category	Insured loss (millions)[1]	Total Damage estimate (millions) [2]	Total Damage in 1996 U.S. Dollars (millions)
Aug. 1992	Hurricane Andrew (Florida, Louisiana)[2]	4	$16,500	26,500	30,475
Jan. 1994	Northridge, Cailifornia, earthquake		12,500		
Sep. 1989	Hurricane Hugo (South Carolina)	4	4,195	7,000	8,490
Sep. 1998	Hurricane Georges		2.900	≈ 4,000	
Oct. 1995	Hurricane Opal (Florida, Alabama)	3	2,100	3,000	3,100
March 1993	"Storm of the Century" (24 eastern states)		1,750	6,000	
Aug. 1969	Hurricane Camille (Mississippi, Louisiana)	5	-	1,400	6,100
Oct. 1991	Oakland, California, fire		1,700		
Sep. 1996	Hurricane Fran	3	1,600	3,200	3,200
Sep. 1992	Hurricane Iniki (Hawaiian Islands)	—	1,600	1,800	2,070
Oct. 1989	Loma Prieta, California, earthquake		960		
Dec. 1983	Winter storms, 41 states		880		
April-May 1992	Los Angeles riots		775		
April 1992	Wind, hail, tornadoes, floods (Texas, Oklahoma)		760		
Sep. 1979	Hurricane Frederic (Mississippi, Alabama)	3	753	2,300	4,330
Sep 1964	Hurricane Dora (southeast Florida)	2	250		1,340
Sep 1960	Hurricane Donna (south Florida)	4	300	387	2,100
Sep. 1938	Great New England Hurricane (Long Island, Rhode Island, Connecticut, Massachusetts)	3	400[3]	600	—

Notes:
1. Total damage costs exceed insurance values because municipal structures like roads are not insured. (Source: *The New York Times,* December 28, 1993, citing insurance industry and State of Florida sources; *Daytona Beach News-Journal* web edition, 12 June 1998).
2. Andrew caused vast property damage in south central Florida, when sub-standard structures were torn apart by the hurricane's winds. This proves that hurricanes are not merely coastal hazards, although coastal residents usually are at greatest risk because of the danger from storm surges. (Source: The Deadliest, Costliest, and Most Intense United States Hurricanes of this Century, NOAA Technical Memorandum NWS TPC-1 (www.nhc.noaa.gov/pastcast.html, 23 Dec 1998).
3. Multiplying the 1938 damage value by 10 gives a crude estimate in 1990's Dollars (data source: Minsinger 1988).

storms that cause catastrophic damage to structures. Only two Category 5 storms have hit the United States since record-keeping began: the 1935 Labor Day hurricane that hit the Florida Keys and killed 600 people, and Hurricane Camille, which devastated the Mississippi coast in 1969, killing 256 and causing 1.4 billion in damage (over $6 billion when converted to 1996 values).

(c) During tropical storms and other weather disturbances, water level changes are caused by two factors:

- *Barometric pressure.* Barometric pressure has an inverse relationship to sea level. As atmospheric pressure increases, the sea surface is depressed so that the net pressure on the seafloor remains constant. Inversely, as atmospheric pressure decreases, surface water rises. The magnitude of the "inverse barometer effect" is about 0.01 m for every millibar of difference in pressure, and in areas affected by tropical storms or hurricanes, the potential barometric surge may be as high as 1.5 m (Carter 1988).

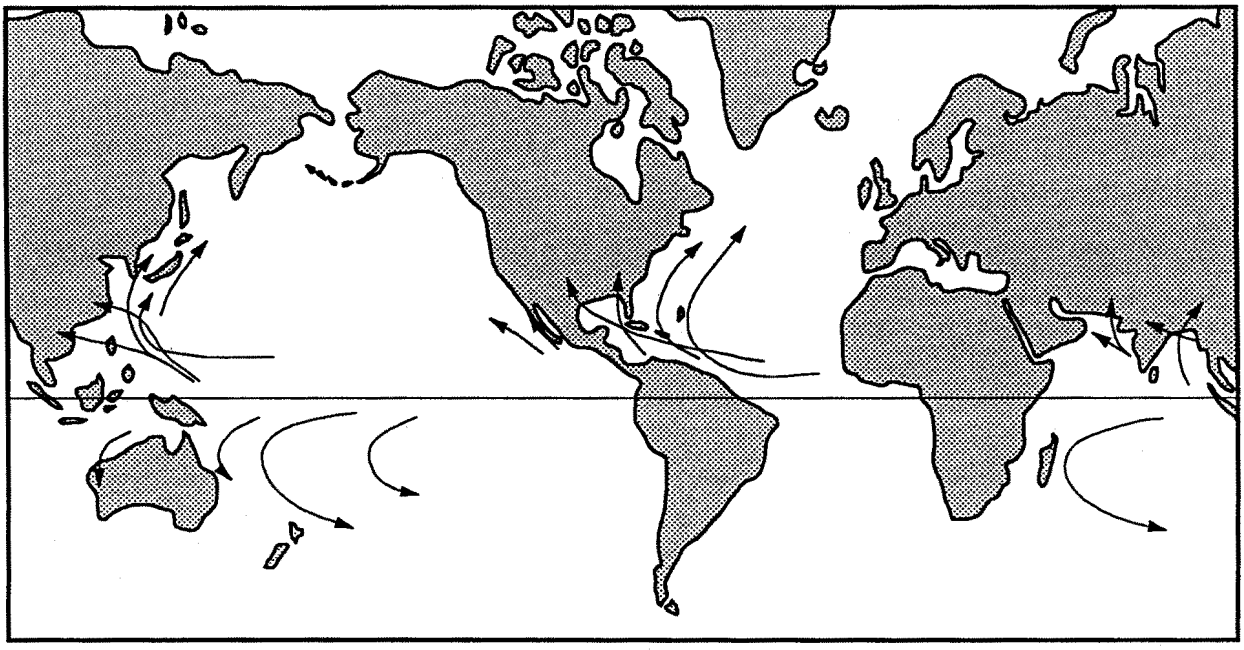

Figure IV-1-11. Worldwide tropical storm pathways (from Cole (1980))

Table IV-1-4
Saffir-Simpson Damage-Potential Scale

Scale Number (category)	Central pressure (millibars)	Wind speed (miles/hr)	Wind speed (m/sec)	Surge (ft)	Surge (m)	Damage
1	≥980	74-95	33-42	4-5	~1.5	Minimal
2	965-979	96-110	43-49	6-8	~2-2.5	Moderate
3	945-964	111-130	50-58	9-12	~2.6-3.9	Extensive
4	920-944	131-155	59-69	13-18	~4-5.5	Extreme
5	<920	>155	>69	>18	>5.5	Catastrophic

(From Hsu (1988); originally from Simpson and Riehl (1981))

- *Storm surges.* In shallow water, winds can pile up water against the shore or drive it offshore. Storm surges, caused by a combination of low barometric pressure and high onshore winds, can raise sea level several meters, flooding coastal property (Figures IV-1-13 and IV-1-14). The Federal Emergency Management Agency (FEMA) determines base flood elevations for the coastal counties of the United States. These elevations include still-water-level flood surges that have a 100-year return interval. In light of rising sea level along most of the United States, it seems prudent that Flood Insurance Rate Maps be periodically adjusted (National Research Council 1987). Besides wind forcing, ocean waves generated by storms can temporarily increase water levels tens of centimeters. Analysis procedures for predicting surge heights are detailed in EM 1110-2-1412.

(6) Extratropical storms. *Extratropical cyclones* (ET's) are cyclones associated with migratory fronts occurring in the middle and high latitudes (Hsu 1988). Although hurricanes are the most destructive storms to pass over the U.S. Atlantic coast, less powerful ET's, more commonly known as winter storms or

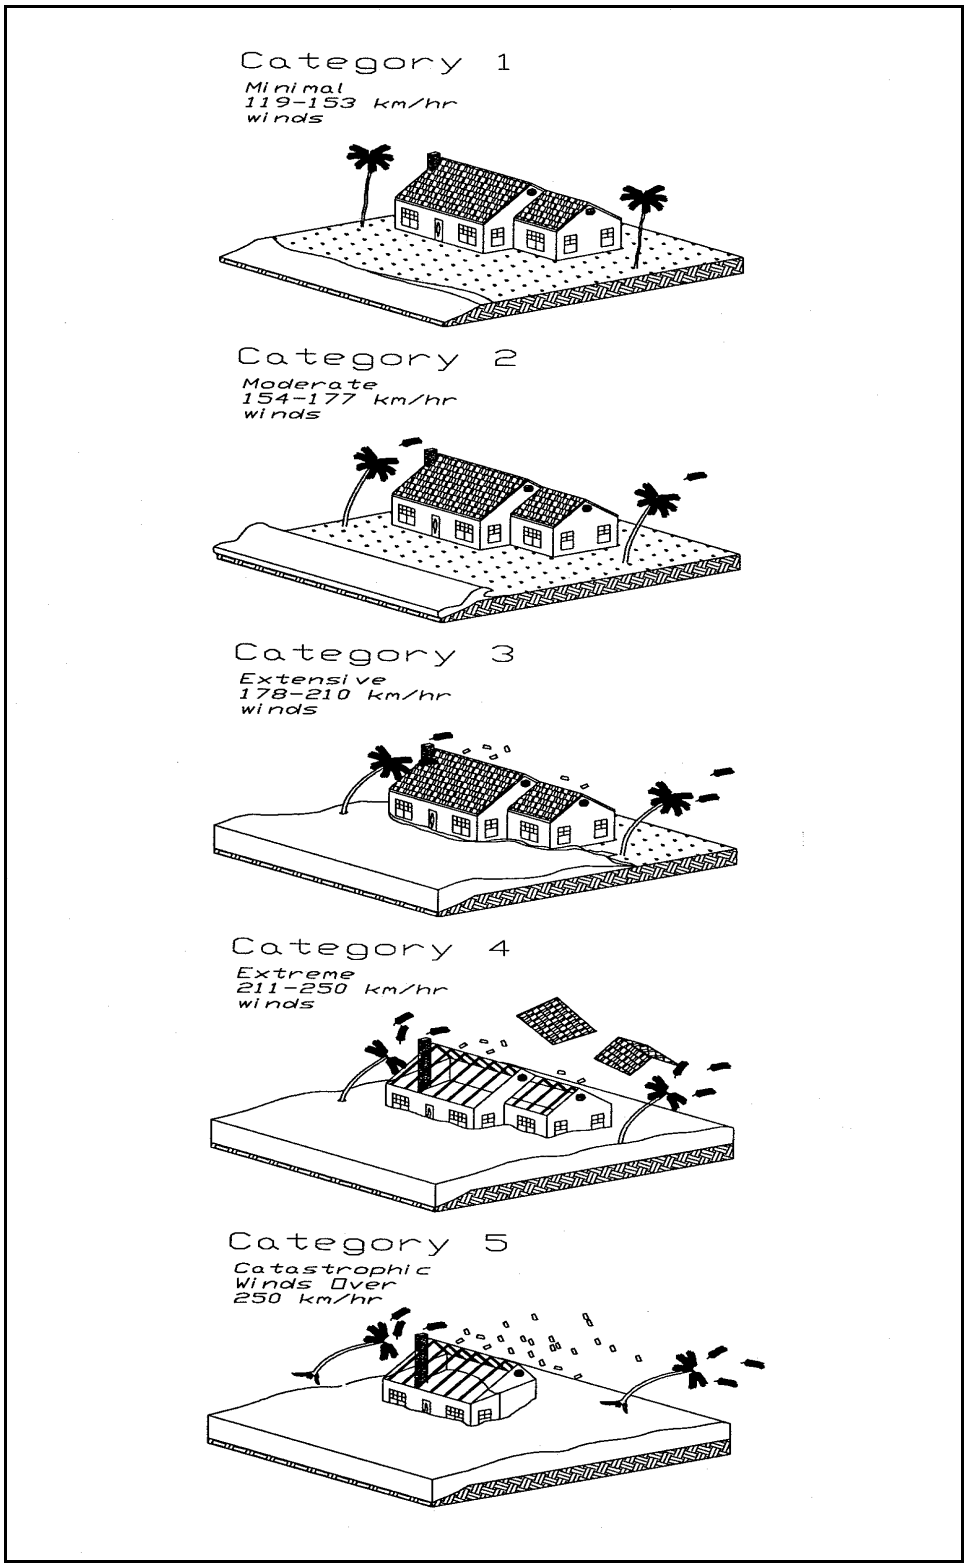

Figure IV-1-12. Graphical representation of the Saffir-Simpson Scale, showing the amount of damage that can be expected during different category hurricanes. Hurricane Andrew, in August 1992, was a Category 5 storm that caused immense damage inland, without a storm surge (Figure modified from Associated Press figure printed in *Vicksburg Post,* 3 Aug 1995)

Figure IV-1-13. Navarre Beach, Florida, November 1995. The house in Santa Rosa Sound was lifted off its foundations and moved back hundreds of meters. Many houses here were built on piles, but during Hurricane Opal, some piles were undermined, while at some properties, waves simply lifted buildings up off their supports. The low area in the foreground is a washover channel

Figure IV-1-14. Hurricane Opal damage at Navarre Beach, Florida, November 1995. The sand underneath the concrete slab washed away, and the unsupported floors collapsed

"northeasters," have also damaged ships, eroded beaches, and taken lives. Northeasters are not as clearly defined as hurricanes and their wind speeds seldom approach hurricane strength. On the other hand, ET's usually cover broader areas than hurricanes and move more slowly; therefore, ET's can generate wave heights that exceed those produced by tropical storms (Dolan and Davis 1992).

(a) Most Atlantic northeasters occur from December through April. Dolan and Davis (1992) have tabulated historic ET's and calculated that the most severe ones are likely to strike the northeast coast in October and January.

(b) The *Halloween Storm* of October 1991 was one of the most destructive northeasters to ever strike the Atlantic coast. The system's lowest pressure dipped to 972 mb on October 30. Sustained winds about 40-60 knots persisted for 48 hr, generating immense seas and storm surges (Dolan and Davis 1992). Another famous northeaster was the *Ash Wednesday Storm* of 1962, which claimed 33 lives and caused great property damage.

(c) In early 1983, southern California was buffeted by the most severe storms in 100 years, which devastated coastal buildings and caused tremendous erosion. During one storm in January 1983, which coincided with a very high tide, the cliffs in San Diego County retreated as much as 5 m (Kuhn and Shepard 1984). Further north, the storm was more intense and cliff retreat of almost 30 m occurred in places. Kuhn and Shepard (1984) speculated that the unusual weather was linked to the eruption of El Chichon Volcano in the Yucatan Peninsula in March 1982. They noted that the 1983 storms in California were the most intense since the storms of 1884, which followed the August 27, 1883, explosion of Krakatoa.

(d) At this time, weather forecasters still have difficulty forecasting the development and severity of ET's. Coastal planners and engineers must anticipate that powerful storms may lash their project areas and need to apply conservative engineering and prudent development practices to limit death and property destruction.

c. Biological factors.

Coastal areas are normally the sites of intense biological activity. This is of enormous geological importance in some areas, while being insignificant and short-lived in others. Biological activity can be constructive; e.g., the growth of massive coral reefs, or it can be destructive, as when boring organisms help undermine sea cliffs. Remains from marine organisms having hard skeletal parts, usually composed of calcium carbonate, contribute to the sediment supply almost everywhere in the coastal environment. These skeletal contributions can be locally important and may even be the dominant source of sediment. Vegetation, such as mangroves and various grasses, plays an important role in trapping and stabilizing sediments. Growth of aquatic plants in wetlands and estuaries is critical in trapping fine-grained sediments, eventually leading to infilling of these basins (if balances between sediment supply and sea level changes remain steady). Kelp, particularly the larger species, can be an important agent of erosion and transportation of coarse detritus such as gravel and cobble. Biological coasts are discussed in greater detail in Part IV-2. Deltaic and estuarine processes, which are greatly influenced by biology, are discussed in Part IV-3.

IV-1-6. Sea Level Changes

a. Background.

(1) General.

(a) Changes in sea level can have profound influence on the geology, natural ecology, and human habitation of coastal areas. A long-term and progressive rise in sea level has been cited as a major cause of erosion and property damage along our coastlines. Predicting and understanding this rise can guide coastal planners in developing rational plans for coastal development and the design, construction, and operation of structures and waterways.

(b) Many geomorphic features on contemporary coasts are the byproducts of the eustatic rise in sea level caused by Holocene climatic warming and melting of continental glaciers. Sea level has fluctuated throughout geologic time as the volume of ocean water has fluctuated, the shape of the ocean basins has changed, and continental masses have broken apart and re-formed.

(c) Sea level changes are the subject of active research in the scientific community and the petroleum industry. The poor worldwide distribution of tide gauges has hampered the study of recent changes (covering the past century) as most gauges were (and still are) distributed along the coasts of industrial nations in the Northern Hemisphere. Readers interested in this fascinating subject are referred to Emery and Aubrey's (1991) excellent book, *Sea Levels, Land Levels, and Tide Gauges.* This volume and Gorman (1991) contain extensive bibliographies. Tabular data and analyses of United States tide stations are printed in Lyles, Hickman, and Debaugh (1988), and worldwide Holocene sea level changes are documented in Pirazzoli (1991). Papers on sea level fluctuations and their effects on coastal evolution are presented in Nummedal, Pilkey, and Howard (1987). Engineering implications are reviewed in National Research Council (1987). Atmospheric carbon dioxide, climate change, and sea level are explored in National Research Council (1983). Houston (1993) discusses the state of uncertainty surrounding predictions on sea level change.

(2) Definitions. Because of the complexity of this topic, it is necessary to introduce the concepts of relative and eustatic sea level:

(a) *Eustatic* sea level change is caused by change in the relative volumes of the world's ocean basins and the total amount of ocean water (Sahagian and Holland 1991). It can be measured by recording the movement in sea surface elevation compared with some universally adopted reference frame. This is a challenging problem because eustatic measurements must be obtained from the use of a reference frame that is sensitive *only* to ocean water and ocean basin volumes. For example, highly tectonic areas (west coasts of North and South America; northern Mediterranean countries) are not suitable for eustatic sea level research because of frequent vertical earth movements (Mariolakos 1990). Tide gauge records from “stable” regions throughout the world have generated estimates of the recent eustatic rise ranging from 15 cm/century (Hicks 1978) to 23 cm/century (Barnett 1984).

(b) A *relative* change in water level is, by definition, a change in the elevation of the sea surface compared with some local land surface. The land, the sea, or both may have moved in *absolute* terms with respect to the earth's geoid. It is exceptionally difficult to detect absolute sea level changes because tide stations are located on land masses that have themselves moved vertically. For example, if both land and sea are rising at the same rate, a gauge will show that relative sea level (rsl) has not changed. Other clues, such as beach ridges or exposed beach terraces, also merely reflect their movement relative to the sea.

(3) Overview of causes of sea level change.

(a) Short-term sea level changes are caused by seasonal and other periodic or semi-periodic oceanographic factors. These include astronomical tides, movements of ocean currents, runoff, melting ice, and regional atmospheric variations. Included in this category are abrupt land level changes that result from volcanic activity or earthquakes. *Short-term* is defined here as an interval during which we can directly see or measure the normal level of the ocean rising or falling (a generation or 25 years). These factors are of particular pertinence to coastal managers and engineers, who are typically concerned with projects expected to last a few decades and who need to anticipate sea level fluctuations in their planning.

(b) Slow, secular sea and land level changes, covering time spans of thousands or millions of years, have been caused by glacioeustatic, tectonic, sedimentologic, climatologic, and oceanographic factors. Sea level was about 100 to 130 m lower during the last glacial epoch (Figure IV-1-15), about 15,000 years before present. Ancient shorelines and deltas can be found at such depths along the edge of the continental shelf (Suter and Berryhill 1985). Changes of this magnitude have been recorded during other geological epochs (Payton 1977).

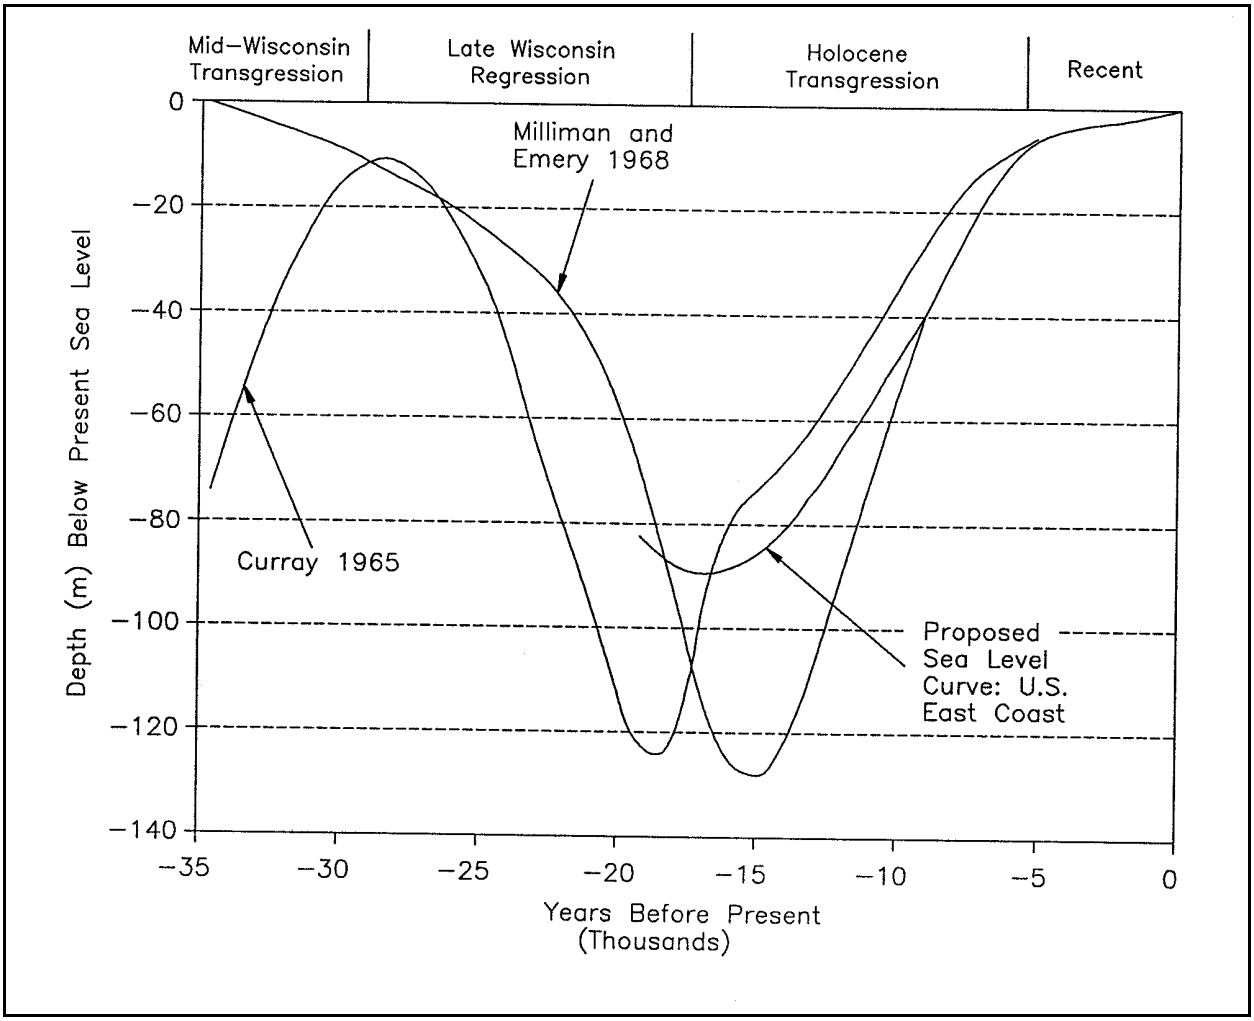

Figure IV-1-15. Sea level fluctuations during the Pleistocene and Holocene epochs (adapted from Nummedal (1983); data from Dillon and Oldale (1978))

(c) Table IV-1-5 lists long-term and short-term factors along with estimates of their effect on sea level. The following paragraphs discuss some factors in greater detail.

b. Short-term causes of sea level change.

(1) Seasonal sea level changes.

(a) The most common of the short-term variations is the seasonal cycle, which in most areas accounts for water level changes of 10 to 30 cm (and in some unusual cases - the Bay of Bengal - as much as 100 cm) (Komar and Enfield 1987). Seasonal effects are most noticeable near river mouths and estuaries. Variations in seasonal river flow may account for up to 21 percent of annual sea level variations in coastal waters (Meade and Emery 1971). Compared to the eustatic rise of sea level, estimated to be up to 20 cm/century, the seasonal factor may be a more important cause of coastal erosion because of its greater year-to-year influence (Komar and Enfield 1987).

(b) Over most of the world, lowest sea level occurs in spring and highest in autumn. Separating the individual factors causing the annual cycle is difficult because most of the driving mechanisms are coherent - occurring in phase with one another. Variations in atmospheric pressure drive most of the annual sea level change (Komar and Enfield 1987).

(2) West coast of North America.

(a) The west coast is subject to extreme and complicated water level variations. Short-term fluctuations are related to oceanographic conditions like the El Niño-Southern Oscillation. This phenomenon occurs periodically when equatorial trade winds in the southern Pacific diminish, causing a seiching effect that travels eastward as a wave of warm water. This raises water levels all along the U.S. west coast. Normally, the effect is only a few centimeters, but during the 1982-83 event, sea level rose 35 cm at Newport, Oregon (Komar 1992). Although these factors do not necessarily cause permanent geologic changes, engineers and coastal planners must consider their potential effects. The most recent El Niño event, during the winter of 1997-98, has been blamed for causing unusual weather in the western United States, including greatly increased rainfall in California and a warm winter in Oregon and Washington. Coastal geological changes caused by the El Niño are difficult to document. It has been argued (especially in the media) that increased rainfall in California caused more mudflows and bluff collapse than normal.

(b) Seasonal winter storms along the Pacific Northwest can combine with astronomical tides to produce elevated water levels over 3.6 m. During the severe storms of 1983, water levels were 60 cm over the predicted level.

(3) Rapid land level changes. Earthquakes are shock waves caused by abrupt movements of blocks of the earth's crust. A notable example occurred during the Great Alaskan Earthquake of 1964, when changes in shoreline elevations ranged from a 10-m uplift to a 2-m downdrop (Hicks 1972; Plafker and Kachadoorian 1966).

(4) Ocean temperature. Changes in the water temperature of upper ocean layers cause changes in water density and volume. As surface water cools, the density of seawater increases, causing a decrease in volume, thus lowering sea level. When temperature increases, the opposite reaction occurs. Variations in water temperature are not simply due to seasonal changes in solar radiation but are primarily caused by changes in offshore wind and current patterns.

Table IV-1-5
Sea Level Changes Along the Coastal Zone

Short-Term (Periodic) Causes	Time scale (P = period)	Vertical Effect[1]
Periodic Sea Level Changes		
Astronomical tides	6-12 hr P	0.2-10+ m
Long-period tides		
Rotational variations (Chandler effect)	14 month P	
Meteorological and Oceanographic Fluctuations		
Atmospheric pressure		
Winds (storm surges)	1-5 days	Up to 5 m
Evaporation and precipitation	Days to weeks	
Ocean surface topography (changes in water density and currents)	Days to weeks	Up to 1 m
El Niño/southern oscillation	6 mo every 5-10 yr	Up to 60 cm
Seasonal Variations		
Seasonal water balance among oceans (Atlantic, Pacific, Indian)		
Seasonal variations in slope of water surface		
River runoff/floods	2 months	1 m
Seasonal water density changes (temperature and salinity)	6 months	0.2 m
Seiches	Minutes-hours	Up to 2 m
Earthquakes		
Tsunamis (generate catastrophic long-period waves)	Hours	Up to 10 m
Abrupt change in land level	Minutes	Up to 10 m

Long-Term Causes	Range of Effect E = Eustatic; L = Local	Vertical Effect[1]
Change in Volume of Ocean Basins		
Plate tectonics and seafloor spreading (plate divergence/convergence) and change in seafloor elevation (mid-ocean volcanism)	E	0.01 mm/yr
Marine sedimentation	E	< 0.01 mm/yr
Change in Mass of Ocean Water		
Melting or accumulation of continental ice	E	10 mm/yr
Release of water from earth's interior	E	
Release or accumulation of continental hydrologic reservoirs	E	
Uplift or Subsidence of Earth's Surface (Isostasy)		
Thermal-isostasy (temperature/density changes in earth's interior)	L	
Glacio-isostasy (loading or unloading of ice)	L	1 cm/yr
Hydro-isostasy (loading or unloading of water)	L	
Volcano-isostasy (magmatic extrusions)	L	
Sediment-isostasy (deposition and erosion of sediments)	L	< 4 mm/yr
Tectonic Uplift/Subsidence		
Vertical and horizontal motions of crust (in response to fault motions)	L	1-3 mm/yr
Sediment Compaction		
Sediment compression into denser matrix	L	
Loss of interstitial fluids (withdrawal of groundwater or oil)	L	$\leq$ 55 mm/yr[1]
Earthquake-induced vibration	L	
Departure from Geoid		
Shifts in hydrosphere, aesthenosphere, core-mantle interface	L	
Shifts in earth's rotation, axis of spin, and precession of equinox	E	
External gravitational changes	E	

[1]Effects on sea level are estimates only. Many processes interact or occur simultaneously, and it is not possible to isolate the precise contribution to sea level of each factor. Estimates are not available for some factors. (Sources: Emery and Aubrey (1991); Gornitz and Lebedeff (1987); Komar and Enfield (1987))
[1] Calculated using Shanghai as an example: 2.7 m subsidence between 1920 and 1970 (Baeteman 1994)

(5) Ocean currents. Because of changes in water density across currents, the ocean surface slopes at right angles to the direction of current flow. The result is an increase in height on the right side of the current (when viewed in the direction of flow) in the Northern Hemisphere and to the left in the Southern Hemisphere. The elevation change across the Gulf Stream, for example, exceeds 1 m (Emery and Aubrey 1991). In addition, major currents in coastal areas can produce upwelling, a process that causes deep colder water to move upward, replacing warmer surface waters. The colder upwelled water is denser, resulting in a regional decrease in sea level.

c. Long-term causes of sea level change.

(1) Tectonic instability. Regional, slow land level changes along the U.S. western continental margin affect relative long-term sea level changes. Parts of the coast are rising and falling at different rates. In Oregon, the northern coast is falling while the southern part is rising relative to concurrent relative sea level (Komar 1992).

(2) Isostacy. *Isostatic adjustment* is the process by which the crust of the Earth attains gravitational equilibrium with respect to superimposed forces (Emery and Aubrey 1991). If a gravitational imbalance occurs, the crust rises or sinks to correct the imbalance.

(a) The most widespread geologically rapid isostatic adjustment is the depression of land masses caused by glaciers and the rebounding caused by deglaciation. In Alaska and Scandinavia, contemporary uplift follows the depression of the crust caused by the Pleistocene ice sheets. Some areas of the Alaska coast (for example, Juneau) are rising over 1 cm/year, based on tide gauge records (Figure IV-1-16) (Lyles, Hickman, and Debaugh 1988).

(b) Isostatic adjustments have also occurred due to changes in sediment load on continental shelves and at deltas. The amount of sediment loading on shelves is not well determined but is probably about 4 mm/year. The effect is only likely to be important at deltas where the sedimentation rate is very high (Emery and Aubrey 1991).

(3) Sediment compaction.

(a) Compaction occurs when poorly packed sediments reorient into a more dense matrix. Compaction can occur because of vertical loading from other sediments, by draining of fluids from the sediment pore space (usually a man-made effect), by desiccation (drying), and by vibration.

(b) Groundwater and hydrocarbon withdrawal is probably the main cause of sediment compaction on a regional scale. Many of the world's great cities are located on coastal plains or on river mouth deltas. Because of the dense population and industrialization, vast quantities of groundwater have been pumped from the subsurface aquifers. The consequence is nearly instantaneous local land subsidence due to sediment compaction, transforming many of these great coastal cities into the sinking cities of the world (Baeteman 1994; see Table IV-1-6). Subsidence exceeding 8 m has been recorded in Long Beach, California, and over 6 m in the Houston-Freeport area (Emery and Aubrey 1991). In Galveston, the annual sea level rise shown on tide records is 0.6 cm/year (Figure IV-1-17) (Lyles, Hickman, and Debaugh 1988). Subsidence at Venice, Italy, caused by groundwater pumping, has been well-publicized because of the threat to architectural and art treasures. Fortunately, subsidence there appears to have been controlled now that alternate sources of water are being tapped for industrial and urban use (Emery and Aubrey 1991).

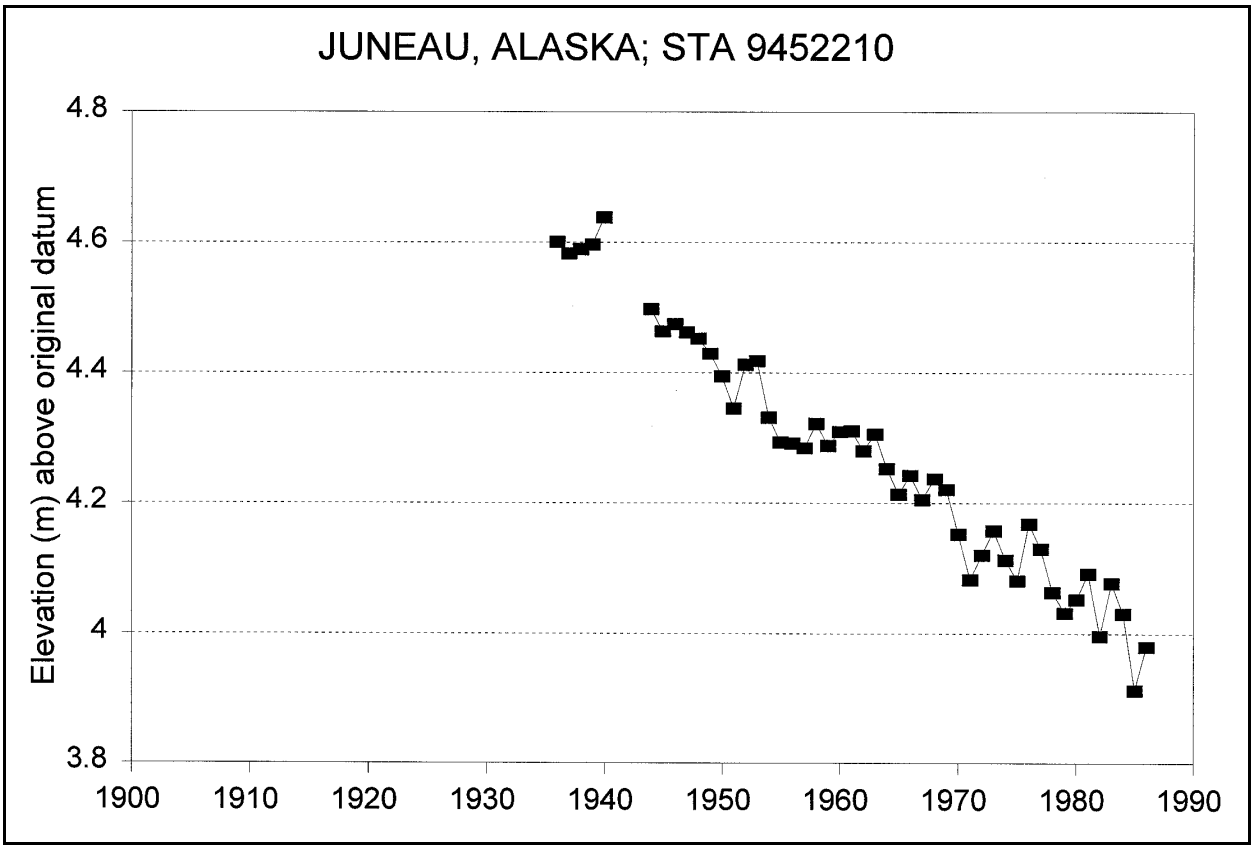

Figure IV-1-16. Yearly mean sea level changes at Juneau, Alaska, from 1936-1986. The fall in sea level shows the effects of isostatic rebound (data from Lyles, Hickman, and Debaugh (1988))

Table IV-1-6
Major World Cities with Recorded Subsidence[1]

City or Region and Country	Subsidence (m)
Tokyo, Japan	4.6
Po Delta, Italy	3.2
Shanghai, China	2.7
Houston, USA	2.7
Tianjin, China	2.5
SW Taiwan	2.4
Taipei, Taiwan	1.9
Bangkok, Thailand	1.6
Ravenna, Italy	1.2
London, England	0.35

[1] Records are not available for many other big cities (e.g., Jakarta, Hanoi, Haiphong, Rangoon, Manila).
From Baeteman (1994)

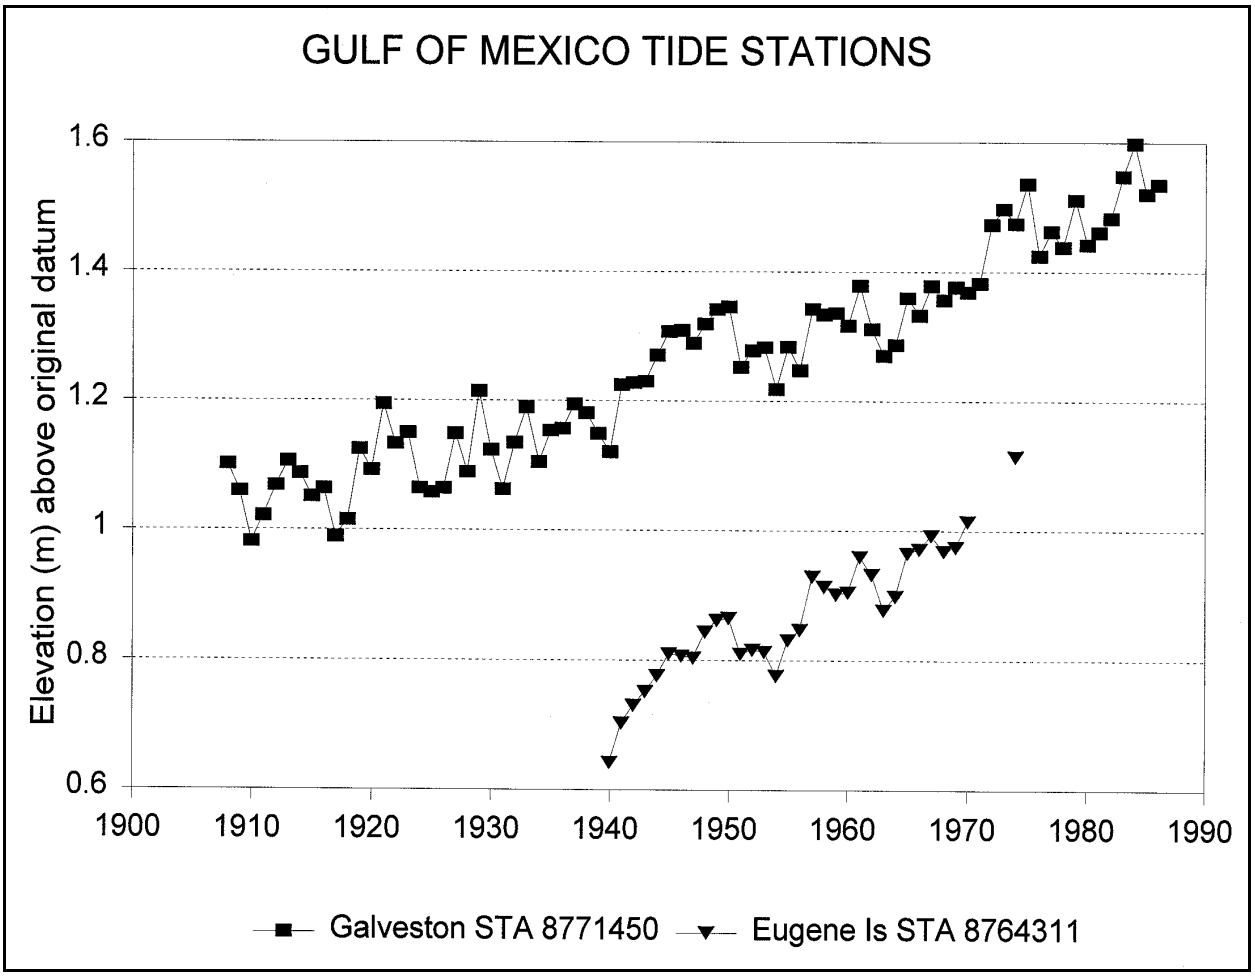

Figure IV-1-17. Yearly mean sea level changes at Galveston, Texas, and Eugene Island, Louisiana. Subsidence of the land around Galveston may be caused by groundwater withdrawal and sediment compaction (data from Lyles, Hickman, and Debaugh (1988))

(c) Significant subsidence occurs in and near deltas, where great volumes of fine-grained sediment accumulate rapidly. Land loss in the Mississippi delta has become a critical issue in recent years because of the loss of wetlands and rapid shoreline retreat. Along with natural compaction of underconsolidated deltaic muds and silts, groundwater and hydrocarbon withdrawal and river diversion might be factors contributing to the subsidence problems in southern Louisiana. Tide gauges at Eugene Island and Bayou Rigaud show that the rate of subsidence has increased since 1960 (Emery and Aubrey 1991). Change in rsl in the Mississippi Delta is about 15 mm/year, while the rate at New Orleans is almost 20 mm/year (data cited in Frihy (1992)).

d. Geologic implications of sea level change.

(1) Balance of sediment supply versus sea level change. Changes in sea level will have different effects on various portions of the world's coastlines, depending on conditions such as sediment type, sediment supply, coastal planform, and regional tectonics. The shoreline position in any one locale responds to the cumulative effects of the various sea level effects (outlined in Table IV-1-7). For simplicity, these factors can be subdivided into two broad categories: sediment supply and relative sea level (rsl) change. Ultimately, shoreline position is a balance between sediment availability and the rate that sea level changes

Table IV-1-7
Relative Effects of Sediment Supply Versus Sea Level Change on Shoreline Position[1]

		Relative Sea Level Change				
		Falling sea level		Stable	Rising sea level	
		Rapid	Slow		Slow	Rapid
Sediment supply	**Rapid net loss**	Neutral	Slow retreat	Medium retreat	Rapid retreat[4]	Extra rapid retreat[2]
	Slow net loss	Slow advance	Neutral	Slow retreat	Medium retreat[6]	Rapid retreat
	Zero net change	Medium advance	Slow advance	Neutral[8]	Slow retreat[9]	Medium retreat
	Low net deposition	Rapid advance	Medium advance[10]	Slow advance[7]	Neutral[3,5]	Slow retreat
	Rapid net deposition	Extra rapid advance	Rapid advance[11]	Medium advance	Slow advance[1]	Neutral

Examples of long-term (years) transgression or regression:

1. Mississippi River Delta - active distributary
2. Mississippi River Delta - abandoned distributary
3. Florida Panhandle between Pensacola and Panama City
4. Sargent Beach, TX
5. Field Research Facility, Duck, NC
6. New Jersey shore
7. Island of Hawaii - volcanic and coral sediment supply
8. Hawaiian Islands without presently active volcanoes
9. South shore of Long Island (sand trapped at inlets is balanced by man-made renourishment and bypassing)
10. Great Lakes during sustained fall in water levels
11. Alaska river mouths

[1] (Table based on a figure in Curray (1964))

(Table IV-1-7). For example, at an abandoned distributary of the Mississippi River delta, rsl is rising rapidly because of compaction of deltaic sediment. Simultaneously, wave action causes rapid erosion. The net result is extra rapid shoreline retreat (the upper right box in Table IV-1-7). The examples in the table are broad generalizations, and some sites may not fit the model because of unique local conditions.

(2) Historical trends. Historical records show the prevalence of shore recession around the United States during the past century (summarized by the National Research Council (1987):

(a) National average (unweighted) erosion rate: 0.4 m/year.

(b) Atlantic Coast: 0.8 m/year (with Virginia barrier islands exhibiting the highest erosion rates).

(c) Gulf Coast: 1.8 m/year (with highest erosion rate in Louisiana, 4.2 m/year).

(d) Pacific coastline: essentially stable (although more than half the shore is hard rock).

Bird (1976) claims that most sandy shorelines around the world have retreated during the past century. However, prograding shores are found where rivers supply excess sediment or where tectonic uplift is in progress.

(3) Specific coastal sites.

(a) Sandy (barrier) coasts. Several models predicting the effects of sea level rise on sandy coasts have been proposed. One commonly cited model is the Bruun rule. The Bruun rule and barrier migration models are discussed in Part IV-2.

(b) Cliff retreat. Cliff retreat is a significant problem in the Great Lakes, along the Pacific coast, and in parts of New England and New York. Increases in water level are likely to accelerate the erosion rate along Great Lakes shores (as shown by Hands (1983) for eastern Lake Michigan). However, along southern California, cliff retreat may be episodic, caused by unusually severe winter storms, groundwater and surface runoff, and, possibly, faulting and earthquakes, factors not particularly influenced by sea level (Kuhn and Shepard 1984). Crystalline cliffs are essentially stable because their response time is so much slower than that of sandy shores. Mechanisms of cliff erosion are discussed in Part IV-2.

(c) Marshes and wetlands. Marshes and mangrove forests fringe or back most of the Gulf and Atlantic coastlines. Marshes have the unique ability to grow upward in response to rising sea level. However, although marshes produce organic sediment, at high rates of rsl rise, additional sediment from outside sources is necessary to allow the marshes to keep pace with the rising sea. Salt marshes are described in Part IV-2-11. Paragraph IV-2-12 describes wetlands, coral and oyster reefs, and mangrove forest coasts. These shores have the natural ability to adjust to changing sea level as long as they are not damaged by man-made factors like urban runoff or major changes in sediment supply.

e. Engineering and social implications of sea level change.

(1) Eustatic sea level rise.

(a) Before engineering and management can be considered, a fundamental question must be asked: Is sea level still rising? During the last decade, the media has “discovered” global warming, and many politicians and members of the public are convinced that greenhouse gases are responsible for rising sea level and the increased frequency of flooding that occurs along the coast during storms. Most scientists accept the findings that the concentrations of greenhouse gasses in the atmosphere have increased greatly in the last century, largely due to industrial and automobile emissions. However, the link between increased gas in the atmosphere and changing sea level is much more difficult to model and verify. Wunsch (1996) has pointed out how difficult it is to separate myth from fact in the politically and emotionally charged issues of climate change and the oceans. The Environmental Protection Agency created a sensation in 1983 when it published a report linking atmospheric carbon dioxide to a predicted sea level rise of between 0.6 and 3.5 m (Hoffman, Keyes, and Titus 1983). Since then, predictions of the eustatic rise have been falling, and some recent evidence suggests that the rate may slow or even that eustatic sea level may drop in the future (Houston 1993).

(b) Possibly more reliable information on Holocene sea level changes can be derived from archaeological sites, wave-cut terraces, or organic material. For example, Stone and Morgan (1993) calculated an average rise of 2.4 mm/year from radiocarbon-dated peat samples from Santa Rosa Island, on the tectonically stable Florida Gulf coast. However, Tanner (1989) states that difficulties arise using all of these methods, and that calculated dates and rates may not be directly comparable.

(c) Based on an exhaustive study of tide records from around the world, Emery and Aubrey (1991) have concluded that it is not possible to assess if a *eustatic* rise is continuing because, while many gauges do record a recent rise in *relative* sea level, an equal number record a fall. Emery and Aubrey state (p. ix):

> In essence, we have concluded that 'noise' in the records produced by tectonic movements and both meteorological and oceanographic factors so obscures any signal of eustatic rise of sea level that the tide gauge records are more useful for learning about plate tectonics than about effects of the greenhouse heating of the atmosphere, glaciers, and ocean water.

They also state (p. 176):

> This conclusion should be no surprise to geologists, but it may be unexpected by those climatologists and laymen who have been biased too strongly by the public's perception of the greenhouse effect on the environment....Most coastal instability can be attributed to tectonism and documented human activities without invoking the spectre of greenhouse-warming climate or collapse of continental ice sheets.

(d) In summary, despite the research and attention devoted to the topic, the evidence about worldwide, eustatic sea level rise is inconclusive. Estimates of the rate of rise range from 0 to 3 mm/year, but some researchers maintain that it is not possible to discover a statistically reliable rate using tide gauge records. In late Holocene time, sea level history was much more complicated than has generally been supposed (Tanner 1989), suggesting that there are many perturbations superimposed on “average” sea level curves. Regardless, the topic is sure to remain highly controversial.

(2) Relative sea level (rsl) changes.

(a) The National Research Council's Committee on Engineering Implications of Changes in Relative Sea Level (National Research Council 1987) examined the evidence on sea level changes. They concluded that rsl, on statistical average, is rising at most tide gauge stations located on continental coasts around the world. In their executive summary, they concluded (p. 123):

> The risk of accelerated mean sea level rise is sufficiently established to warrant consideration in the planning and design of coastal facilities. Although there is substantial local variability and statistical uncertainty, average relative sea level over the past century appears to have risen about 30 cm relative to the East Coast of the United States and 11 cm along the West Coast, excluding Alaska, where glacial rebound has resulted in a lowering of relative sea level. Rates of relative sea level rise along the Gulf coast are highly variable, ranging from a high of more than 100 cm/century in parts of the Mississippi delta plain to a low of less than 20 cm/century along Florida's west coast.

However, they, too, noted the impact of management practices:

> Accelerated sea level rise would clearly contribute toward a tendency for exacerbated beach erosion. However, in some areas, anthropogenic effects, particularly in the form of poor sand management practices at channel entrances, constructed or modified for navigational purposes, have resulted in augmented erosion rates that are clearly much greater than would naturally occur. Thus, for some years into the future, sea level rise may play a secondary role in these areas.

(b) Figure IV-1-18 is a summary of estimates of local rsl changes along the U.S. coast (National Research Council 1987). Users of this map are cautioned that the values are based on tide records only from

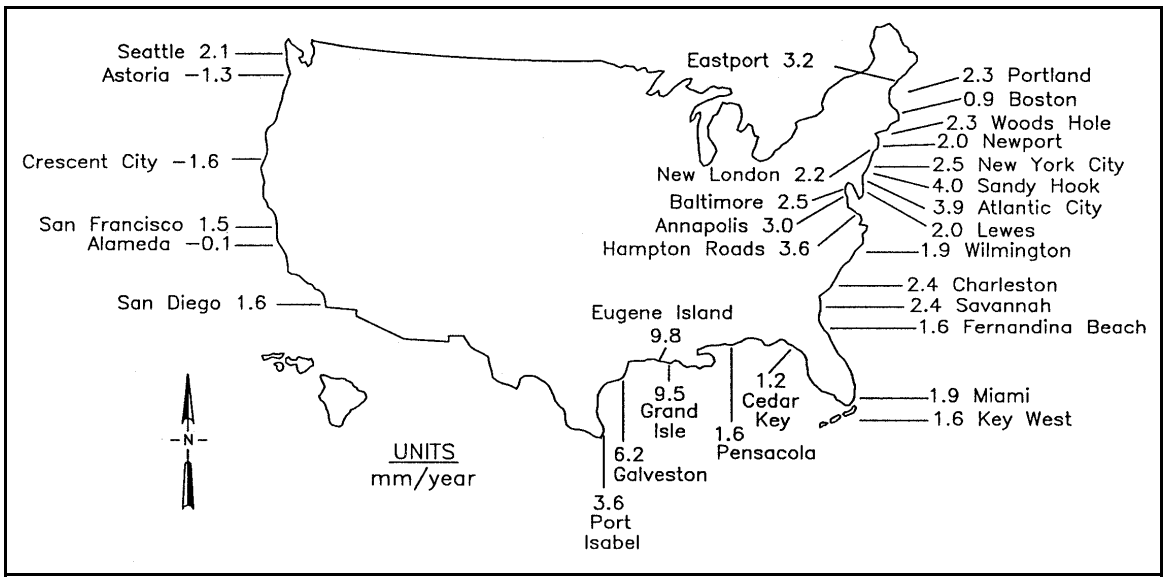

Figure IV-1-18. Summary of estimates of local rsl rise along the continental United States in millimeters per year. Values are based on tide gauge records during the period 1940-1980 (from National Research Council (1987))

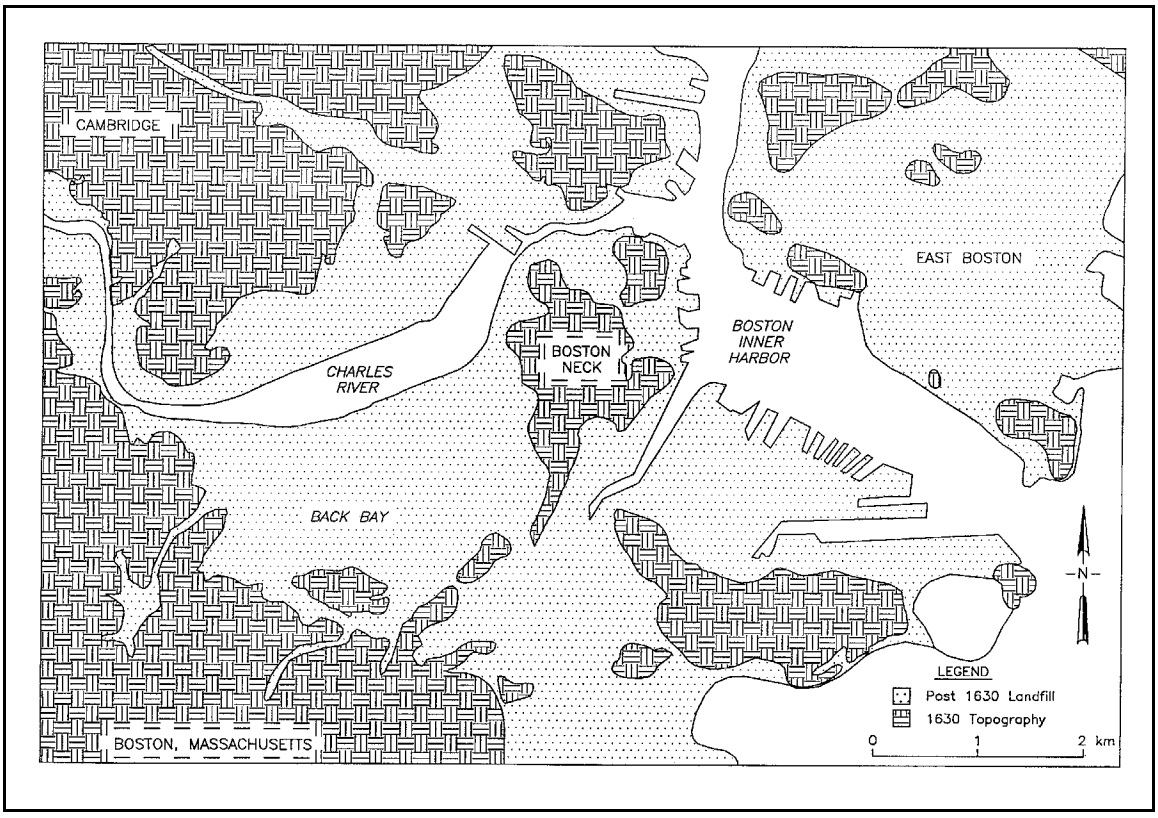

Figure IV-1-19. Landfilling in Boston, MA, since 1630 has more than doubled the urban area (unfortunately, at the expense of destroying what must have been highly productive wetlands) (from Rosen, Brenninkmeyer, and Maybury (1993))

1940-1980 and that much regional variability is evident. The figure provides general information only; for project use, detailed data should be consulted, such as the tide gauge statistics printed in Lyles, Hickman and Debaugh (1988) (examples of three tide stations are plotted in Figures IV-1-16 and IV-1-17) or the statistics available from the NOAA web site.

(3) Engineering response and policy.

(a) Whatever the academic arguments about eustatic sea level, engineers and planners must anticipate that changes in rsl may occur in their project areas and need to incorporate the anticipated changes in their designs and management plans.

(b) Because of the uncertainties surrounding sea level, the U.S. Army Corps of Engineers (USACE) has not endorsed a particular rise (or fall) scenario. Engineer Regulation (ER) 1105-2-100 (28 December 1990) states the official USACE policy on sea level rise. It directs that:

> Feasibility studies should consider which designs are most appropriate for a range of possible future rates of rise. Strategies that would be appropriate for the entire range of uncertainty should receive preference over those that would be optimal for a particular rate of rise but unsuccessful for other possible outcomes.

Potential rsl rise should be considered in every coastal and estuarine (as far inland as the new head of tide) feasibility study that USACE undertakes. Project planning should consider what impact a higher rsl rise would have on designs based on local, historical rates.

(4) Impacts of rising sea level on human populations.

(a) Rising sea level raises the spectre of inundated cities, lost wetlands, and expensive reconstruction of waterways and ports. About 50 percent of the U.S. population lives in coastal counties (1980 census data reported in Emery and Aubrey (1991)), and the number is likely to increase. There has not been a long history of understanding and planning for sea level rise in the United States, but other countries, particularly Holland and China, have coped with the problem for thousands of years (National Research Council 1987). There are three principal ways that people could adapt to rising sea level:

- Retreat and abandonment.
- Armoring by erecting dikes and dams to keep out the sea.
- Construction on landfills and piers.

(b) Among the areas most susceptible to inundation caused by rise in rsl are deltas. Deltas are naturally sinking accumulations of sediment whose subaerial surface is a low-profile, marshy plain. Already, under present conditions, subsidence imposes especially severe hardships on the inhabitants in coastal Bangladesh (10 mm/year) and the Nile Delta (2 mm/year), two of the most densely populated regions on earth (Emery and Aubrey 1991). Even a slow rise in sea level could have devastating effects. How could these areas be protected? Thousands of kilometers of seawalls would be needed to protect a broad area like coastal Bangladesh from the sea and from freshwater rivers. Civil works projects on this scale seem unlikely in developing countries, suggesting that retreat will be the only recourse (National Research Council 1983). Nevertheless, despite the immense cost of large-scale coastal works, the Netherlands has reclaimed from the sea a large acreage of land, which is now used for towns and agriculture.

(c) Retreat can be either a gradual (planned or unplanned) process, or a catastrophic abandonment (National Research Council 1987). The latter has occurred in communities where buildings were not allowed to be rebuilt after they were destroyed or damaged by storms. The State of Texas followed this approach on Galveston Island after Hurricane Alicia in 1983 and the State of Rhode Island for some south shore communities after the Great New England Hurricane of 1938. Construction setback lines represent a form of controlled retreat. Seaward of setback lines, new construction is prohibited. City managers and coastal planners often have difficulty in deciding where setback lines should be located, and their decisions are bitterly contested by property developers who wish to build as close to the beach as possible.

(d) Most of the world's coastal cities are subject to inundation with even a modest rise of sea level. In 1990, of the 15 biggest "megacities" (population > 10 million, such as Tokyo, Shanghai, Buenos Aires, and Calcutta) 12 were in coastal areas (Young and Hale 1998). Unfortunately, 25 to 50 percent of these urban populations live in poverty, a situation that makes coastal management and planning for changing sea level very difficult. Nevertheless, irresistible political pressure will surely develop to defend cities against the rising sea because of the high concentration of valuable real estate and capital assets. Defense will most probably take the form of dikes like the ones that protect large portions of Holland and areas near Tokyo and Osaka, Japan, from flooding. Dikes would be needed to protect low-lying inland cities from rivers whose lower courses would rise at the same rate as the sea. Already, New Orleans (which is below sea level), Rotterdam, and other major cities located near river mouths are kept dry by levees. These levees might have to be raised under the scenario of rising sea level. Storm surge barriers, like the ones at New Bedford, Massachusetts, Providence, Rhode Island, and the Thames, below London, England, might have to be rebuilt to maintain an adequate factor of safety.

(e) Landfilling has historically been a common practice, and many coastal cities are partly built on landfill. Boston's waterfront, including the airport and the Back Bay, is built on 1800's fill (Figure IV-1-19; Whitehill 1968). Large areas around New York City, including parts of Manhattan and Brooklyn, have been filled since the 1600's (Leveson 1980). Venice, one of the world's great architectural treasures, occupies a cluster of low islands in the lagoon of Venice, at the head of the Adriatic Sea. In the early 1700's, Peter the Great built his monumental new capital of Saint Petersburg on pilings and fill in the estuary of the Neva River. Artificial land, which is usually low, is particularly susceptible to rising sea level. Although dikes and levees will probably be the most common means to protect cities threatened by the rising sea, there is a precedent in the United States for raising the level of the land surface where structures already exist: Seattle's downtown was raised about 3 m in the early 1900's to prevent tidal flooding. The elevated streets ran along the second floor of buildings, and the original sidewalks and store fronts remained one floor down at the bottom of open troughs. Eventually, the open sidewalks had to be covered or filled because too many pedestrians and horses were injured in falls.

f. Changes in sea level - summary.

(1) Changes in sea level are caused by numerous physical processes, including tectonic forces that affect land levels and seasonal oceanographic factors that influence water levels on various cycles (Table IV-1-5). Individual contributions of many of these factors are still unknown.

(2) Estimates of the eustatic rise in sea level range from 0 to 3 mm/year. Emery and Aubrey (1991) have strongly concluded that it is not possible to detect a statistically verifiable rate of eustatic sea level rise because of noise in the signals and because of the poor distribution of tide gauges worldwide.

(3) Arguments regarding eustatic sea level changes may be more academic than they are pertinent to specific projects. The rate of *relative* sea level change varies greatly around the United States. Coastal planners need to consult local tide gauge records to evaluate the potential movement of sea level in their project areas.

(4) In many areas, coastal management (mismanagement) practices have the greatest influence on erosion, and sea level changes are a secondary effect (Emery and Aubrey 1991; National Research Council 1987).

(5) USACE does not endorse a particular sea level rise (or fall) scenario. ER 1105-2-100 (28 December 1990) directs that feasibility studies must consider a range of possible future rates of sea level rise. Project planning should use local, historical rates of rsl change.

IV-1-7. Cultural (Man-Made) Influences on Coastal Geology

a. Introduction. Man has modified many of the world's coastlines, either directly, by construction or dredging, or indirectly, as a result of environmental changes that influence sediment supply, runoff, or climate. Human activity has had the most profound effects on the coastal environment in the United States and the other industrial nations, but even shorelines in lesser-developed countries have not been immune to problems wrought by river diversion and loss of wetlands. The most common practices that significantly alter the coastal environment are the construction of coastal works such as jetties and groins and the development of property on and immediately inland of the beach. Historically, many cities have developed on the coast. Although originally most were located in bays or other protected anchorages, many have grown and spread to the open coast. Prominent United States examples include New York, Boston, San Diego, and Los Angeles. Still other communities originally began as resorts on barrier islands and have since grown into full-size cities; examples include Atlantic City, Ocean City, Virginia Beach, and Miami Beach. Land use practices well inland from the coast also often have important effects on coastal sedimentation. These factors are more difficult to detect and analyze because, sometimes, the affecting region is hundreds of kilometers inland. For example, dam construction can greatly reduce the natural supply of sediment brought to the coast by streams and rivers, while deforestation and agricultural runoff may lead to increased sediment load in rivers.

b. Dams/Reservoirs. In many coastal areas, the major source of sediment for the littoral system is from streams and rivers. Dams and reservoirs obstruct the transport of sediment to the littoral system by creating sediment traps. These structures also restrict peak flows, which reduce sediment transport of material that is available downstream of the structures. The net effect is sediment starvation of coastal areas that previously received riverine sediment. If the losses are not offset by new supplies, the results are shrinking beaches and coastal erosion (Schwartz 1982). The most prominent example is the accelerated erosion of the Nile Delta that has occurred since the Aswan Low Dam (1902) and the Aswan High Dam (1964) almost totally blocked the supply of sediment to the coast (Frihy 1992). The Rosetta promontory has been eroding at an average rate of 55 m/year between 1909 and the present. Loss of nutrient-laden silt from the Nile's annual spring floods has also had bad effects on agriculture in the Nile valley and delta and has damaged fisheries in the eastern Mediterranean. Portions of the southern California coast have also suffered this century from loss of fluvially supplied sediment (e.g., Point Arguello, cited by Bowen and Inman (1966)). Increased erosion of the Washington shore near Grays Harbor may be due to the loss of sediment from the Columbia River, which has been massively dammed since the 1930's and 1940's.

c. Erosion control and coastal structures. Coastal structures such as jetties, groins, seawalls, bulkheads, and revetments are probably the most dramatic cause of man-induced coastal erosion (*Shore Protection Manual* 1984). Any coastal structure will have some effect on local sediment dynamics, and in some cases, the effect may extend downdrift for many kilometers.

d. Modification of natural protection.

(1) Destructive effects. The destruction of dunes and beach vegetation, development of backshore areas, and construction on the back sides of barrier islands can increase the occurrence of overwash during storms. In many places, sand supply has diminished because much of the surface area of barriers has been paved and covered with buildings. The result has been backshore erosion and increased barrier island breaching. In most coastal areas of the United States, one need merely visit the local beaches to see examples of gross and callous coastal development where natural protection has been compromised. Carter (1988) reviews examples from the United Kingdom. Serious damage has occurred to biological shores around the world as a result of changes in runoff and sediment supply, increased pollution, and development.

(2) Constructive efforts. Sand dunes are often stabilized using vegetation and sand fences. Dunes afford protection against flooding of low-lying areas. Dunes are also stabilized to prevent sand from blowing over roads and farms. Dunes are discussed in Part IV-2-6.

e. Beach renourishment (fill). An alternative for restoring beaches without constructing groins or other hard structures is to bring sand to the site from offshore by dredges or from inland sources by truck. This is the only coastal management that actually adds sand back into the littoral system (Pope 1997). Although conceptually renourishment seems simple enough, in practice, the planning, design, application, and maintenance of beach renourishment projects are sophisticated engineering and geologic procedures. For design and monitoring information, the reader is referred to Part V-4, Tait (1993), and Stauble and Kraus (1993). *Shore and Beach,* Vol 61, No. 1 (January 1993) is a special issue devoted to the beach renourishment project at Ocean City, Maryland. Stauble et al. (1993) evaluate the Ocean City project in detail. Krumbein (1957) is a classic description of sediment analysis procedures for specifying beach fills. One of the most successful U.S. renourishment projects has been at Miami Beach, Florida (reviewed in Carter (1988)).

f. Mining.

(1) Beach mining can directly reduce the amount of sediment available to the littoral system. In most areas of the United States, beach sand can no longer be exploited for commercial purposes because sand is in short supply, and the health of dunes and biological communities depends vitally on the availability of sand. Strip mining can indirectly affect the coast due to increased erosion, which increases sediment carried to the sea by rivers (unless the sediment is trapped behind dams).

(2) In Britain, an unusual situation developed at Horden, County Durham, where colliery waste was dumped on the shore. The waste material formed a depositional bulge in the shore. As the sediment from Horden moved downcoast, it was sorted, with the less dense coal forming a surface placer on the beach that is commercially valuable (Carter 1988).

g. Stream diversion.

(1) Stream diversion, both natural and man-made, disrupts the natural sediment supply to areas that normally receive fluvial material. With diversion for agriculture or urban use, the results are similar to those produced by dams: sediment that normally would be carried to the coast remains trapped upriver. Its residence time in this artificial storage, decades or centuries, may be short on geological time scales but is long enough to leave a delta exposed to significant erosion.

(2) Natural diversion occurs when a river shifts to a new, shorter channel to the sea, abandoning its less efficient former channel. An example of this process is the gradual occupation of the Atchafalaya watershed by the Mississippi River. If this process were to continue to its natural conclusion, the present Balize ("Birdfoot") delta would be abandoned, causing it to erode at an ever faster rate, while a new delta

would form in Atchafalaya Bay (Coleman 1988). The evolution of the Mississippi River is discussed in Part IV-3-3.

h. Agriculture. Poor farming practices lead to exposure of farmlands and increased erosion rates. Eroded soil is easily carried away by streams and rivers and is ultimately deposited in estuaries and offshore. The consequence of this process is progradation of the depositional areas. If rivers have been dammed, the sediment load is trapped behind the dams in the artificial lakes, and in that case does not get carried to the open sea.

i. Forestry. Deforestation is a critical problem in many developing nations, where mountainsides, stripped of their protective trees, erode rapidly. The soil is carried to the sea, where local coastlines prograde temporarily, but upland areas are left bereft of invaluable topsoil, resulting in human poverty and misery and in the loss of animal habitat. Reckless slash-and-burn practices have destroyed many formerly valuable timber resources in Central America, and some southeast Asian countries have already cut down most of their trees (Pennant-Rea 1994). Fortunately, Malaysia and Indonesia are beginning to curb illegal timber cutting and export, a trend which hopefully will spread to other countries. Unfortunately, the financial turmoil that engulfed Asia in 1998 will probably set back efforts to promote responsible resource management.

Chapter IV-2
Coastal Classification and Morphology

IV-2-1. Introduction

a. Since ancient times, men have gone to sea in a variety of vessels to obtain food and to transport cargo and passengers to distant ports. To navigate safely, sailors needed an intimate knowledge of the appearance of the coast from place to place. By the time that systematic study of coastal geology and geomorphology began, there already existed a large body of observational knowledge about seacoasts in many parts of the world and a well-developed nomenclature to portray coastal landforms. Geologists in the 19th and 20th centuries described coastal landforms, examined their origin and development as a function of geologic character, history, and dynamic processes, and devised classification schemes to organize and refine their observations.

b. The first part of this chapter discusses the coastal classification of Francis Shepard (1973). The second part describes specific coastal environments found around the United States following Shepard's outline.

IV-2-2. Coastal Classification

a. Introduction. By its very nature, the coast is an incredibly complex and diverse environment, one that may defy organization into neat compartments. Nevertheless, the quest for understanding how shorelines formed and how human activities affect these processes has demanded that classification schemes be devised. Most have grouped coastal areas into classes that have similar features because of having developed in similar geological and environmental settings.

b. Early classifications. Many early geologists took a genetic approach to classification and distinguished whether the coast had been primarily affected by rising sea level (submergence), falling sea level (emergence), or both (compound coasts) (Dana 1849; Davis 1896a; Gulliver 1899; Johnson 1919; Suess 1888).

c. Later classifications. The best known of the modern classifications are those of Cotton (1952), Inman and Nordstrom (1971), Shepard (1937), with revisions in 1948, 1971 (with Harold Wanless), 1973, and 1976, and Valentin (1952). Except for Inman and Nordstrom (1971), these classifications emphasized onshore and shoreline morphology but did not include conditions of the offshore bottom. This may be a major omission because the submarine shoreface and the shelf are part of the coastal zone. Surprisingly few attempts have been made to classify the continental shelf. Shepard (1948; 1977) and King (1972) discussed continental shelf types, but their classifications are not detailed and contain only a few broadly defined types.

d. Coastal classification of Francis Shepard. Possibly the most widely used coastal classification scheme is the one introduced by Shepard in 1937 and modified in later years. It divides the world's coasts into primary coasts - formed mostly by non-marine agents - and secondary coasts - shaped primarily by marine processes. Further subdivisions occur according to which specific agent, terrestrial or marine, had the greatest influence on coastal development. The advantage of Shepard's classification is that it is more detailed than others, allowing most of the world's coasts to be incorporated. Although gradational shore types exist, which are difficult to classify, most coasts show only one dominant influence as the cause of their major characteristics (Shepard 1973). Because of its overall usefulness, Shepard's 1973 classification is reproduced in Table IV-2-1. Specific coasts are discussed in detail in this chapter, approximately following the outline of Shepard's table.

Table IV-2-1
Classification of Coasts (Continued)

Excerpt from SUBMARINE GEOLOGY, 3rd ed. by Francis P. Shepard. Copyright 1948, 1963, 1973 by Francis P. Shepard. Reprinted by permission of Harper Collins Publishers.	Paragraph No.
I. *Primary coasts* Configuration due to nonmarine processes.	
A. *Land erosion coasts* Shaped by subaerial erosion and partly drowned by postglacial rise of sea level (with or without crustal sinking) or inundated by melting of an ice mass from a coastal valley.	
1. *Ria coasts (drowned river valleys)* Usually recognized by the relatively shallow water of the estuaries which indent the land. Commonly have V-shaped cross section and a deepening of the axis seaward except where a barrier has built across the estuary mouth.	IV-2-3
2. *Dendritic* Pattern resembling an oak leaf due to river erosion in horizontal beds or homogeneous material.	
3. *Trellis* Due to river erosion in inclined beds of unequal hardness.	
(a) *Drowned glacial erosion coasts* Recognized by being deeply indented with many islands. Charts show deep water (commonly more than 100 m) with a U-shaped cross section of the bays and with much greater depth in the inner bays than near the entrance. Hanging valleys and sides usually parallel and relatively straight, in contrast to the sinuous rias. Almost all glaciated coasts have bays with these characteristics.	IV-2-4
(b) *Fjord coasts* Comparatively narrow inlets cutting through mountainous coasts.	
(c) *Glacial troughs* Broad indentations, like Cabot Strait and the Gulf of St. Lawrence or the Strait of Juan de Fuca.	
4. *Drowned karst topography* Embayments with oval-shaped depressions indicative of drowned sinkholes. This uncommon type occurs locally, as along the west side of Florida north of Tarpon Springs, the east side of the Adriatic, and along the Asturias coast of North Spain.	
B. *Subaerial deposition coasts*	IV-3-3
1. *River deposition coasts* Largely due to deposition by rivers extending the shoreline since the slowing of the postglacial sea level rise.	
2. *Deltaic coasts*	
(a) *Digitate (birdfoot),* the lower Mississippi Delta.	
(b) *Lobate,* western Mississippi Delta, Rhone Delta.	
(c) *Arcuate,* Nile Delta.	
(d) *Cuspate,* Tiber Delta.	
(e) *Partly drowned deltas* with remnant natural levees forming islands.	
3. *Compound delta coasts* Where a series of deltas have built forward a large segment of the coast, for example, the North Slope of Alaska extending east of Point Barrow to the Mackenzie.	
4. *Compound alluvial fan coasts straightened by wave erosion*.	
5. *Glacial deposition coasts*	
(a) *Partially submerged moraines* Usually difficult to recognize without a field study to indicate the glacial origin of the sediments constituting the coastal area. Usually modified by marine erosion and deposition as, for example, Long Island.	
(b) *Partially submerged drumlins* Recognized on topographic maps by the elliptical contours on land and islands with oval shorelines, for example, Boston Harbor and West Ireland (Guilcher 1965).	
(c) *Partially submerged drift features*	IV-2-6
6. *Wind deposition coasts* It is usually difficult to ascertain if a coast has actually been built forward by wind deposition, but many coasts consist of dunes with only a narrow bordering sand beach.	
(a) *Dune prograded coasts* Where the steep lee slope of the dune has transgressed over the beach.	
(b) *Dune coasts* Where dunes are bordered by a beach.	
(c) *Fossil dune coasts* Where consolidated dunes (eolianites) form coastal cliffs.	
7. *Landslide coasts* Recognized by the bulging earth masses at the coast and the landslide topography on land.	
C. *Volcanic coasts*	IV-2-7
1. *Lava-flow coasts* Recognized on charts either by land contours showing cones, by convexities of shoreline, or by conical slopes continuing from land out under the water. Slopes of 10° to 30° common above and below sea level. Found on many oceanic islands.	
2. *Tephra coasts* Where the volcanic products are fragmental. Roughly convex but much more quickly modified by wave erosion than are lava-flow coasts.	
3. *Volcanic collapse or explosion coasts* Recognized in aerial photos and on charts by the concavities in the sides of volcanoes.	
D. *Shaped by diastrophic movements*	
1. *Fault coasts* Recognized on charts by the continuation of relatively straight steep land slopes beneath the sea. Angular breaks at top and bottom of slope.	
(a) *Fault scarp coasts* For example, northeast side of San Clemente Island, California.	
(b) *Fault trough or rift coasts* For example, Gulf of California and Red Sea, both being interpreted as rifts.	
(c) *Overthrust* No examples recognized but probably exist.	

(Continued)

Table IV-2-1 (Concluded)	Paragraph No.
2. *Fold coasts* Difficult to recognize on maps or charts but probably exist.	
3. Sedimentary extrusions	
(a) *Salt domes* Infrequently emerge as oval-shaped islands. Example: in the Persian Gulf.	
(b) *Mud lumps* Small islands due to upthrust of mud in the vicinity of the passes of the Mississippi Delta.	
E. *Ice coasts* Various types of glaciers form extensive coasts, especially in Antarctica.	
II. *Secondary coasts* Shaped primarily by marine agents or by marine organisms. May or may not have been primary coasts before being shaped by the sea.	
A. Wave erosion coasts	IV-2-8
1. *Wave-straightened cliffs* Bordered by a gently inclined seafloor, in contrast to the steep inclines off fault coasts.	
(a) *Cut in homogeneous materials.*	
(b) *Hogback strike coasts* Where hard layers of folded rocks have a strike roughly parallel to the coast so that erosion forms a straight shoreline.	
(c) *Fault-line coasts* Where an old eroded fault brings a hard layer to the surface, allowing wave erosion to remove the soft material from one side, leaving a straight coast.	
(d) *Elevated wave-cut bench coasts* Where the cliff and wave-cut bench have been somewhat elevated by recent diastrophism above the level of present-day wave erosion.	
(e) *Depressed wave-cut bench coasts* Where the wave-cut bench has been somewhat depressed by recent diastrophism so that it is largely below wave action and the wave-cut cliff plunges below sea level.	
2. *Made irregular by wave erosion* Unlike ria coasts in that the embayments do not extend deeply into the land. *Dip coasts* Where alternating hard and soft layers intersect the coast at an angle; cannot always be distinguished from trellis coasts.	
(a) *Heterogeneous formation coasts* Where wave erosion has cut back the weaker zones, leaving great irregularities.	
B. *Marine deposition coasts* Coasts prograded by waves and currents.	
1. Barrier coasts.	
(a) *Barrier beaches* Single ridges.	IV-2-9
(b) *Barrier islands* Multiple ridges, dunes, and overwash flats.	
(c) *Barrier spits* Connected to mainland.	
(d) *Bay barriers* Sand spits that have completely blocked bays.	
(e) *Overwash fans* Lagoonward extension of barriers due to storm surges.	
2. *Cuspate forelands* Large projecting points with cusp shape. Examples include Cape Hatteras and Cape Canaveral.	
3. *Beach plains* Sand plains differing from barriers by having no lagoon inside.	
4. *Mud flats or salt marshes* Formed along deltaic or other low coasts where gradient offshore is too small to allow breaking waves.	IV-2-11
C. *Coasts* built by organisms	IV-2-12
1. *Coral reef coasts* Include reefs built by coral or algae. Common in tropics. Ordinarily, reefs fringing the shore and rampart beaches are found inside piled up by the waves.	
(a) *Fringing reef coasts* Reefs that have built out the coast.	
(b) *Barrier reef coasts* Reefs separated from the coast by a lagoon.	
(c) *Atolls* Coral islands surrounding a lagoon.	
(d) *Elevated reef coasts* Where the reefs form steps or plateaus directly above the coast.	
2. *Serpulid reef coasts* Small stretches of coast may be built out by the cementing of serpulid worm tubes onto the rocks or beaches along the shore. Also found mostly in tropics.	
3. *Oyster reef coasts* Where oyster reefs have built along the shore and the shells have been thrown up by the waves as a rampart.	
4. *Mangrove coasts* Where mangrove plants have rooted in the shallow water of bays, and sediments around their roots have been built up to sea level, thus extending the coast. Also a tropical and subtropical development.	
5. *Marsh grass coasts* In protected areas where salt marsh grass can grow out into the shallow sea and, like the mangroves, collect sediment that extends the land. Most of these coasts could also be classified as mud flats or salt marshes.	

e. Classification schemes for specific environments.

(1) River systems. Coleman and Wright (1971) developed a detailed classification for rivers and deltas.

(2) Great Lakes of North America. The Great Lakes have unique characteristics that set them apart from oceanic coastlines. One of the most comprehensive attempts to include these factors in a classification scheme was developed by Herdendorf (1988). It was applied to the Canadian lakes by Bowes (1989). A

simpler scheme has been used by the International Joint Commission as a basis for studies of shoreline erosion (Stewart and Pope 1992).

IV-2-3. Drowned River Coasts - Estuaries[1]

a. Introduction. An enormous amount of technical literature is devoted to the chemistry and biology of estuaries. In recent years, much research has been devoted to estuarine pollution and the resulting damage to fish and animal habitat. For example, the famous oyster harvesting in Chesapeake Bay has been almost ruined in the last 30 years because of overfishing, urban runoff, and industrial pollution. As a result, the unique way of life of the Chesapeake oystermen, who still use sailing vessels, may be at an end. Possibly because most attention has centered on the biological and commercial aspects of estuaries, our geological understanding of them is still rudimentary (Nichols and Biggs 1985). The estuarine environment can be defined as the complex of lagoon-bay-inlet-tidal flat and marsh that make up 80 to 90 percent of the U.S. Atlantic and Gulf coasts (Emery 1967). Clearly it is vital that we gain a better understanding of their sedimentary characteristics and dynamics.

b. Literature. Only the briefest introduction to estuarine processes and sediments can be presented in this chapter. The purpose of this section is to introduce estuarine classification, regional setting, and geology. The reader is referred to Nichols and Biggs (1985) for an overview of the geology and chemistry of estuaries and for an extensive bibliography. Other general works include Dyer (1979), Nelson (1972), and Russell (1967). Cohesive sediment dynamics are covered in Metha (1986), and the physics of estuaries is covered in van de Kreeke (1986). Research from the 1950's and 1960's is reviewed in Lauff (1967).

c. Classification. Many attempts have been made to define and classify estuaries using geomorphology, hydrography, salinity, sedimentation, and ecosystem parameters (reviewed in Hume and Herdendorf (1988)). A geologically based definition, which accounts for sediment supply pathways, is used in this text.

d. Definitions. Estuaries are confined bodies of water that occupy the drowned valleys of rivers that are not currently building open-coast deltas. The most common definition of an estuary describes it as a body of water where "...seawater is measurably diluted with fresh water derived from land drainage" (Pritchard 1967). Therefore, estuaries would include bodies of water where salinity ranges from 0.1 ‰ (parts per thousand) to about 35 ‰ (Figure IV-2-1). However, this chemical-based definition does not adequately restrict estuaries to the setting of river mouths, and allows, for example, lagoons behind barrier islands to be included. Dalrymple, Zaitlin, and Boyd (1992) felt that the interaction between river and marine processes was an attribute essential to all true estuaries. Therefore, they proposed a new geologically based definition of estuary as:

> ...the seaward portion of a drowned valley system which receives sediment from both fluvial and marine sources and which contains facies influenced by tide, wave, and fluvial processes. The estuary is considered to extend from the landward limit of tidal facies at its head to the seaward limit of coastal facies at its mouth.

These limits are schematically shown in Figure IV-2-1.

e. Time relationships and evolution.

(1) Estuaries, like other coastal systems, are ephemeral. River mouths undergo continuous geological evolution, of which estuaries represent one phase of a continuum (Figure IV-2-2). During a period of high

[1] Material in this section has been condensed from Dalrymple, Zaitlin, and Boyd (1992).

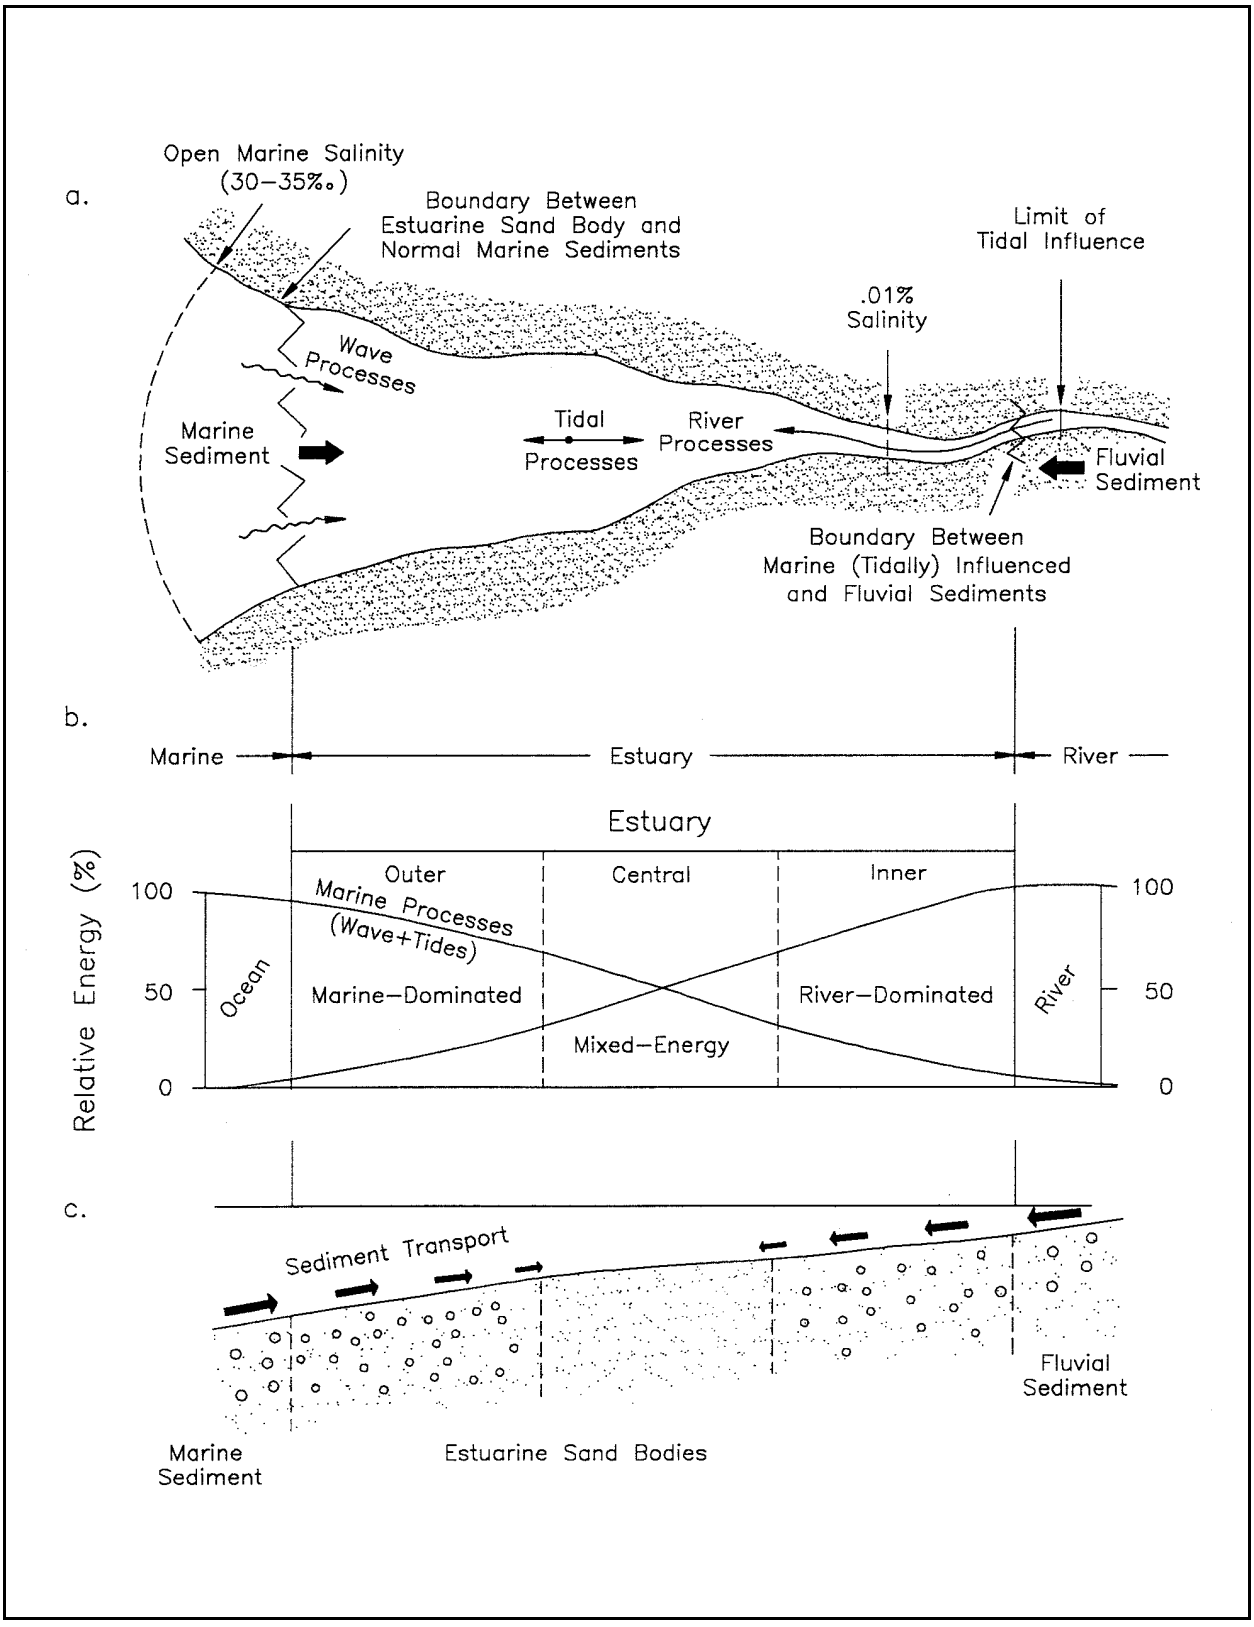

Figure IV-2-1. (a) Plan view of distribution of energy and physical processes in estuaries; (b) Schematic definition of estuary according to Dalyrmple, Zaitlin, and Boyd (1992); (c) Time-averaged sediment transport paths

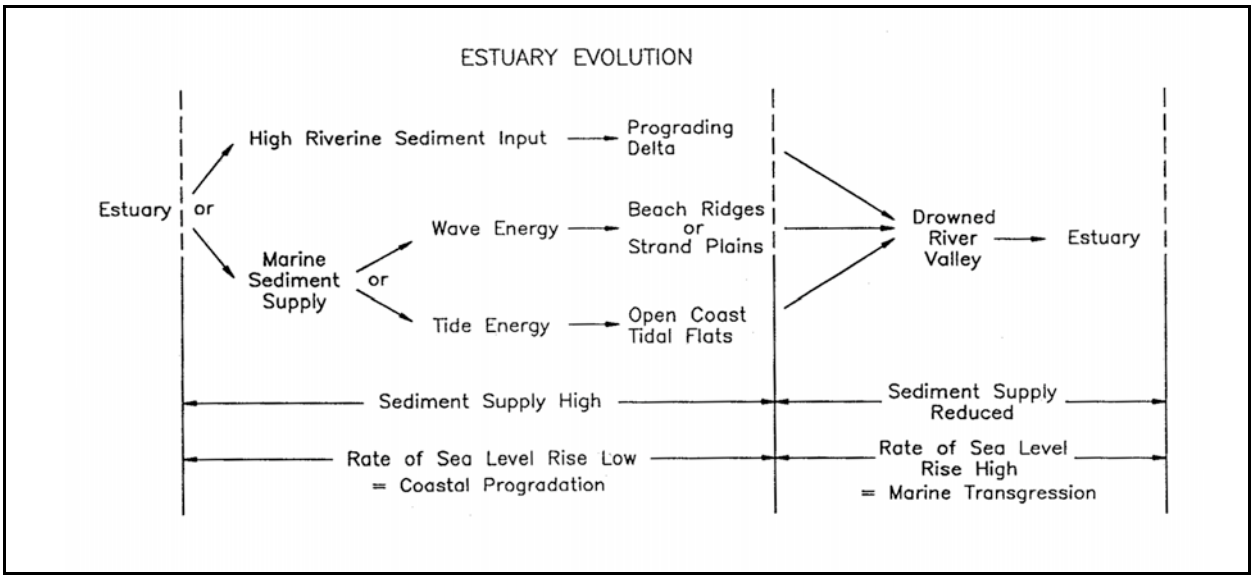

Figure IV-2-2. Estuary/prograding coast evolution. Estuaries are part of a continuum of coastal landforms. With high riverine or marine sediment supply, the shore progrades (left half of figure). Later, if sediment supply is reduced, the river valley is drowned, resulting in an estuary (right half of figure)

sediment supply and low rate of sea level rise, an estuary is gradually filled. Three coastal forms may result, depending on the balance between riverine input and marine sediment supply:

(a) If the sediment is supplied by a river, a delta is formed, which, as it grows, progrades out into the open sea (left side of Figure IV-2-3).

(b) If, instead, most sediment is delivered to the area by marine processes, a straight, prograding coast is formed. This might be in the form of beach ridges or strand plains if wave energy is dominant, or as open-coast tidal flats if tidal energy is dominant.

(c) Later, if sea level rises at a higher rate, then the river valley may be flooded, forming a new estuary (right side of Figure IV-2-3).

(2) Under some conditions, such as when sea level rise and sediment supply are in balance, distinguishing whether a river mouth should be classified as an estuary or as a developing delta may be difficult. Dalrymple, Zaitlin, and Boyd (1992) suggest that the direct transport of bed material may be the most fundamental difference between estuaries and deltas. They state that the presence of tight meanders in the channels suggests that bed-load transport is landward in the region seaward of the meanders and, as a consequence, the system is an estuary. However, if the channels are essentially straight as far as the coast, bed load is seaward throughout the system and it can be defined as a delta.

(3) Fluvial systems are controlled by their erosional base level and the sediment supply. During periods of lowered sea level, rivers incise the lower reaches of their valleys and discharge increasing amounts of sediment out onto the shelf. Deltas accumulate and fluvial channels are cut, dissecting parts of the delta plain (described in greater detail in Part IV-3-3). At the lowest stands of sea level, estuaries almost disappear and are confined to river valleys (Baeteman 1994). When sea level rises again, the valleys are flooded and the estuaries reappear.

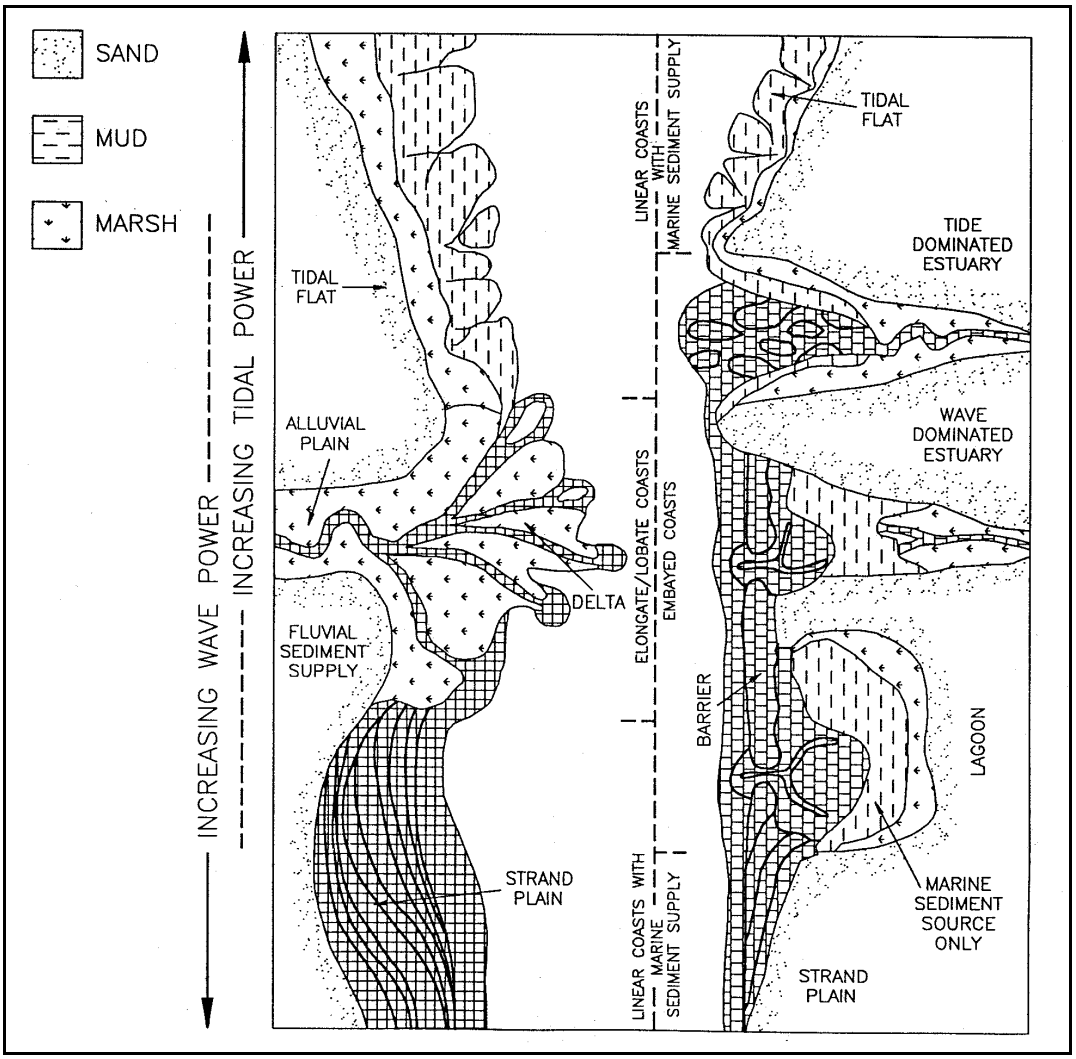

Figure IV-2-3. Estuary evolution, based on changes in wave or tidal power. The left half of the figure shows a prograding coast that results during times of high sediment supply. The right side shows how estuaries develop during reduced sediment supply (also refer to Figure IV-2-2). Adapted from Boyd, Dalrymple, and Zaitlin (1992)

f. Overall geomorphic characteristics. The geologic definition of estuary implies that sediment supply does not keep pace with the local sea level rise; as a result, estuaries become sinks for terrestrial and marine sediment. Sedimentation is the result of the interaction of wave, tide, and riverine forces. All estuaries, regardless of whether they are wave- or tide-dominated, can be divided into three zones (Figure IV-2-1):

(1) The *outer zone* is dominated by marine processes (wave and tidal currents). Because of currents, coarse sediment tends to move up into the mouth of the estuary.

(2) The *central zone* is characterized by relatively low energy, where wave and tidal currents are balanced over the long term by river currents. The central zone is an area of net convergence of sediment and usually contains the finest-grained bed load present in the estuary.

(3) The *inner zone* is river-dominated and extends upriver to the limit of tidal influence. The long-term (averaged over years) bed load transport in this region is seaward.

g. Energy factors and sedimentary structures.

(1) Wave-dominated estuaries.

(a) This type of estuary is characterized by high wave energy compared to tidal influence. Waves cause sediment to move alongshore and onshore into the mouth of the estuary, forming sandbars or subaerial barriers and spits (Figure IV-2-4a). The barrier prevents most of the wave energy from entering the central basin. In areas of low tide range and small tidal prism, tidal currents may not be able to maintain the inlet, and storm breaches tend to close during fair weather, forming enclosed coastal ponds. Sediment type is well-distributed into three zones, based on the variation of total energy: coarse sediment near the mouth, fine in the central basin, and coarse at the estuary head. A marine sand body forms in the high wave energy zone at the mouth. This unit is composed of barrier and inlet facies, and, if there is moderate tide energy, sand deposited in flood-tide deltas (Hayes 1980).

(b) At the head of the estuary, the river deposits sand and gravel, forming a bay-head delta. If there is an open-water lagoon in the central basin, silts and fine-grained organic muds accumulate at the toe of the bay-head delta. This results in the formation of a prodelta similar to the ones found at the base of open-coast deltas (deltaic terms and structures are discussed in Part IV-3). Estuaries that are shallow or have nearly filled may not have an open lagoon. Instead, they may be covered by extensive salt marshes crossed by tidal channels.

(2) Tide-dominated estuaries.

(a) Tide current energy is greater than wave energy at the mouth of tide-dominated estuaries, resulting in the development of elongate sandbars (Figure IV-2-4b). The bars dissipate wave energy, helping protect the inner portions of the estuary. However, in funnel-shaped estuaries, the incoming flood tide is progressively compressed into a decreasing cross-sectional area as it moves up the bay. As a result, the velocity of the tide increases until the effects of the amplification caused by convergence are balanced by frictional dissipation. The velocity-amplification behavior is known as *hypersynchronos* (Nichols and Biggs 1985). Because of friction, the tidal energy decreases beyond a certain distance in the estuary, eventually becoming zero.

(b) As in wave-dominated estuaries, riverine energy also decreases downriver from the river mouth. The zone where tide and river energy are equal is sometimes called a balance point and is the location of minimum total energy. Because the total-energy minimum is typically not as low as the minimum found in wave-dominated estuaries, tide-dominated estuaries do not display as clear a zonation of sediment facies. Sands are found along the tidal channels, while muddy sediments accumulate in the tidal flats and marshes along the sides of the estuary (Figure IV-2-4b). In the central, low-energy zone, the main tidal-fluvial channel consistently displays a sinuous, meandering shape. Here, the channel develops alternate bars at the banks and, sometimes, in mid-channel.

(c) A bay-head delta is usually not present in the river-dominated portion of tidally dominated estuaries. Instead, the river channel merges directly into a single or a series of tidal channels that eventually reach the sea.

(3) Estuarine variability.

(a) Wave-to-tide transition. As tide energy increases relative to wave energy, the barrier system at the mouth of the estuary becomes progressively more dissected by tidal inlets, and elongate sandbars form along

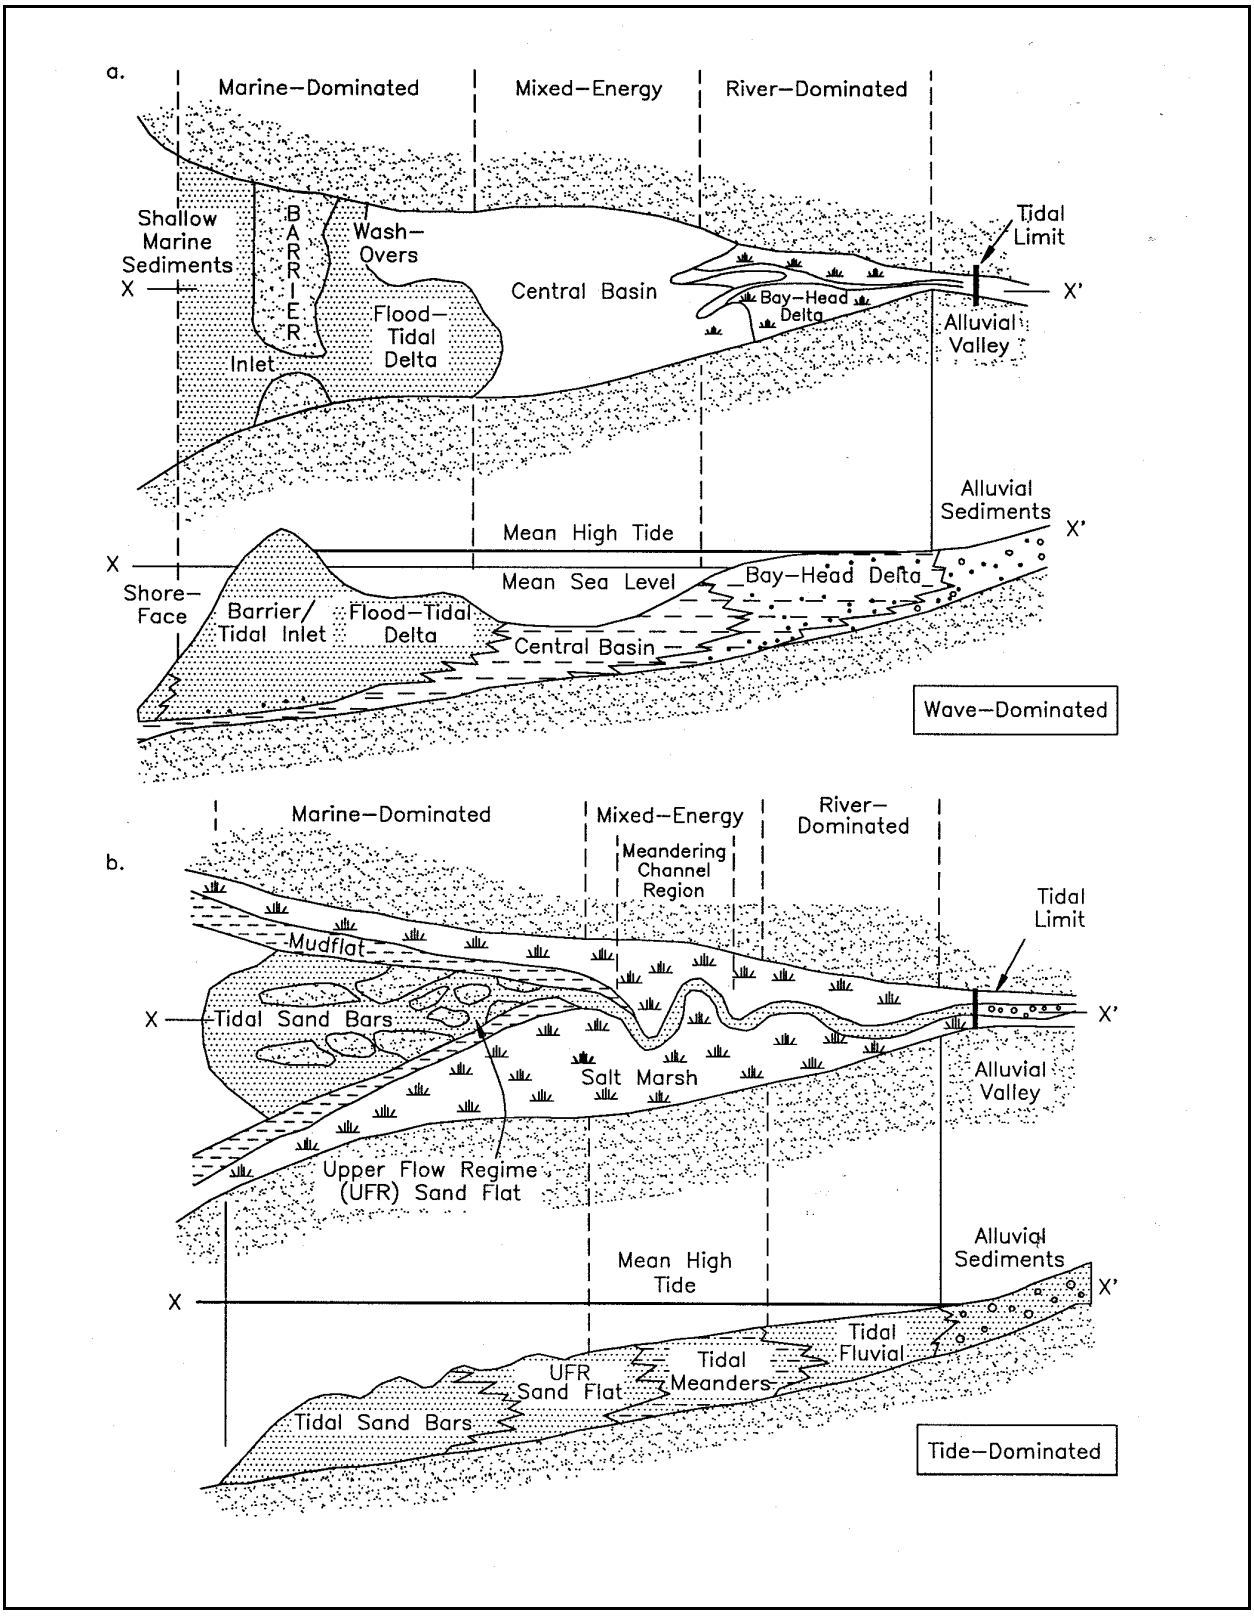

Figure IV-2-4. Morphologic models of (a) wave-dominated and (b) tide-dominated estuaries (adapted from Dalyrmple, Zaitlin, and Boyd (1992)). Wave-dominated estuaries are common along the mid-Atlantic coast of the United States. Tide-dominated estuaries are found in Maine, Massachusetts, and the mid-Atlantic Bight

the margins of the tidal channels. As energy levels increase in the central, mixed-energy part of the estuary, marine sand is transported further up into the estuary, and the muddy central basin is replaced by sandy tidal channels flanked by marshes.

(b) Effects of tide range. The inner end of an estuary has been defined as the limit of detectable tidal influence. Therefore, the gradient of the coastal zone and the tide range have a great influence on the length of estuaries (Dalrymple, Zaitlin, and Boyd 1992). Estuaries become longer as gradient decreases and tide range increases.

(c) Influence of valley shape. The shape of the flooded valley and the pre-existing geology also control the size of the estuary and the nature of sediment deposition. This is particularly evident during the early phases of estuary infilling, before erosion and deposition have modified the inherited geology. For example, tidal-wave amplification is less likely to occur in irregular valleys (Nichols and Biggs 1985). The resulting estuaries are more likely to become wave-dominated. Chesapeake Bay, with its extensive system of tributary valleys, is an example of this type. In contrast, estuaries that initially or later have developed a funnel shape are more likely to be tide-dominated and hypersynchronous (for example, the Gironde Estuary of France.)

(d) Geologic setting. Coastal plain gradient, part of the overall plate tectonic setting, is one factor that determines estuary volume. Sea level rise over a flat coastal plain on a passive margin like the Gulf of Mexico creates long estuaries with large volume. An equivalent rise on a steep, active-margin coast like the U.S. Pacific coast will result in a much smaller estuary volume (Boyd, Dalrymple, and Zaitlin 1992).

h. Estuarine sediments.

(1) Because estuaries occupy drowned river valleys, they function as sinks for enormous volumes of sediment. Estuarine sediments are derived from various sources including rivers, the continental shelf, local erosion, and biological activity. Sedimentation is controlled by tides, river flow, waves, and meteorology. The lower-energy conditions of estuaries, as opposed to those found on open coasts, allow for the deposition of fine-grained silts, muds, clays, and biogenic materials. Estuarine sediments are typically soft and tend to be deposited on smooth surfaces that limit turbulence of the moving water. When allowed to accumulate, these materials consolidate and undergo various chemical and organic changes, eventually forming cohesive sediments.

(2) The shores of estuaries and certain open-water coasts in low-energy environments (e.g., coastal Louisiana, Surinam, Bangladesh, and Indonesia) are characterized as having smooth, low-sloping profiles with turbid water occurring along the shore and extending well offshore (Suhayda 1984). These areas usually exhibit low and vegetated backshores and mud flats that are exposed at low tide. These conditions are also found in Chesapeake and Delaware Bays.

(3) Nichols and Biggs (1985) describe the movement of estuarine sediments as consisting of four processes:

(a) Erosion of bed material.

(b) Transportation.

(c) Deposition on the bed.

(d) Consolidation of deposited sediment.

These processes strongly depend on estuarine flow dynamics and sediment particle properties. The properties most important for cohesive sediments are interparticle bonding and chemical behavior because these parameters make cohesive sediment respond quite differently to hydrodynamic forces than do noncohesive sediments. Due to the cohesive bonding, consolidated materials (clays and silts) require higher forces to mobilize, making them more resistant to erosion. However, once cohesive sediment is eroded, fine-grained clays and silts can be transported at much lower velocity than is required for the initiation of erosion.

IV-2-4. Drowned Glacial Erosion Coasts

a. Introduction. During the Pleistocene epoch, massive continental glaciers, similar to the present Antarctic and Greenland ice caps, covered broad parts of the continents. The glaciers waxed and waned in cycles, probably because of climatic variations, causing vast changes to the morphology of coastal regions in the northern latitudes. As a result, glacially modified features dominate the northern coasts and continental shelves, although in many areas marine processes have reworked the shore and substantially modified the glacial imprint.

b. Erosion and sediment production. Because glacial ice is studded with rock fragments plucked from the underlying rock, a moving glacier performs like a giant rasp that scours the underlying land surfaces. This process, driven by the great size and weight of the ice sheets, caused enormous erosion and modification to thousands of square kilometers during the Pleistocene epoch.

(1) Fjords. The most spectacular erosion forms are drowned glacial valleys known, as *fjords*, that indent the coasts of Alaska, Norway, Chile, Siberia, Greenland, and Canada (Figure IV-2-5). The over-deepened valleys were invaded by the sea as sea level rose during the Holocene epoch. Today, fjords retain the typical U-shaped profile that is also seen in formerly glaciated mountain valleys. Fjords and other drowned glacial erosion features give Maine a spectacular, rugged coastline (Figure IV-2-6).

(2) Depositional features. As a glacier moves, huge amounts of sediment are incorporated into the moving mass. When the ice melts at the glacial front's furthest advance, the sediment load is dropped. Although the major part of the transported material is dumped in the form of a terminal moraine, some sediments are carried further downstream by meltwater streams (Reineck and Singh 1980). The result is a number of distinctive geomorphic features such as drumlins, fjords, moraines, and outwash plains that may appear along the coast or on the submerged continental shelf (Figure IV-2-7). During submergence by the transgressing sea, the features may be modified to such a degree that their glacial origin is lost. This is especially true of outwash, which is easily reworked by marine processes. The original town of Boston was settled on drumlins in the 1600's (Figure IV-1-18), and the islands in Boston Harbor are reworked drumlins (Figure IV-2-8). Nantucket Island, Block Island, and Long Island are partially submerged moraines that have been extensively reworked (Figure IV-2-9).

c. Variability. Glaciated coasts typically display a greater variety of geomorphic forms than are seen in warmer latitudes. The forms include purely glacial, glacio-fluvial, and marine types (Fitzgerald and Rosen 1987). Complexity is added by marine reworking, which can produce barriers, shoals, gravel shores, and steep-cliffed shores. Because of the steep slopes of many glacial coasts, slumping and turbidity flow are major erosive agents. In northern latitudes, the shallow seafloor is gouged by icebergs. In summary, classification of shores in drowned glacial environments can be a major challenge because of the complicated geological history and the large diversity of structures.

d. Atlantic coast. A fundamental division of coastal characteristics occurs along the Atlantic coast of North America due to the presence of glacial moraines. The Wisconsin terminal moraine formed a prominent series of islands (i.e., Long Island, Block Island, Nantucket, and Martha's Vineyard) and offshore banks

Figure IV-2-5. Glacial fjord coast: Alaska (Lake George, with Surprise glacier in the background)

(Georges and Nova Scotian Banks). South of the moraine, the topography is flatter and more regular, except for piedmont streams, which intersect the coastal plain.

e. Offshore geology. Coasts altered by glaciers usually have offshore regions that are highly dissected by relict drainage systems. These sinuous stream channels display highly irregular and varied topography and are composed of sediment types ranging from outwash sand and gravels to till. Note that relict stream channels are also found on continental shelves in temperate climates, for example, off the coast of Texas (Suter and Berryhill 1985). Channels from both temperate and colder environments, and the associated shelf-margin deltas, were formed during late Quaternary lowstands of sea level and are indicators of the position of ancient coastlines.

IV-2-5. River Deposition Coasts - Deltas

Deltas are discussed in Part IV-3. Because energy factors and deltaic structures are intimately linked, morphology and river mouth hydrodynamics are discussed together.

IV-2-6. Wind Deposition Coasts - Dunes

a. Introduction. Sand dunes are common features along sandy coastlines around the world. The only climatic zone lacking extensive coastal dunes is the frozen Arctic and Antarctic (although thin dune sheets on the coast of McMurdo Sound, Antarctica, have been described by Nichols (1968)). Sediment supply is probably the most crucial factor controlling growth of dunes; while there is rarely a lack of wind in most coastal areas, some lack sufficient loose sediment (Carter 1988). Dunes serve multiple valuable purposes:

Figure IV-2-6. Drowned glacial erosion coast: Maine (Potts Point, South Harpswell, near Brunswick, July 1994). Rock headlands and ridges run southwest into the Gulf of Maine

as recreational areas, as habitat for various species of birds, as shore protection, and as temporary sources and sinks of sand in the coastal environment. Although dunes are found along many sandy coasts, they are finite resources and need to be protected and preserved. The seminal work on dunes is Brigadier R.A. Bagnold's *The Physics of Blown Sand and Desert Dunes* (Bagnold 1941). More than 50 years after its publication, this book continues to be cited because of its sound basis on the laws of physics and its readability. Part III-4 of the *Coastal Engineering Manual* reviews the physics of wind-blown sediment transport and presents methods that can be used to estimate transport volumes.

b. Origin of dunes. Many large dune fields are believed to have originated when sea level was lower and sediment supply was greater (Carter 1988). Many are on prograding shorelines, although shoreline advance does not seem to be a requirement for dune formation. In northwest Europe, most of the dunes formed from shelf debris that moved onshore during the late Pleistocene and early Holocene by rising sea level. Dune-building phases have been interrupted by periods of relative stability, marked by the formation of soils. The dunes at Plum Island, Massachusetts, may have formed after 1600 (Goldsmith 1985).

c. Sediment sources. The normally dry backshore of sandy beaches may be the most common source of dune sands. A flat or low-relief area inland of the coastline is needed to accommodate the dunes, and there must be predominant onshore or alongshore winds for at least part of the year. To move sand from the beach to the dunes, wind speed must exceed a threshold velocity for the particular size of sand available. If the sand is damp or if the grains must move up a slope, the velocities required for sediment transport are greatly increased. The foreshore of the beach can also be a source of sand if it dries between tidal cycles. This is especially true in areas where there is only one high tide per day (diurnal), allowing a greater amount of time

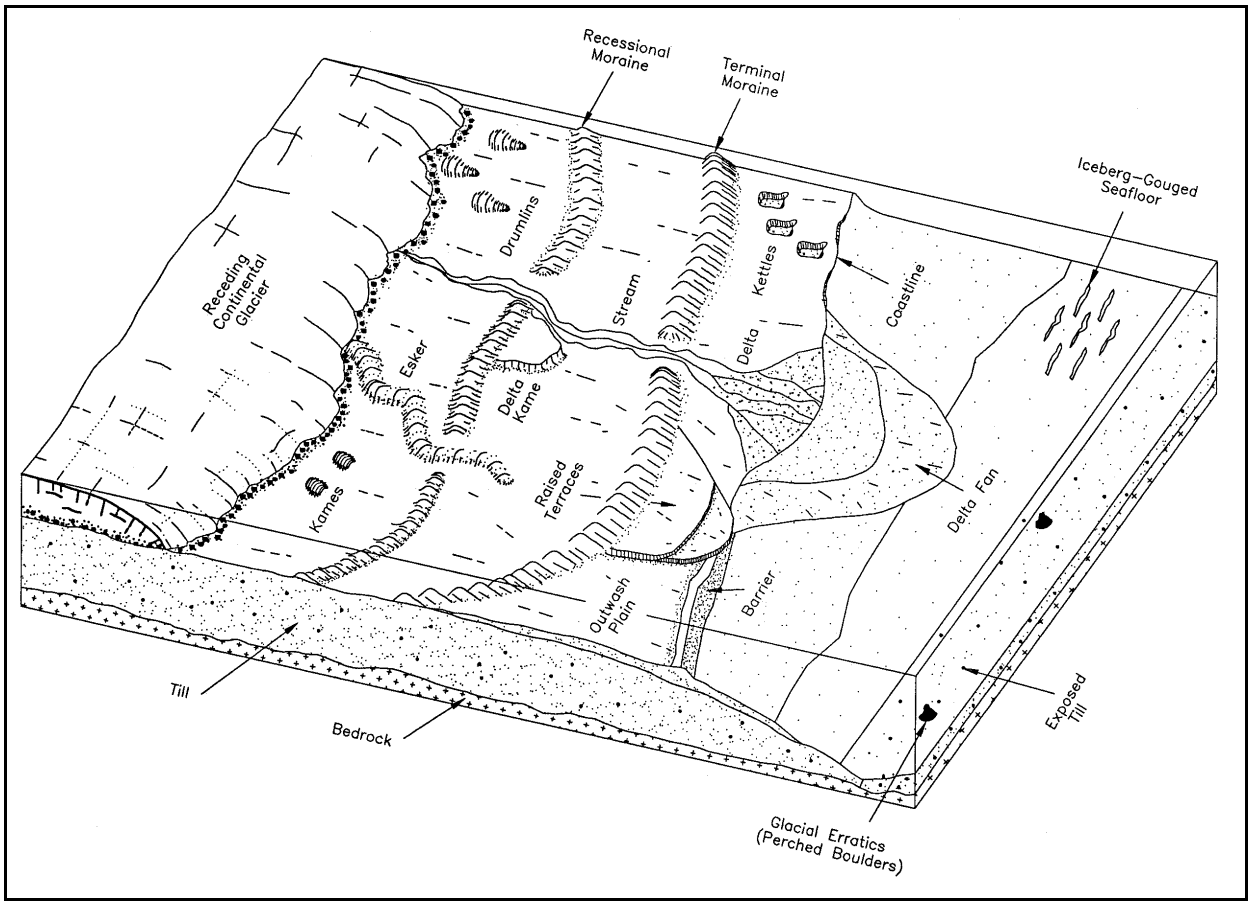

Figure IV-2-7. Typical glacial depositional structures

for the foreshore to dry between inundations. Sand storage in dunes must be estimated as one component of sediment budget calculations (EM 1110-2-1502).

d. Modification and stability. Most dunes show evidence of post-depositional modifications. These include:

(1) Physical changes - slumping, compaction. Sand grains become rounded, frosted, and better sorted.

(2) Chemical alterations - oxidation, leaching, calcification. (The latter can solidify a dune, making it much more resistant to erosion.)

(3) Biological effects - reactivation, humification, soil formation.

The stability of dunes varies greatly, usually depending on vegetation cover. Dunes in arid climates are often not vegetated and are mobile. However, coastal dunes are normally vegetated by plant species adapted to the harsh coastal environment (Figure IV-2-10). Many dune grasses have long roots, rhizomes, and runners that help hold sand in place. In addition, dense vegetation displaces the aerodynamic boundary of the wind velocity profile upwards. This process produces a net downward momentum flux, promoting sediment trapping (Carter 1988).

Figure IV-2-8. Islands in Boston Harbor, Massachusetts (August 1988 - view looking south). These are glacial drumlins that have been extensively reworked by contemporary marine processes. The town of Winthrop (with a tall water tower) is on the drumlin in the center. Deer Island, in the harbor, is attached to Winthrop with a causeway

Figure IV-2-9. Glacial till bluffs just west of Montauk Point, Long Island, New York, facing the Atlantic Ocean (March 1998). As the bluffs erode, the fine material is carried away by waves, leaving a lag of boulders and cobble on the shoreface. In this area, the seafloor offshore is also covered with gravel, cobble, and coarse sand. Sand from the Montauk bluffs is carried by littoral currents to the west, where it nourishes the barrier beaches of Long Island's south shore

Figure IV-2-10. Partly vegetated coastal sand dunes. Rhizomes help hold sand in place and colonize the dune grasses. Eastern Alabama on the Morgan peninsula east of the mouth of Mobile Bay (March 1991). This area was devastated by Hurricane Frederic in 1979 and is slowly recovering. Commercial construction now threatens these dunes

e. Dune vegetation. American beach grass (*Ammophilia breviligulata*) is the most common dune plant in the United States northeast and on the west coast. Along the Gulf coast and the southeast, sea oats (*Uniola paniculata*) is the most abundant species on the dunes. Both plants are remarkably adapted to this environment and are essential to dune stability. They are tolerant of salt spray and occasional inundation by salt water. Growth is stimulated by sand burial, which occurs frequently on the dune. The plant leaves help trap sand on the dune by raising the laminar boundary layer of the wind velocity profile and causing eolian deposition. Regrowth occurs even after rapid deposition of sand up to 1 m thick. Plant growth is by seed and by rhizome extension. Rhizome extension allows rapid plant distribution to help stabilize the surface of the

dune, and allows upward growth of the plant to keep pace with sand deposition. Vehicle and foot traffic that damage the vegetation can greatly diminish dune stability.

f. Dune fauna. Dunes may appear to be harsh and inhospitable environments, but they are hosts to many species of animals. A wide variety of invertebrates are present, including species as large as crabs. Numerous shorebirds and upland birds use the dune zone for foraging and nesting. Other vertebrates, such as rabbit, fox, deer, etc., frequent the dune in search of food.

g. Classification. Dunes can be described or classified on the basis of physical description (external form and internal bedding) or genetic origin (mode of formation). Smith (1954) devised a descriptive classification system that has been widely used. It established the following types (Figure IV-2-11):

(1) Foredunes. Mounds or ridges directly by the beach. Serve as storm buffer.

(2) Parabolic dunes. Arcuate sand ridges with the concave portion facing the beach. Rare; often form downwind of pools or damp areas.

(3) Barchan dunes. Crescent-shaped dunes with the extremities (horns) extending downwind (caused by the horns migrating more rapidly than the central portions). Sometimes show incomplete sand cover moving over a nonerodible pavement.

(4) Transverse dune ridges. Ridges oriented perpendicular or oblique to the dominant winds. Their form is asymmetrical with steep lee and gentle upwind slopes.

(5) Longitudinal (seif) dunes. Dune ridges elongated parallel to the wind direction and symmetrical in profile. Occur in groups over wide areas; feature sinuous crestlines.

(6) Blowouts. Hollows or troughs cut into dunes; may be caused when vehicles or pedestrians damage vegetation (Figure IV-2-12).

(7) Attached dunes. Formations of sand that have accumulated around obstacles such as rocks (Figure IV-2-13).

h. Shoreline protection. In many areas, dunes serve a vital role in protecting inland areas from storm surges and wave attack. As a result, many communities require that buildings be erected behind the dunes or beyond a certain distance (a *setback*) from an established coastline. Unfortunately, the protection is ephemeral because severe storms can overtop and erode the dunes, and changes in sediment supply or local wind patterns (sometimes caused by structures and urban development) can leave them sand-starved. If dunes are cut for roads or for walkways, they become particularly vulnerable to erosion. However, compared with hard structures like seawalls, many communities prefer the protection provided by dunes because of aesthetic considerations.

i. Dune restoration. Historically, sand dunes have suffered from human pressure, and many dune systems have been irreversibly altered by man, both by accident or design. Many coastal areas in Europe, North America, Australia, and South Africa, which had once-stable forested dunes, have been deforested. The early settlers to New England in the 1600's severely damaged the dune vegetation almost immediately upon their arrival by overgrazing and farming. Dune rebuilding and revegetation have had a long history, mostly unsuccessful (Goldsmith 1985). Recent restoration practices have been more effective (Knutson 1976, 1978; Woodhouse 1978). The two main methods for rebuilding or creating coastal dunes are artificial planting and erecting sand fences. Hotta, Kraus, and Horikawa (1991) review sand fence performance.

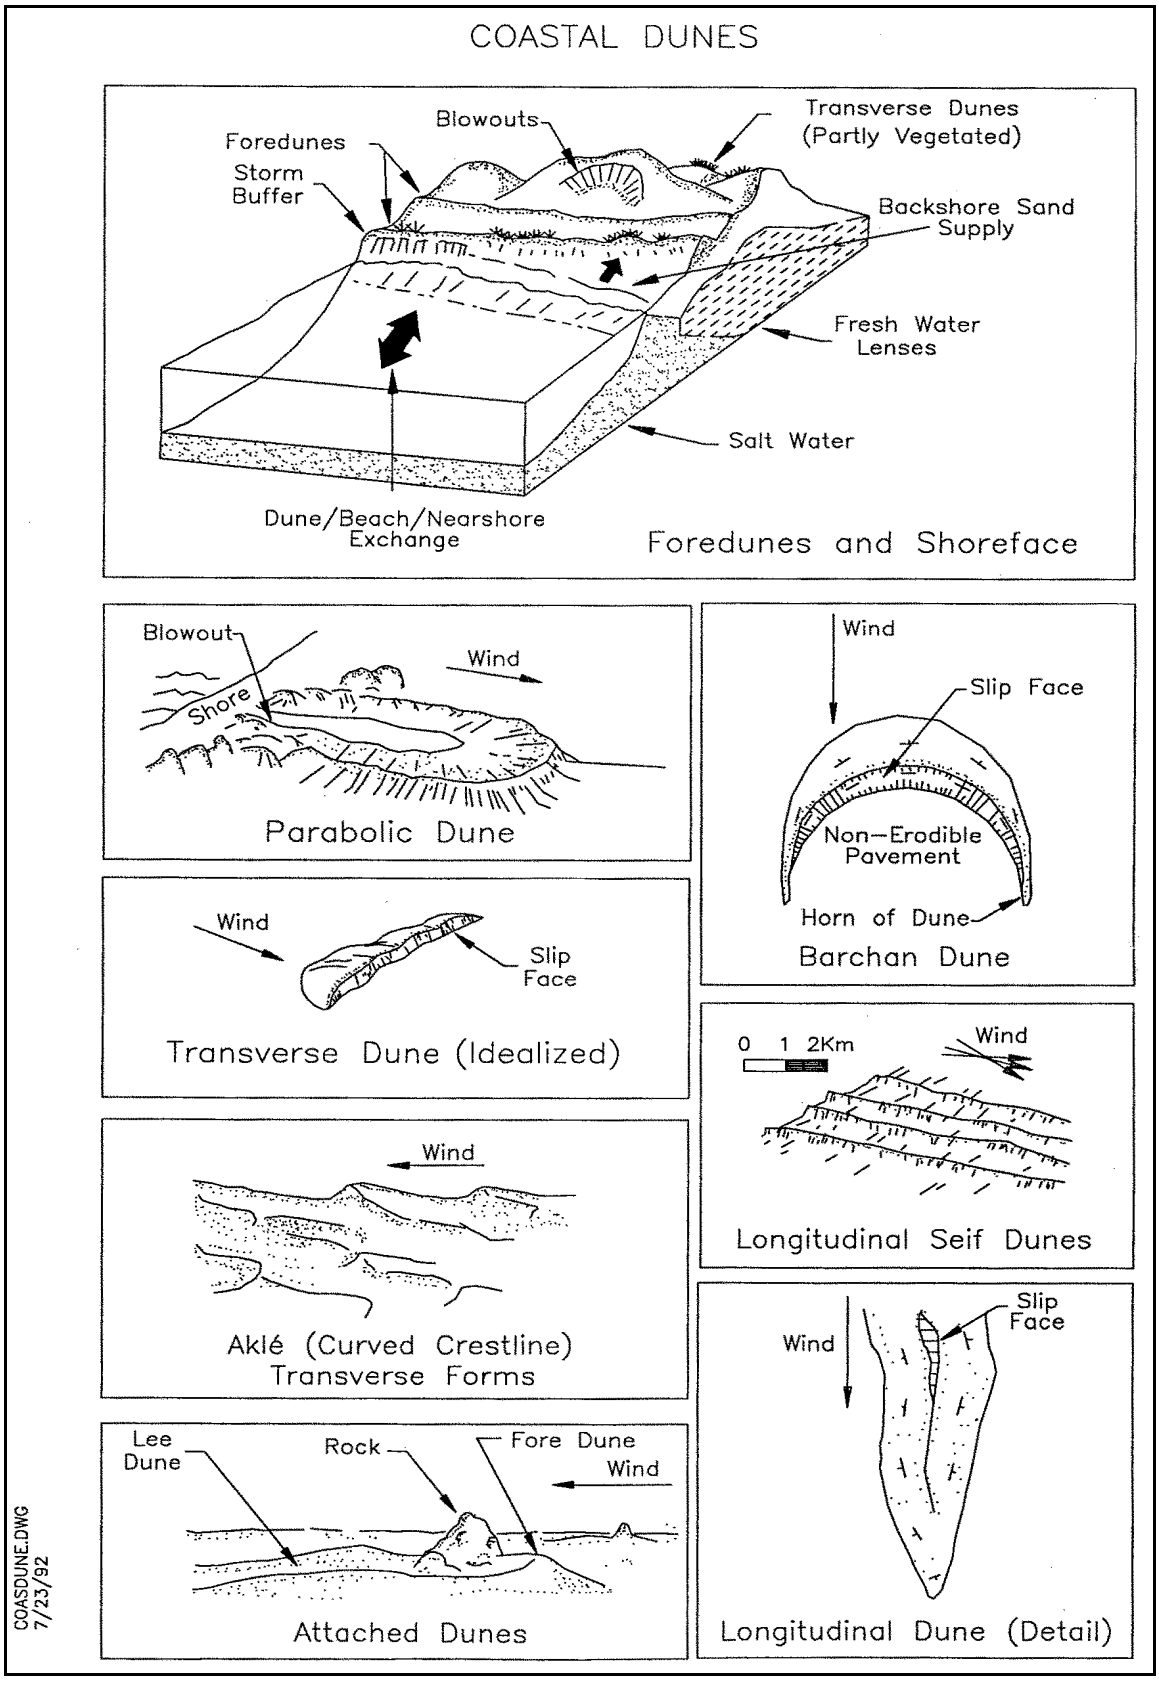

Figure IV-2-11. Variety of dune types (adapted from Carter (1988), Reading (1986), and Flint (1971))

Figure IV-2-12. Blowout in dunes. Eastern Alabama on the Morgan peninsula east of the mouth of Mobile Bay (April 1995)

Figure IV-2-13. Huge dune anchored to a rock outcrop in the eastern Sinai Desert (January 1979). The dune is more than 15 m high. Most of valley floor is hard-packed sand, although there are pockets of loose sand that impede vehicle traffic. As of 1979, many of the bedouins in this area were already using pickup trucks instead of camels

Coastal dune management and conservation practices are reviewed in Carter, Curtis, and Sheehy-Skeffington (1992).

IV-2-7. Volcanic Coasts

a. Introduction and definitions. *Volcanoes* are vents in the earth's surface through which magma and associated gases and ash erupt (Bates and Jackson 1984). Often, conical mountains are formed around the vents as repeated eruptions deposit layer upon layer of rock and ash. Therefore, the definition is extended to include the hill or mountain built up around the opening by the accumulation of rock materials.

(1) The fundamental importance of volcanism to mankind has been clearly documented around the world. The entire west coast of the Unites States is highly active tectonically and most of the continent's volcanoes are within 200 km of the coast. There are more than 260 distinct volcanoes younger than five million years in the Unites States and Canada, most of which are in Alaska and the Hawaiian Islands (Wood and Kienle 1990). Fifty-four have erupted in historic times, and distant memories of others are recounted in Native American legends.

(2) Volcanoes are important to coastal studies for many reasons:

(a) They provide sediment to the littoral environment. Material may reach the coast directly via ash fall-out and lava flows or may be transported by rivers from an inland source (e.g., Mount St. Helens).

(b) Vulcanism affects coastal tectonics (e.g., west coasts of North and South America).

(c) Shoreline geometry is affected by the formation of volcanic islands (Aleutians) and by lava that flows into the sea (Hawaiian Islands).

(d) Shoreline erodability ranges from very erodable for ash and unconsolidated pyroclastic rubble to very resistant for basalt.

(e) Volcanoes can pose a serious threat to coastal communities.

(f) Volcanic debris can choke rivers and harbors.

(3) This section briefly discusses general concepts of volcanism and describes features unique to volcanic shores. Examples from Alaska and the Hawaiian Islands illustrate the differences between composite and shield volcanoes and their associated coastlines. For the general reader, *Exploring our Living Planet*, published by the National Geographic Society (Ballard 1983), is a readable and interesting introduction to plate tectonics, hotspots, and volcanism.

b. General geology. Two classes of volcanoes can be identified, based on the explosiveness of their eruptions and composition of their lava. The ones in the Aleutians and along the west coasts of North and South America are known as *composite* volcanoes and are renowned for their violent eruptions. The paroxysmal explosion of Mount St. Helens on May 18, 1980, which triggered devastating mudflows and floods, killing 64 people, serves as a remarkable example. Composite eruptions produce large amounts of explosive gas and ash and build classic, high-pointed, conic mountains. In contrast, the Hawaiian Islands are *shield* volcanoes: broad, low, basalt masses of enormous volume. Shield eruptions are typically

nonexplosive, and the highly liquid nature of their lava[1] accounts for the wide, low shape of the mountains. Volcanism affects the shore on two levels:

(1) The large-scale geologic setting of the continental margin affects sedimentation and overall coastal geology. Margins subject to active tectonism (and volcanism) are typically steep, with deep water occurring close to shore. Rocks are often young. High mountains close to shore provide a large supply of coarse sediments, and muddy shores are rare. Much sediment may be lost to deep water, particularly if it is funneled down submarine canyons. This is a one-way process, and the sediment is permanently lost to the coastal zone.

(2) Small-scale structures on volcanic shores may differ from those on clastic passive margins. Sediment supply may be frequently renewed from recent eruptions and may range greatly in size. Ash may be quickly destroyed in the sea, while basalt boulders may be tremendously resistant. Hardened shores at the sites of recent lava flows are difficult settings for harbor construction.

c. Composite volcanoes - coastal Alaska. The coastal geology of Alaska is incredibly complex, having been shaped by fault tectonics, volcanism, glaciation, fluvial processes, sea level changes, and annual sea ice. More than 80 volcanoes have been named in the Aleutian arc, which extends for 2,500 km along the southern edge of the Bering Sea and the Alaskan mainland (Wood and Kienle 1990). Over 44 have erupted, some repeatedly, since 1741, when written records began. Aleutian arc volcanism is the result of the active subduction of the Pacific Plate beneath the North America Plate (Figure IV-2-14).

(1) Volcanoes have influenced the Aleutian Arc in two ways. First, they have been constructive agents, creating islands as eruption after eruption has vented rock and ash. In some places, fresh lava or mudflows accompanying eruptions have buried the existing coast, extending the shore seaward. The eruptions of Mts. Katmai and Novarupta in 1912 produced ash layers 3 to 15 m thick. The Katmai River and Soluka Creek carried vast amounts of loose ash to the sea, filling a narrow bay and burying a series of old beach ridges (Shepard and Wanless 1971). Usually, loose mudflow and ash deposits are reworked rapidly by waves, providing sediment for beach development. In addition, for years after an eruption, streams may carry rock and ash to the coast, allowing the coast to locally prograde. The second effect has been destructive, and small islands have been largely destroyed by volcanic explosions. Bogoslof, in the eastern Aleutians, is an example in which both rapid construction and destruction have influenced the island's shape over time (Shepard and Wanless 1971).

(2) Clearly, a history of volcanic instability would be a major consideration for a coastal engineer planning a harbor or project. Most new volcanic islands are uninhabited, but harbors may be needed for refuge, military, or commercial purposes. During World War II, air fields and harbors were built quickly on formerly uninhabited Aleutian Islands. Some islands can supply stone for construction at other locations, requiring loading facilities for boats or barges.

d. Shield volcanoes - Hawaii. Each of the Hawaiian islands is made up of one or more huge shield volcanoes rising from the ocean floor. The islands are at the southern end of a chain of seamounts that extends 3,400 km to the northwest and then turns north and extends another 2,300 km toward Kamchatka as the Emperor Seamounts. More than 100 volcanoes, representing a volume of greater than one million cubic kilometers, make the Hawaiian-Emperor chain the most massive single source of volcanic eruption on earth (Wood and Kienle 1990). The submerged seamounts become successively older away from Hawaii.

---

[1] *Lava* is the term used for molten rock (and gasses within the liquid) that have erupted onto the earth's surface. *Magma* refers to molten rock that is still underground.

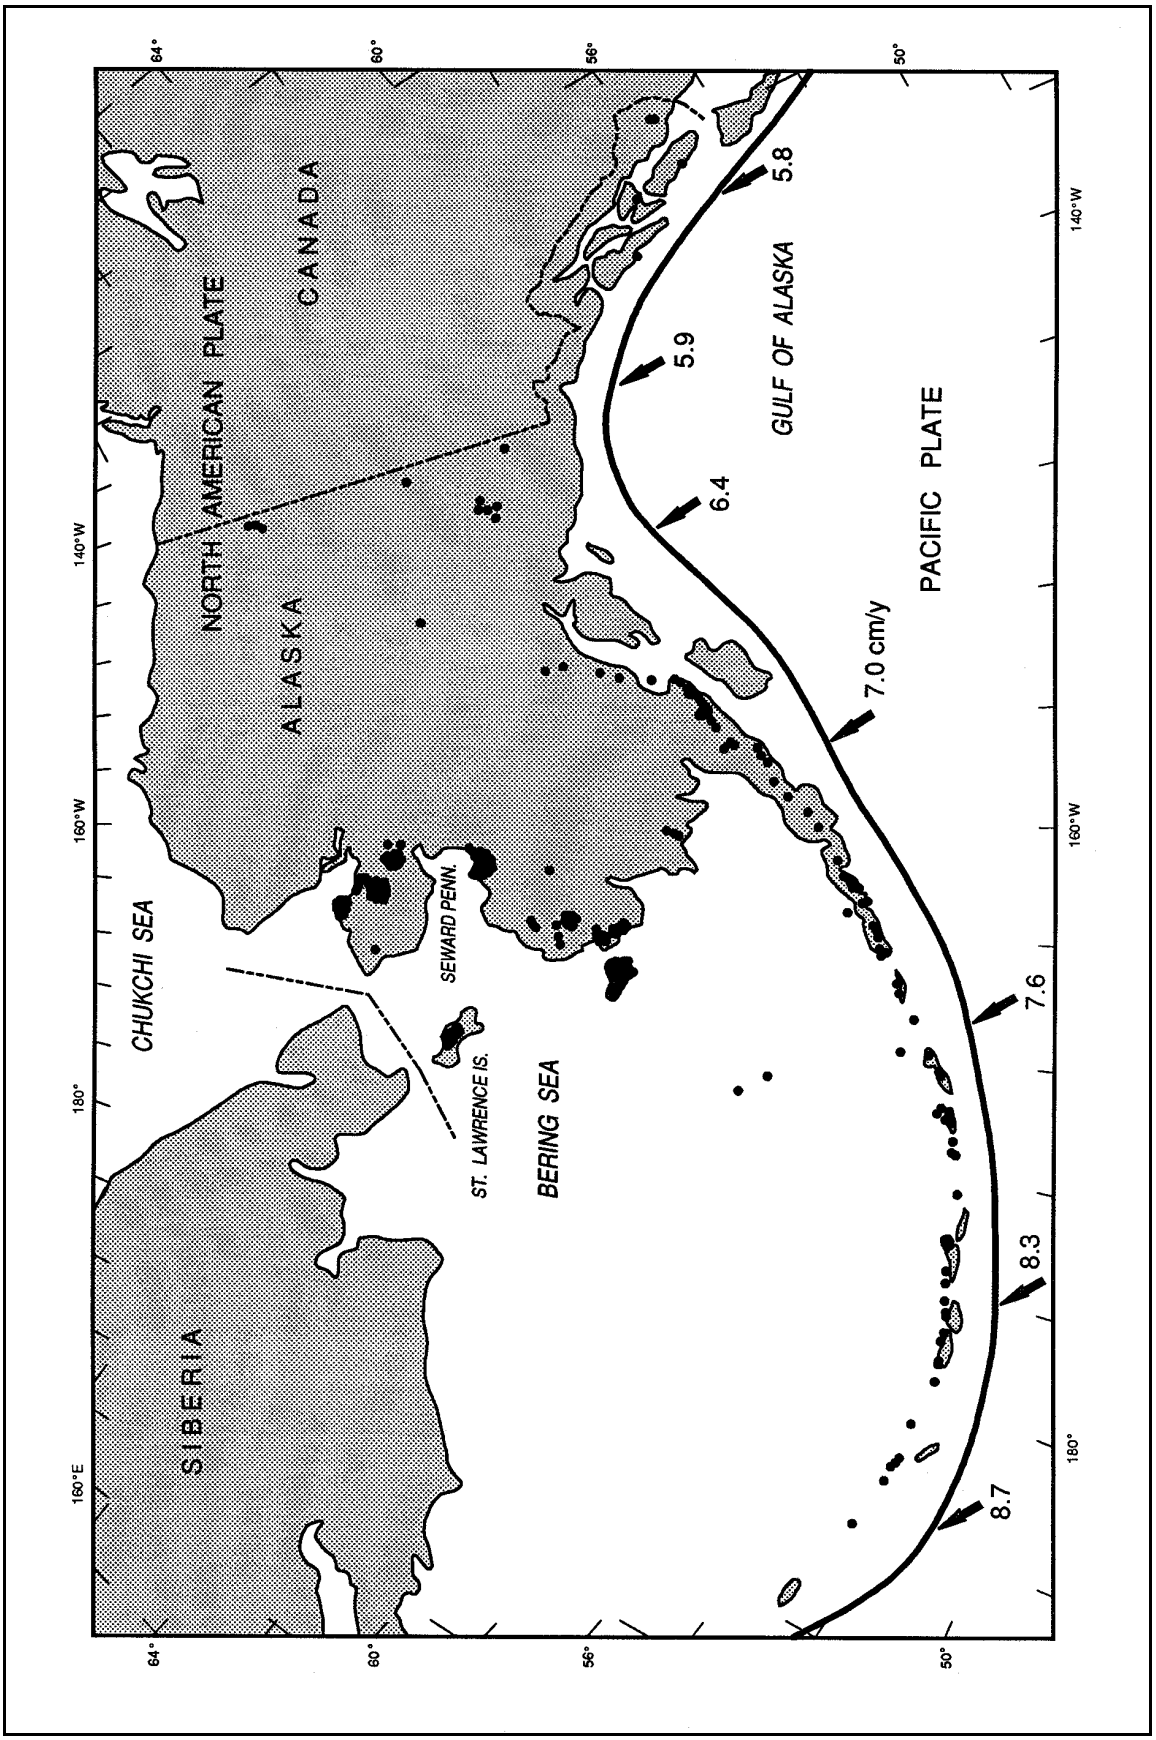

Figure IV-2-14. Alaskan volcanoes along the Aleutian Island arc, marking the boundary between the North American and the Pacific crustal plates. Arrows indicate subduction of the Pacific Plate in cm/year

Meiji Seamount, about to be subducted beneath Kamchatka, is 75-80 million years (my) old, Kilauea is only 0.4 my, while Loihi Seamount, south of the big island of Hawaii, is the newest member of the chain and has not yet emerged from the sea. The islands are found over a semipermanent "hot spot," a site where it is believed that a plume of hot, geochemically primitive material rises convectively through the mantle, interacts with the lithosphere, and vents on the seafloor (Dalrymple, Silver, and Jackson 1973). The Pacific plate is postulated to be moving over the hot spot at a rate of about 13 cm/yr, based on ages of the major vents on Hawaii (Moore and Clague 1992).

(1) Although the coastlines of the Hawaiian Islands are geologically young, wave erosion and the growth of coral reefs have modified most of the shores. Coastal plains have formed around the base of some volcanoes and between others (for example, the intermontaine plateau between Koolau and Waianae on Oahu). The plains are partly alluvial and partly raised reefs (Shepard and Wanless 1971). The greater parts of the Hawaiian coasts are sea cliffs, some as high as 1,000 m on the windward sides of the islands. There are also extensive beaches, the best of which tend to be on the western sides of the islands, protected from waves generated by the northeast trade winds. On southwestern Kauai near Kekaha, there are prograding beach ridges. Surprisingly, most of the beaches are composed not of volcanic debris but primarily of biogenic sediment. The rare volcanic sand beaches are found at the mouths of the larger rivers or along coasts where recent lava flows have killed the coral reefs (Shepard and Wanless 1971). Many beaches are undergoing serious erosion, and finding suitable sources of sand for renourishment has been difficult. This is a critical problem because tourism is a major part of the Hawaiian economy, and the beaches are among the great attractions.

(2) An example from the island of Hawaii helps illustrate the rugged nature of these volcanic shores. Hawaii, at the southeast end of the island chain, has been built up from at least seven independent volcanoes (Moore and Clague 1992). Mauna Loa, a huge dome at the southern end of the island, rises to 4,100 m above the sea (8,500 m above the seafloor). Kilauea, a low dome that rises out of the southeast side of Mauna Loa, has had a remarkable history of eruptions since 1800. Because of the porosity of the lavas, few permanent streams flow down the island, although rainfall on the windward side is heavy. The southeast coast of the island is a barren, rugged rock shore built up from hundreds of Kilauea lava flows (Figure IV-2-15). In Figure IV-2-15, the foreground is cracked, barren basalt, while the plateau in the background supports a cover of grass. The vertical cliffs are about 10 m high and in areas have been notched or undercut by the surf. Small steep pocket beaches consisting of black volcanic sands have developed in some notches. Because of the harsh wave climate and tectonic instability, coastal engineering in the Hawaiian Islands is particularly challenging (Figure IV-2-16).

e. Hazards posed by volcanoes.

(1) Introduction. Coastal projects and communities are subject to four general types of hazards caused by volcanic eruptions:

(a) Explosion-generated tsunamis that can flood coastal areas.

(b) Direct burial by lava or ash (recently experienced in Hawaii, Iceland, and Sicily).

(c) Burial or disruption by mudflows and fluvial sediment from inland eruptions, and changes in stream drainage and coastal sediment-discharge patterns.

(d) Loss of life and destruction from explosions.

Figure IV-2-15. Southeast coast of Hawaii, near Kalpana. Rugged cliffs are built up of many lava flows. Small pocket beaches form between headlands when the cliffs are undermined and loose sediment accumulates

Volcanoes seem a remote hazard to most people, but the danger is imminent and real to those who live in certain parts of the earth, especially along the boundaries of the earth's tectonic plates. Fortunately, fewer than 100 people have been killed by eruptions in Hawaii, where the volcanism is less explosive (Tilling, Heliker, and Wright 1987).

(2) Earthquakes and tsunamis.

(a) *Tsunamis* are waves created by ocean-bottom earthquakes, submarine landslides, and volcanic explosions. These long-period waves can travel across entire oceans at speeds exceeding 800 km/hr, causing extensive damage to coastal areas. The cataclysmic explosion of Krakatau on August 27, 1883, generated waves 30 m high that swept across the Sunda Strait, killing 36,000 coastal villagers on Java and Sumatra. One explosion produced one of the loudest noises in history, which was heard at a distance of 4800 km. The Hawaiian islands are particularly vulnerable to tsunamis caused by disturbances around the Pacific rim. The tsunami of April 1, 1946, generated towering walls of water that swept inland, damaging many coastal structures on the islands. In areas, the water rose to 16 m above the normal sea level. Photographs of the waves and the resulting damage are printed in Shepard and Wanless (1971) (Francis Shepard was living on Oahu at the time and vividly describes how the waves smashed his bungalow, forcing him and his wife to flee for their lives). On July 17, 1998, a wall of water 7 m high hit the northwest coast of Papua, New Guinea without warning, following a 7.0 magnitude earthquake about 30 km off the coast in the Pacific Ocean. Some 6,000 villagers perished in this tragedy.

Figure IV-2-16. Laupahoehoe Harbor, Island of Hawaii, Hawaii. Found on the steep and rugged northeast coast of Hawaii, this harbor provides the only access to the fertile Hamakua coast fishing grounds. This is a hostile environment, as shown by the basalt boulders tossed onto the boat ramp by storm waves

(b) Clearly, there is little that can be done to protect against the random and unpredictable tsunamis. A warning network has been established to notify people around the Pacific of earthquakes and the possibility that destructive waves may follow. Coastal residents are urged to heed these warnings!

(3) Ash and fluvial sediment. When Mount St. Helens exploded on May 18, 1980, 390 m of the top of the mountain was blown off, spewing a cloud of dust and ash high into the stratosphere. From its north flank, an avalanche of hot debris and scalding gasses created immense mudflows, burying the upper 24 km of the North Toutle valley to a depth of 50 m. Lahars, formed from dewatering of the debris avalanche, blocked the shipping channel of the Columbia River. This created an enormous dredging task for the U.S. Army Corps of Engineers, and ultimately much of the dredged material had to be disposed at sea. Dredging related to the explosion continues 18 years after the eruption, as material continues to move downstream from mountain watersheds.

(4) Explosive destruction. Communities close to volcanoes may be destroyed by the explosion and the inhabitants killed by poisonous gasses and superheated steam.

(a) The coastal example frequently cited is the destruction of St. Pierre on Martinique by the violent explosion of Montagne Pelée on May 8, 1902. A glowing cloud overran St. Pierre and spread fan-like over the harbor. Practically instantly, the population of more than 30,000 was smothered with toxic gas and incinerated (Bullard 1962).

(b) The cloud that destroyed St. Pierre consisted of superheated steam filled with even hotter dust particles, traveling more than 160 km/hr. The term *nuée ardente* is now used to describe this type of swiftly flowing, gaseous, dense, incandescent emulsion. It is also used as a synonym for the Peléan type of eruption.

IV-2-8. Sea Cliffs - Diastrophic, Erosional, and Volcanic

a. Sea cliffs are the most spectacular geomorphic features found along the world's coastlines. This section concentrates on bedrock cliffs, with *bedrock* defined as "the solid rock that underlies gravel, soil, or other superficial material" (Bates and Jackson 1984). Bedrock cliffs are found along most of the U.S. and Canadian Pacific coast, in Hawaii, along the Great Lakes shores, and in Maine. South of Maine along the Atlantic coast, cliffs are rare except for some examples in New Hampshire, Massachusetts, and Rhode Island. The eastern end of Long Island, Montauk Point, consists of rapidly eroding till bluffs (Figure IV-2-9). Cliffs constitute portions of the coastlines of Spain, Italy, Greece, Turkey, Iceland, and the South American nations facing the Pacific Ocean. Shorelines with cliffs may be both emergent or submergent. For more information, Trenhaile's (1987) *The Geomorphology of Rock Coasts* presents a comprehensive and global review of cliffs, shore platforms, and erosion and weathering processes.

b. Bedrock cliffs are composed of all three major rock types: igneous, sedimentary, and metamorphic.

(1) ***Intrusive igneous rock***, such as granite, cools and solidifies beneath the earth's surface, while *extrusive igneous rock*, such as basalt, is formed by lava above ground (it may erupt underwater or on land). Usually, igneous rocks are highly resistant; however, two properties affect their susceptibility to weathering and erosion (de Blij and Muller 1993):

(a) *Jointing* is the tendency of rocks to develop parallel sets of fractures without obvious external movement like faulting.

(b) *Exfoliation*, caused by the release of confining pressure, is a type of jointing which occurs in concentric shells around a rock mass.

(2) ***Sedimentary rock*** results from the deposition and lithification (compaction and cementation) of mineral grains derived from other rocks (de Blij and Muller 1993). This category also includes rock created by precipitation (usually limestone).

(a) The particles (clasts) that make up *clastic sedimentary rock* can range in size from windblown dust to waterborne cobbles and boulders. The vast majority of sedimentary rocks are clastic. Common examples include sandstone, composed of lithified sand (usually consisting mostly of quartz), and shale, made from compacted mud (clay minerals). Many cliffs along the south shore of Lake Erie are shale.

(b) *Nonclastic sedimentary rocks* are formed by precipitation of chemical elements from solution in marine and freshwater bodies because of evaporation and other physical and biological processes. The most common nonclastic rock is limestone, composed of calcium carbonate ($CaCO_3$) precipitated from seawater by marine organisms (and sometimes also incorporating marine shell fragments). Many of the Mediterranean cliffs are limestone and are very vulnerable to dissolution.

(3) ***Metamorphic rocks*** are preexisting rocks changed by heat and pressure during burial or by contact with hot rock masses. Common examples include:

(a) *Quartzite*, a very hard, weathering-resistant rock, formed from quartz grains and silica cement.

(b) *Marble*, a fine-grained, usually light-colored rock formed from limestone.

(c) *Slate*, a rock that breaks along parallel planes, metamorphosed from shale.

c. Sea cliffs are formed by three general processes:

(1) Volcanic eruptions and uplift caused by local volcanism (discussed in paragraph IV-2-7).

(2) Diastrophic activity that produces vertical movement of blocks of the crust.

(3) Erosional shorelines - partial drowning of steep slopes in hilly and mountainous terrain and resulting erosion and removal of sediment.

d. Sea cliffs, often found on tectonically active coasts, may be created by two mechanisms. First, if a block of the coast drops, a newly exposed fault plane may be exposed to the sea. The opposite process may occur: a block may be uplifted along a fault plane, exposing a formerly exposed portion of the shoreface to marine erosion. Older cliffs may be raised above sea level and be temporarily protected from further erosion. Earlier shorelines, sometimes tens of meters above the present sea level, are marked by notches or wave-cut platforms (sometimes termed uplifted marine terraces) (Figure IV-2-17). Terraces marking the highstand of eustatic (absolute) sea level have been traced around the world. Deep water is often found immediately offshore of faulted coasts. Cliffs that extend steeply into deep water are known as plunging cliffs.

e. Erosional coasts may be straight or may be irregular, with deeply indented bays. The way the shore reacts to inundation and subsequent marine erosion depends on both the wave climate and the rock type.

(1) Wave-straightened coasts. Cliffs are often found along shores where wave erosion rather than deposition is the dominant coastal process. Exposed bedrock, high relief, steep slopes, and deep water are typical features of erosional shorelines (de Blij and Muller 1993). When islands are present, they are likely to be remnants of the retreating coast rather than sandy accumulations being deposited in shallow water. The sequence of events that create a straightened coast are illustrated in Figure IV-2-18. The original coastline includes headlands and embayments (a). As waves attack the shore, the headlands are eroded, producing steep sea cliffs (b). The waves vigorously attack the portion of the cliff near sea level, where joints, fissures, and softer strata are especially vulnerable. The cliffs are undermined and caves are formed. Pocket beaches may accumulate between headlands from sediment carried by longshore currents. Especially durable pinnacles of rock may survive offshore as stacks or arches. Over time, the coast is straightened as the headlands are eroded back (c).

(a) Beaches. Beaches may form at the base of cliffs if the rubble that has fallen from the cliff face (known as talus) is unconsolidated or friable and breaks down rapidly under wave attack (Figures IV-2-9 and IV-2-15). If the rock debris is durable, it may serve to armor the shore, protecting it from further wave attack except during the most severe storms.

(b) Wave-cut platforms. At the base of cliffs that have been progressively cut back by waves, near-horizontal platforms may form just below sea level. These rocky platforms may be of substantial width, depending on lithology and the time that sea level has been at that height (Figure IV-2-17). The platforms may be clean or may be covered with rubble fallen from the adjacent cliffs.

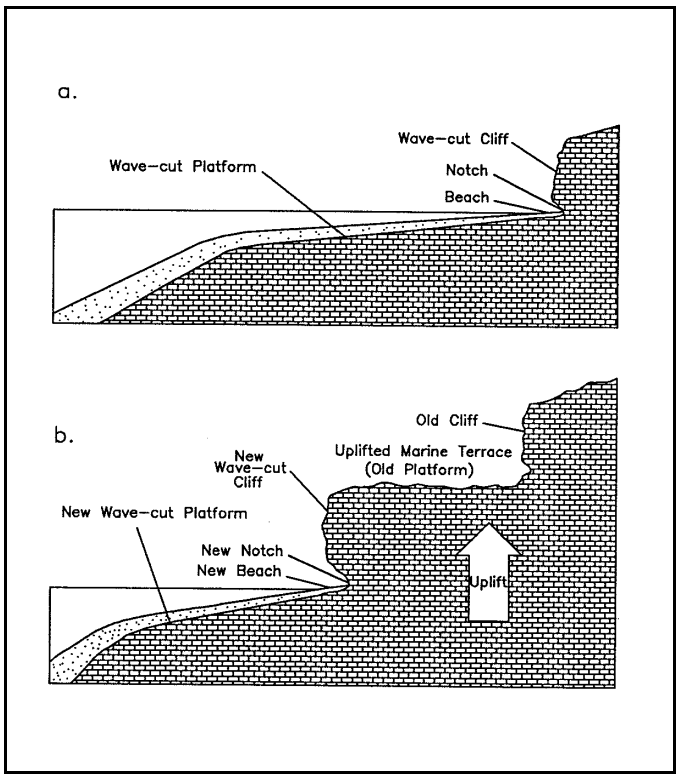

Figure IV-2-17. Wave-cut platform exposed by tectonic uplift. Sediment that accumulated on the platform may temporarily protect the cliff from further erosion

(2) Creation of irregular shorelines. In some mountainous terrains, rising sea level results in deeply incised coastlines. This process is illustrated in Figure IV-2-19. As the sea rises, a river valley is inundated. Once exposed to the sea, the new shoreline is subject to dissolution and biological attack. In southern France, Italy, Greece, and Turkey, thousands of deep embayments are found in the coastal limestone hills. The fact that the wave climate in the Mediterranean is relatively calm (compared with the open oceans) suggests that erosional processes other than wave attack have been instrumental in creating these steep, indented shores. An irregular shore may also be formed when differing rock types outcrop at the coast. Massive rocks, especially igneous and metamorphic ones, withstand erosion better than most sedimentary rocks, which are usually friable and contain bedding planes and fractures. The Pacific coast of Washington off the Olympic Peninsula is irregular because of the complex geology and variety of exposed rock formations (Figure IV-2-20).

e. Marine cliffs are degraded by many physical and biological factors.

(1) Wave attack is most likely the primary mechanism that causes cliffs to erode (Komar 1976). The hydraulic pressure exerted by wave impact reaches values sufficient to fracture the rock. Sand and rock fragments hurled at the cliff by waves grind away at the surface. Komar (1976) states that wave erosion occurs chiefly during storms, but admits that little quantitative research has been conducted. Once a cliff has been undercut at its base, the overlying rock, left unsupported, may collapse and slide down to the shoreline (Figures III-5-21, IV-2-21, and IV-2-22). Temporarily, the talus protects the cliff, but over time the rubble is reduced and carried away, leaving the fresh cliff face exposed to renewed wave attack.

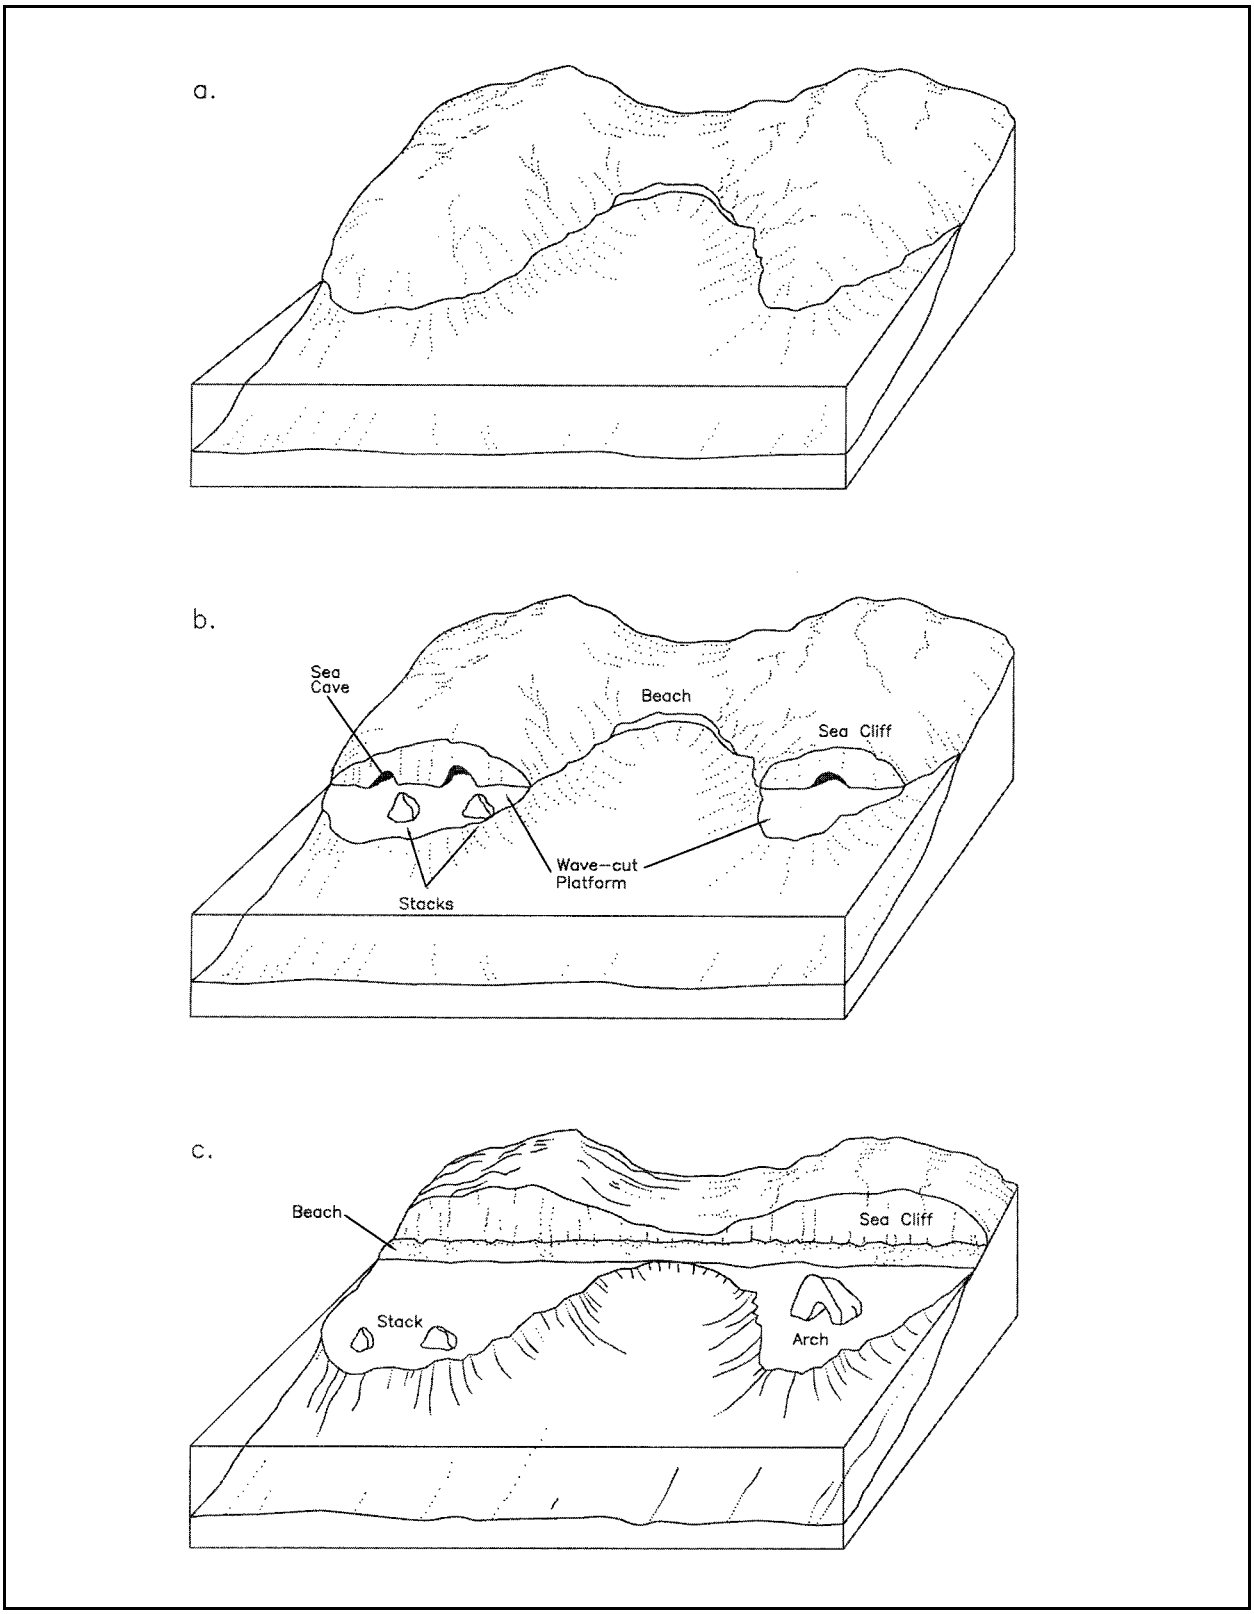

Figure IV-2-18. Wave erosion of an indented coastline produces a straightened, cliff-bound coast. Wave-cut platforms and isolated stacks and arches may remain offshore. Many such features are found along the Washington, Oregon, and California coast (adapted from de Blij and Muller (1993))

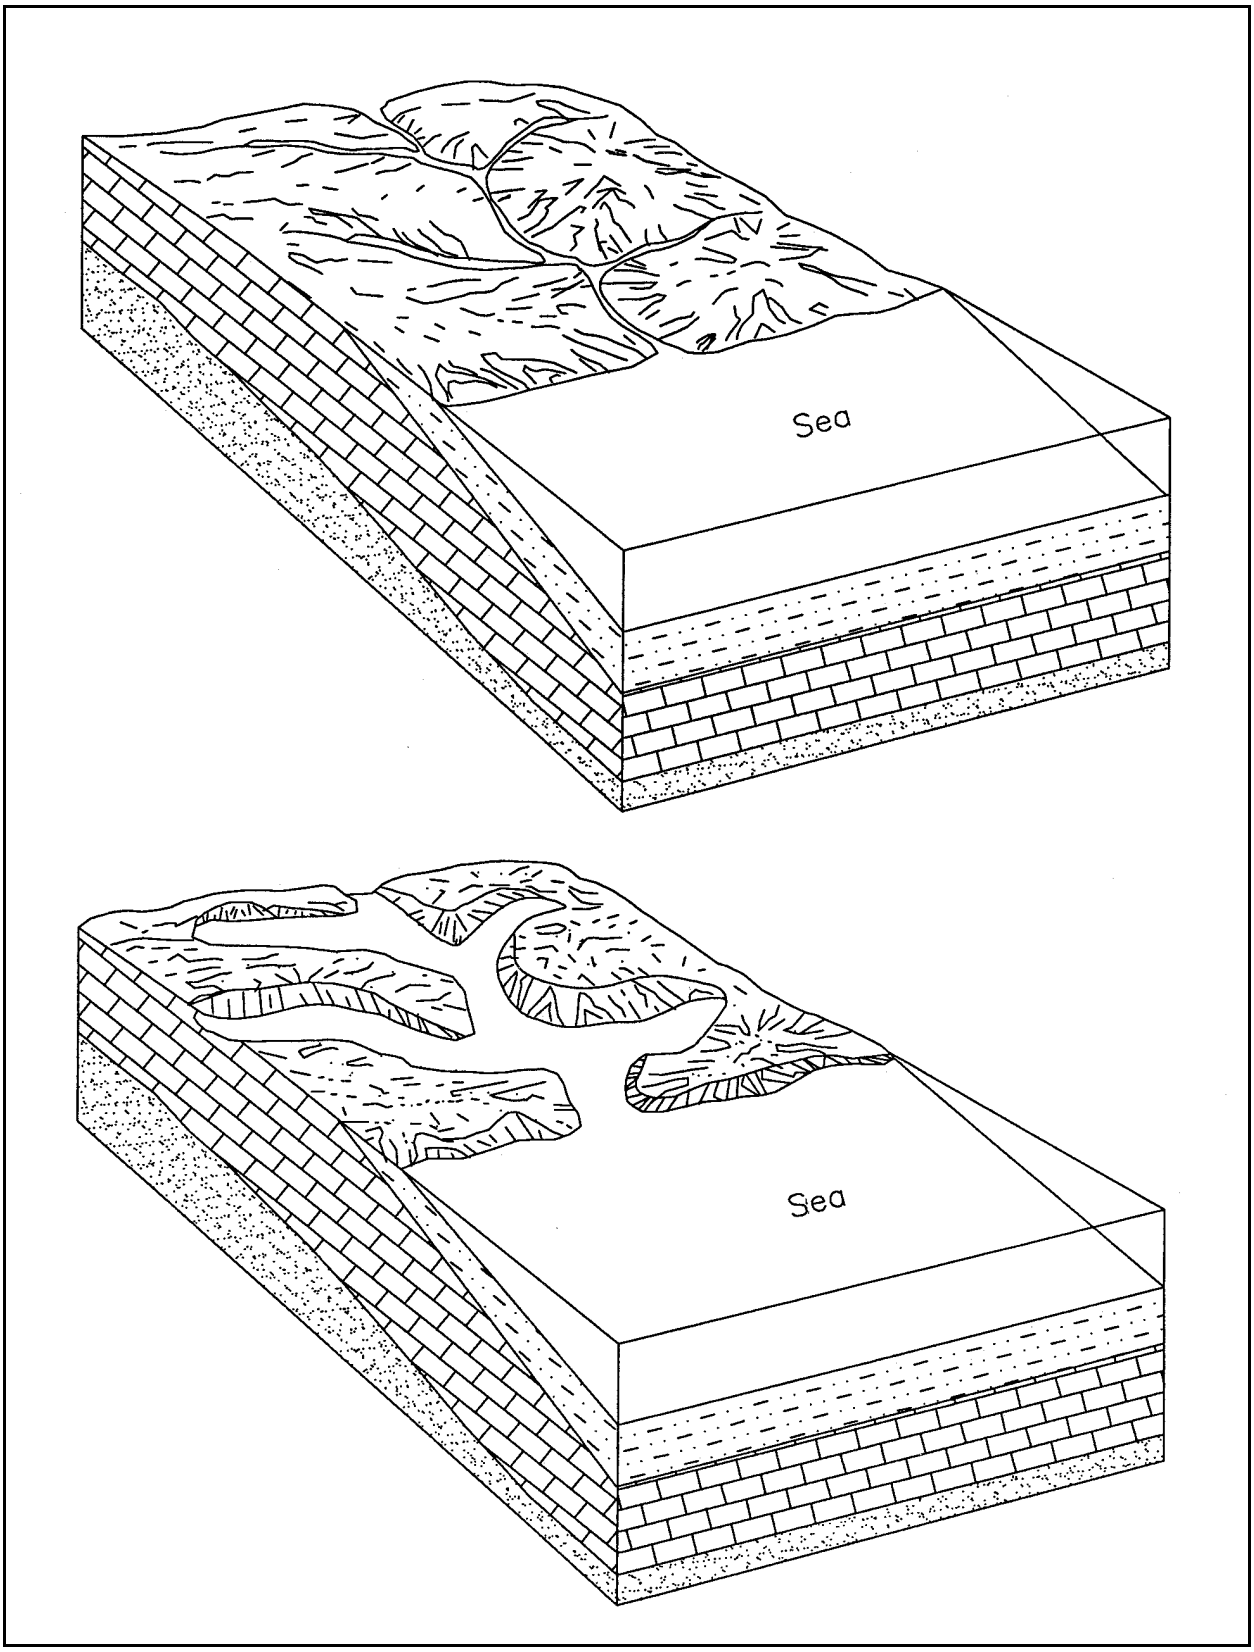

Figure IV-2-19. Inundation of a mountainous area by rising sea level or land subsidence produces a deeply indented shoreline

Figure IV-2-20. Pacific Ocean coast of Olympic Peninsula, Washington, near Jefferson Cove (September 1971). Rugged shore consists of resistant rock headlands with pocket beaches. Much of the beach sediment is cobble and coarse clasts derived from the adjacent cliffs. The beaches are often covered with logs and driftwood

(2) In addition to waves, weathering processes weaken and crumble sea cliffs. Ice wedging in cold climates progressively weakens the rock. Plant roots grow and expand in cracks. Lichens secrete acids that etch the rock surface. Groundwater can lubricate impermeable rock surfaces, upon which large masses of overlying rock can slip. This process is responsible for large slumps in the shale bluffs in Lakes Erie and Ontario (Figure III-5-21).

(3) Mollusks and burrowing animals can weaken otherwise resistant massive rocks. Komar (1976) lists burrowing mollusks such as *Pholadidae* and *Lithophaga*, and periwinkles, worms, barnacles, sponges, and sea urchins as having been observed to erode rock. Boring algae can also weaken rock (Figure IV-2-23).

(4) Under normal circumstances, surface seawater is saturated with calcium carbonate ($CaCO_3$), therefore minimizing dissolution of limestone or $CaCO_3$-cemented sediments. Marine organisms can locally increase the acidity of the water in high-tide rock basins and other protected locations. Small pockets found

Figure IV-2-21. A section of cliff, projecting out from the shore, is likely to collapse soon. To the left, rubble at sea level marks the location of a previous slump. The lower cliffs are poorly cemented conglomerate while the higher, vertical cliffs (above the trees), are limestone (near Nauplió, Greece, April 1992)

at water's edge, often housing periwinkles and other animals, may have been caused by biochemical leaching.

(5) Salt weathering is caused by the pressure exerted by NaCl and other salts in the capillaries of rocks. The weathering is caused by:

(a) Changes of volume induced by hydration.

(b) Expansion of salt crystals caused by temperature changes.

(c) Crystal growth from solution.

The main factor in determining the efficacy of chemical weathering is the amount of water available for chemical reactions and the removal of soluble products. This suggests, but does not necessarily restrict, that the greatest chemical weathering will occur in hot, humid climates (Trenhaile 1987).

IV-2-9. Marine Deposition Coasts - Barriers

a. Introduction.

(1) Barriers are narrow, elongate sand ridges rising slightly above the high tide level and extending generally parallel with the coast, but separated from the mainland by a lagoon or marsh (Bates and Jackson

Figure IV-2-22. Lake Michigan shore south of St. Joseph, Michigan (November 1993). A triangle-shaped wedge of the bluff has recently slumped. The bluffs in this area have suffered rapid retreat, and many homes have been destroyed. At least three factors account for the erosion: (a) offshore downcutting of the till lake bottom; (b) wave attack on the bluffs; (c) ice expansion and lubrication of bedding planes caused by groundwater

1984). The term *barrier* identifies the sand ridges as ones that protect parts of the coast from direct wave attack of the open ocean. In this manual, barrier will refer to the overall structure (sometimes called a barrier complex), which includes the beach, submerged nearshore features, underlying sediments, and the lagoon between the barrier and the mainland (Figure IV-2-24). Inlets and channels can also be considered part of a barrier system.

(2) The term *beach* is sometimes used as a synonym for barrier, but this can lead to confusion because a beach is a geomorphic shore type found throughout the world, even on volcanic or coralline coastlines where barriers are rare. Whereas all barriers include beaches, not all beaches are barriers.

(3) The following sections describe general barrier island morphology, history, and formation, subjects that have fascinated geologists for more than 100 years. The emphasis will be on long-term changes, covering periods of years or centuries. The purpose is to explain factors that lead to barrier migration or evolution. Longshore sediment transport, details on the morphology of sandy shorefaces, and the normal effects of waves and tides will be covered in Part IV-3, "Coastal Morphodynamics." This distinction is arbitrary because, clearly, the day-to-day processes that affect beaches also influence barrier development. In addition, the evolution of barriers during the Holocene Epoch is intimately related to sea level changes (see Part IV-1). These factors underscore the complex interrelationships that exist throughout the coastal zone and the difficulty of separating the constituent elements.

Figure IV-2-23. Cemented conglomerate with many pits and cavities shows evidence of dissolution. The rock mass has been undercut over 1 m (near Nauplió, Greece). Note that the conglomerate is distinctly graded, with fine grains near the bottom and cobble near the top

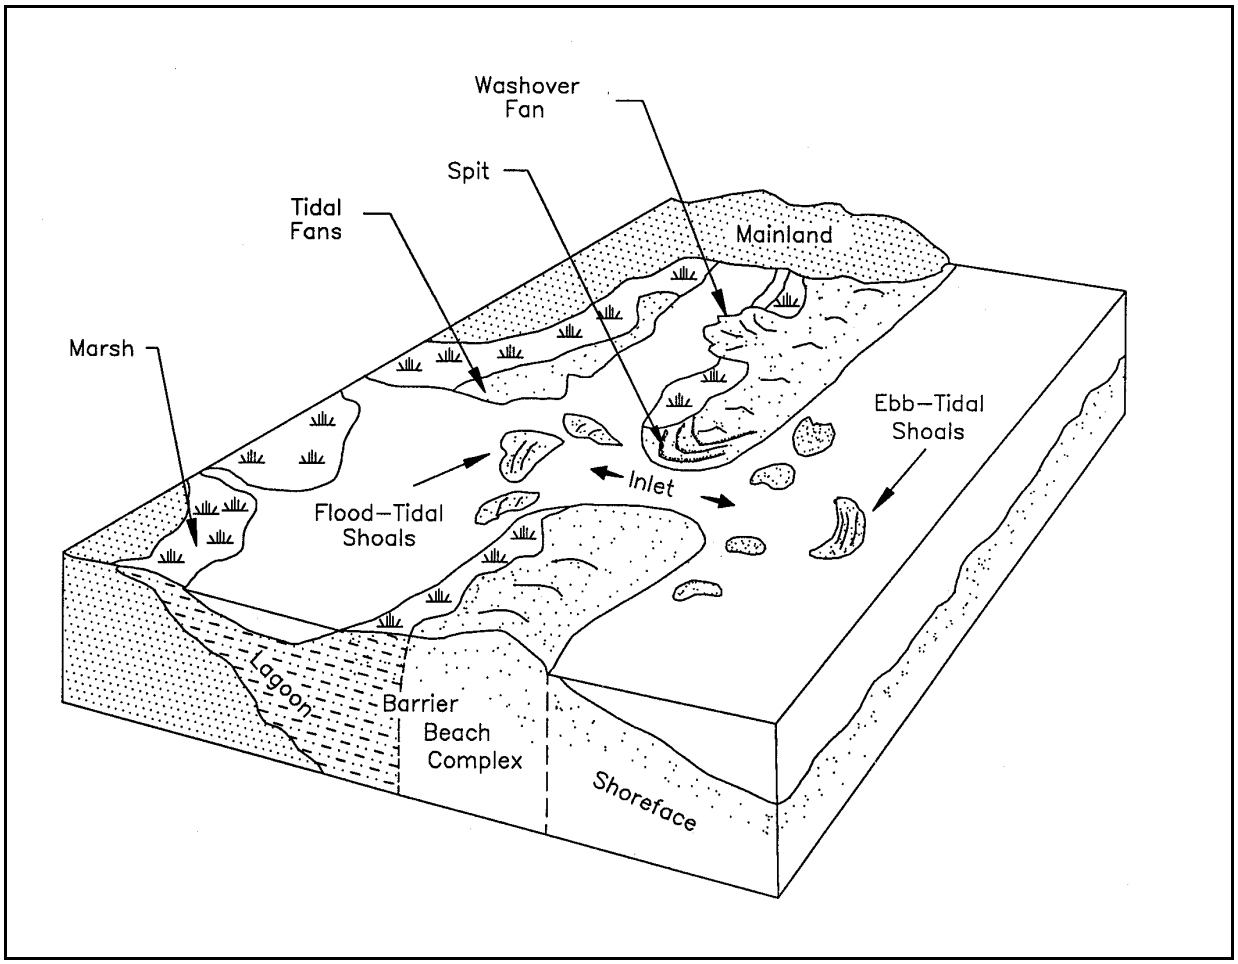

Figure IV-2-24. A three-dimensional view of features commonly found in barrier island systems, including the back barrier, overwash fans, and lagoons. The lagoons often become estuaries, particularly if sediment is supplied by both rivers and inlets

(4) The long-term and widespread interest in barrier islands is largely due to their great economic importance. Ancient buried barriers are important petroleum reservoirs. Contemporary barriers protect lagoons and estuaries, which are the breeding grounds for many marine species and birds. In addition, barrier islands are among the most important recreational and residential regions. In recent years, man's adverse impact on these fragile ecological and geological environments has led to increased need to study their origins and development to improve coastal management and preserve these critical resources for the future.

(5) An enormous literature on barrier islands exists. Nummedal (1983) provides a readable and concise overview. Leatherman's (1979) book is a compilation of papers on U.S. east coast and Gulf of Mexico barriers. Many seminal papers on barrier island evolution have been reprinted in Schwartz (1973). Textbooks by Carter (1988), Davis (1985), King (1972a), and Komar (1976) discuss barriers and include voluminous reference lists. Classic papers on beach processes have been reprinted in Fisher and Dolan (1977).

b. Distribution of barrier coasts. Barrier islands are found around the world (Table IV-2-2). They are most common on the trailing edges of the migrating continental plates (Inman and Nordstrom 1971)[1]. This type of plate boundary is usually non-mountainous, with wide continental shelves and coastal plains. Over 17 percent of the North American coastline is barrier, most of it along the eastern seaboard facing the Atlantic Ocean and the Gulf of Mexico. Table IV-2-3 lists the lengths of barriers and spits in the United States. Of the Atlantic states, Maine and New Hampshire have the fewest barriers because their coasts are largely composed of igneous rock. Massachusetts, with mostly glacial moraines and outwash along the coast, has the surprising total of 184 km of spits and barriers. Of the continental states, Florida has the most barriers and spits, totaling over 1,000 km for both the Atlantic and the Gulf of Mexico. Most of the shorelines facing the Gulf of Mexico consist of barrier islands. A portion of Florida's west coast, where wave energy is low, is mangrove swamp, but the Panhandle is famous for its glistening white barriers.

Table IV-2-2
Worldwide Distribution of Barrier Island Coasts

Continent	Barrier Length (km)	% of World Total Barriers	% of Continent's Coastline that is Barrier
N. America	10,765	33.6	17.6
Europe	2,693	8.4	5.3
S. America	3,302	10.3	12.2
Africa	5,984	18.7	17.9
Australia	2,168	6.8	11.4
Asia	7,126	22.2	13.8
Total	32,038	100.0	

From Cromwell (1971)

Almost the entire shore of Texas consists of long barriers, which continue south into Mexico. Extensive barriers are also found on the Gulf of Alaska north of Bering Strait. Including numerous spits in the Aleutians and the Gulf of Alaska, the state of Alaska has almost 1,300 km of barrier in total, exceeding Florida. The United States total shown in Table IV-2-3 is 4,882 km, about half the North American total computed by Cromwell (1971). For more information, the most extensive survey of United States barriers was documented in the *Report to Congress: Coastal Barrier Resources System* (Coastal Barriers Study Group 1988).

c. General coastal barrier structure. The barrier shore type covers a broad range of sizes and variations. Three general classes of barrier structures can be identified (Figure IV-2-25):

(1) Bay barriers - connected to headlands at both ends and enclosing a bay or wetland.

(2) Spits - attached to a sediment source and growing downdrift. May be converted to a barrier island if a storm cuts an inlet across the spit. May evolve into bay barriers if they attach to another headland and completely enclose a lagoon.

[1] *The trailing edge* of a continent is moving away from an active spreading center. For example, the Atlantic coast of the United States is a trailing edge because new seafloor is being formed along the mid-Atlantic ridge, causing the Atlantic Ocean to grow wider (Figure IV-1-2). The Pacific coast is a *leading edge* because the oceanic plates are being subducted (consumed) at various trenches and are therefore becoming smaller.

Table IV-2-3
Barrier Islands and Spits of the United States

Ocean or Sea	State	Total Length (km)[1]
Atlantic	Maine	11.4
	New Hampshire	2.5
	Massachusetts [2]	184.4
	Rhode Island [3]	17.6
	New York [4]	152.2
	New Jersey	106.0
	Delaware [5]	33.7
	Maryland [5]	49.2
	Virginia [5]	126.0
	North Carolina	380.7
	South Carolina	234.2
	Georgia	159.0
	Florida	533.3
	Atlantic coast total	**1990**
Gulf of Mexico	Florida	478.5
	Alabama	92.7
	Mississippi	59.5
	Louisiana	151.9
	Texas	498.0
	Gulf of Mexico total	**1281**
Pacific - Continental USA	Washington [6]	63.9
	Oregon	91.9
	California	65.4
	Pacific total	**221**
Beaufort, Chukchi, Bering Seas, Gulf of Alaska, Bristol Bay	Alaska total (incl. Aleutians)	**1266**
Lakes Superior, Huron, Michigan, Ontario, Erie	Combined Great Lakes states	**124**
United States total [2,3,4,5,6]		**4882**

Source: Unpublished data generated during the Corps of Engineers' Barrier Island Sediment Study (BISS), 1989.
[1] Length of barriers measured from U.S. Geological Survey topographic maps. Includes barriers and spits enclosing a body of water or marsh, not the total length of beaches in the United States. No data available for Puerto Rico, Virgin Islands, Pacific Trust Territories.
[2] Includes Nantucket and Martha's Vineyard Islands.
[3] Does not include Narragansett Bay.
[4] Atlantic Ocean only; does not include spits in Long Island Sound or Great Peconic Bay.
[5] Does not include Chesapeake Bay.
[6] Includes spits in Strait of Juan de Fuca. Does not include Long Beach Peninsula, enclosing Willapa Bay.

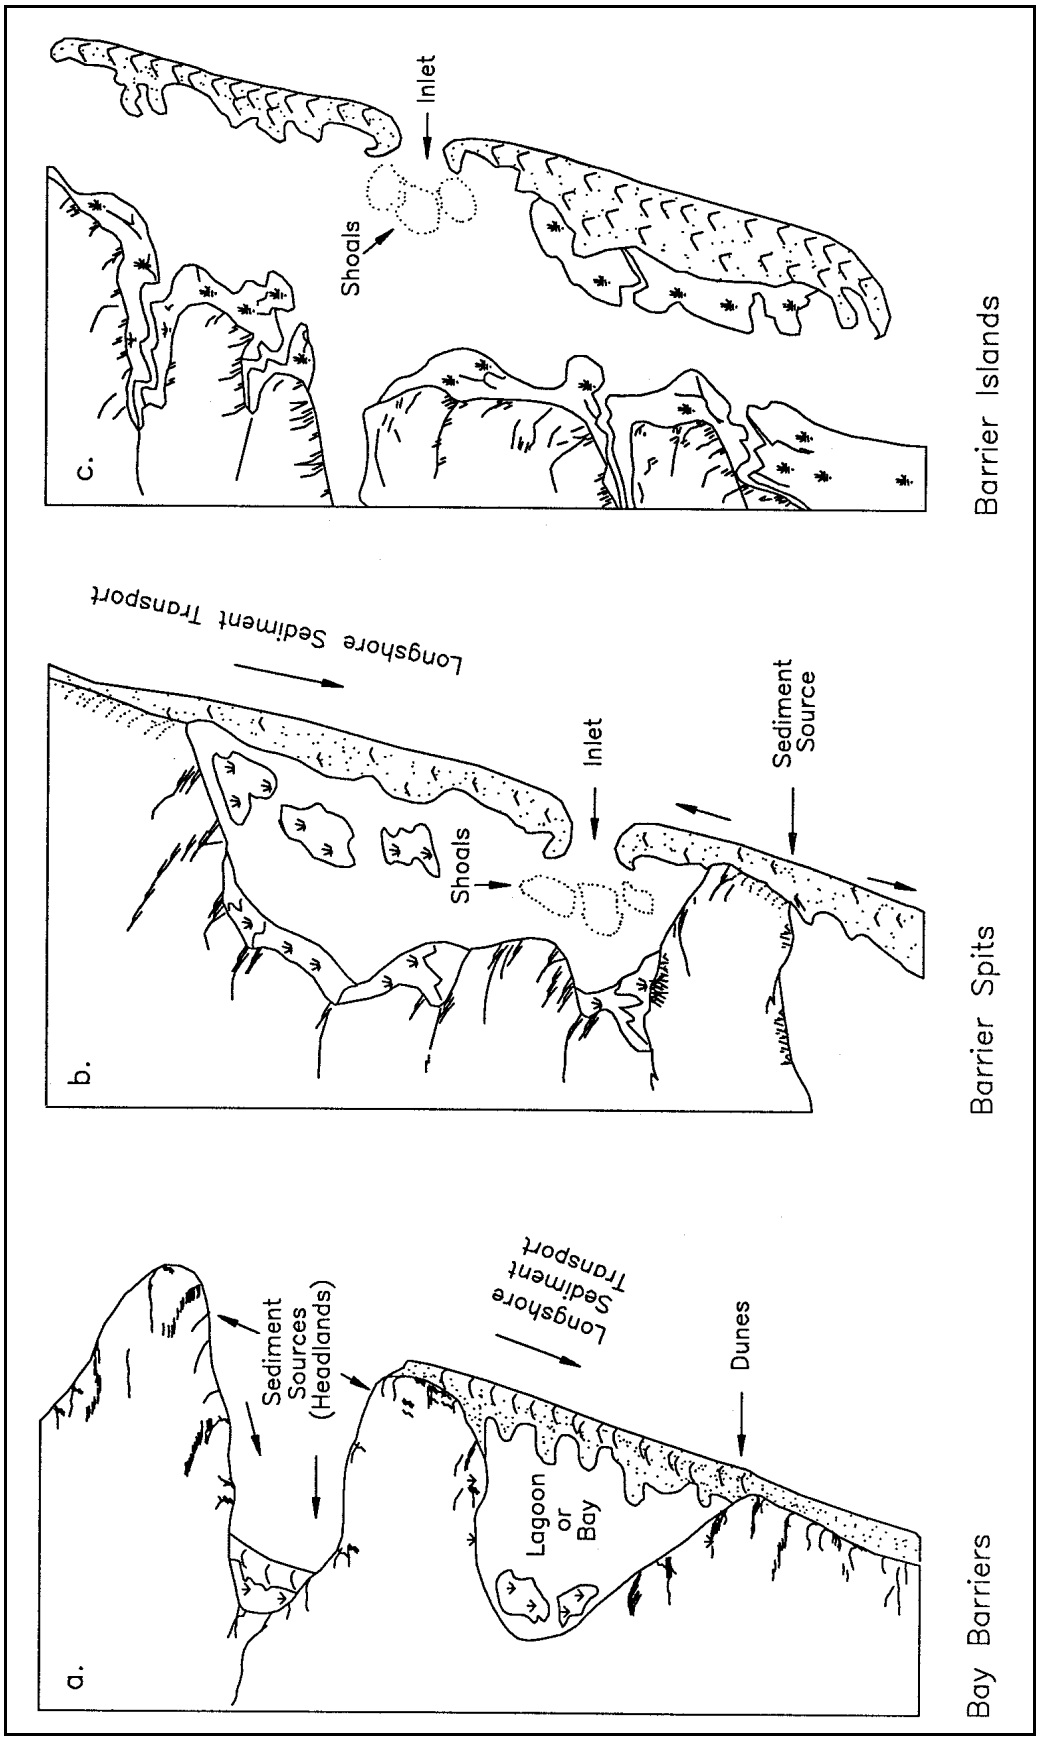

Figure IV-2-25. General barrier types: bay, spit, and island

(3) Barrier islands - linear islands that are not attached to the mainland but that enclose a bay, pond, or marsh/wetland. A series of these islands extending along the coast are defined as a barrier chain.

d. Origin and evolution. The origin of barrier islands has been a topic of debate among geologists for over a century (Schwartz 1973). The differing theories suggest that there are probably several types of barriers, each undergoing its own form of development due to unique physical and geologic factors. Three main theories have evolved, all of which have fierce supporters and critics.

(1) Emergence model. De Beaumont in 1845 was the first naturalist formally to present a theory of barrier island formation. It was supported and modified by the influential Johnson (1919). These researchers theorized that barrier emergence began with the formation of an offshore sand shoal, which consisted of material reworked from the seafloor by waves. Over time, the shoal would accumulate ever more sand and grow vertically, eventually emerging above the sea surface (Figure IV-2-26). Wave swash and wind deposition would continue to contribute sand to the shoal, allowing it to grow larger and larger. Hoyt (1967) objected to this hypothesis because he was unaware of any examples of bars emerging above water and surviving wave action, although the growth of submerged bars was well-recorded. Otvos (1970) reported evidence from the Gulf coast supporting the emergence of submarine shoals (he conveniently noted that subsequent migration of barriers might completely obscure the conditions of formation of the original barrier).

(2) Submergence model. The submergence concept was refined by Hoyt (1967) and has received much support. In this model, the initial physical setting is a mainland beach-and-dune complex with a marsh separating the beach from higher terrain inland. Rising sea level floods the marsh, creating a lagoon that separates the beach from the mainland (Figure IV-2-27). Presumably, usually the sea level rise is part of a worldwide pattern (eustatic), but it may be caused in part by local submergence. Once formed, maintenance of the barrier becomes a balance of sediment supply, rate of submergence, and hydrodynamic factors.

(3) Spit detachment model. The third major model calls for the growth of sandspits due to erosion of headlands and longshore sediment transport (Figure IV-2-28). Periodically, the spit may be breached during storms. The furthest portion of the spit then becomes a detached barrier island, separated by a tidal inlet from the portion that is still attached to the mainland. Gilbert (1885) may have been the first geologist to suggest the spit hypothesis, based on his studies of ancient Lake Bonneville, but the hypothesis lay dormant for many years because of Johnson's (1919) objections. In recent years, it has received renewed support because the cycle of spit growth and breaching can be seen in many locations (for example, at Cape Cod, Massachusetts (Giese 1988)).

(4) Combined origin model. Schwartz (1971) concluded that barrier island formation is most probably a combination of all of the above mechanisms. He felt that only a few examples of barriers could be cited as having been formed by only one method. Most systems were much more complex, as demonstrated by the barriers of southern Louisiana, which were formed by a combination of submergence and spit detachment (Penland and Boyd 1981).

e. Barrier response to rising sea level.

(1) Many of the barriers in the United States, particularly along the Atlantic coast, are eroding, causing serious economic and management challenges. What is responsible for this erosion?

(2) Sea level and sediment availability are probably the major factors that determine barrier evolution (Carter 1988). Three sea level conditions are possible: rising, falling, and stationary. Rising and falling sea

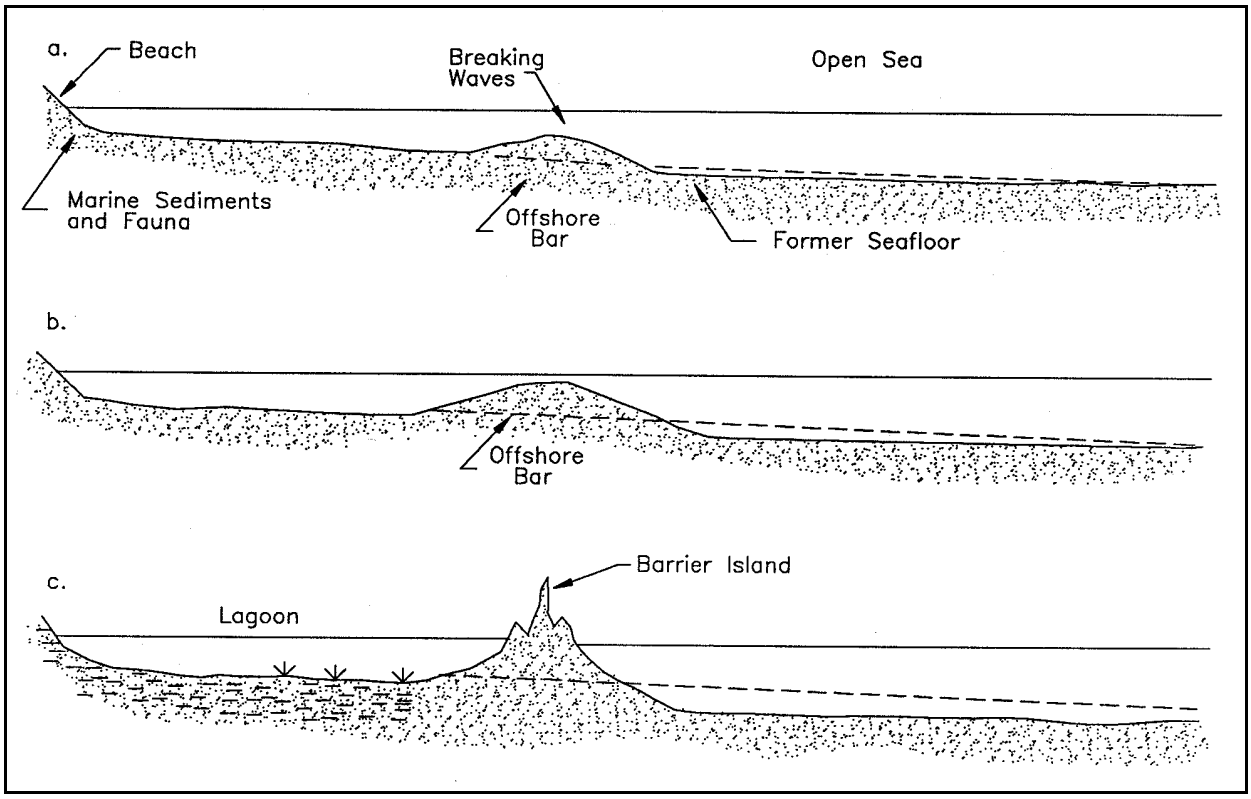

Figure IV-2-26. Emergence model of barrier island formation (modified from Hoyt (1967)), (a) Waves erode the seafloor, forming a sandbar, (b) The bar continues to grow higher and wider, (c) Bar is converted to an island, enclosing a lagoon on the landward side

usually result in great sediment movement as barriers adjust. A stationary stage, however, allows the shore to adjust slowly and achieve equilibrium between sediment supply and dynamic processes. Commonly, if sea level rises and sediment supply is constant, a barrier retreats (*transgression* of the sea). On the other hand, if sea level is rising but a large amount of sediment is supplied locally by rivers or eroding headlands, a particular barrier may be stable or may even aggrade upwards (see Table IV-1-6). However, many other factors can intervene: local geological conditions, biological activity, susceptibility to erosion, the rate of sea level change. Therefore, each location must be evaluated individually.

(3) Given the condition of rising sea level along the eastern United States, what are the mechanisms that cause barrier retreat? Three models of shoreline response to rising sea level have been proposed (Figure IV-2-29). These assume that an equilibrium profile is maintained as the shoreline is displaced landward and upward. In addition, overall sediment budget is balanced and energy input is constant.

(a) The first model, often called the Bruun Rule (Bruun 1962), assumes that sediment eroded from the shoreface is dispersed offshore. As water level rises, waves erode the upper beach, causing the shoreline to recede. Conceptually, this erosion supplies sediment for upward building for the outer part of the profile. The model assumes that the initial profile shape will be reestablished farther inland but at a height above the original position equal to the rise in water level z. Therefore, the retreat of the profile x can be calculated from the following relationship (a modified version of the Bruun Rule):

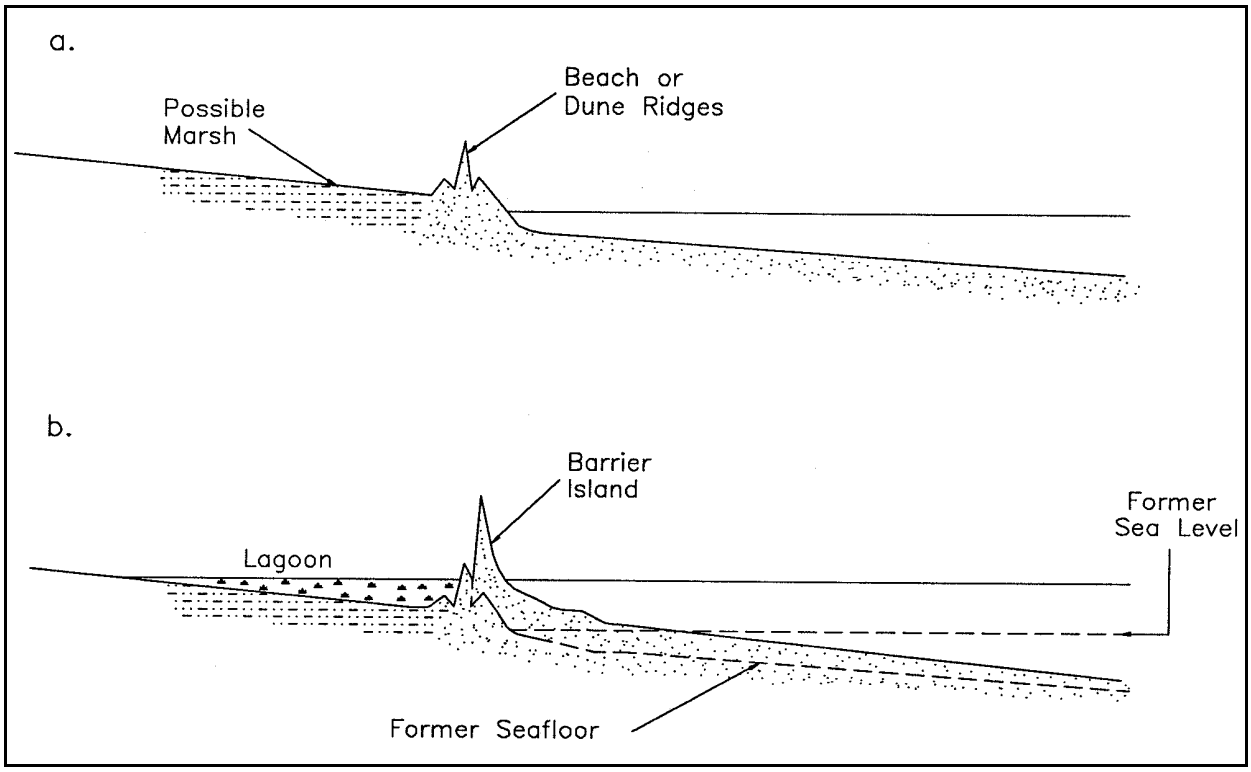

Figure IV-2-27. Submergence model of barrier island formation (modified from Hoyt (1967)), (a) Beach or sand dune ridges form near the shoreline, (b) Rising sea level floods the area landward of the ridge, forming a barrier island and lagoon. Sediment must be available to allow the island to grow vertically as sea level rises

$$x = \frac{zX}{Z} \tag{IV-2-1}$$

where the terms *x, z, X,* and *Z* are shown in Figure IV-2-29a. Attempts to verify the Bruun rule have been ambiguous, and modifications to the model have been proposed (Dolan and Hayden 1983). The most successful studies required long-term data sets, such as the profiles from Lake Michigan examined by Hands (1983). His research showed that the shoreface profile requires a considerable time (years or decades) to adjust to water level changes. It is unclear whether the Bruun Rule would apply if an ample supply of sediment were available during rising sea level. Would the barrier essentially remain in place while sand eroded from the shoreface or newly supplied sand was dispersed offshore to maintain the profile? The Bruun Rule and some of its underlying assumptions are discussed in greater detail in Part IV-3.

(b) Landward migration of a barrier by the rollover model applies to coasts where washover processes are important. As sea level rises, material is progressively stripped from the beach and shoreface and carried over the barrier crest by waves. The sand is deposited in the lagoon or marsh behind the barrier (Figure IV-2-30). Dillon (1970) documented this process along the southern Rhode Island coast. As the barrier moves landward (rolls over itself), lagoonal sediments may eventually be exposed on open shoreface. Evidence of this can be seen in Rhode Island during winter storms, when large pieces of peat are thrown up on the beach. Dingler, Reiss, and Plant (1993) have described a model of beach erosion and overwash deposition on the Isles Dernieres, off southern Louisiana. They attributed a net annual beach retreat of

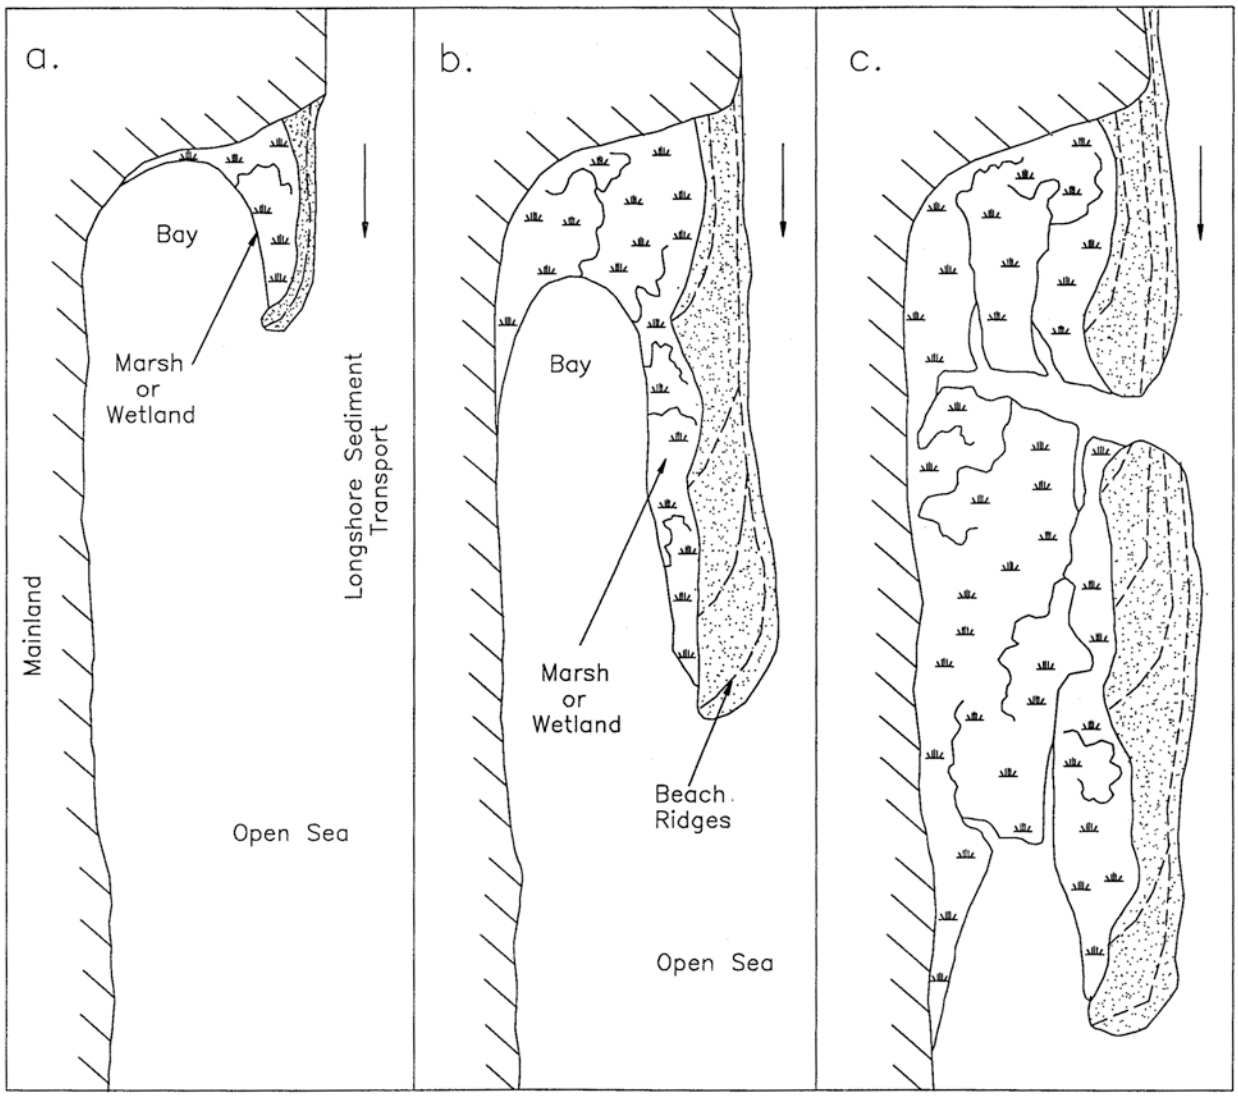

Figure IV-2-28. Barrier island formation from spit (modified from Hoyt (1967)), (a) Spit grows in direction of longshore drift, supplied from a headland, (b) Spit continues to grow downdrift, marsh begins to fill semi-protected bay, (c) Part of spit is breached, converting it to a barrier island

greater than 10 m/yr to winter cold-front-driven storms that removed sediment from the beach face and infrequent hurricanes that shifted a substantial quantity of sediment to the backshore. For the most part, rollover is a one-way process because little of the sand carried over the barrier into the lagoon is returned to the open shoreface.

(c) The barrier overstepping model suggests that a barrier may be drowned, remaining in place as sea level rises above it. Several hypotheses have been proposed to explain how this process might occur:

- If the rate of sea level rise accelerates, the barrier may be unable to respond quickly by means of roll-over or other mechanisms. Carter (1988) cites research that suggests that gravel or boulder barriers are the most likely to be stranded.

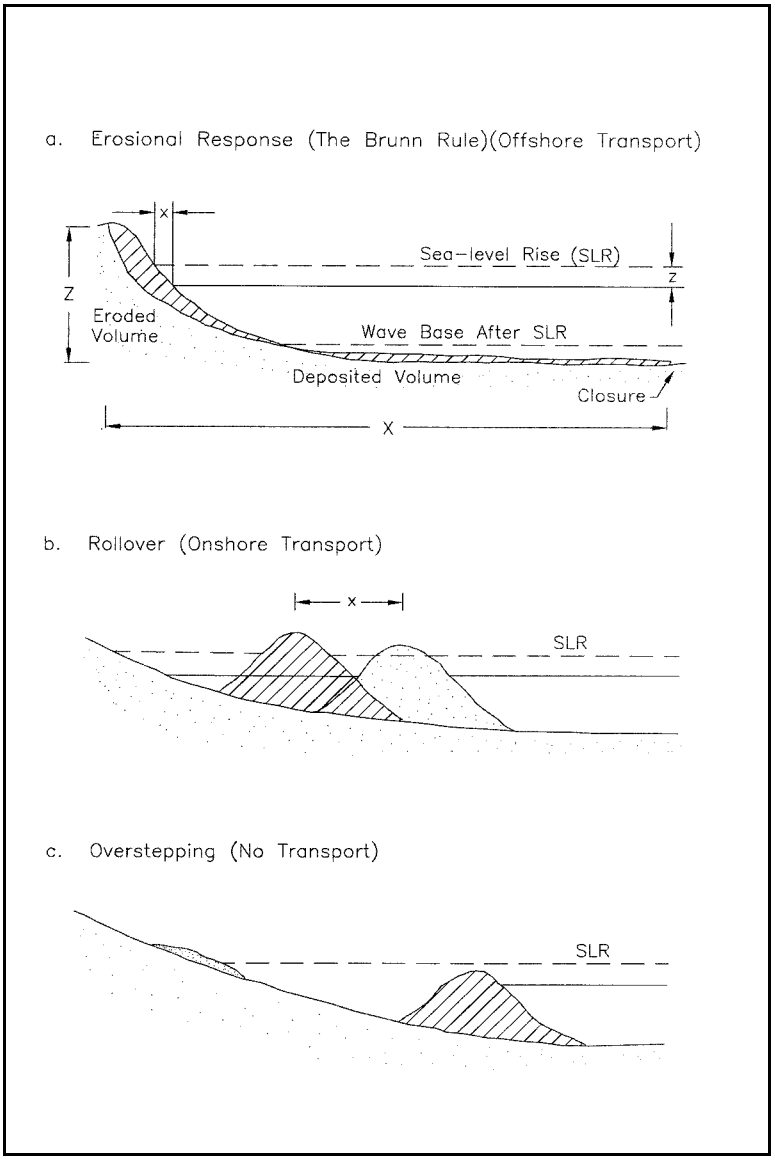

Figure IV-2-29. Three models of shoreline response to sea level rise: (a) Erosional response model/Bruun Rule assumes offshore dispersal of eroded shoreline materials; (b) Island rollover model assumes that barriers migrate landward according to the rate of sea level rise; (c) Overstepping model assumes submergence in place (adapted from Carter (1988))

- A modest influx of sediment may retard barrier migration enough to allow overstepping. If a constant volume of sediment is available, the new material must be distributed over a wider and wider base as sea level rises. The result is that vertical growth per unit time decreases. Eventually, the barrier is overtopped and the surf zone jumps forward to the bay shoreline that was formerly protected.

Figure IV-2-30. Westhampton Beach, Long Island, New York (March 1994 - view looking north towards Moriches Bay). In December 1992, the barrier island breached here during a northeaster, and 60 houses were destroyed. A large overwash fan can be seen in the bay, and to the left are houses that survived the storm. This is an example of the rollover mechanism, when sand from the ocean-facing shoreface is carried over the barrier and deposited in the back bay. The breach was repaired by the Corps of Engineers during 1993 using sand dredged from offshore. This low stretch of the barrier is particularly vulnerable, with several earlier breaches on record. In summer 1998, new homes were again being built here

- A barrier may remain in place because of a dynamic equilibrium that develops between landward and seaward sediment transport. As sea level rises, tidal prism of the lagoon increases, resulting in more efficient ebb transport. During this time, an increasing amount of washover occurs, but the effect is counteracted because sediment is being returned to the exposed shoreface. If little or no new sediment is added to the system, the sea eventually rises above the barrier crest, allowing the surf zone to jump landward to a new location (the formerly protected mainland shore).

- All three of these mechanisms may come into play at various times, depending upon environmental conditions. Sediment supply may be the crucial factor, however. Some stranded barriers, such as the ones in the northeastern Gulf of Mexico, may have maintained vertical growth because of an adequate sediment supply (Otvos 1981).

(4) In all likelihood, barriers respond to all three of the migration models, depending upon timing and local conditions such as sediment supply or preexisting topography (Carter 1988). During the initial stages of sea level rise, the shore erodes and material is dispersed offshore (the Bruun Rule). As the barrier becomes narrower, washover carries more and more sediment to the back lagoon. Eventually, the barrier may become stranded and be drowned. These models have been criticized because they are two-dimensional and do not account for variations in longshore drift. The criticisms are valid because drift is sure to vary greatly as barriers are progressively reshaped or drowned. As a result, pockets of temporarily prograding barriers may remain along a generally retreating coastline.

(5) In summary, several models have been advanced to explain how barrier islands respond to rising sea level. However, because the interactions in the coastal zone are so complex, trying to reduce barrier evolution to a series of simple scenarios is unrealistic. Much more research is needed to define the many factors that contribute to barrier evolution.

IV-2-10. Marine Deposition Coasts - Beaches

a. Introduction. Marine and lacustrine beaches comprise one of the most widely distributed coastal geomorphic forms around the world. Their importance as a buffer zone between land and sea and as a recreational and economic resource has stimulated studies by earth scientists for well over a century. Although much has been learned about how beaches form and how they are modified, the coastal environment is incredibly complex, and each location responds to unique geologic conditions and physical processes. Some of these variable factors include:

(1) Seasonal cycles.

(2) Long-term trends.

(3) Changes in relative sea level.

(4) Variations in sediment supply.

(5) Meteorological cycles.

As a result, it is difficult to characterize beaches and predict future developments without the benefit of long-term studies and observations. The following sections describe the morphology and sediments of beaches and define terms (also see Table IV-1-1). For additional information and extensive bibliographies, the reader is referred to Carter (1988), Davis (1985), Komar (1976, 1983), and Schwartz (1973, 1982).

b. General definition. ***Beach*** is defined as a gently sloping accumulation of unconsolidated sediment at the edge of a sea or other large body of water (including lakes and rivers). The landward limit may be marked by an abrupt change in slope where the beach meets another geomorphic feature such as a cliff or dune. Although this landward boundary has been consistently accepted in the literature, the seaward limit has been more broadly interpreted. Some authors have included the surf zone and the bar and trough topography in their definition because the processes that occur in the surf zone directly affect the exposed portion of the beach. The length of beaches varies greatly. Some stretch for hundreds of kilometers, such as those on the Carolina Outer Banks. Others, called pocket beaches, are restricted by headlands and may be only a few tens of meters long.

c. Major subdivisions. Beaches are part of the littoral zone, the dynamic interface between the ocean and the land. The littoral zone is bounded on one side by the landward limit of the beach and extends tens or hundreds of meters seaward to beyond the zone of wave breaking (EM 1110-2-1502). Beaches can be divided into two major zones: the foreshore and the backshore.

(1) Foreshore.

(a) The foreshore extends from the low-water line to the limit of wave uprush at high water (Figure IV-1-2). The upper portion of the foreshore is a steep slope where the high water uprush occurs. The seaward, lower, portion of the foreshore is sometimes called the *low-water or low-tide terrace.* This terrace often features low, broad ridges separated by shallow troughs, known as ridges and runnels (Figure IV-2-31).

Figure IV-2-31. Ridge and runnel system, low water terrace, Charlestown Beach, Rhode Island. Sea grass debris in the foreground marks the height of the wave runup during the previous high tide. Where should the "shoreline" be defined on this beach?

Because the foreshore is frequently subject to wave swash, it usually has a smoother surface than the backshore. There may be a minor step near the low-water mark, called the *plunge step.* Often, shell or gravel is concentrated at the base of this step, while the sediments to either side are much finer.

(b) The foreshore is sometimes called the *beachface.* However, beachface is also used in a more restricted sense to designate the steepened portion of the upper foreshore where the high-water wave uprush occurs. Therefore, it is recommended that foreshore and beachface not be used synonymously and that beachface be restricted to its upper foreshore definition.

(2) Backshore.

(a) The backshore extends from the limit of high water uprush to the normal landward limit of storm wave effects, usually marked by a foredune, cliff, structure, or seaward extent of permanent vegetation. The backshore is not affected by waves regularly, but only during storms, when high waves and storm surges allow reworking of backshore sediments. Between inundations, the backshore develops a rough surface because of vehicle or animal traffic and the development of wind-blown bed forms. On eroding beaches, the backshore may be missing, and the normal high-water uprush may impinge directly on cliffs or structures.

(b) Alternate terms for backshore are backbeach and berm. "Berm" is a common term because backshore areas are sometimes horizontal and resemble man-made berms. However, many beaches have a sloping backshore that does not resemble a berm, and some have more than one berm, representing the effects of several storms. Thus, berm is not synonymous with backshore, but may be a suitable description for selected areas. The term is sometimes used in beachfill and beach erosion control design.

(3) Coastline (or shoreline). The boundary between the foreshore and backshore, the high water line (hwl), is often defined to be the coastline. This is a practical definition because this land-water interface can be easily recognized in the field and can be approximated on aerial photographs by a change in color or shade of the beach sand (Crowell, Leatherman, and Buckley 1991). In addition, the coastline marked on the topographic sheets ("T-sheets") typically represents this same hwl, allowing a direct comparison between historic maps and aerial photographs. Some researchers have equated the coastline with the low-water line, but this boundary is not always marked by any evident feature or change in sand color. In various studies, one can find shoreline defined by almost any level datum. These inconsistencies make it difficult to compare shoreline maps prepared by different surveyors or agencies. Definition of "shoreline" often is controversial because it affects the legal definition of setback lines and other constraints placed on development in the coastal zone. A more detailed discussion of hwl identification is presented in Anders and Byrnes (1991); Crowell, Leatherman, and Buckley (1991); and Gorman, Morang, and Larson (1998).

d. Beach material.

(1) Sand beaches. On most of the coasts of the United States, the predominant beach material is sand (between 0.0625 and 2.0 mm, as defined by the Wentworth classification). Most sand beaches are composed mostly of quartz, with lesser percentages of feldspars, other minerals, and lithic (rock) fragments. Table IV-2-4 lists beach sediment types and common locations.

Table IV-2-4
Types of Beach Sediment

Type	Typical Locations
Quartz sand	East Coast of U.S. between Rhode Island and North Florida, Gulf Coast between West Florida and Mexico, portions of West Coast of U.S. and Great Lakes
Calcite shell debris	South Florida, Hawaii
Volcanic sand	Hawaii, Aleutians, Iceland
Coral sand	South Florida, Bahamas, Virgin Islands, Pacific Trust Territory
Rock fragments	Maine, Washington, Oregon, California, Great Lakes
Clay balls	Great Lakes, Louisiana

(2) Coarse beaches. Coarse beaches contain large amounts of granule-, pebble-, cobble-, and boulder-sized material (larger than 2.0 in the Wentworth classification). These beaches, found in the northeast, in the Great Lakes, and in mountainous reaches of the Pacific coast, occur under conditions where:

(a) Local streams flow with enough velocity to carry large particles to the shore.

(b) Coarse material underlies the beach (often found in areas influenced by glaciation or on metamorphic coasts).

(c) Coarse material is exposed in cliffs behind the beach (Figure IV-2-9).

The constituent material may be primarily angular rock fragments, especially if the source area, such as a cliff, is nearby (Figure IV-2-32). If the source area is far away, the most common rock types are likely to be quartzite or igneous rock fragments because these hard materials have a relatively long life in the turbulent beach environment. Softer rocks, such as limestone or shale, are reduced more readily to sand-sized particles

Figure IV-2-32. Shale beach and bluffs, southeast shore of Lake Erie, near Evans, New York. Bedding planes in the shale are lubricated by groundwater, and freeze-thaw cycles split the rock along the planes. The rubble on the beach breaks down quickly, leaving a grey sand with plate-shaped grains

by abrasion and breakage during their movement to the coast and by subsequent beach processes. Coarse beaches usually have a steeper foreshore than sand beaches.

(3) Biogenic beaches. In tropical areas, organically produced (biogenic) calcium carbonate in the form of skeletal parts of marine plants and animals can be an important or dominant constituent. The more common particles are derived from mollusks, barnacles, calcareous algae, Bryozoa, echinoids, coral, Foraminifera, and ostacods. The percentage of biogenic material in a beach varies with the rate of organic production and the amount of terrigenous material being contributed to the shore.

IV-2-11. Salt Marshes

Coastal salt marshes are low-lying meadows of herbaceous plants subject to periodic inundations. During the constructional phase of a coastline, a marsh develops when sediment deposition exceeds sediment removal by waves. Three critical conditions are required for marsh formation: abundant sediment supply, low wave energy, and a low surface gradient. Once sediment accumulation reaches a critical height, the mud flats are colonized by halophytic plants that aid in trapping sediment when flooding occurs and add organic material to the substrate.

a. Distribution of salt marshes. Marshes occur in low-energy coastal locations, and the bay side of most barriers is fringed by tidal marsh or tidal flats. Likewise, mainland shorelines adjacent to bays are also typically fringed by marsh. Along the mainland of the United States, three regional marsh types have been recognized: (1) New England marsh; (2) Atlantic and Gulf Coastal Plain marsh; and (3) Pacific coast marsh

(Frey and Basan 1985). As much as 80 to 90 percent of the Atlantic and Gulf coasts have been bordering marsh around lagoons, estuaries, and deltaic environments (Inman and Nordstrom 1971). However, along the West Coast, less than 20 percent of the coastline has marsh because Pacific marshes are usually restricted to protected locations in river mouth lagoons or tectonically controlled bays. Morphologically and sedimentologically, Pacific marshes are similar to Atlantic and Gulf coast types, although they do differ in flora species and in the unequal semidiurnal range of tides.

New England marshes are adapted to high tide ranges, high wave energy, and cold winters. Atlantic Coastal Plain marshes are abundant and almost continuous from New York to northern Florida. The warm weather, low tide range, and low wave energy coastline of both the Atlantic and Gulf coastal areas of southern Florida gives rise to mangrove marshes. The deltaic plain of Louisiana supports a unique type of marsh called "flotant," which is marsh flora sitting atop organic rich ooze. The ooze is a soft substrate that may be several meters thick over harder substrates. The rest of the Gulf Coast has fringing marsh behind its barriers.

b. Classification of salt marshes.

(1) Regional conditions such as temperature, sediment distribution, pH, Eh, and salinity contribute to the zonation of a marsh area. Plant successions, sediment accumulation, and marsh expansion vary but most marshes can be divided into two fundamental zones: low and high. Low marshes are younger, lower topographically, and usually subjected to the adjacent estuarine and marine processes. High marshes are older, occupy a higher topographic position, are more influenced by upland conditions, and are subjected to substantially fewer tidal submersions per year. The boundaries for these zones and their relationship to a given datum may differ from one coast to another. Differences in marsh boundaries might be related to tidal regularity and substrate composition. On the Atlantic coast, the tides are generally regular and near equal in semidiurnal range, whereas those on the Pacific coast are markedly unequal in semidiurnal range. Gulf Coast marshes are subjected to irregular and small-amplitude tides. Consequently, the demarcation of high and low marshes is not well-defined.

(2) Plant structures and animals are significant contributors to sediment accumulation in salt marshes (Howard and Frey 1977). Grasses dampen wind-generated waves. Stems and levees impede current flow, which helps trap suspended sediment (Deery and Howard 1977). The most obvious mechanism of sediment entrapment is the plant root system. Plant roots may extend more than a meter in depth along Georgia stream-side marshes and up to 50 cm in some adjacent habitats (Edwards and Frey 1977).

c. Sediment characteristics.

(1) Introduction.

(a) Salt marshes generally contain finer, better-sorted sediment than other intertidal environments. However, marsh substrates reflect the local and regional sediment sources. Along the Atlantic coast and shelf of the United States, Hathaway (1972) recognized two distinct clay mineral facies. The northern clay-mineral facies, extending from Maine to Chesapeake Bay, is primarily composed of illite, chlorite, and traces of feldspar and hornblende. The southern clay-mineral facies, which extends from Chesapeake to the South, is composed of chiefly kaolinite and montmorillonite.

(b) In New England and along many northern coasts overseas, peat is an important soil component of marsh substrate. Peat forms from the degradation of roots, stems, or leaves of marsh plants, particularly *Spartina* (Kerwin and Pedigo 1971). In contrast, peat is not a significant component of the southern coastal marshes except in Louisiana and Florida (Kolb and van Lopik 1966). The southern marsh substrate generally consists of silt- and clay-size sediment with a large percentage of carbon material. The major sources of organic carbon in most coastal marshes are in-situ plants and animal remains.

(c) Southern marshes can have up to 60 percent silt and up to 55 percent clay. Rapid biological decay and constant flushing prevent the accumulation of thick organic deposits. The exception to this is the "flotant" marshes, which may have over 50 percent organics. In the Unified Soil Classification, the substrate would be considered a fine-grained soil, and the field engineer could anticipate silt, clay, or organic-dominant material with low to high plasticity. Much of the organics present in marshes are incompletely oxidized, which if released into the lagoon/bay by excavation, can profoundly affect the water chemistry.

(2) Marsh plants.

(a) Marsh plants are typically tall, salt-tolerant grasses. About 20 genera of salt marsh plants are found worldwide, with the most important in North America being *Spartina*, *Juncus*, and *Salicornia* (Chapman 1974). Salt marshes are the temperate (and arctic) counterparts of tropical mangrove forests. They generally develop in shallow, low-energy environments where fine-grained sediments are deposited over sandy or till substrates (Figure IV-2-33). As the fine sediments build upward, the marsh plants can take root and become established. The established vegetation increases sediment trapping and leads to more rapid upward and outward building of marsh hummocks, which form the foundation of the marsh. The vegetation also creates lower energy conditions by absorbing wave energy and reducing current velocities, thus allowing accelerated sediment deposition.

(b) Like mangrove forests, many species of invertebrates, fish, birds, and mammals inhabit salt marshes and the adjacent tidal creeks during all or part of their life cycles. Thus, marshes are important to commercial and sport fishermen and hunters. In addition, several marsh species are considered endangered.

(c) Also like mangrove forests, man's main detrimental impact on these marshes has been dredge-and-fill operations for land reclamation and mosquito control. Air and water pollution are also serious problems. Although extensive areas of salt marsh remain on the east and Gulf coasts of North America, significant areas have been lost to development. The situation is much worse on the west coast, where most of the coastal marsh lands have been filled and perhaps permanently destroyed. Efforts to restore degraded coastal marshes have not generally been successful.

(3) Sediment transport and processes.

(a) Typically, most marshes have very slow rates of sediment accumulation, amounting to only a few millimeters per year (Pethick 1984). Natural and man-induced changes can have deleterious effects on marsh growth. For example, building levees or altering the drainage pattern can result in erosion and permanent marsh loss. Not only is suspended sediment important to vertical growth of the marsh, but biologic components, particularly organic detritus suspended in the water column, are critical to marsh health. The exchange of sediment and nutrients is dependent on the exchange between the local bodies of water.

(b) A marsh sediment budget usually includes consideration of the following factors (Davis 1985):

- Riverine sources.
- Offshore or longshore transport.

Figure IV-2-33. Estuary of the Sprague River, Maine (a small river facing the Gulf of Maine west of Popham Beach State Park). This is a typical New England salt marsh, with sinuous channels that alternately flood and drain depending on the stage of the tide. In the past, straight channels were often dug in such marshes to allow more efficient draining to reduce mosquito infestation

- Barrier washover.
- Headlands.
- Eolian transport.
- In situ organic material (i.e., peat, plant detritus, and feces).
- Other terrestrial sources.

(4) Engineering problems. In light of growing concerns to preserve natural coastal marshes and the need to implement the national policy of "no net wetland losses," many agencies are researching ways to manage and implement wetland technology. Studies have identified numerous man-made and natural causes of wetland loss in the coastal zone:

(a) Sediment deficits. Man-made modifications of natural fluvial systems interfere with natural delta-building processes.

(b) Shoreline erosion. Along many marsh shorelines, the rates of retreat have increased because of hurricanes and other storms, engineering activities along the coast, and boating.

(c) Subsidence. Sinking of the land due to natural compaction of estuarine, lagoonal, and deltaic sediments results in large-scale disappearance of wetlands. This effect is exacerbated in some areas (e.g., Galveston Bay) by subsidence caused by groundwater and oil withdrawal.

(d) Sea level rise. Eustatic sea level rise is partially responsible for increased rates of erosion and wetland loss.

(e) Saltwater intrusion. Increased salinities in wetlands harm vegetation, which makes the wetlands more vulnerable to erosion.

(f) Canals. Canals increase saltwater intrusion and disrupt the natural water flow and sediment transport processes.

(5) Marsh restoration. Many agencies, including the U.S. Army Corps of Engineers, are conducting research in the building and restoration of marshes, are developing marsh management techniques, and are developing regulatory guidelines to minimize land loss. Under the Wetlands Research Program sponsored by the USACE, new technology in a multidisciplined approach is being developed. A useful publication is the "Wetlands Research Notebook" (U.S. Army Engineer Waterways Experiment Station 1992), which is a collection of technical notes covering eight field problem areas focusing on wetlands activities in support of USACE civil works projects.

IV-2-12. Biological Coasts

a. Introduction.

(1) On many coasts, such as open wetlands, coral reef, and mangrove forest, biological organisms and processes are of primary importance in shaping the morphology. In contrast, on many other coasts, such as typical sandy beaches, biological activities do not appear to be of major significance when compared to the physical processes at work. Nevertheless, it is important to realize that biological processes are occurring on all shores; all man-made shoreline modifications must address the impact of the modification on the biological community.

(2) The types of organisms that can exist on a coast are ultimately controlled by interrelated physical factors. These include wave climate, temperature, salinity, frequency of storms, light penetration, substrate, tidal range, and the amounts of sediments and nutrients available to the system. Of these, the most important may be wave climate. The amount of wave energy dissipated at a shoreline per unit time ultimately has a dominant influence on whether the substrate is rock, sand, or silt; on the water clarity; on the delivery of nutrients; and, most importantly, on an organism's physical design and lifestyle. The physical forces exerted by a large breaking wave are several orders of magnitude greater than the typical lateral forces affecting organisms in most other environments. For example, mangroves and salt marshes require low wave-energy climates to provide suitable substrate and to keep from being physically destroyed. On the other hand, reef-building corals require reasonably high wave-energy environments to maintain the water clarity, to deliver nutrients, to disperse larvae, to remove sediment, and to limit competition and predation.

(3) Another first-order physical condition controlling biological organisms is temperature. For example, this is the primary factor that restricts mangroves and coral reefs to the tropics. Also, the formation of ice in coastal waters has a major impact on Arctic communities.

(4) Unlike many physical processes on coastlines, biological processes are generally progradational in nature, extending shorelines seaward. Reef-building organisms produce hard substrate and sediments, in addition to sheltering areas behind the reefs. Some mollusks, calcareous algae (*Hallemeda sp.*, etc.), barnacles, echinoids, bryozoa, and worms produce significant amounts of sediment. Under low-energy

conditions in the deep sea and sheltered waters, diatoms and radiolaria produce sediments. Mangroves, salt marsh, and dune vegetation trap and stabilize sediments. The erosional effect of organisms that burrow into sediments or that bore into rocks is usually of lesser importance.

b. High wave-energy coasts. Higher plants have not evolved mechanisms to enable them to physically withstand high wave-energy environments. Thus, simple plants, mainly algaes, form the bases of the food chains for these marine coastal communities.

(1) Coral reefs. Coral reefs are massive calcareous rock structures that are slowly secreted by simple colonial animals that live as a thin layer on the rock surface. The living organisms continually build new structures on top of old, extending the reefs seaward toward deeper water and upward toward the surface. Reef-building corals have algae living within their tissues in a symbiotic relationship. The algae supplies food to the coral and the coral supplies shelter and metabolic wastes as nutrients to the algae. Shallow coral reefs worldwide occupy some 284,300 km^2, about 1.2 percent of the world's continental shelf area (Spalding, Ravilious, and Green 2001). While some corals are found in temperate and Arctic waters, reef-building corals are limited by water temperature to the tropics, mainly between the latitudes of 30 deg north and south. Bermuda, in the North Atlantic, warmed by the Gulf Stream, is the highest latitude location where active coral reefs are presently found. In the United States, coral reefs are found throughout the Florida Keys and the east and west coasts of Florida, in the Hawaiian Islands, the Pacific Trust Territories, Puerto Rico, and the Virgin Islands.

(a) Reef-building corals require clear water. The corals need to be free of sediments in order to trap food particles, and their algae require sufficient light for photosynthesis. While corals can remove a certain amount of sediment from their upper surfaces, heavy siltation will bury and kill them. Light penetration limits the depth of most reef-building corals to the upper 30-50 m, though some corals grow much deeper. The upper limit of reef growth is controlled by the level of low tide. Corals cannot stand more than brief exposures out of the water (for example, during the occasional passage of a deep wave trough).

(b) While coral reefs produce rock structure, they also produce calcareous sediments. Waves and currents pulverize coral skeletons into sand-size particles. However, on many reefs, calcareous algae (Hallemeda sp.) produce a majority of the sediments. The crushed calcareous shells of other animals, such as mollusks, sea urchins, and sand dollars, also provide sediment.

(c) Coral reefs rival tropical rain forests as being among the most complex communities on earth, and rock-producing reef communities are among the most ancient life forms found in the fossil record. Because of their complexity, the dynamics of coral reefs are not yet well understood. At least 100,000 species have been named and described, but the total number inhabiting the world's reefs may exceed one million species. Scientific knowledge of the ecology of reefs has almost entirely accumulated over the last 50 years, since the development of underwater scuba breathing apparatus in the 1940's.

(d) One of the critical ecological issues of our times is the rapid degradation of coral reefs around the world by various natural and human activities. Corals are highly sensitive to increases in temperature, exhibiting a stress response known as coral bleaching. In 1998, a global mass bleaching caused mass mortalities in many areas. Worldwide, however, humans are driving more profound changes to reefs than are natural phenomena. The most widespread impacts are water pollution, dredge and fill operations, over-harvesting of fish and shellfish, and the harvesting of some corals for jewelry. For example, in Indonesia, the world's largest coral nation, 82 percent of the corals are at risk from the illegal practice of dynamite fishing (which is also devastating to fish populations). Even far from the coast, deforestation, urban sprawl, and sloppy agriculture produce vast quantities of sediment and pollution that enter the sea and degrade reefs in the vicinity of river mouths.

(e) Controlled dredging around reefs is possible and is done routinely, causing minimal impact to reef communities. Mechanical damage (from cutter heads, chains, anchors, and pipelines) is often of equal or greater concern than suspended sediment production. Improvements in navigation and positioning have made dredging near reefs more viable. Nevertheless, careful monitoring is mandated in most cases.

(f) Reefs are of major economic importance to the communities along which they are located. For millenia, coastal peoples relied on coral reefs as a source of food. Spurgeon (1992) classifies their economic benefits as:

* Direct extractive uses - fisheries, building material.

* Direct non-extractive uses - tourism.

* Indirect uses - biological support for a variety of other ecosystems.

Reef tourism is now a major global industry. Diving tourism is ubiquitous and now occurs in 91 countries and states (Spalding, Ravilious, and Green 2001). One major benefit of mass tourism is that it had brought to public consiousness the issues of the fragility of reef ecosystems and the need to preserve the world's remaining reefs. Marine protected areas are becoming a critical tool in the preservation of remaining reefs, and some 660 protected areas worldwide incorporate reefs. Tourist income is helping some remote communities police and protect their reefs. The downside of mass tourism is the haphazard growth of infrastructure along the shore. Many vacation communities are built on remote coasts where resources, such as fresh water, are scarce and where trash and sewage effluent are not properly managed.

(g) An additional benefit of reefs is the shelter from waves that they provide to adjacent shores. As an example, the south and southwestern coast of Sri Lanka is battered by waves that travel unhindered across the Indian Ocean. In the past, the coral reefs that surrounded the coast served as buffers against the intense wave energy. But illegal reef breaking and coral mining, combined with negative impacts of tourism and development (sewage, agricultural pollution, physical damage) have greatly reduced the effectiveness of the reef barriers. As a result, much of the Sri Lankan south coast is now experiencing severe erosion (Young and Hale 1998).

(h) Stoddard (1969) has identified four major forms of large-scale coral reef types: fringing reefs, barrier reefs, table reefs, and atolls.

(i) *Fringing reefs* generally consist of three parts: a fore reef, a reef crest, and a back reef. The *fore reef* usually rises steeply from deep water. It may have spur and groove formations of coral ridges interspersed with sand and rubble channels. The *reef crest* usually forms a continuous wall rising to the low tide level. This usually occurs within a few hundred meters from shore. The seaward side of this area, called the *buttress zone*, receives the brunt of the wave action. Between the reef crest (or flat) and the shoreline, the reef usually deepens somewhat in the back reef area. This area typically contains much dead coral as well as rock, rubble, sand, and/or silt. It also contains live coral heads, algae, eel grass, etc. Fringing reefs form as the beginning stages in the evolution of atolls and possibly barrier reefs.

(j) *Barrier reefs* grow on the continental shelf where suitable solid substrate exists to serve as a foundation. Their form is typically a long coral embankment separated from the mainland by a lagoon that may be several kilometers wide. The lagoon is usually flat-floored and may be as much as 16 km wide and 35 to 75 m in depth. Although similar to fringing reefs, barrier reefs are much more massive, the reef crests are much further from shore, and the back reef areas are deeper. Protected shorelines behind barrier reefs are characterized by mangrove swamps and are usually progradational. The seafloor on the seaward side slopes steeply away into deeper water and is covered by coral rubble.

(k) *Table reefs* grow from shallow banks on the seafloor that have been capped with reef-forming organisms. They cover extensive areas but do not form barriers or enclose lagoons.

(l) *Atolls* are ring-shaped reefs that grow around the edges of extinct volcanic islands, enclosing lagoons of open water. The shallow lagoons may contain patch reefs. Atolls are primarily found in isolated groups in the western Pacific Ocean. Small low islands composed of coral sand may form on these reefs. These islands may hold enough of a fresh water lens to support human life, but the islands are quite vulnerable to inundation and to tropical storms. The first theory concerning the development of atolls, the subsidence theory proposed by Charles Darwin in 1842, has been shown to be basically correct (Strahler 1971). Figure IV-2-34 illustrates the evolution of an atoll.

(m) The development of atolls begins with an active volcano rising from the ocean floor and forming a volcanic island. As the volcano ceases activity, a fringing reef forms along the shore. Over geologic time, erosion of the volcanic island and subsidence due to general aging of the ocean basin cause the island to drop below sea level. The actively growing fringing reef keeps pace with the subsidence, building itself upward until a barrier reef and lagoon are formed. As the center of the island becomes submerged, the reef continues its upward growth, forming a lagoon. During the development, the lagoon floor behind the reef accumulates coral rubble and other carbonate sediments, which eventually completely cover the subsiding volcanic island.

(2) Worm reefs. A type of biogenic reef that is not related to coral reefs is that produced by colonies of tubeworms. Serpulid worms and Sabellariid worms are two types known to form significant reef structures by constructing external tubes in which they live. The Serpulids build their tubes from calcareous secretions and the Sabellariids by cementing particles of sand and shell fragments around their bodies. Colonies of these worms are capable of constructing massive structures by cementing their tubular structures together. As new tubes are continually produced over old ones, a reef is formed. These reefs typically originate from a solid rocky bottom, which acts as an anchoring substrate. Worm reefs are most commonly found in sub-tropical and tropical climates (e.g., east coast of Florida). Reefs of this nature can play an important role in coastal stabilization and the prevention of coastal erosion.

(3) Oyster reefs. Oysters flourish under brackish water conditions in lagoons, bays, and estuaries. The oysters cement their shells to a hard stable substrata including other oyster shells. As new individuals set onto older ones, a reef is formed. These reefs can form in temperate as well as tropic waters.

(a) Oysters found around the United States are part of the family *Ostreidae*. The Eastern, or American oyster (*Crassostrea virginica*) is distributed along the entire east coast of North America from the Gulf of St. Lawrence through the Gulf of Mexico to the Yucatan and the West Indies. The other major North American species is *Ostrea lurida*, which ranges along the Pacific coast from Alaska to Baja California (Bahr and Lanier 1981).

(b) Intertidal oyster reefs range in size from isolated scattered clumps a meter high to massive solid mounds of living oysters anchored to a dead shell substrate a kilometer across and 100 m thick (Pettijohn 1975). Reefs are limited to the middle portion of the intertidal zone, with maximum elevation based on a minimum inundation time. The uppermost portion of a reef is level, with individual oysters pointing upwards. At the turn of the century, vast oyster flats were found along the Atlantic coast in estuaries and bays. In South Carolina, the flats covered acres and sometimes square miles (cited in Bahr and Lanier (1981)).

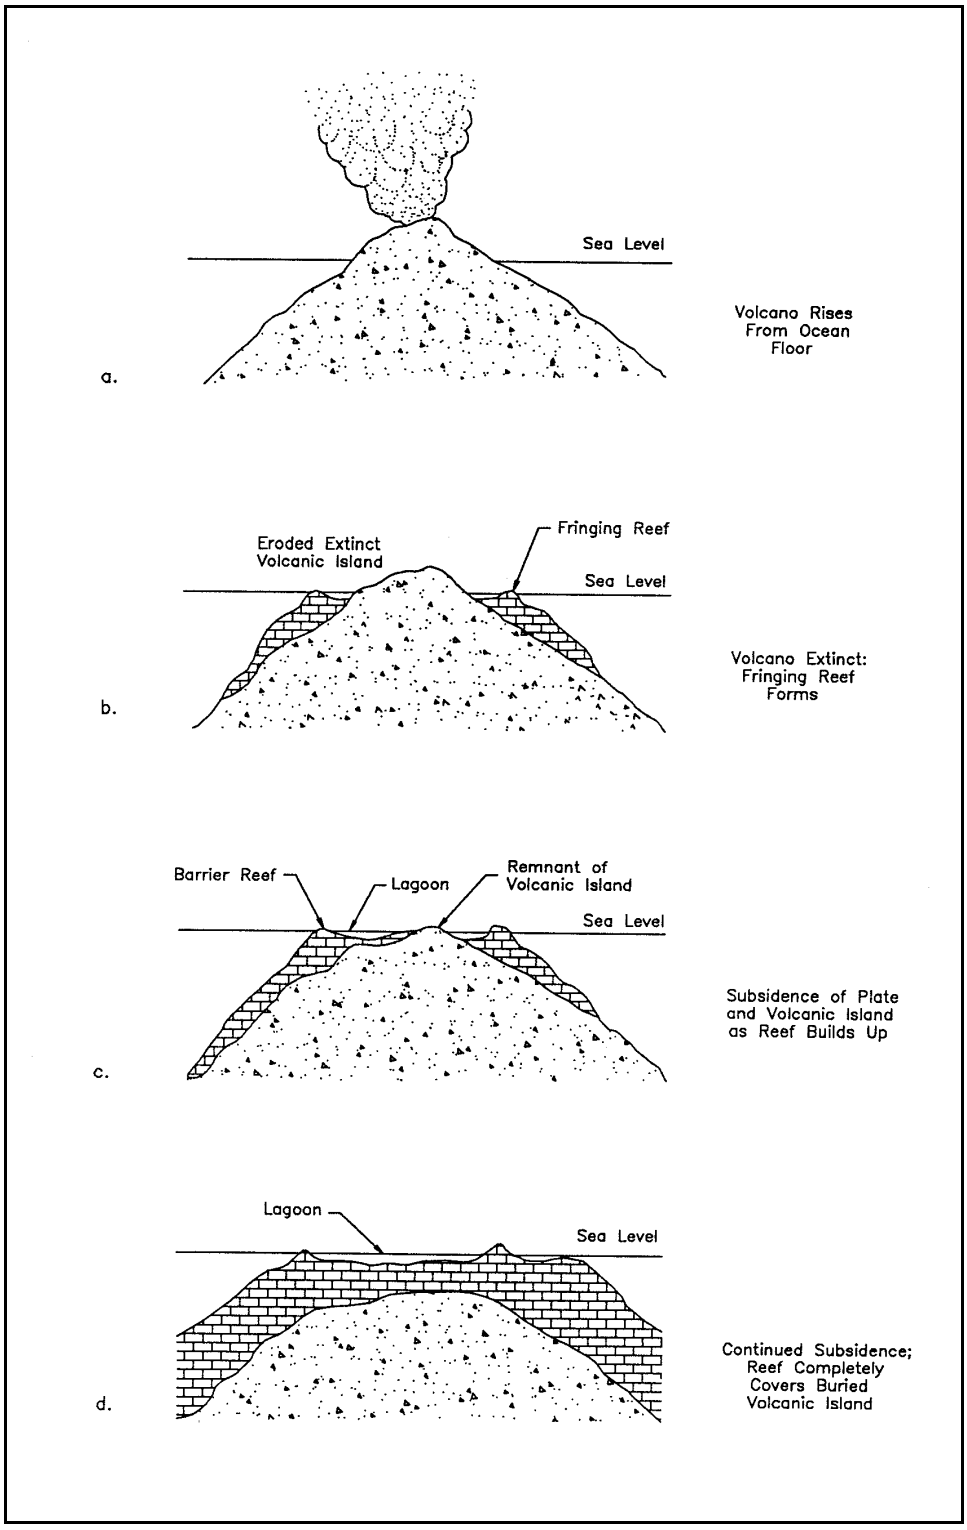

Figure IV-2-34. Evolution of a coral island: (a) Active volcano rising from the seafloor, (b) Extinct volcanic island with fringing reef, (c) Subsiding island; reef builds upward and seaward, forming barrier reef, (d) Continued subsidence causing remnant volcanic island to be completely submerged. Growth continues upward and seaward until remnant volcano is covered (adapted from Press and Siever (1986))

(c) Oyster reefs serve an important biological role in the coastal environment. The reefs are a crucial habitat for numerous species of microfauna and macrofauna. The rough surface of a reef flat provides a huge surface area for habitation by epifauna, especially vital in the marsh-estuarine ecosystem that is often devoid of other hard substrate. The high biological productivity of reef environments underscores one of the reasons why reefs must be protected and preserved.

(d) Oyster reefs play important physical and geological roles in coastal dynamics because they are wave-resistant structures that can biologically adapt to rising sea level. Reefs affect the hydrologic regime of salt marsh estuaries in three ways: by modifying current velocities, by passively changing sedimentation patterns, and by actively augmenting sedimentation by biodeposition. (Biological aggradation increases the size of suspended particles and increases their settling rates.) As reefs grow upward and laterally, modify energy fluxes by damping waves and currents, and increase sedimentation, they ultimately produce major physiographic changes to their basins. These changes can occur on short time scales, on the order of hundreds of years (Bahr and Lanier 1981). During geologic history, massive reefs have accumulated in many areas, some of which became reservoirs for oil and gas.

(e) Although oysters are adapted to a wide range of temperature, turbidity, and salinity conditions, they are highly susceptible to man-made stresses. These stresses on oyster communities can be classified into eight categories (Bahr and Lanier 1981):

- Physical sedimentation, especially from dredging or boat traffic.
- Salinity changes due to freshwater diversion or local hydrologic alterations.
- Eutrophication (oxygen depletion) due to algae growth in water that is over-enriched with organic matter.
- Toxins from industrial and urban runoff.
- Physical impairment of feeding structures by oil.
- Thermal loading, primarily from power plants.
- Overharvesting.
- Loss of wetlands.

There has been a recorded significant decline in the health and extent of living United States east coast oyster reefs since the 1880's, although the data are sometimes conflicting because ground-level surveys are difficult to conduct (Bahr and Lanier 1981). It is easy to account for the declines of reefs near population and industrial centers, but the declines are more difficult to explain in more pristine areas of the coast (e.g. the Georgia coast near Sapelo Island). Population changes may be due, in part, to natural cycles of temperature and salinity or fecundity.

(f) Because oyster reefs are susceptible to fouling and silting, it is important that geologists and engineers consider sediment pathways during the planning phases of coastal construction and dredging projects or stream diversion and other watershed changes. As discussed earlier, dredging near reefs is technically feasible as long as careful technique is observed and environmental conditions are monitored.

(g) In summary, oyster reefs serve critical biological and physical purposes in the estuarine and coastal marsh environment. They enhance biological productivity, provide stable islands of hard substrate in

otherwise unstable soft muddy bottoms, modify hydrodynamic flows and energy fluxes. With respect to shore protection, reefs are a biological wave damper that can accommodate rising sea level as long as they are alive. It is essential that reefs be protected from wanton destruction by pollution and other stresses imposed by human development.

(4) Rocky coasts.

(a) Kelp beds. Kelp forests are formed by various species of algae that attach to hard substrate with a root-like system called a *holdfast*. Some (prominently *Macrosistus sp.*) can grow many tens of meters in length up to the water surface, where their tops float and continue to grow. The plants are quite rubbery and can withstand significant wave action. Kelp beds are found along rocky shorelines having cool clear water. In North America, they occur along much of the Pacific coast and, to a lesser extent, along the North Atlantic coast. Kelp beds are, to some extent, the functional temperate latitude counterpart of coral reefs (Carter 1988).

(b) Kelp biological communities. Kelp beds harbor extensive biological communities that include fish, sea otters, lobster, starfish, mollusks, abalones, and many other invertebrates. In addition, kelp beds absorb wave energy, helping to shelter beaches. Man's main impact has been the commercial harvesting of various portions of this community, including the kelp. In the past, hunting sea otters for their pelts allowed sea urchins to multiply, and the overpopulation of sea urchins grazed and destroyed many beds. Today, the reestablishment of some sea otter populations has led to conflicts with shell fishermen. Water pollution is also a problem in some areas.

(c) Rock reefs and shorelines. Submerged rock reefs provide substantial habitat for organisms. They provide a place of attachment for sessile organisms, and the crevices provide living spaces and havens of refuge for mobile organisms such as fish and lobsters. These structures are a boon to sports fishermen, and many artificial reefs have been built on sandy seafloors out of a wide array of materials. Rocky shorelines have communities of organisms living in the intertidal and subtidal zones. These may or may not be associated with offshore kelp bed or coral reef communities.

(5) Sandy coasts. Much of the biological activity on sandy coasts is confined to algae, various invertebrates, and fish living within the water column. Of these, fish, shrimp, and crabs have the greatest economic importance. In addition, there are infaunal filter feeders, mainly mollusks and sand dollars, that live just beneath the sand surface.

(a) One important and often overlooked biological activity on some sandy beaches is their use as nesting areas by a variety of migratory animals. These include sea turtles, birds, marine mammals, and fish. In North America, many of these species are threatened or endangered, including all five species of sea turtles and some birds such as the piping plover, the snowy plover, and the least tern. For most of these species, their problems are directly related to conflicts with man's recreational use of beaches and the animals' inability to use alternate nesting sites. Fortunately, some states have implemented serious ecological programs to help save these threatened species. For example, Florida has rigorous laws preventing disruption of nesting turtles, and many Florida municipalities have found that maintaining healthy natural biological communities is an excellent way to lure tourists.

(b) Plants occupying sand dunes are characterized by high salt tolerance and long root systems that are capable of extending down to the freshwater table (Goldsmith 1985). Generally, these plants also generate rhizomes that grow parallel to the beach surface. Beach plants grow mainly in the back beach and dune areas beyond the zone of normal wave uprush. The plants trap sand by producing low energy conditions near the ground where the wind velocity is reduced. The plants continue to grow upward to keep pace with the accumulation of sand, although their growth is eventually limited by the inability of the roots to reach

dependable water. The roots also spread and extend downward, producing a thick anchoring system that stabilizes the back beach and dune areas. This stabilization is valuable for the formation of dunes, which provide storm protection for the entire beach. The most common of these plants are typically marram grass, saltwort, American sea grass, and sea oats. With time, mature dunes may accumulate enough organic nutrients to support shrub and forest vegetation. The barrier islands of the U.S. Atlantic coast and the Great Lakes shores support various species of *Pinus*, sometimes almost to the water's edge.

c. Low wave-energy coasts. In locations where the wave climate is sufficiently low, emergent vegetation may grow out into the water. Protection from wave action is typically afforded by local structures, such as headlands, spits, reefs, and barrier islands. Thus, the vegetation is usually confined to the margins of bays, lagoons, and estuaries. However, in some cases, the protection may be more regional in extent. Some of the mangrove forests in the Everglades (south Florida) and some of the salt marshes in northwest Florida and Louisiana grow straight into the open sea. The same is true for freshwater marshes in bays and river mouths in the Great Lakes.

(1) General.

(a) Only a few higher plants possess a physiology that allows them to grow with their roots in soils that are continuously saturated with salt water. These are the mangroves of the tropics and the salt marsh grasses of the higher latitudes. The inability of other plants to compete or survive in this environment allows small groups of species or single species to cover vast tracts of some coastal areas. These communities typically show zonations with different species dominant at slightly different elevations, which correspond to different amounts of tidal flooding. The seaward limit of these plants is controlled by the need for young plants to have their leaves and branches above water. To this end, some mangroves have seedlings that germinate and begin growing before they drop from the parent tree. Upland from these communities, a somewhat larger number of other plants, such as coconuts and dune grasses, are adapted to live in areas near, but not in, seawater.

(b) Understanding and appreciation of the importance of these types of coastal areas are growing. Former attitudes that these areas were mosquito-infested wastelands imminently suitable for dredge- and-fill development are being replaced by an appreciation of their great economic importance as nursery grounds for many species of fish and shellfish, of their ability to remove pollutants, of their ability to protect upland commercial development from storms, of their fragility, and of their beauty.

(2) Mangroves.

(a) *Mangroves* include several species of low trees and shrubs that thrive in the warm, shallow, saltwater environments of the lower latitudes. Worldwide, there are over 20 species of mangroves in at least 7 major families (Waisel 1972). Of these, the red, white, and black mangroves are dominant in south Florida and the Caribbean. They favor conditions of tidal submergence, low coastal relief, saline or brackish water, abundant fine sediment supply, and low wave energy. Mangroves have the ability to form unique intertidal forests that are characterized by dense entangled networks of arched roots that facilitate trapping of fine sediments, thereby promoting accretion and the development of marshlands. The *prop roots* and *pneumatophores* also allow the plants to withstand occasional wave action and allow oxygen to reach the roots in anaerobic soils. The prime example in the United States is the southwest shore of Florida, in the Everglades National Park.

(b) Mangrove coasts are crucial biological habitats to a wide variety of invertebrates, fish, birds, and mammals. In the past, the primary cause of their destruction has been dredge-and-fill operations for the reclamation of land and for mosquito control.

d. Other sources of biogenic sediment in the coastal zone. In areas of high biological activity, organically derived sediments may account for a significant proportion of the sediment composition, especially where terrigenous sediment supplies are low. These biogenic materials, consisting of remains of plants and animals and mineral matter produced by plants and animals, accumulate at beaches, estuaries, and marshlands.

(1) The most familiar types of biogenic sediments are hard calcareous skeletal parts and shell fragments left behind by clams, oysters, mussels, corals, and other organisms that produce calcareous tests. In tropical climates, the sediment commonly consists of coral fragments and calcareous algal remains. Siliceous tests are produced by most diatoms and radiolaria. Sediments predominately containing carbonate or calcareous material are generally referred to as *calcarenites*, while sediments composed predominantly of siliceous matter are referred to as *diatomites* or *radiolarites*, depending upon which organism is most responsible for the sediment (Shepard 1973). In the Great Lakes and some inland U.S. waterways, the zebra mussel has proliferated since the mid-1980's, and now some shorefaces are covered with mussel shell fragments to a depth of over 10 cm. The mussels are a serious economic burden because they choke the inlets of municipal water systems and coolant pipes.

(2) In some areas, wood and other vegetation may be introduced into the sediments in large quantities. This is especially common near large river mouths and estuaries. This organic material may become concentrated in low energy environments such as lakes and salt marshes, eventually producing an earthy, woody composition known as *peat* (Shepard 1973). Peat exposed on the shoreface has been used as an indicator of marine transgression and barrier island retreat (Figure IV-2-35) (Dillon 1970). In Ireland and Scotland, peat is dried and used as a fuel.

IV-2-13. Continental Shelf Geology and Topography

a. Introduction. The geology of the world's continental shelves is of direct significance to coastal engineers and managers in two broad areas. First, the topography of the shelf affects coastal currents and wave climatology. Wave refraction and circulation models must incorporate shelf bathymetry. Bathymetry was incorporated in the wave hindcast models developed by the USACE Wave Information Study (See references in Part II-8). Second, offshore topography and sediment characteristics are of economic importance when offshore sand is mined for beach renourishment or dredged material is disposed offshore.

b. Continental shelf sediment studies.

(1) The Inner Continental Shelf Sediment and Structure (ICONS) study was initiated by the Corps of Engineers in the early 1960's to map the morphology of the shallow shelf and find sand bodies suitable for beach nourishment. This program led to a greater understanding of shelf characteristics pertaining to the supply of sand for beaches, changes in coastal and shelf morphology, longshore sediment transport, inlet migration and stabilization, and led to a better understanding of the Quaternary shelf history. ICONS reports are listed in Table IV-2-5.

Figure IV-2-35. Peat horizon exposed on the shoreface, Ditch Plains, Long Island, New York (March 1998). The peat is in-situ, indicating that lagoonal sediments accumulated here before the barrier beach retreated over the marsh. The peat layer was about 1 m above the ocean water level at the time the photograph was taken. The dune resting on the peat is about 2 m thick

(2) Since the 1970's, the Minerals Management Service (MMS), a bureau of the U.S. Department of the Interior, has been tasked with managing the mineral resources of the Outer Continental Shelf. In conducting its mission, the MMS has sponsored many surveys and studies of mineral resources on the continental shelf. These studies can be accessed via the MMS' Environmental Studies Program Information System (ESPIS) at:

http://mmspub.mms.gov/espis/

(3) For beach renourishment projects, U.S. Army Corps of Engineers Districts typically obtain information on sand resources near the proposed project area from various sources:

(a) In-house studies, typically from vibracoring or rotary borings.

(b) Contracts with marine geophysics/geotechnical surveyors.

(c) The U.S. Geological Survey.

(e) State and local agencies.

New geographic data collected by the Federal Government is documented with Metadata that can be accessed from various computer servers. Unfortunately, there is no consistent method of cataloging historical data or reports. Users who need information on sand resources near the coast must contact the Corps District responsible for that particular area.

c. Continental shelf morphology. Surficial sediment on the continental shelves is largely dependent upon the type of coast (i.e. collision, or leading, versus trailing) and the presence of rivers that supply material to the coast.

(1) Leading edge shelves, such as the Pacific coasts of North and South America, are typically narrow and steep. Submarine canyons, which sometimes cut across the shelves almost to the shore (Shepard 1973), serve as funnels that carry sediment down to the abyssal plain. Normally, very little sand is available offshore.

(2) Trailing edge shelves are, in contrast, usually wide and flat, and the heads of canyons usually are located a considerable distance from shore. Nevertheless, a large amount of sediment is believed to move down these canyons (Emery 1968). Off the United States Atlantic coast, the broad continental shelf contains a vast amount of sand. Unfortunately, much of this sand is not available for beach renourishment because it is either too far from shore or its composition is incompatible with the beaches where it is to be placed (i.e., contains too much rock, shell fragment, mud, or organic material or the grain size is different than the size of the native material where it is to be placed).

d. Examples of specific features - Atlantic seaboard.

(1) The continental shelf of the Middle Atlantic Bight of North America, which is covered by a broad sand sheet, is south of the region directly influenced by Pleistocene glacial scouring and outwash. This sand sheet is divided into broad, flat, plateau-like compartments dissected by shelf valleys that were excavated during the Quaternary lowstands of the sea. Geomorphic features on the shelf include low-stand deltas (cuspate deltas), shoal and cape retreat massifs (bodies of sand that formed during a transgressive period), terraces and scarps, cuestas (asymmetric ridges formed by the outcrop of resistant beds), and sand ridges (Figure IV-2-36) (Swift 1976; Duane et al. 1972).

(2) The larger geomorphic features of the Middle Atlantic Bight are constructional features molded into the Holocene sand sheet and altered in response to storm flows. Off the coasts of Delaware, Maryland, and Virginia, shoreface-connected shoals appear to have formed in response to the interaction of south-trending, shore-parallel, wind-generated currents with wave- and storm-generated bottom currents during winter storms. Storm waves aggrade crests, while fair-weather conditions degrade them. A second shoal area further offshore at the 15-m depth is indicative of a stabilized sea level at that elevation. These shoals may be suitable sources of sand for beach renourishment. However, the often harsh wave conditions off the mid-Atlantic seaboard may limit the economic viability of mining these shoals. The origin and distribution of Atlantic inner shelf sand ridges are discussed in McBride and Moslow (1991).

(3) Linear shoals of the Middle Atlantic Bight tend to trend northeast (mean azimuth of 32 deg) and extend from the shoreline at an angle between 5 and 25 deg. Individual ridges range from 30 to 300 m in length, are about 10 m high, and have side slopes of a few degrees. The shoal regions extend for tens of kilometers. The crests are composed of fine-medium sand, while the ridge flanks and troughs are composed of very fine-fine sand. The mineralogy of shoals reflects that of the adjacent beaches.

e. Riverine influence.

(1) Rivers provide vast amounts of sediment to the coast. The 28 largest rivers of the world, in terms of drainage area (combined size of upland drainage area and subaerial extent of deltas), discharge across trailing-edge and marginal sea coasts (Inman and Nordstrom 1971). Because the larger rivers drain onto trailing edge coasts, these shores tend to have larger amounts of available sediment, which is deposited across a wide continental shelf. The sediment tends to remain on the shelf and is only lost to the abyssal plains when deltas prograde out across the continental rise (e.g., the Mississippi and Nile Deltas) or when submarine canyons are incised across the shelf (e.g., Hudson River sediment funnels down the Hudson Canyon).

(2) The Columbia River, which is the 29th largest river in the world, is the largest one to drain across a collision coast. Until dams were built during the mid-20th century, the Columbia carried a major sediment load, which was deposited on the ebb shoal off its mouth. This shoal provided the sand that formed the Long Beach peninsula and fed the beaches as far north as the Olympic Peninsula. The Columbia appears to be an exception - on most collision coasts, canyons frequently cut across the shelf almost to the shore (Shepard 1973), therefore resulting in the direct loss of sediment from the coastal zone.

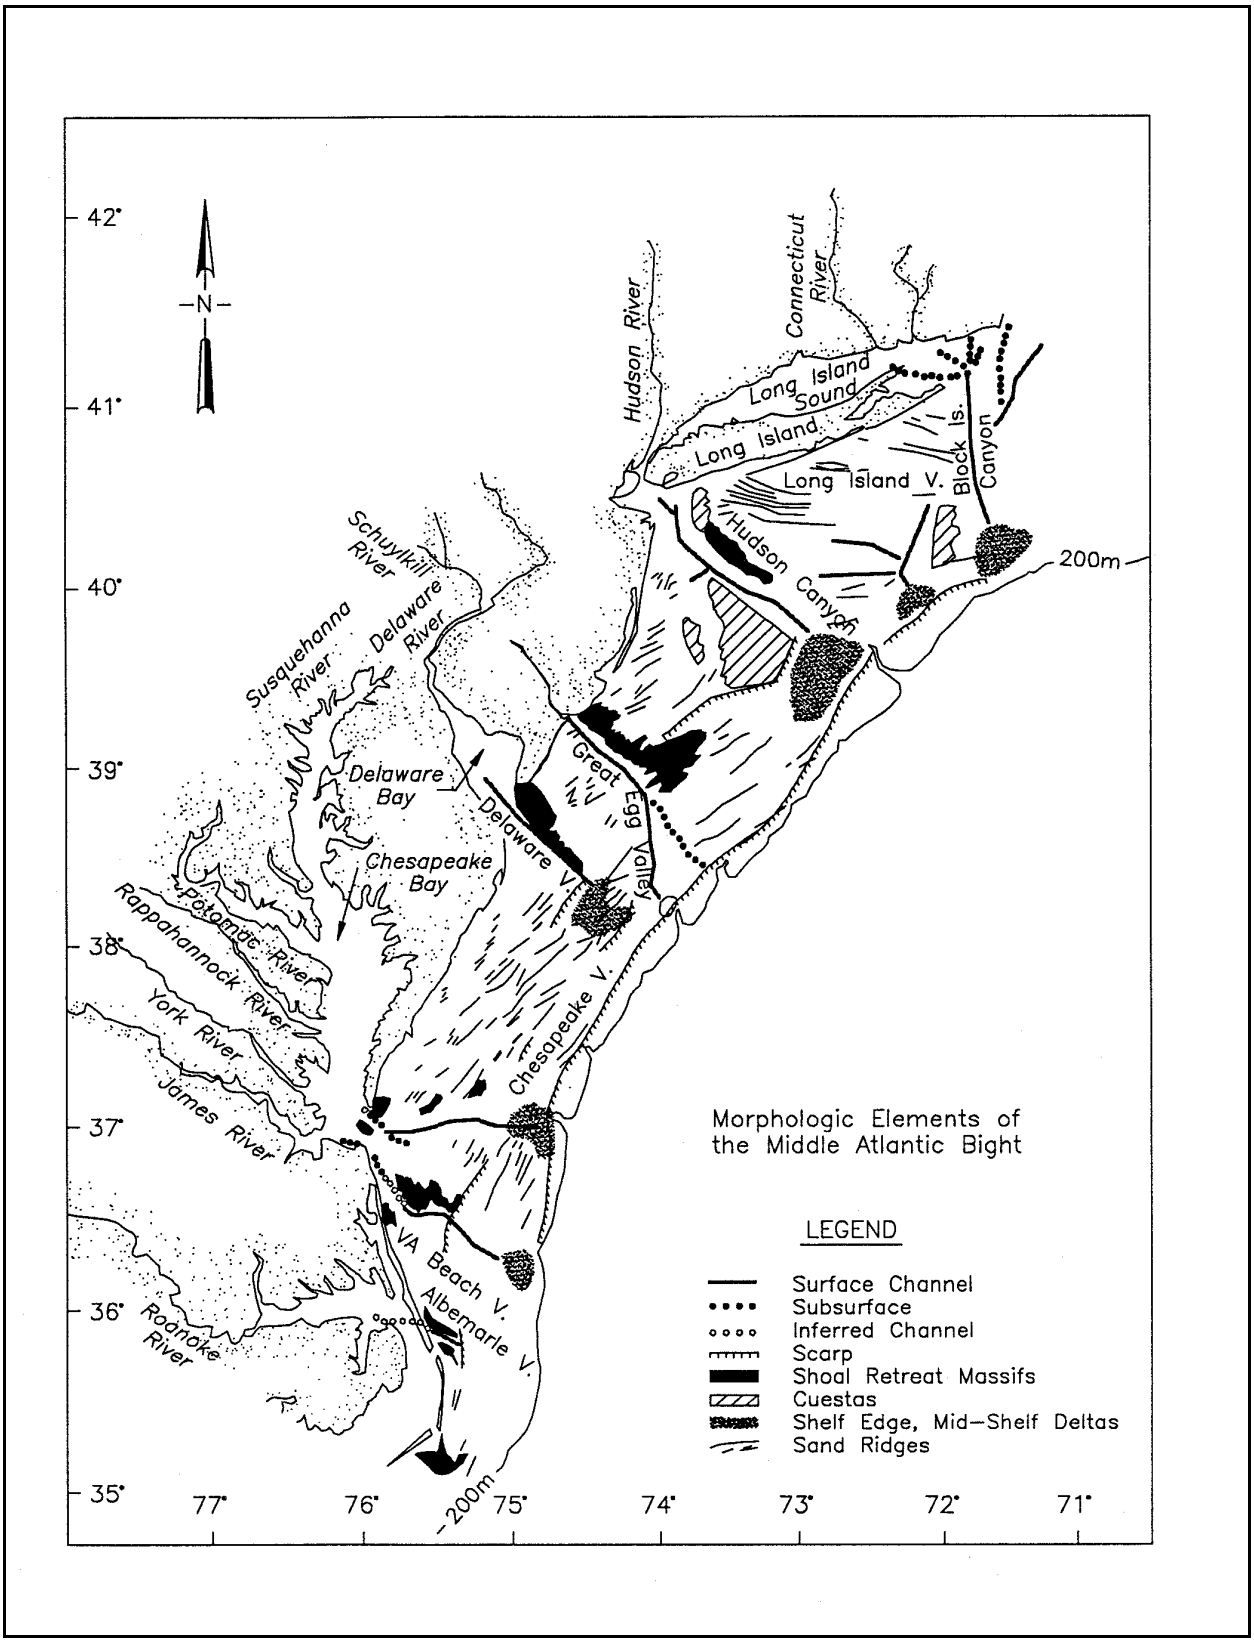

Figure IV-2-36. Morphology of the Middle Atlantic Bight (from Swift (1976)). Sand ridges close to shore may be suitable sources of sand for beach renourishment

Chapter IV-3
Coastal Morphodynamics

IV-3-1. Introduction

a. This chapter discusses the morphodynamics of three coastal environments: deltas, inlets, and sandy shores. The divisions are somewhat arbitrary because, in many circumstances, the environments are found together in limited areas. For example, within a major river delta like the Mississippi, there are sandy beaches, bays where cohesive sediments accumulate, and inlets which funnel water in and out of the bays. Coastal features and environments are also not constant over time. For example, as we discussed in Part IV-2, estuaries, deltas, and beach ridge shores are elements of a landform continuum that extends over time. Which particular environment or shore type is found at any one time depends on sea level rise, sediment supply, wave and tide energy, underlying geology, climate, rainfall, runoff, and biological productivity.

b. Based on the fact that physical conditions along the coast are constantly changing, it can be argued that there is no such thing as an "equilibrium" state for any coastal form. This is true not only for shoreface profiles but also for deltas, which continue to shift over time in response to varying wave and meteorologic conditions. In addition, man continues to profoundly influence the coastal environment throughout the world, changing natural patterns of runoff and littoral sediment supply and constantly rebuilding and modifying engineering works. This is true even along undeveloped coastlines because of environmental damage such as deforestation, which causes drastic erosion and increased sediment load in rivers. The reader is urged to remember that coastal landforms are the result of the interactions of a myriad of physical processes, man-made influences, global tectonics, local underlying geology, and biology.

c. Cohesive shores, another one of the primary geologic terrains found around the world, have been discussed in Part III-5, "Erosion, Transport, and Deposition of Cohesive Shores."

IV-3-2. Introduction to Bed Forms

a. Introduction. When sediment is moved by flowing water, the individual grains are usually organized into morphological elements called *bed forms.* These occur in a baffling variety of shapes and scales. Some bed forms are stable only between certain values of flow strength. Often, small bed forms (ripples) are found superimposed on larger forms (dunes), suggesting that the flow field may vary dramatically over time. Bed forms may move in the same direction as the current flow, may move against the current (antidunes), or may not move at all except under specific circumstances. The study of bed form shape and size is of great value because it can assist in making quantitative estimates of the strength of currents in modern and ancient sediments (Harms 1969, Jopling 1966). Bed form orientations are indicators of flow pathways. This introduction to a complex subject is by necessity greatly condensed. For details on interpretation of surface structures and sediment laminae, readers are referred to textbooks on sedimentology such as Allen (1968, 1984, 1985); Komar (1998); Leeder (1982); Lewis (1984); Middleton (1965); Middleton and Southard (1984); and Reineck and Singh (1980).

b. Environments. In nature, bed forms are found in three environments with greatly differing characteristics:

(1) Rivers - unidirectional and channelized; large variety of grain sizes.

(2) Sandy coasts and bays - semi-channelized, unsteady, reversing (tidal) flows.

(3) Continental shelves - deep, unchannelized; dominated by geostrophic flows, storms, tidal currents, wave-generated currents.

c. Classification. Because of the diverse natural settings and the differing disciplines of researchers who have studied sedimentology, the classification and nomenclature of bed forms have been confusing and contradictory. The following classification scheme, proposed by the Society for Sedimentary Geology (SEPM) Bed forms and Bedding Structures Research Group in 1987 (Ashley 1990) is suitable for all subaqueous bed forms:

(1) Ripples. These are small bed forms with crest-to-crest spacing less than about 0.6 m and height less than about 0.03 m. It is generally agreed that ripples occur as assemblages of individuals similar in shape and scale. On the basis of crestline trace, Allen (1968) distinguished five basic patterns of ripples: straight, sinuous, catenary, linguoid, and lunate (Figure IV-3-1). The straight and sinuous forms may be symmetrical in cross section if subject to primarily oscillatory motion (waves) or may be asymmetrical if influenced by unidirectional flow (rivers or tidal currents). Ripples form a population distinct from larger-scale dunes, although the two forms share a similar geometry (Figure IV-3-2). The division between the two populations is caused by the interaction of ripple morphology and bed, and possibly shear stress. At low shear stresses, ripples are formed. As shear stress increases above a certain threshold, a "jump" in behavior occurs, resulting in the appearance of the larger dunes (Allen 1968).

(2) Dunes. Dunes are flow-transverse bed forms with spacings from under 1 m to over 1,000 m that develop on a sediment bed under unidirectional currents. These large bed forms are ubiquitous in sandy environments where water depths are greater than about 1 m, sand size coarser than 0.15 mm (very fine sand), and current velocities are greater than about 0.4 m/sec. In nature, these flow-transverse forms exist as a continuum of sizes without natural breaks or groupings (Ashley 1990). For this reason, "dune" replaces terms such as megaripple or sand wave, which were defined on the basis of arbitrary or perceived size distributions. Unfortunately, the term "sand wave" is still used in the literature, often with only the vaguest indication of what size feature is being described. For descriptive purposes, dunes can be subdivided as small (0.6- to 5-m wavelength), medium (5-10 m), large (10-100 m), and very large (> 100 m). In addition, the variation in pattern across the flow must be specified. If the flow pattern is relatively unchanged perpendicular to its overall direction and there are no eddies or vortices, the resulting bed form will be straight-crested and can be termed two-dimensional (Figures IV-3-3a and IV-3-4). If the flow structure varies significantly across the predominant direction and vortices capable of scouring the bed are present, a three-dimensional bed form is produced (Figure IV-3-5).

(3) Plane beds. A plane bed is a horizontal bed without elevations or depressions larger than the maximum size of the exposed sediment. The resistance to flow is small, resulting from grain roughness, which is a function of grain size. Plane beds occur under two hydraulic conditions:

(a) The transition zone between the region of no movement and the initiation of dunes (Figure IV-3-6).

(b) The transition zone between ripples and antidunes, at mean flow velocities between about 1 and 2 m/sec (Figure IV-3-6).

(4) Antidunes. Antidunes are bed forms that are in phase with water-surface gravity waves. Height and wavelength of these bedforms depend on the scale of the system and characteristics of the fluid and bed material (Reineck and Singh 1980). Trains of antidunes gradually build up from a plane bed as water velocity increases. As the antidunes increase in size, the water surface changes from planar to wave-like. The water waves may grow until they are unstable and break. As the sediment antidunes grow, they may

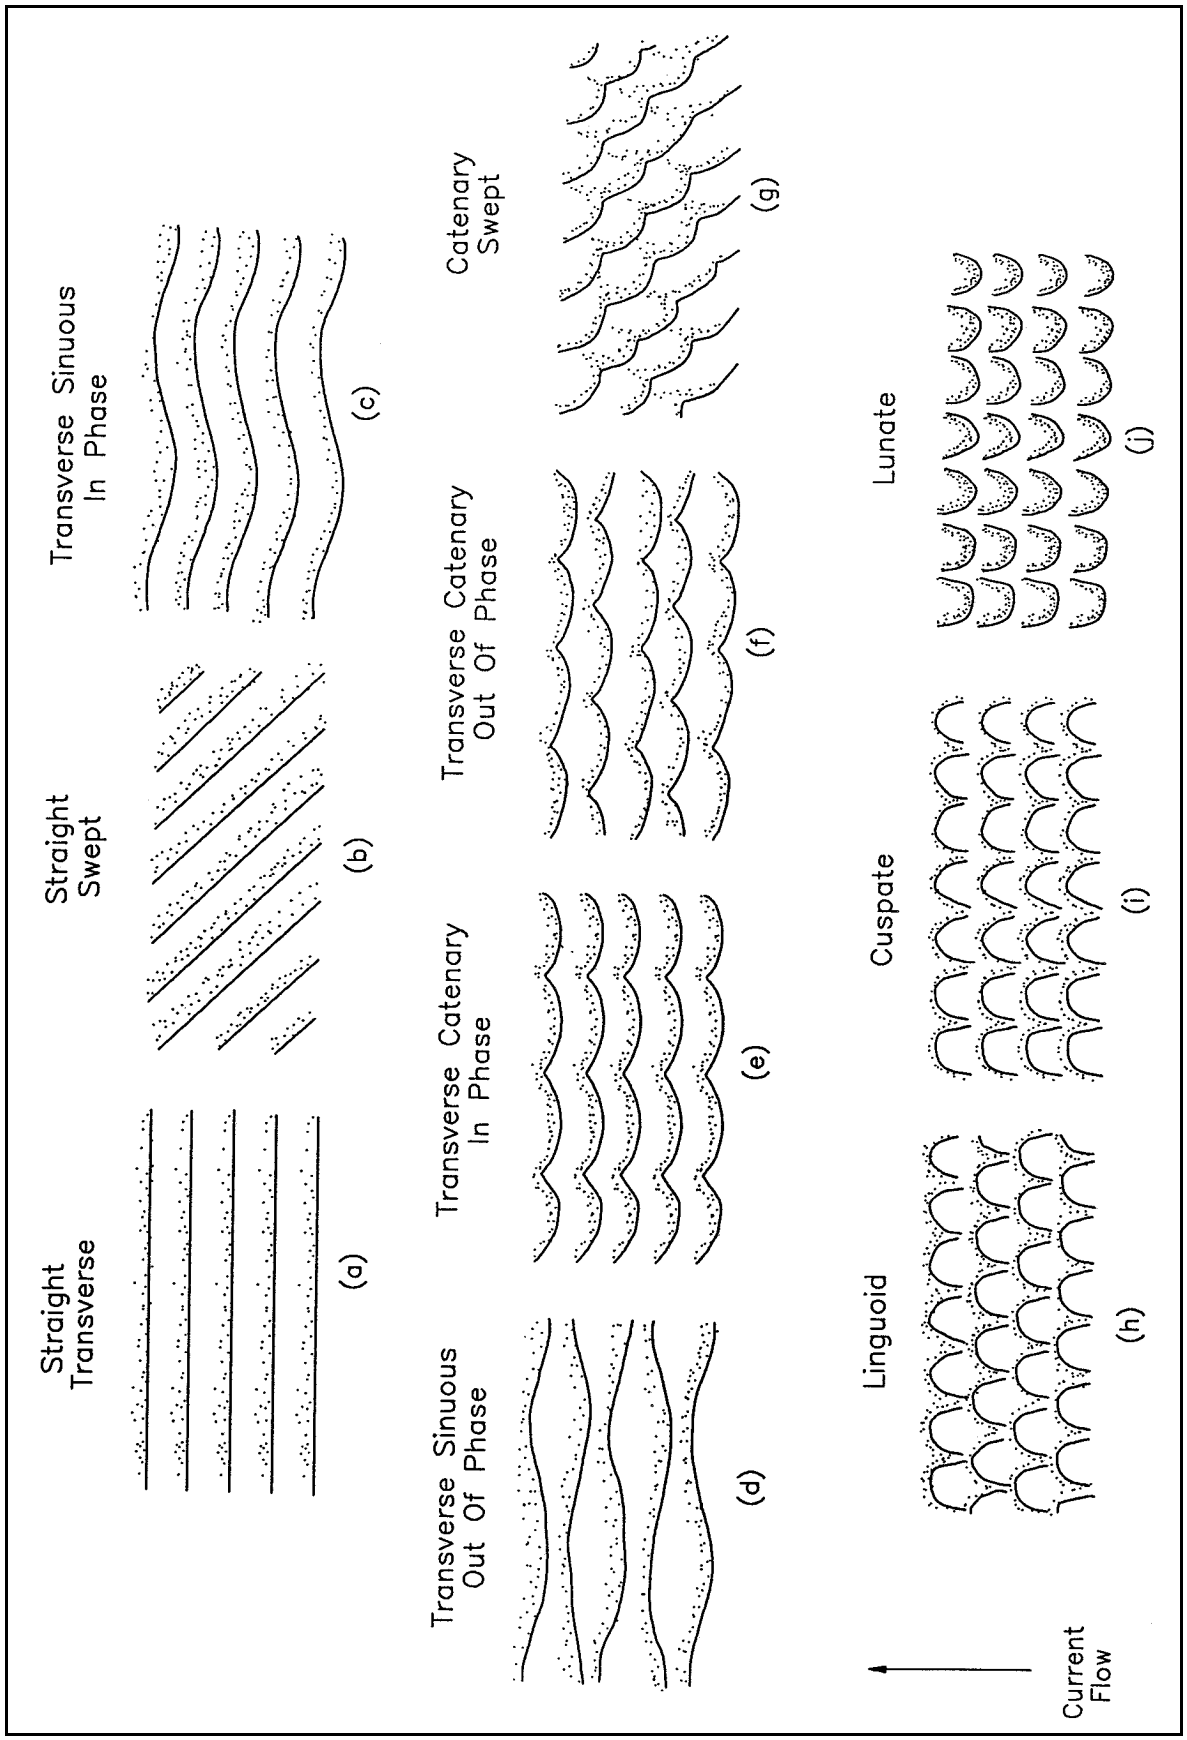

Figure IV-3-1. Sediment ripples. Water flow is from bottom to top, and lee sides and spurs are stippled (modified from Allen (1968))

Figure IV-3-2. Ripples in a runnel, now exposed during low tide. Flow was from upper left to lower right. Complicated pattern is best classified as transverse sinuous out of phase (type d) in Figure IV-3-1. Photographed at Bon Secour Wildlife Refuge, near Gulf Shores, Alabama

migrate upstream or downstream, or may remain stationary (the name "antidune" is based on early observations of upstream migration).

d. Velocity - grain size relationships. Figure IV-3-6 (from Ashley (1990)) illustrates the zones where ripples, dunes, planar beds, and antidunes are found. The figure summarizes laboratory studies conducted by various researchers. These experiments support the common belief that large flow-transverse bed forms (dunes) are a distinct entity separate from smaller current ripples. This plot is very similar to Figure 11.4 in Graf's (1984) hydraulics text, although Graf uses different axis units.

IV-3-3. Deltaic Processes[1]

a. Introduction. River deltas, which are found throughout the world, result from the interaction of fluvial and marine (or lacustrine) forces. According to Wright (1985), "deltas are defined more broadly as coastal accumulations, both subaqueous and subaerial, of river-derived sediments adjacent to, or in close proximity to, the source stream, including the deposits that have been secondarily molded by waves, currents, or tides." The processes that control delta development vary greatly in intensity around the world. As a result, delta-plain landforms span the spectrum of coastal features and include:

Despite the pronounced variety of worldwide environments where deltas are found, all actively-forming deltas have at least one common attribute: a river supplies clastic sediments to the coast and inner shelf more rapidly than marine processes can remove these materials. Whether a river is sufficiently large to transport enough sediment to overcome erosive marine processes depends upon the climate, geology, and nature of the drainage basin, and, most important, the overall size of the basin. The following paragraphs discuss delta classification, riverine flow, sediment deposition, and geomorphic structures associated with deltas.

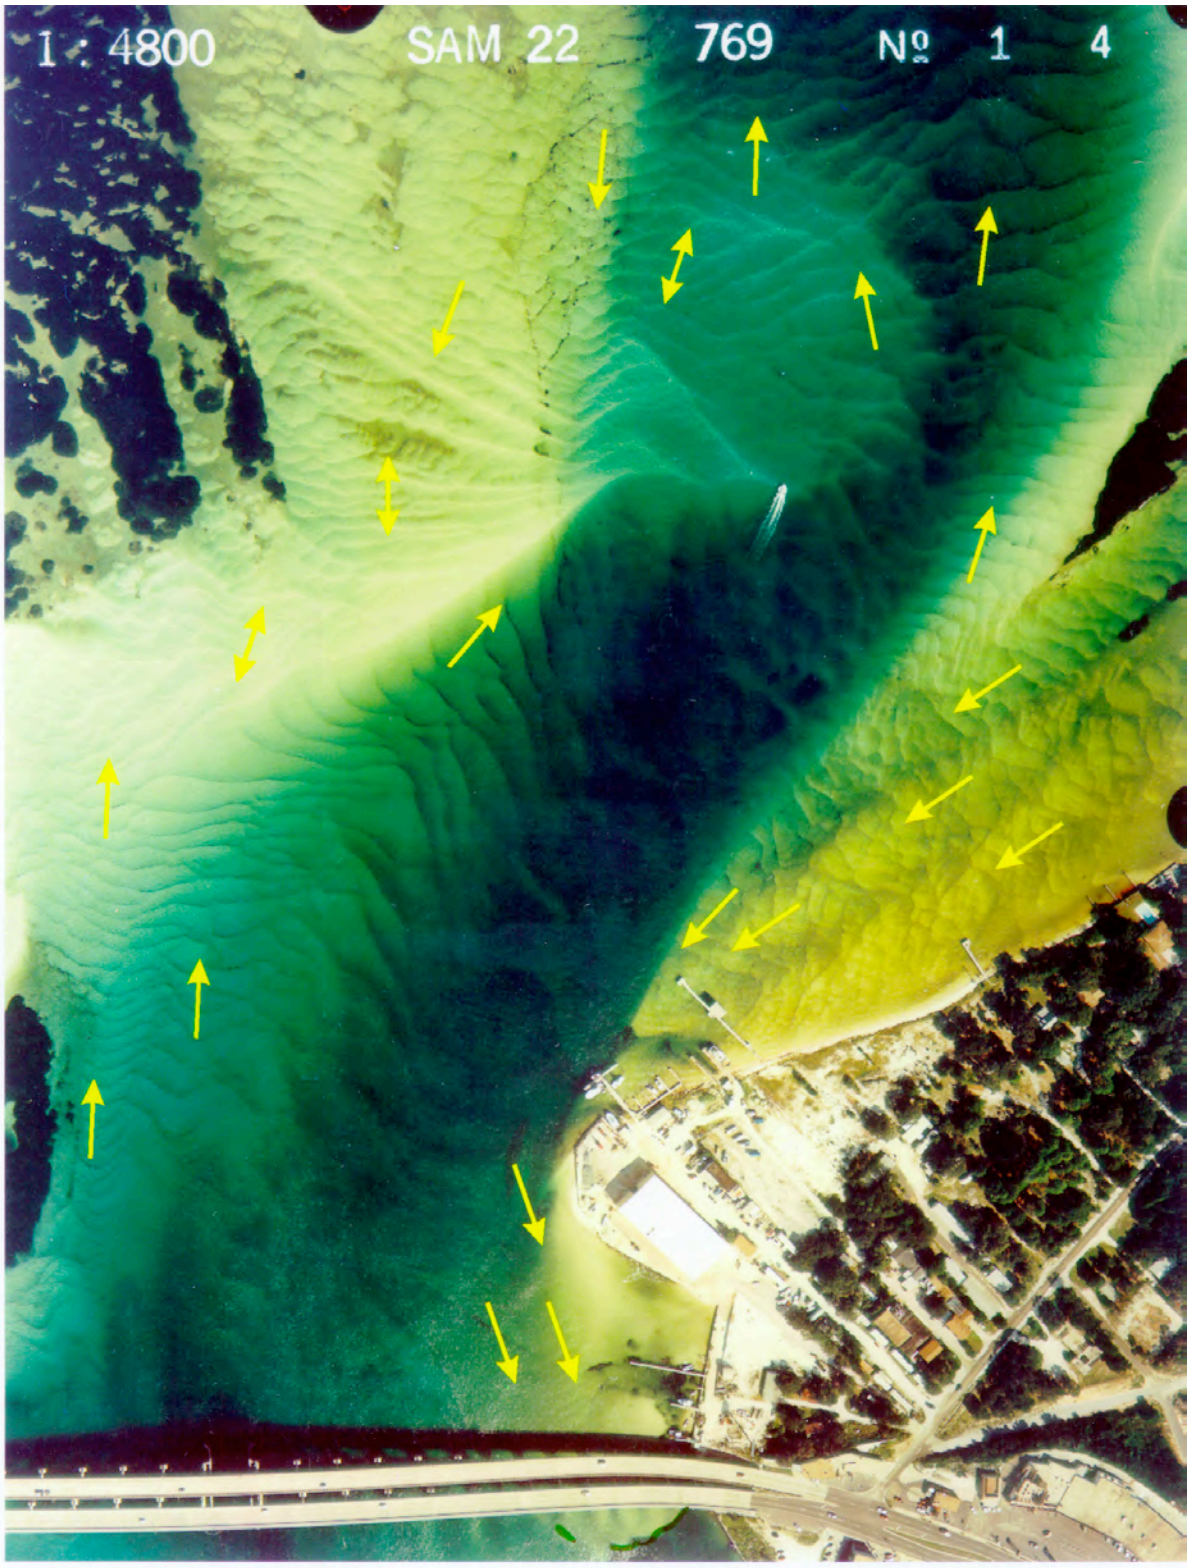

Figure IV-3-5. Flood shoal, East Pass, Florida (23 Sep 1987). North is to the top. The Gulf of Mexico is about 1 km south of the Hwy 98 bridge at the bottom of the image. Dunes in the main channel are flood-oriented (toward the top of the image), while bed forms in the marginal channels are ebb-oriented (Photograph courtesy of USAED, Mobile)

b. General delta classification. Coleman and Wright (1975) identified six broad classes of deltas using an energy criteria. These models have been plotted on Figure IV-3-7 according to the relative importance of river, wave, and tide processes. However, Wright (1985) acknowledged that because each delta has unique and distinct features, no classification scheme can adequately encompass the wide variety of environments and structures found at deltas around the world.

c. Delta-forming processes.

(1) Force balance. Every delta is the result of a balance of forces that interact in the vicinity of the river mouth. A river carries sediment to the coast and deposits it beyond the mouth. Tidal currents and waves rework the newly deposited sediments, affecting the shape and form of the resulting structure. The long-term evolution of a delta plain becomes a function of the rate of riverine sediment input and the rate and pattern of sediment reworking, transport, and deposition by marine processes after the initial deposition. On a large scale, gross deltaic shape is also influenced by receiving basin geometry, regional tectonic stability, rates of subsidence caused by compaction of newly deposited sediment, and rate of sea level rise.

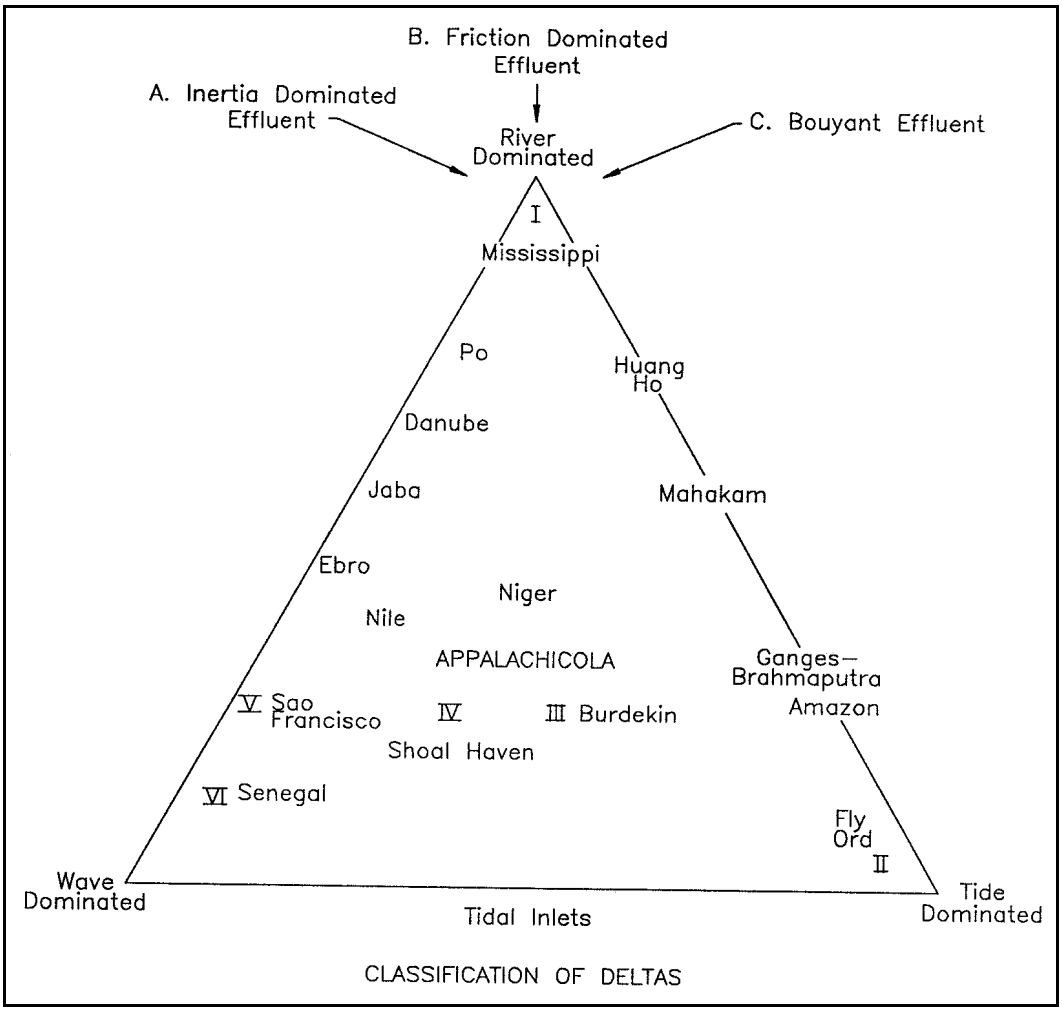

Figure IV-3-7. Classification of deltas

(2) River-dominant deltas.

(a) River-dominant deltas are found where rivers carry so much sediment to the coast that the deposition rate overwhelms the rate of reworking and removal due to local marine forces. In regions where wave energy is very low, even low-sediment-load rivers can form substantial deltas.

(b) When a river is completely dominant over marine forces, the delta shape develops as a pattern of prograding, branching distributary channels (resembling fingers branching from a hand). Interdistributary features include open bays and marshes. A generalized isopach map for this type of delta (Type I in Coleman and Wright's (1975) classification) is shown in Figure IV-3-8. A prime example is the Mississippi River, which not only transports an enormous amount of sediment, but also empties into the low wave-energy, low tide-range Gulf of Mexico (Figure IV-3-9). The Fraser River, which flows into the sheltered Strait of Georgia, is another example (Figure IV-3-10). The Mississippi is discussed in more detail later.

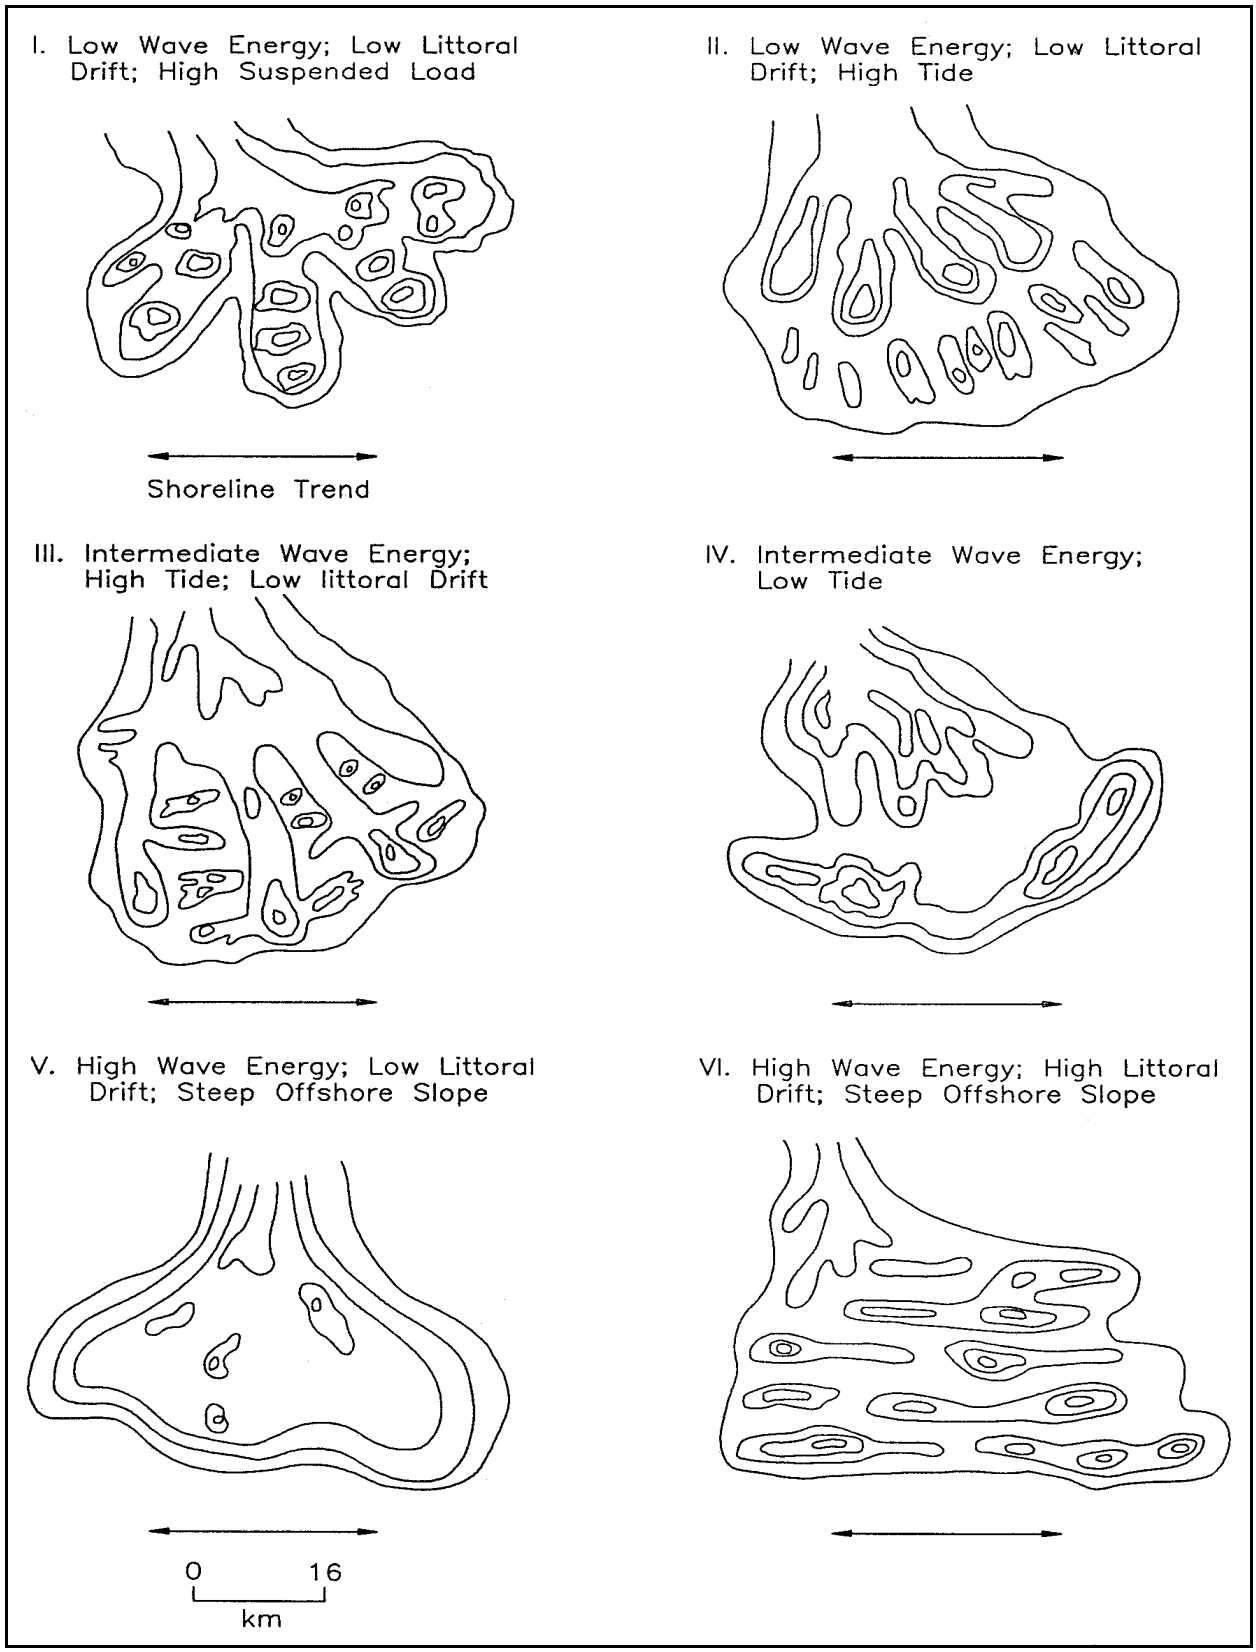

Figure IV-3-8. Isopach map for river-dominant deltas

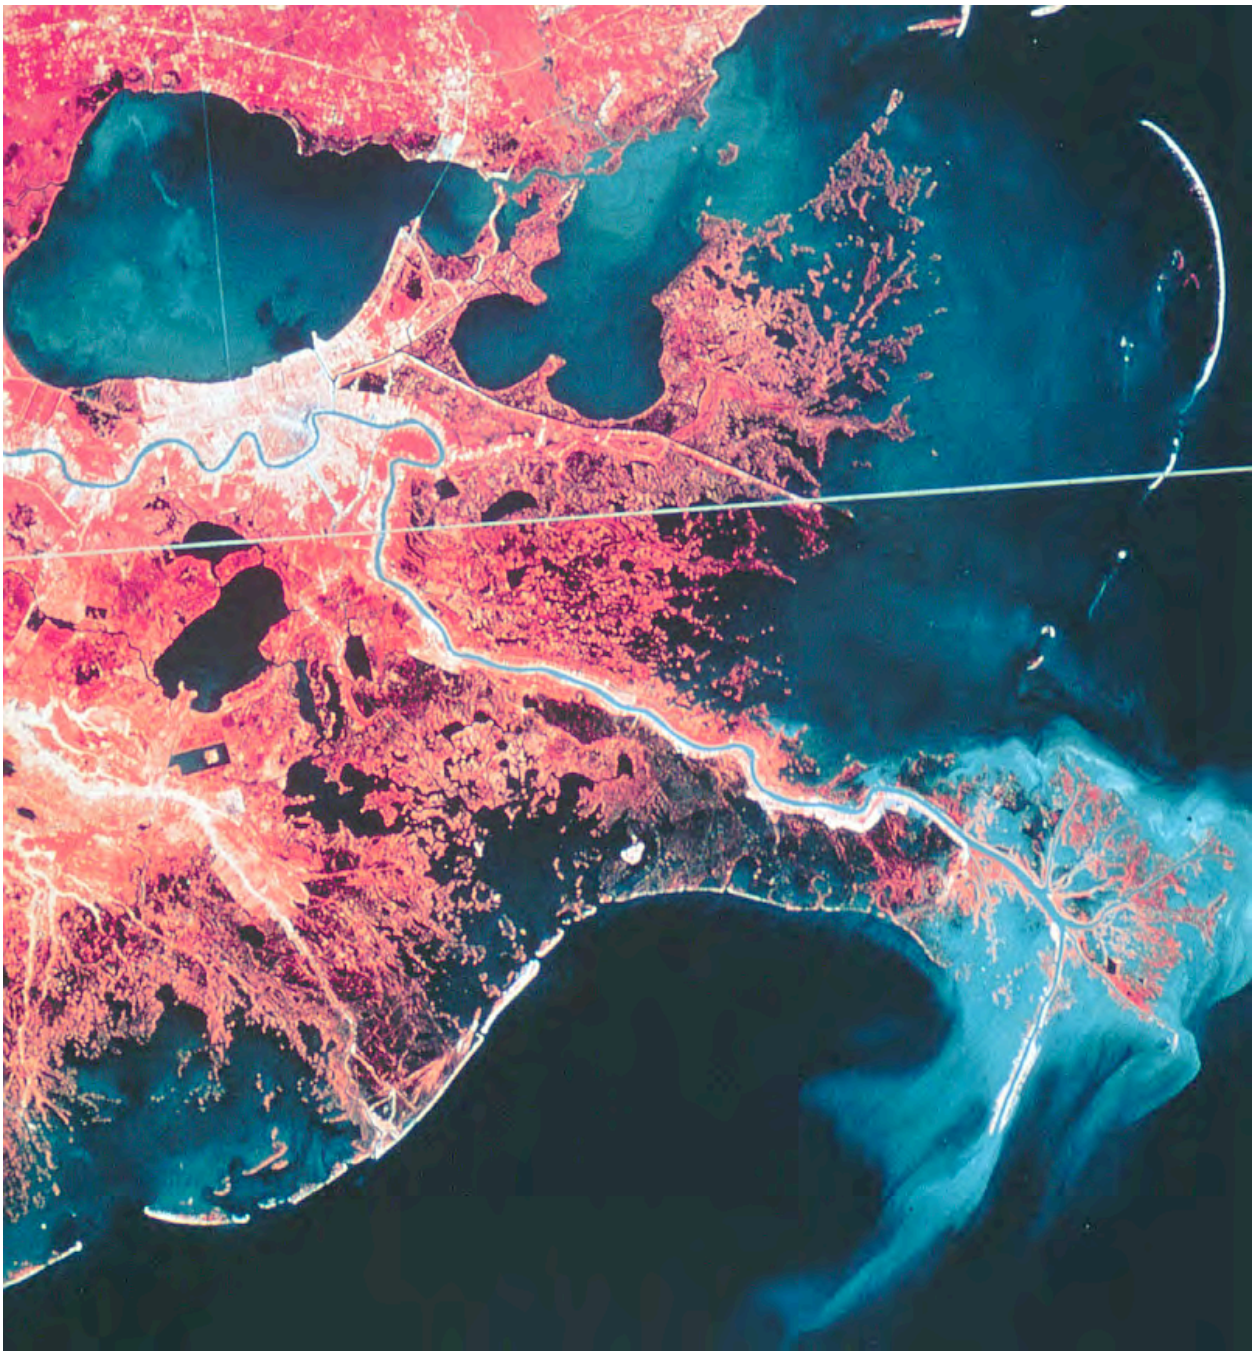

Figure IV-3-9. Mississippi River Delta. The river, which flows into the Gulf of Mexico, has several outlets that are dredged by the Corps of Engineers almost continuously. The city of New Orleans is at the upper left of the image immediately south of Lake Pontchartrain. Landsat 2 image (date unknown)

(3) Wave-dominant deltas.

(a) At wave-dominant deltas, waves sort and redistribute sediments delivered to the coast by rivers and remold them into shoreline features such as beaches, barriers, and spits. The morphology of the resulting delta reflects the balance between sediment supply and the rate of wave reworking and redistribution. Wright and Coleman (1972, 1973) found that deltas in regions of the highest nearshore wave energy flux developed

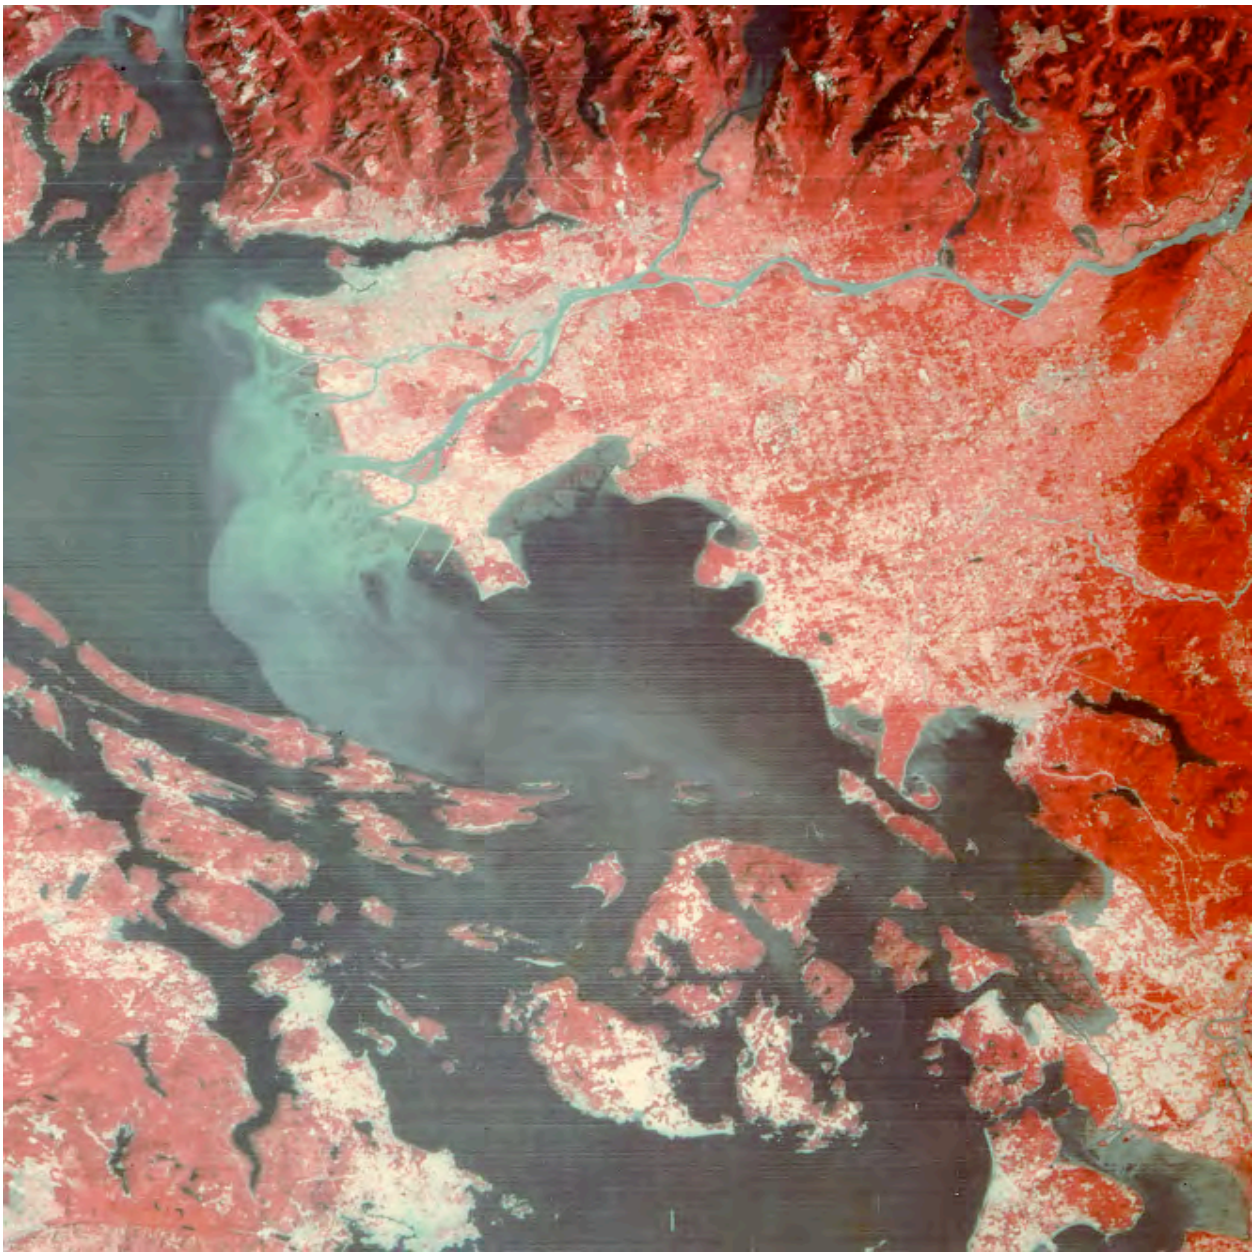

Figure IV-3-10. Fraser River Delta, British Columbia. The river flows into the sheltered Strait of Georgia past the city of Vancouver. The strait has high tidal currents, as shown by the plume of turbid water flowing to the southeast. This delta is also Class I, riverine-dominated (NASA ERTS, 12 Aug 1973)

the straightest shorelines and best-developed interdistributary beaches and beach-ridge complexes (Figure IV-2-3).

(b) Of 16 deltas compared by Wright and Coleman (1972, 1973), the Mississippi was the most river-dominated while the Senegal in west Africa was the other extreme, the most wave-dominated. A model of the Senegal (Type VI in Figure IV-3-8) shows that abundant beach ridges are parallel to the prevailing shoreline trend and that the shore is relatively straight as a result of high wave energy and a strong unidirectional littoral drift.

(c) An intermediate delta form is represented by the delta of the Rio São Francisco del Norte in Brazil (Type V in Figure IV-3-8). Distributary-mouth-bar deposits are restricted to the immediate vicinity of the river mouth and are quickly remolded by waves. Persistent wave energy redistributes the riverine sediment to form extensive sand sheets. The exposed delta plain consists primarily of beach ridges and aeolian dunes.

(4) Tide-dominant deltas.

Three important processes characterize tide-dominated deltas:

(a) At the river mouths, mixing obliterates vertical density stratification, eliminating the effects of buoyancy.

(b) For part of the year, tidal currents may be responsible for a greater fraction of the sediment-transporting energy than the river. As a result, sediment transport in and near the river mouth is bidirectional over a tidal cycle.

(c) The location of the land-sea interface and the zone of marine-riverine interactions is greatly extended both vertically and horizontally. Examples of deltas that are strongly influenced by tides include the Ord (Australia), Shatt-al-Arab (Iraq), Amazon (Brazil), Ganges-Brahmaputra (Bangladesh), and the Yangtze (China). Characteristic features of river mouths in macrotidal environments are bell-shaped, sand-filled channels and linear tidal sand ridges. The crests of the ridges, which have relief of 10-20 m, may be exposed at low tide. The ridges replace the distributary-mouth bars found at other deltas and become the dominant sediment-accumulation form. As the delta progrades over time, the ridges grow until they are permanently exposed, forming large, straight tidal channels (Type II in Figure IV-3-8). An example of a macrotidal delta is the Ord of Western Australia and the Essex River Delta in Massachusetts (Figure IV-3-11).

(5) Intermediate forms.

(a) As stated above, the morphology of most deltas is a result of a combination of riverine, tidal, and wave forces. One example of an intermediate form is the Burdekin Delta of Australia (Type II in Figure IV-3-8). High waves redistribute sands parallel to the coastline trend and remold them into beach ridges and barriers. Within the river mouths, tidal currents produce sand-filled river channels and tidal creeks. This type of delta displays a broad range of characteristics, depending upon the relative strength of waves versus tides. In addition, features may vary seasonally if runoff and wave climate change. Other examples include the Irrawaddy (Burma), Mekong (Vietnam), and Red (Vietnam) Deltas (Wright 1985).

(b) The fourth model of delta geometry is characterized by offshore bay-mouth barriers that shelter lagoons, bays, or estuaries into which low-energy deltas prograde (Type IV, Figure IV-3-8). Examples include the Appalachicola (Florida Panhandle), Sagavanirktok (Alaska), and Shoalhaven (southeastern Australia) Deltas (Wright 1985). In contrast to the river-dominant models, the major accumulation of prodelta mud occurs landward of the main sand body (the barrier), and at the same elevation, within the protected bay. Although suspended fines reach the open sea, wave action prevents mud accumulation as a distinct unit over the open shelf.

d. Deltaic components and sediments.

(1) Generally, all deltas consist of four physiographic zones: an alluvial valley, upper deltaic plain, lower deltaic plain, and subaqueous deltaic plain (Figure IV-3-12). The deposition that occurs adjacent to and between the distributory channels accounts for most of the subaerial delta. In the case of the Mississippi

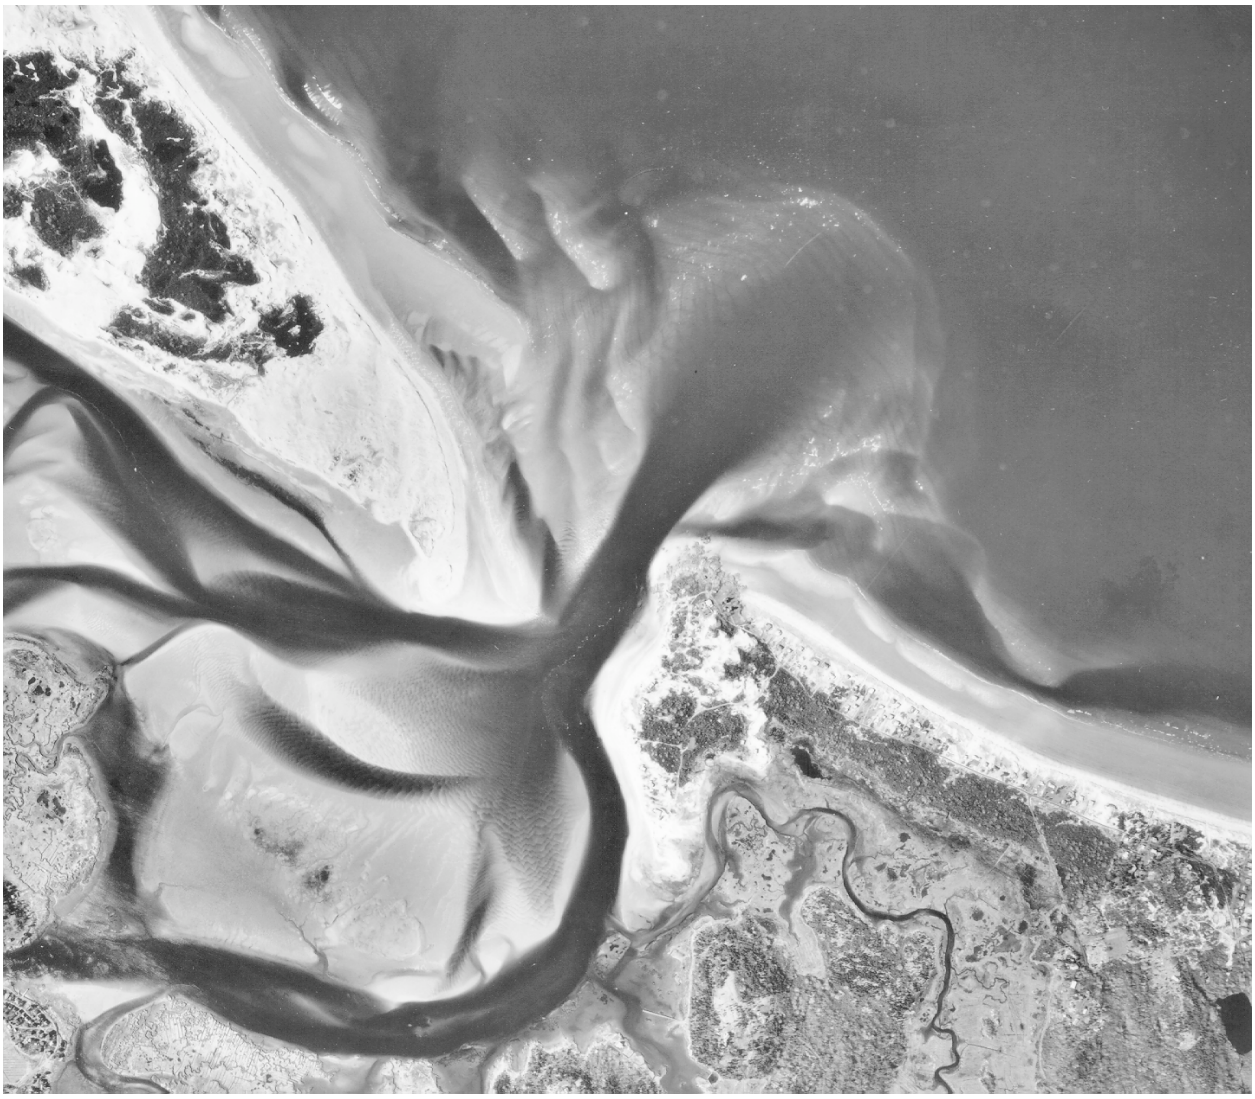

Figure IV-3-11. Mouth of the Essex River, Massachusetts (23 April 1978). This delta is Class II, high tide and low wave energy, or possibly Class III, intermediate wave and high tide. This river mouth is anchored on the south by rock outcrops. Formerly, there may have been more open water in the back bays, and the morphology would have resembled an inlet in a barrier spit

delta, significant sand accumulates in the interdistributory region when breaks in the levees occur, allowing river water to temporarily escape from the main channel. These accumulations are called *crevasse splays*.

(2) The subaqueous plain is the foundation over which the modern delta progrades (as long as the river occupies the existing course and continues to supply sufficient sediment). The subaqueous plain is characterized by a seaward-fining of sediments, with sand being deposited near the river mouths and clays settling further offshore. The seawardmost unit of the plain is the prodelta. It overlies the sediments of the inner continental shelf and consists of a blanket of clays deposited from suspension. The prodelta of the Mississippi ranges from 20 to 50 m thick and extends seaward to water depths of 70 m. The Mississippi's prodelta contains pods of distributory mouth bar sands and their associated cross bedding, flow structures, and shallow-water fauna. These pods may be slump blocks carried down to the prodelta by submarine landslides (Prior and Coleman 1979). Slumping and mudflow are mechanisms that transport large masses of sediment down to the edge of the continental slope and possibly beyond. These mass movements are a

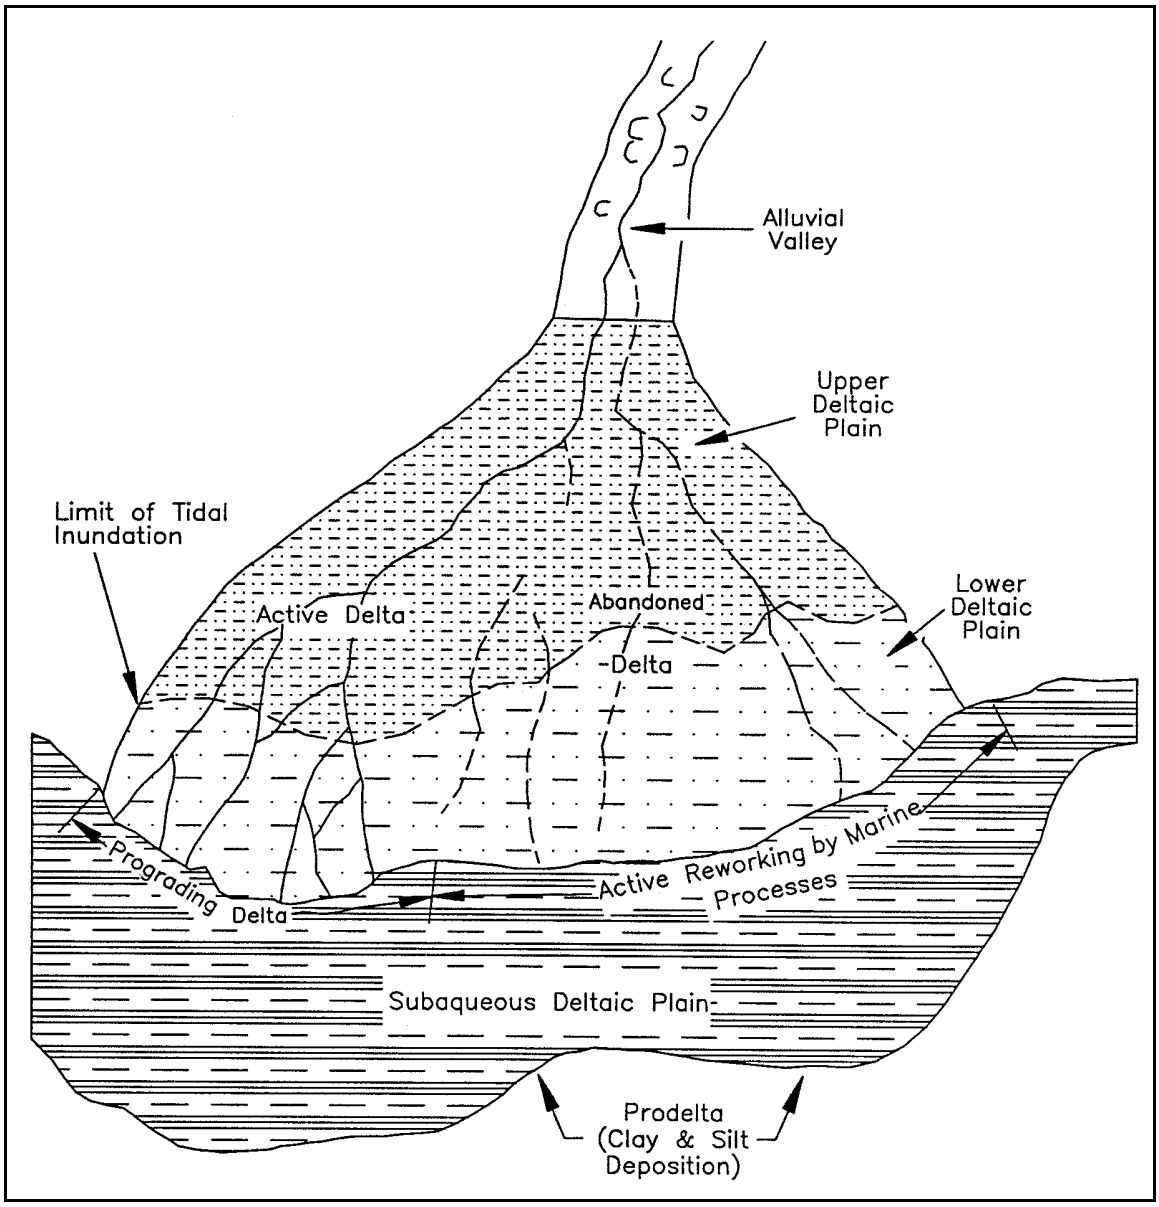

Figure IV-3-12. Basic physiographic units common to all deltas (from Wright (1985))

serious hazard to oil drilling and production platforms. Mud diapirs, growth faults, mud/gas vents, pressure ridges, and mudflow gullies are other evidence of sediment instability on the Mississippi Delta (Figure IV-3-13). Additional details of this interesting subject are covered in Coleman (1988), Coleman and Garrison (1977), Henkel (1970), and Prior and Coleman (1980).

(3) Above the delta front, there is a tremendous variability of sediment types. A combination of shallow marine processes, riverine influence, and brackish-water faunal activity causes the interdistributory bays to display an extreme range of lithologic and textural types. On deltas in high tide regions, the interdistributory bay deposits are replaced by tidal and intertidal flats. West of the Mississippi Delta is an extensive chenier plain. Cheniers are long sets of sand beach ridges, located on mudflats.

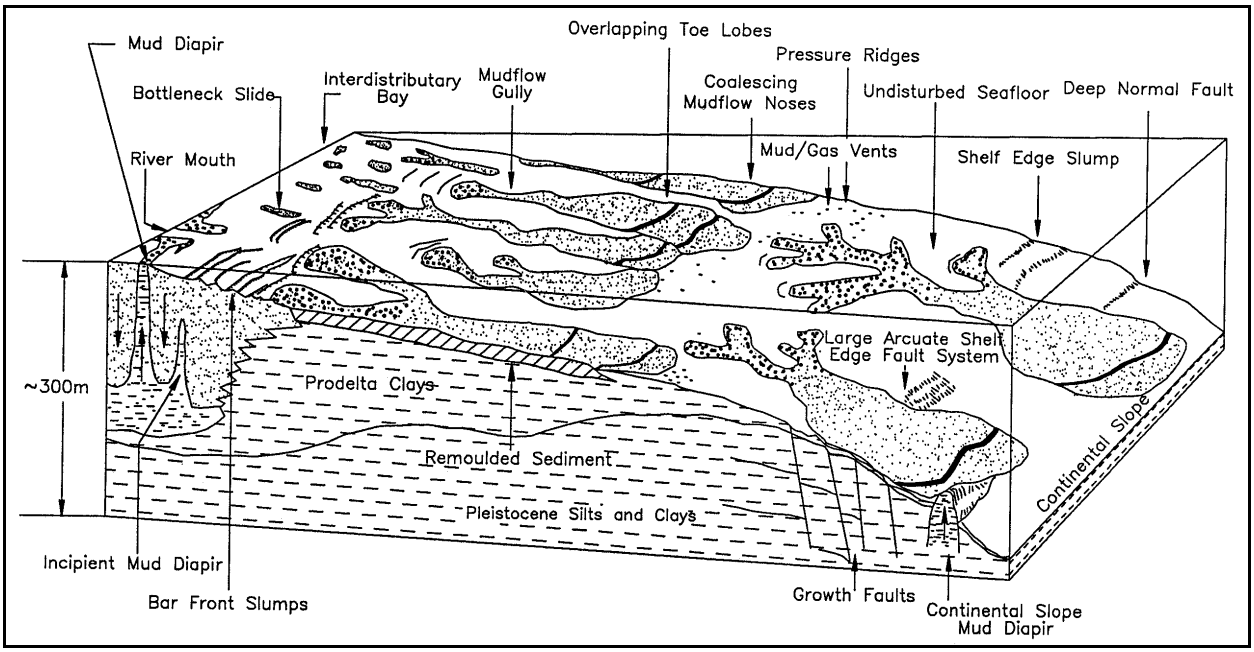

Figure IV-3-13. Structures and types of sediment instabilities on the Mississippi Delta (from Coleman (1988))

e. River mouth flow and sediment deposition.

(1) River mouth geometry and river mouth bars are influenced by, and in turn influence, effluent dynamics. This subject needs to be examined in detail because the principles are pertinent to both river mouths and tidal inlets. Diffusion of the river's effluent and the subsequent sediment dispersion depend on the relative strengths of three main factors:

(a) Inertia of the issuing water and associated turbulent diffusion.

(b) Friction between the effluent and the seabed immediately seaward of the mouth.

(c) Buoyancy resulting from density contrasts between river flow and ambient sea or lake water.

Based on these forces, three sub-classes of deltaic deposition have been identified for river-dominated deltas (Figure IV-3-7). Two of these are well illustrated by depositional features found on the Mississippi Delta.

(2) Depositional model type A - inertia-dominated effluent.

(a) When outflow velocities are high, depths immediately seaward of the mouth tend to be large, density contrasts between the outflow and ambient water are low, and inertial forces dominate. As a result, the effluent spreads and diffuses as a turbulent jet (Figure IV-3-14a). As the jet expands, its momentum decreases, causing a reduction of its sediment carrying capacity. Sediments are deposited in a radial pattern, with the coarser bed load dropping just beyond the point where the effluent expansion is initiated. The result is basinward-dipping foreset beds.

(b) This ideal model is probably unstable under most natural conditions. As the river continues to discharge sediment into the receiving basin, shoaling eventually occurs in the region immediately beyond the mouth (Figure IV-3-14b). For this reason, under typical natural conditions, basin depths in the zone of the

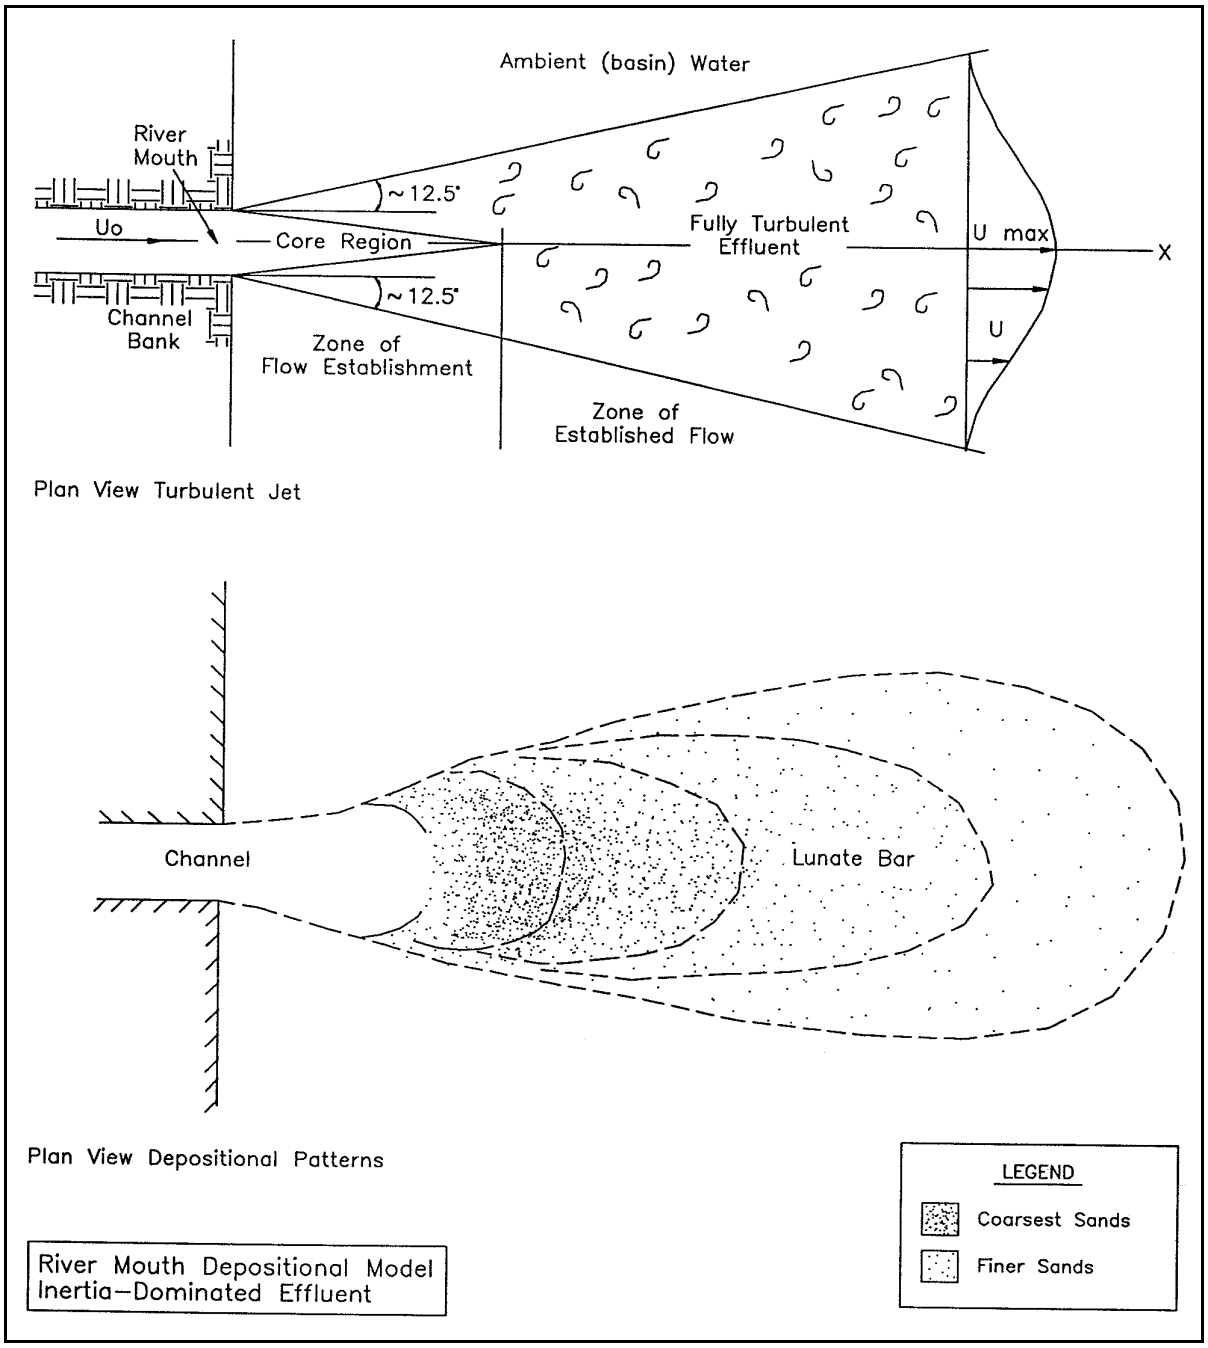

Figure IV-3-14. Plan view of depositional Model A, inertia-dominated effluent (adapted from Wright (1985)) (Continued)

jet's diffusion are unlikely to be deeper than the outlet depth. Effluent expansion and diffusion become restricted horizontally as a plane jet. More important, friction becomes a major factor in causing rapid deceleration of the jet. Model 'A' eventually changes into friction-dominated Model 'B'.

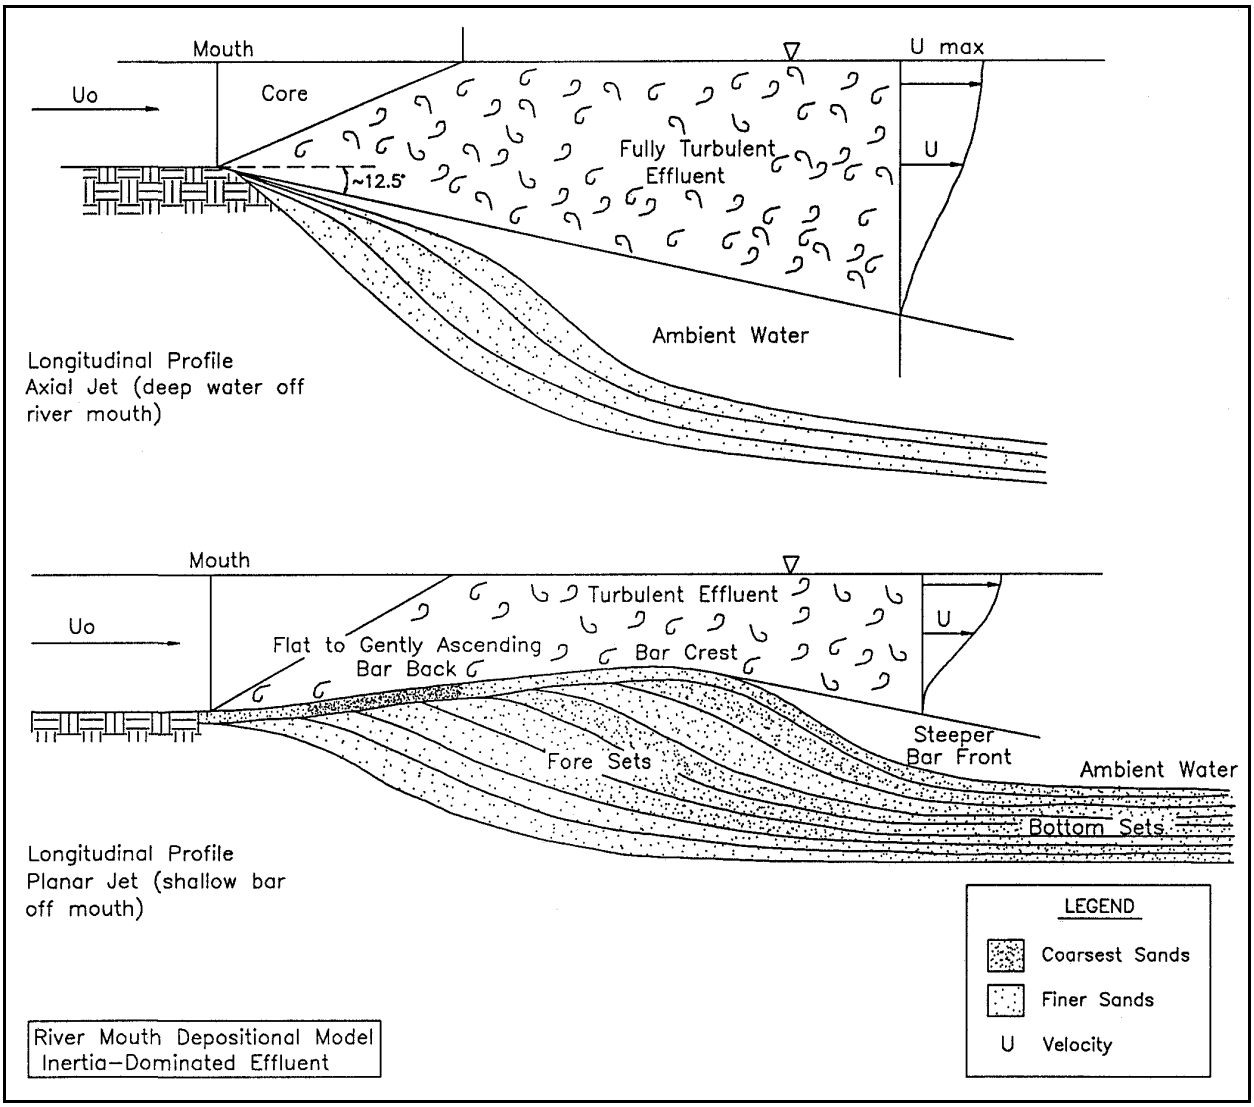

Figure IV-3-14. (Concluded)

(3) Depositional model type B - friction-dominated effluent.

(a) When homopycnal,[1] friction-dominated outflow issues over a shallow basin, a distinct pattern of bars and subaqueous levees is formed (Figure IV-3-15). Initially, the rapid expansion of the jet produces a broad, arcuate radial bar. As deposition continues, natural subaqueous levees form beneath the lateral boundaries of the expanding jet where the velocity decreases most rapidly. These levees constrict the jet from expanding further. As the central portion of the bar grows upward, channels form along the lines of greatest turbulence, which tend to follow the subaqueous levees. The result is the formation of a bifurcating channel that has a triangular middle-ground shoal separating the diverging channel arms. The flow tends to be concentrated into the divergent channels and to be tranquil over the middle ground under normal conditions.

[1] River water and ambient water have the same density (for example, a stream entering a freshwater lake).

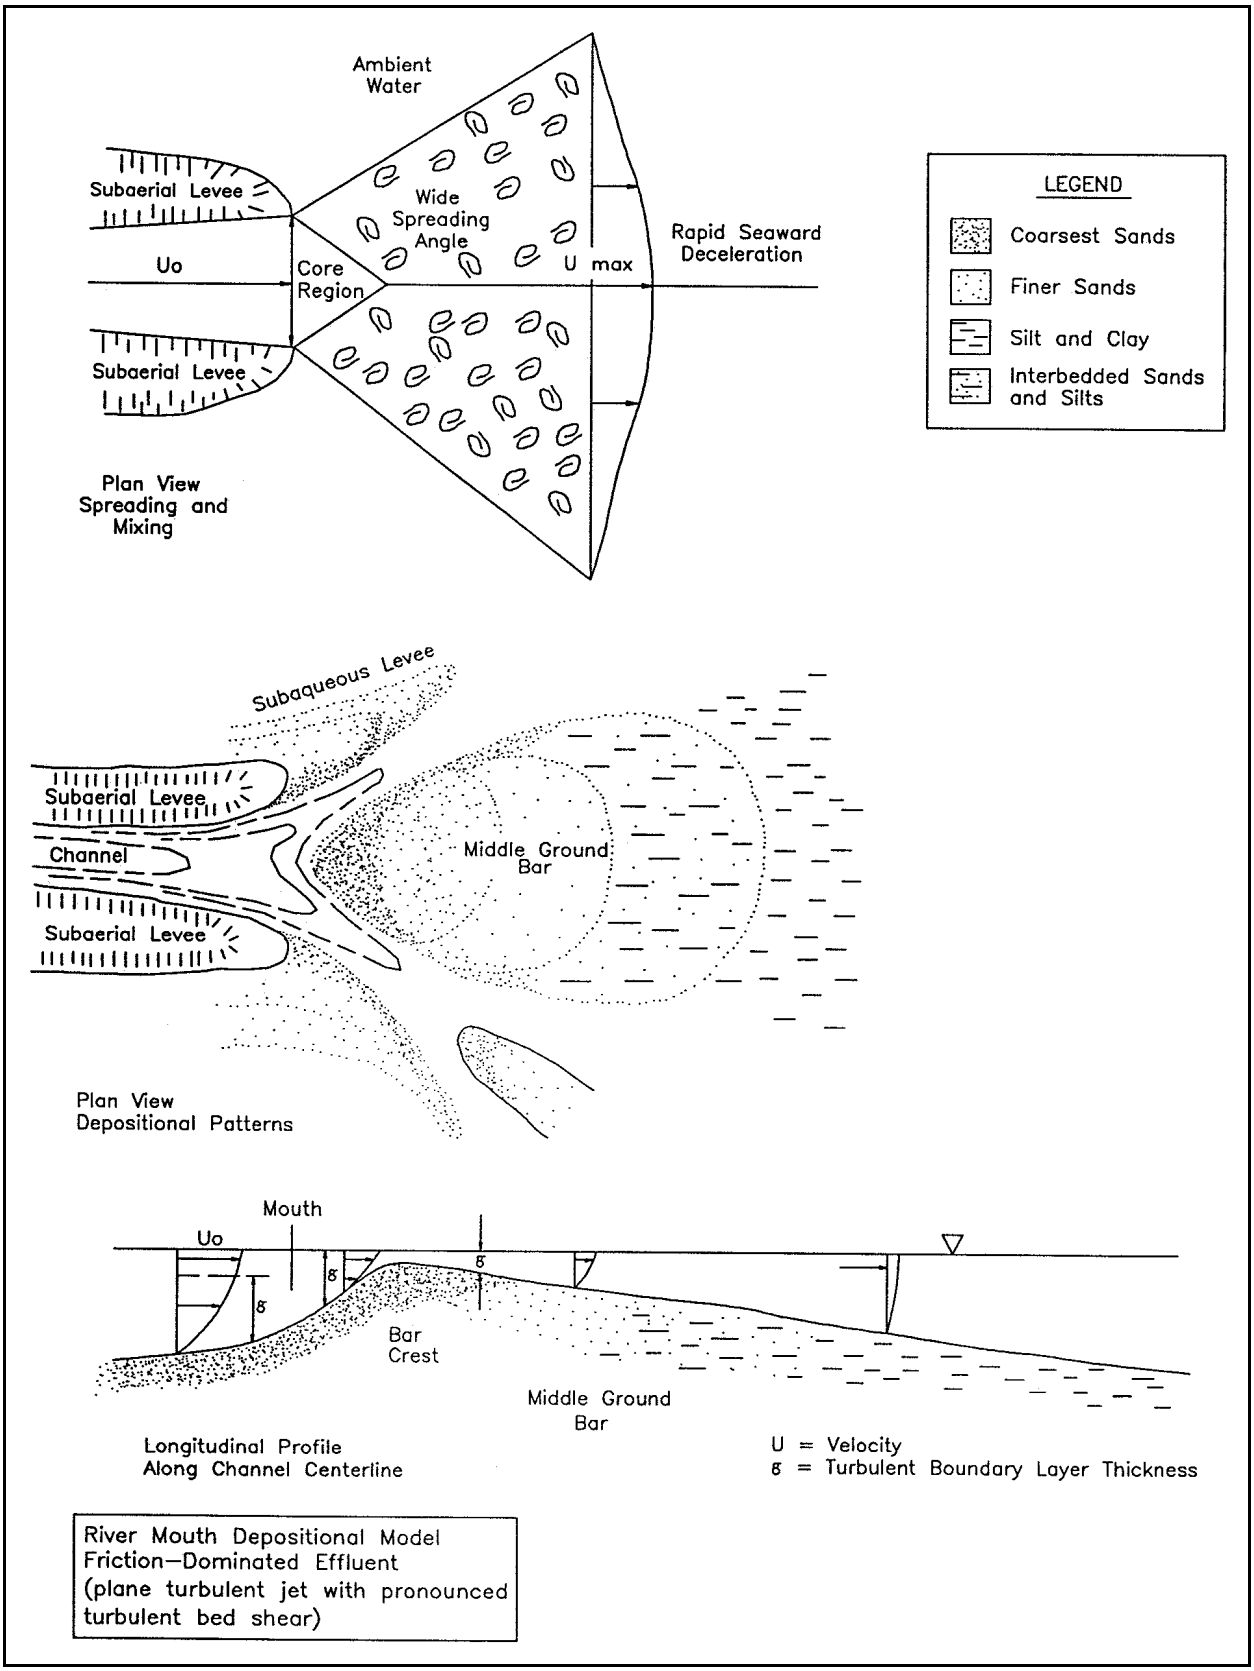

Figure IV-3-15. Depositional model type B, friction-dominated effluent (adapted from Wright (1985))

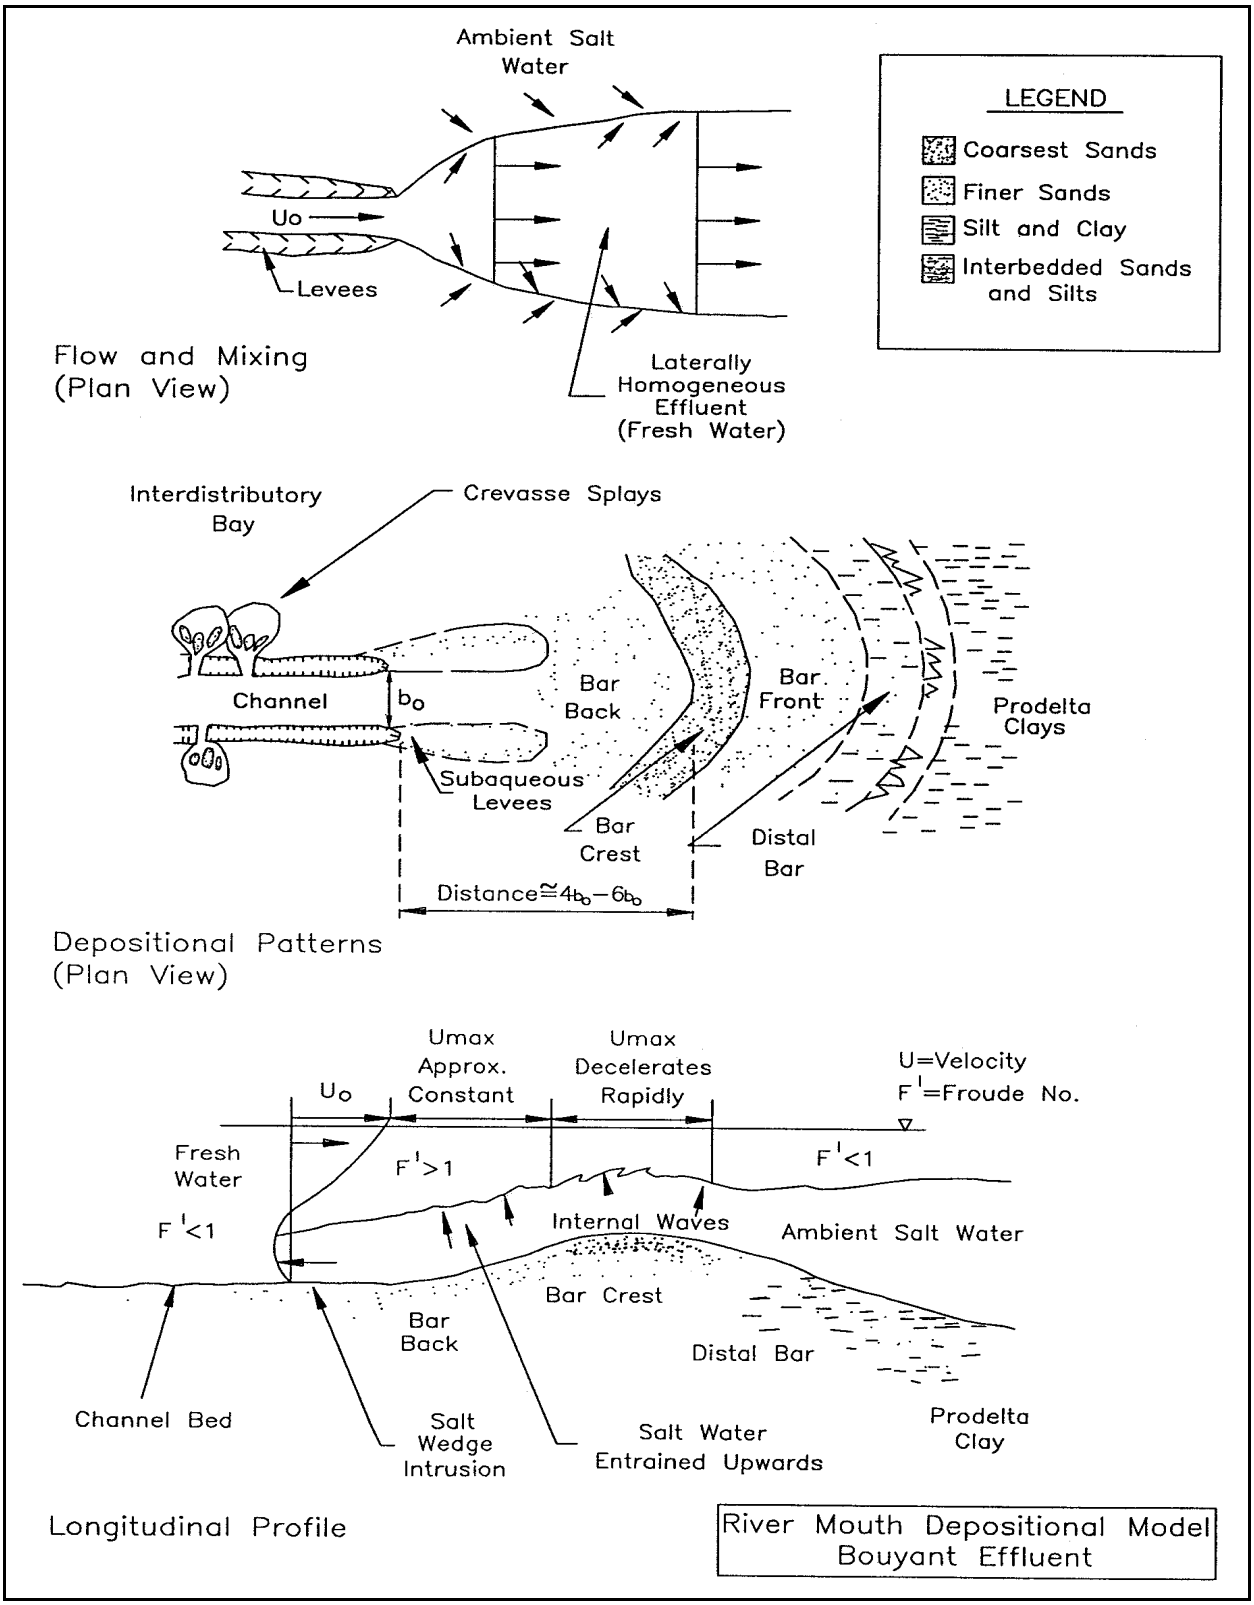

Figure IV-3-16. River mouth bar crest features, depositional model type C, buoyant effluent (adapted from Wright (1985)) (Continued)

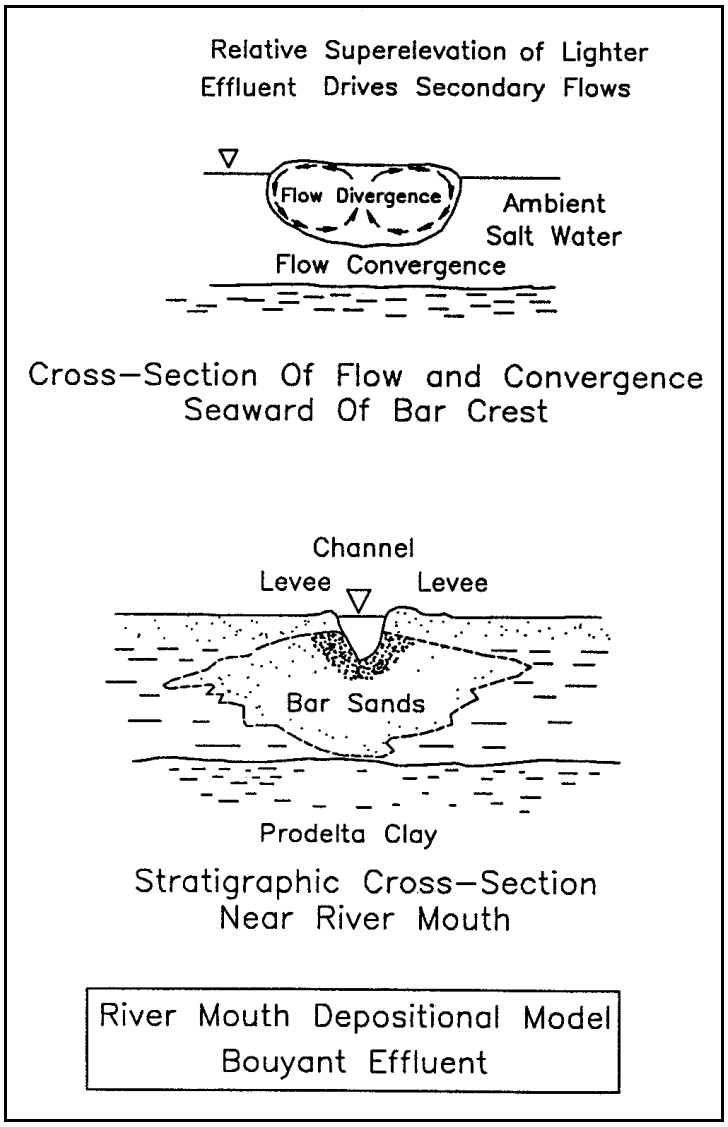

Figure IV-3-16. (Concluded)

(b) This type of bar pattern is most common where nonstratified outflow enters a shallow basin. Examples of this pattern (known as *crevasse splays* or *overbank splays*) are found at crevasses along the Mississippi River levees. These secondary channels run perpendicular to the main Mississippi channels and allow river water to debouch into the broad, shallow interdistributory bays. This process forms the major subaerial land (marsh) of the lower Mississippi delta (Coleman 1988).

(4) Depositional model type C - buoyant effluent.

(a) Stratification often occurs when fresh water flows out into a saline basin. When the salt wedge is well developed, the effluent is effectively isolated from the effects of bottom friction. Buoyancy suppresses mixing and the effluent spreads over a broad area, thinning progressively away from the river mouth (Figure IV-3-16). Deceleration of the velocity of the effluent is caused by the upward entrainment of seawater across the density interface.

(b) The density interface between the freshwater plume and the salt wedge is often irregular due to internal waves (Figure IV-3-16a). The extent that the effluent behaves as a turbulent or buoyant jet depends largely on the Froude number *F'*:

$$F' = \frac{U^2}{\gamma g h'} \tag{IV-3-1}$$

where

U = mean outflow velocity of upper layer (in case of stratified flow)

g = acceleration of gravity

h' = depth of density interface

$$\gamma = 1 - (\rho_f/\rho_s) \tag{IV-3-2}$$

where

ρ_f = density of fresh water

ρ_s = density of salt water

As *F'* increases, inertial forces dominate, accompanied by an increase in turbulent diffusion. As *F'* decreases, turbulence decreases and buoyancy becomes more important. Turbulence is suppressed when *F'* is less than 1.0 and generally increases as *F'* increases beyond 1.0 (Wright 1985).

(c) The typical depositional patterns associated with buoyant effluent are well represented by the mouths of the Mississippi River (Wright and Coleman 1975). Weak convergence near the base of the effluent inhibits lateral dispersal of sand, resulting in narrow bar deposits that prograde seaward as laterally restricted "bar-finger sands" (Figure IV-3-16b). The same processes presumably prevent the subaqueous levees from diverging, causing narrow, deep distributory channels. Because the active channels scour into the underlying distributory-mouth bar sands as they prograde, accumulations of channel sands are usually limited. Once the channels are abandoned, they tend to fill with silts and clays. It is believed that the back bar and bar crest grow mostly from bed-load transport during flood stages. The subaqueous levees, however, appear to grow year-round because of the near-bottom convergence that takes place during low and normal river stages.

f. Mississippi Delta - Holocene history, dynamic changes.

(1) General. The Mississippi River, which drains a basin covering 41 percent of the continental United States (3,344,000 sq km), has deposited an enormous mound of unconsolidated sediment in the Gulf of Mexico. The river has been active since at least late Jurassic times and has dominated deposition in the northern Gulf of Mexico. Many studies have been conducted on the Mississippi Delta, leading to much of our knowledge of deltaic sedimentation and structure. The ongoing research is a consequence of the river's critical importance to commerce and extensive petroleum exploration and production in the northern Gulf of Mexico during the last 50 years.

(2) Deposition time scales. The Mississippi Delta consists of overlapping deltaic lobes. Each lobe covers 30,000 sq km and has an average thickness of about 35 m. The lobes represent the major sites of the river's deposition. The process of switching from an existing lobe to a new outlet takes about 1500 years

(Coleman 1988). Within a single lobe, deposition in the bays occurs from overbank flows, crevasse splays, and biological production. The bay fills, which cover areas of 250 sq km and have a thickness of only 15 m, accumulate in only about 150 years. Overbank splays, which cover areas of 2 sq km and are 3 m thick, occur during major floods when the natural levees are breached. The mouths of the Mississippi River have prograded seawards at remarkable rates. The distributory channels can form sand bodies that are 17 km long, 8 km wide, and over 80 m thick in only 200 years (Coleman 1988).

(3) Holocene history. During the last low sea level stand, 18,000 years ago, the Mississippi River entrenched its valley, numerous channels were scoured across the continental shelf, and deltas were formed near the shelf edge (Suter and Berryhill 1985). As sea level rose, the site of deposition moved upstream to the alluvial valley. By about 9,000 years before present, the river began to form its modern delta. In more recent times, the shifting deltas of the Mississippi have built a delta plain covering a total area of 28,500 sq km. The delta switching, which has occurred at high frequency, combined with a rapidly subsiding basin, has resulted in vertically stacked cyclic sequences. Because of rapid deposition and switching, in a short time the stacked cyclic deltaic sequences have attained thicknesses of thousands of meters and covered an area greater than 150,000 sq km (Coleman 1988). Figure IV-3-17 outlines six major lobes during the last 7,500 years.

(4) Modern delta. The modern delta, the Balize or Birdfoot, began to prograde about 800 to 1,000 years ago. Its rate of progradation has diminished recently and the river is presently seeking a new site of deposition. Within the last 100 years, a new distributory, the Atchafalaya, has begun to divert an increasing amount of the river's flow. Without river control structures, the new channel would by now have captured all of the Mississippi River's flow, leading to rapid erosion of the Balize Delta. (It is likely that there would be a commensurate deterioration of the economy of New Orleans if it lost its river.) Even with river control projects, the Atchafalaya is actively building a delta in Atchafalaya Bay (lobe 6 in Figure IV-3-17).

g. Sea level rise and deltas.

(1) Deltas experience rapid local relative sea level rise because of the natural compaction of deltaic sediments from dewatering and consolidation. Deltas are extremely vulnerable to storms because the subaerial surfaces are flat and only slightly above the local mean sea level. Only a slight rise in sea level can extend the zone subject to storm surges and waves further inland. As stated earlier, delta evolution is a balance between the accumulation of fluvially supplied sediment and the reworking, erosion, and transport of deltaic sediment by marine processes (Wright 1985). Even a river like the Mississippi, which has a high sediment load and drains into a low wave-energy basin, is prograding only in the vicinity of the present distributory channels, the area defined as the active delta (Figures IV-3-9 and IV-3-12).

(2) Deltas are highly fertile agriculturally because of the steady supply of nutrient-laden soil. As a result, some of the world's greatest population densities - over 200 inhabitants per square kilometer - are found on deltas (*The Times Atlas of the World* 1980):

(a) Nile Delta, Egypt.

(b) Chang Jiang (Yangtze), China.

(c) Mekong, Vietnam.

(d) Ganga (Ganges), Bangladesh.

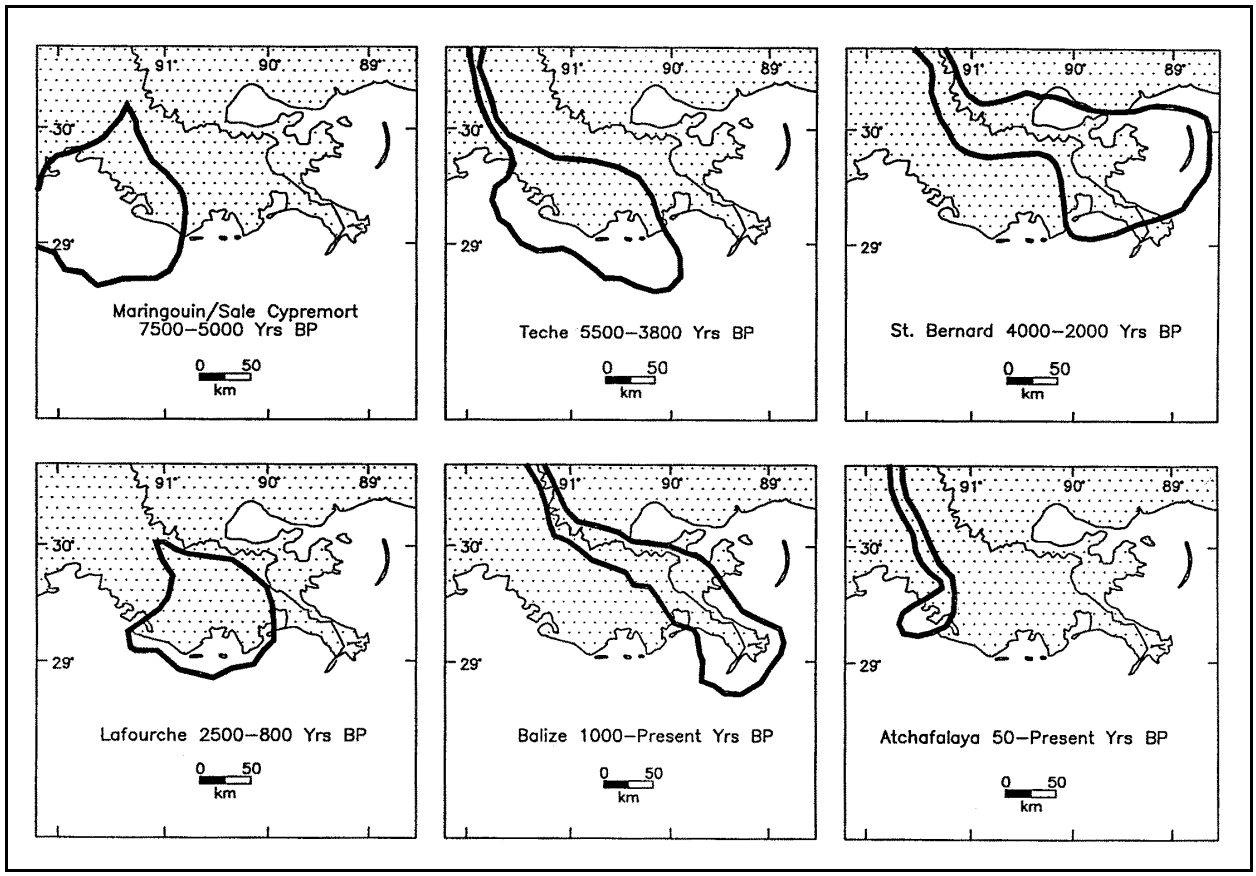

Figure IV-3-17. Shifting sites of deltaic sedimentation of the Mississippi River (from Coleman (1988))

These populations are very vulnerable to delta land loss caused by rising sea level and by changes in sediment supply due to natural movements of river channels or by upland man-made water control projects.

(3) Inhabitants of deltas are also in danger of short-term changes in sea level caused by storms. Tropical storms can be devastating: the Bay of Bengal cyclone of November 12, 1970, drowned over 200,000 persons in what is now Bangladesh (Carter 1988). Hopefully, public education, improving communications, better roads, and early warning systems will be able to prevent another disaster of this magnitude. Coastal management in western Europe, the United States, and Japan is oriented towards the orderly evacuation of populations in low-lying areas and has greatly reduced storm-related deaths. In contrast to the Bay of Bengal disaster, Hurricane Camille (August 17-20, 1969), caused only 236 deaths in Louisiana, Mississippi, Alabama, and Florida.

IV-3-4. Coastal Inlets

a. Introduction.

(1) Coastal inlets play an important role in nearshore processes around the world. *Inlets* are the openings in coastal barriers through which water, sediments, nutrients, planktonic organisms, and pollutants are exchanged between the open sea and the protected embayments behind the barriers. In the United States, the classical image of an inlet is of an opening in one of the Atlantic or Gulf of Mexico barrier islands, but inlets are certainly not restricted to barrier environments or to shores with tides. On the West Coast and in the Great

Lakes, many river mouths are considered to be inlets, while in the Gulf of Mexico, the wide openings between the barriers, locally known as passes, are also inlets. Inlets can be cut through unconsolidated shoals or emergent barriers as well as through clay, rock, or organic reefs (Price 1968). There is no simple, restrictive definition of inlet; based on the geologic literature and on regional terminology, almost any opening in the coast, ranging from a few meters to several kilometers wide, can be called an inlet. Inlets are important economically to many coastal nations because harbors are often located in the back bays, requiring that the inlets be maintained for commercial navigation. At many inlets, the greatest maintenance cost is incurred by repetitive dredging of the navigation channel. Because inlets are hydrodynamically very complex, predictions of shoaling and sedimentation have often been unsatisfactory. A better understanding of inlet sedimentation patterns and their relationship to tidal and other hydraulic processes can hopefully contribute to better management and engineering design.

(2) Tidal inlets are analogous to river mouths in that sediment transport and deposition patterns in both cases reflect the interaction of outflow inertia and associated turbulence, bottom friction, buoyancy caused by density stratification, and the energy regime of the receiving body of water (Wright and Sonu 1975). However, two major differences usually distinguish lagoonal inlets from river mouths, sometimes known as fluvial or riverine inlets (Oertel 1982).

(a) Lagoonal tidal inlets experience diurnal or semidiurnal flow reversals.

(b) Lagoonal inlets have two opposite-facing mouths, one seaward and the other lagoonward. The sedimentary structures which form at the two openings differ because of differing energy, water density, and geometric factors.

(3) The term *lagoon* refers to the coastal pond or embayment that is connected to the open sea by a tidal inlet. The *throat* of the inlet is the zone of smallest cross section, which, accordingly, has the highest flow velocities. The *gorge* is the deepest part of an inlet and may extend seaward and landward of the throat (Oertel 1988). *Shoal* and *delta* are often used interchangeably to describe the ebb-tidal sand body located at the seaward mouth of an inlet.

b. Technical literature. Pioneering research on the stability of inlets was performed by Francis Escoffier (1940, 1977). O'Brien (1931, 1976) derived general empirical relationships between tidal inlet dimension and tidal prism. Keulegan (1967) developed algorithms to relate tidal prism to inlet cross section. Bruun (1966) examined inlets and littoral drift, and Bruun and Gerritsen (1959, 1961) studied bypassing and the stability of inlets. Hubbard, Oertel, and Nummedal (1979) described the influence of waves and tidal currents on tidal inlets in the Carolinas and Georgia. Hundreds of other works are referenced in the USACE *General Investigation of Tidal Inlets* (GITI) reports (Barwis 1976), in special volumes like *Hydrodynamics and Sediment Dynamics of Tidal Inlets* (Aubrey and Weishar 1988), in textbooks on coastal environments (Carter 1988; Cronin 1975; Komar 1998), and in review papers (Boothroyd 1985; FitzGerald 1988). Older papers on engineering aspects of inlets are cited in Castañer (1971). There are also numerous foreign works on tidal inlets: Carter (1988) cites references from the British Isles; Sha (1990) from the Netherlands; Nummedal and Penland (1981) and FitzGerald, Penland, and Nummedal (1984) from the North Sea coast of Germany; and Hume and Herdendorf (1988, 1992) from New Zealand. More references are listed in Parts II-6 and V-6.

c. Classification of inlets and geographic distribution.

(1) Tidal inlets are found around the world in a broad range of sizes and shapes. Because of their diversity, it has been difficult to develop a suitable classification scheme. One approach has been to use an energy-based criteria, in which inlets are ranked according to the wave energy and tidal range of the environment in which they are located (Figure IV-1-10).

(2) Regional geological setting can be a limiting factor restricting barrier and, in turn, inlet development. Most inlets are on trailing-edge coasts with wide coastal plains and shallow continental shelves (e.g., the Atlantic and Gulf of Mexico shores of the United States). High relief, leading-edge coastlines have little room for sediment to accumulate either above or below sea level. Sediment tends to collect in pockets between headlands, few lagoons are formed, and inlets are usually restricted to river mouths. The Pacific coast of North America, in addition to being steep, is subject to high wave energy and has far fewer inlets than the Atlantic.

(3) Underlying geology may also control inlet location and stability. Price and Parker (1979) reported that certain areas along the Texas coast were always characterized by inlets, although the passes tended to migrate back and forth along a limited stretch of the shore. The positions of these permanent inlets were tectonically controlled, but the openings were maintained by tidal harmonics and hydraulics. If storm inlets across barriers were not located at the established stable pass areas, the inlets usually closed quickly. Some inlets in New England are anchored by bedrock outcrops and therefore cannot move freely (for example, the Essex River mouth, Figure IV-3-11).

d. Hydrodynamic processes in inlets. See Part II-6.

e. Geomorphology of tidal inlets. Tidal inlets are characterized by large sand bodies that are deposited and shaped by tidal currents and waves. The *ebb-tide shoal* (or delta) is a sand mass that accumulates seaward of the mouth of the inlet. It is formed by ebb tidal currents and is modified by wave action. The *flood-tide shoal* is an accumulation of sand at the landward opening of an inlet that is mainly shaped by flood currents (Figure IV-3-18). Depending on the size and depth of the bay, a flood shoal may extend into open water or may merge into a complex of meandering tributary channels, point bars, and muddy estuarine sediments.

(1) Ebb-tidal deltas (shoals).

(a) A simplified morphological model of a natural (unjettied) ebb-tidal delta is shown in Figure IV-3-18. The delta is formed from a combination of sand eroded from the gorge of the inlet and sand supplied by longshore currents. This model includes several components:

- A main *ebb channel*, scoured by the ebb jets.
- *Linear* bars that flank the main channel, the result of wave and tidal current interaction.
- A *terminal lobe*, located at the seaward (distal) end of the ebb channel. This is the zone where the ebb jet velocity drops, resulting in sediment deposition.
- *Swash platforms*, which are sand sheets located between the main ebb channel and the adjacent barrier islands.
- *Swash bars* that form and migrate across the swash platforms because of currents (the swash) generated by breaking waves.
- *Marginal flood channels*, which often flank both updrift and downdrift barriers.

Inlets with jetties often display these components, although the marginal flood channels are usually missing.

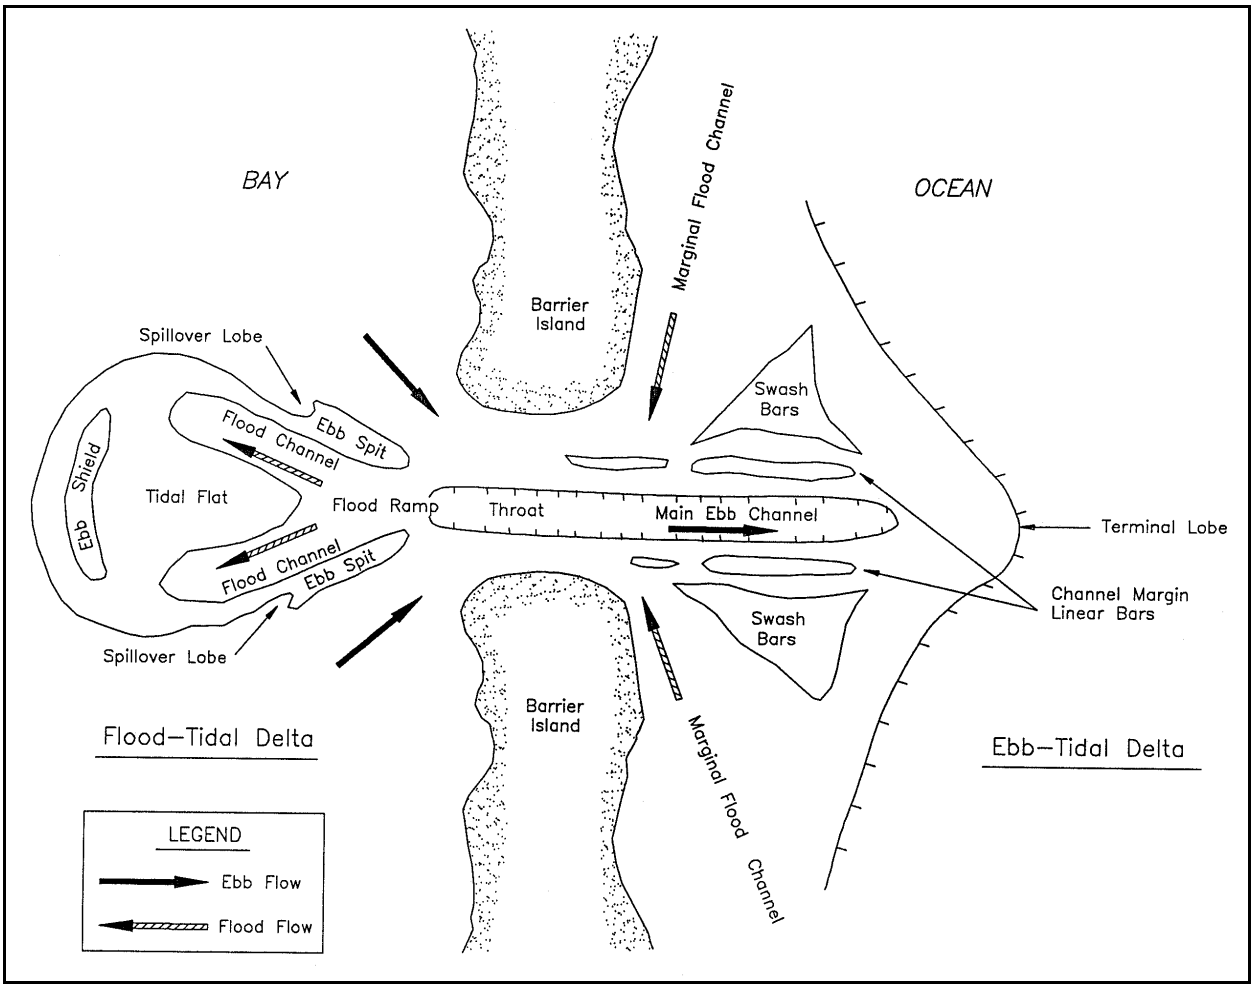

Figure IV-3-18. Definition diagram of a tidal inlet with well-developed flood and ebb deltas (from Boothroyd (1985) and other sources)

(b) For the Georgia coast, Oertel (1988) described simple models of ebb-delta shape and orientation which depended on the balance of currents (Figure IV-3-19). With modifications, these models could apply to most inlets. When longshore currents were approximately balanced and flood currents exceeded ebb, a squat, symmetrical delta developed (Figure IV-3-19a) (example: Panama City, Florida). If the prevailing longshore currents exceeded the other components, the delta developed a distinct northerly or southerly orientation (Figures IV-3-19b and 19c). Note that some of the Georgia ebb deltas change their orientation seasonally, trending north for part of the year and south for the rest. Finally, when inlet currents exceeded the forces of longshore currents, the delta was narrower and extended further out to sea (Figure IV-3-19d) (example: Brunswick, Georgia).

(c) Based on studies of the German and Georgia bights, Nummedal and Fischer (1978) concluded that three factors were critical in determining the geometry of the inlet entrance and the associated sand shoals:

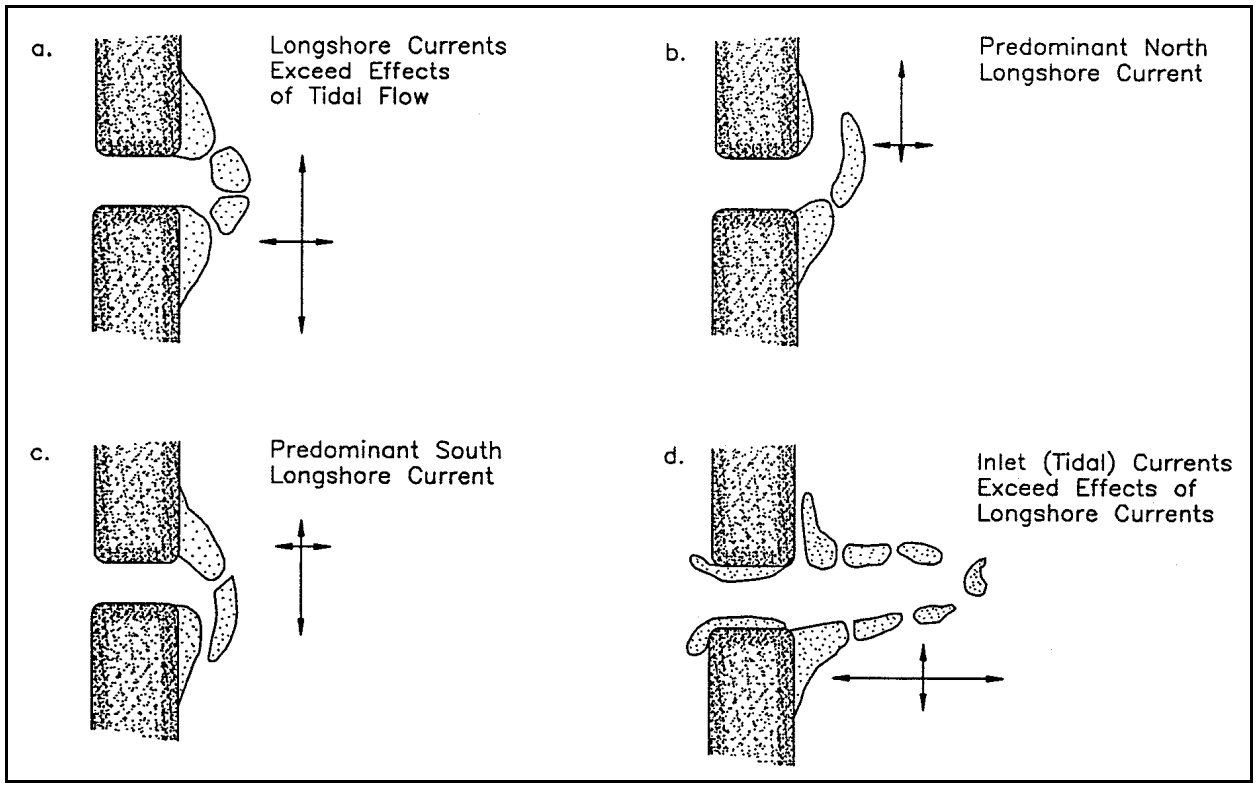

Figure IV-3-19. Four different shapes of ebb-tidal deltas, modified by the relative effects of longshore versus tidal currents (from Oertel (1988))

- Tide range.
- Nearshore wave energy.
- Bathymetry of the back-barrier bay.

For the German and Georgia bights, the latter factor controls velocity asymmetry through the inlet gorge, resulting in greater seaward-directed sediment transport through the inlet than landward transport. This factor has aided the development of large ebb shoals along these coasts, even though the German coast is subject to high wave energy. Back bay area and geometry are likely crucial factors that need to be incorporated in a comprehensive inlet classification scheme.

(d) Net sediment movement. At Price Inlet, South Carolina (FitzGerald and Nummedal 1983) and North Inlet, South Carolina (Nummedal and Humphries 1978), because of peak ebb currents, the resulting seaward-directed sediment transport far exceeded the sediment moved landward during flood. However, ebb velocity dominance does not necessarily mean that net sediment movement is also seaward. At Sebastian Inlet, on Florida's east coast, Stauble et al. (1988) found that net sediment movement was landward although the tidal hydraulics displayed higher ebb currents. The authors concluded that sediment carried into the inlet with the flood tide was deposited on the large, and growing, flood shoal. During ebb tide, current velocities over the flood shoal were too low to remobilize as much sediment as had been deposited on the shoal by the flood tide. The threshold for sediment transport was not reached until the flow was in the relatively narrow throat. In this case, the flood shoal had become a sink for sediment carried into the inlet. Stauble et al. (1988) hypothesized that this pattern of net landward sediment movement, despite ebb hydraulic dominance, may occur at other inlets in microtidal shores that open into large lagoons.

(e) The ebb-tidal deltas along mixed-energy coasts (e.g., East and West Friesian Islands of Germany, South Carolina, Georgia, Virginia, and Massachusetts) are huge reservoirs of sand. FitzGerald (1988) states that the amount of sand in these deltas is comparable in volume to that of the adjacent barrier islands. Therefore, on mixed-energy coasts, minor changes in volume of an ebb delta can drastically affect the supply of sand to the adjacent beaches. In comparison, on wave-dominated barrier coasts (e.g., Maryland, Outer Banks of North Carolina, northern New Jersey, Egypt's Nile Delta), ebb-tidal deltas are more rare and therefore represent a much smaller percentage of the overall coastal sand budget. As a result, volumetric changes in the ebb deltas have primarily local effects along the nearby beaches.

(f) Using data from tidal inlets throughout the United States, Walton and Adams (1976) showed that there is a direct correspondence between an inlet's tidal prism and the size of the ebb-tidal delta, with some variability caused by changes in wave energy. This research underscores how important it is that coastal managers thoroughly evaluate whether proposed structures might change the tidal prism, thereby changing the volume of the ebb-tide shoal and, in turn, affecting the sediment budget of nearby beaches.

(g) Ocean City, Maryland, is offered as an example of the effect of inlet formation on the adjacent coastline: the Ocean City Inlet was formed when Assateague Island was breached by the hurricane of 23 August 1933. The ebb-tide shoal has grown steadily since 1933 and now contains more than 6×10^6 m^3 of sand, located a mean distance of 1,200 m offshore. Since 1933, the growth of the ebb delta combined with trapping of sand updrift of the north jetty have starved the downdrift (southern) beaches, causing the shoreline along the northern few kilometers of Assateague Island to retreat at a rate of 11 m/year (data cited in FitzGerald (1988)) (Figures IV-3-20 and IV-3-21).

(h) In contrast to Ocean City, the decrease in inlet tidal prisms along the East Friesian Islands has been beneficial to the barrier coast. Between 1650 and 1960, the area of the bays behind the island chain decreased by 80 percent, mostly due to reclamation of tidal flats and marshlands (FitzGerald, Penland, and Nummedal 1984). The reduction in area of the bays reduced tidal prisms, which led to smaller inlets, smaller ebb-tidal shoals, and longer barrier islands. Because of the reduced ebb discharge, less sediment was transported seaward. Waves moved ebb-tidal sands onshore, increasing the sediment supply to the barrier beaches.

(i) In many respects, ebb-tide deltas found at tidal inlets are similar to deltas formed at river mouths. The comparison is particularly applicable at rivers where the flow temporarily reverses during the flood stage of the tide. The main difference between the two settings is that river deltas grow over time, fed by fluvially supplied sediment. In contrast, at many tidal inlets, only limited sediment is supplied from the back bay, and the ebb deltas are largely composed of sand provided by longshore drift or reworked from the adjacent beaches. Under some circumstances, inlets and river mouths are in effect the same coastal form. During times of low river flow, the mouth assumes the characteristics of a tidal inlet with reversing tidal currents dominating sedimentation. During high river discharge, currents are unidirectional and fluvial sediment is deposited seaward of the mouth, where it can help feed the growth of a delta. Over time, a tidal inlet that connects a pond to the sea can be converted to a river mouth. This occurs when the back bay fills with fluvial sediment and organic matter. Eventually, rivers that formerly drained into the lagoon flow through channels to the inlet and discharge directly into the sea (for example, see the photograph of the Essex River Delta, Figure IV-3-11).

Figure IV-3-20. Ocean City Inlet, Maryland, September 1933. Ocean City is on Fenwick Island in the top center of the image, the Atlantic Ocean is to the right, and Assateague Island is on the bottom. This photograph was taken only one month after a hurricane breached the barrier island. Note waves breaking at the edge of a small ebb shoal. (Photograph from Beach Erosion Board archives)

(2) Flood-tidal deltas (shoals).

(a) A model of a typical flood-tide shoal is shown in Figure IV-3-18. Flood shoals with many of these features have been described in meso- and micro-tidal environments around the world (Germany (Nummedal and Penland 1981); Florida's east coast (Stauble et al. 1988); Florida's Gulf of Mexico coast (Wright, Sonu, and Kielhorn 1972); and New England (Boothroyd 1985)). The major components are:

Figure IV-3-21. Ocean City Inlet, Maryland, 11 September 1995. Before the 1933 hurricane breached the barrier island, Assateague and Fenwick Islands were joined and had a straight shoreline. The former shoreline ran approximately along the seaward-most road (Photograph provided by USAE District, Baltimore)

- The *flood ramp*, which is a seaward-dipping sand surface dominated by flood-tidal currents. Sediment movement occurs in the form of sand waves (dunes), which migrate up the ramp.

- *Flood channels*, subtidal continuations of the flood ramp.

- The *ebb shield*, the high, landward margin of the tidal delta that helps divert ebb-tide currents around the shoal.

- *Ebb spits*, high areas mainly formed by ebb currents with some interaction with flood currents.

- *Spillover lobes*, linguoid, bar-like features formed by ebb-tidal current flow over low areas of the ebb shield.

(b) Although this model was originally derived from studies in mesotidal, mixed-energy conditions, it is also applicable to more wave-dominated, microtidal inlets (Boothroyd 1985). However, flood-tide shoals apparently are not formed in macrotidal shores.

(c) The high, central portion of a flood-tidal delta often extends some distance into an estuary or bay. This is the oldest portion of the delta and is usually vegetated by marsh plants. The marsh cap extends up to the elevation of the mean high water. The marsh expands aerially by growing out over the adjacent tidal flat. The highest, marsh-covered part of a flood shoal, or sometimes the entire shoal, is often identified on navigation charts as a "middle ground."

(3) Bed forms.

(a) Inlets contain a broad range of bed forms, from ripples due to oscillatory waves to dunes and antidunes caused by tidal currents. Water mass stratification can influence inlet flow and, therefore, bed form orientation. When a lagoon contains brackish water, salt wedge dynamics can occur, where the incoming flood flows under less dense bay water. Mixing between the two waters occurs along a horizontal density interface. During ebb tide, a buoyant planar jet forms at the seaward opening of the inlet similar to the effluent from rivers.

(b) Wright, Sonu, and Kielhorn (1972) described how density stratification affected flow at the Gulf of Mexico and Choctawhatchee Bay openings of East Pass, Florida. During flood tide, drogues and dye showed that the incoming salty Gulf of Mexico water met the brackish bay water at a sharp density front and then dove underneath (Figure IV-3-22). The drogues indicated that the sea water intruded at least 100 m beyond the front into Choctawhatchee Bay. This was the reason that bed forms within the channels displayed a flood orientation over time. This flood orientation can be seen in aerial photographs (Figure IV-3-5).

f. Inlet stability and migration.[1]

(1) Background. Inlets migrate along the coast - or remain fixed in one location - because of complex interactions between tidal prism, wave energy, and sediment supply. Some researchers consider the littoral system to be the principal sediment source that influences the stability of inlets (Oertel 1988). Not all of the sediment in littoral transport is trapped at the mouths of inlets; at many locations, a large proportion may be bypassed by a variety of mechanisms. Inlet sediment bypassing is defined as "the transport of sand from the updrift side of the tidal inlet to the downdrift shoreline" (FitzGerald 1988). Bruun and Gerritsen (1959) described three mechanisms by which sand moves past tidal inlets:

- Wave-induced transport along the outer edge of the ebb delta (the terminal lobe).
- The transport of sand in channels by tidal currents.
- The migration of tidal channels and sandbars.

They noted that at many inlets, bypassing occurred through a combination of these mechanisms. As an extension of this earlier work, FitzGerald, Hubbard, and Nummedal (1978) proposed three models to explain inlet sediment bypassing along mixed-energy coasts. The models are illustrated in Figure IV-3-23 and are discussed below.

[1] Material in this section has been adapted from FitzGerald (1988).

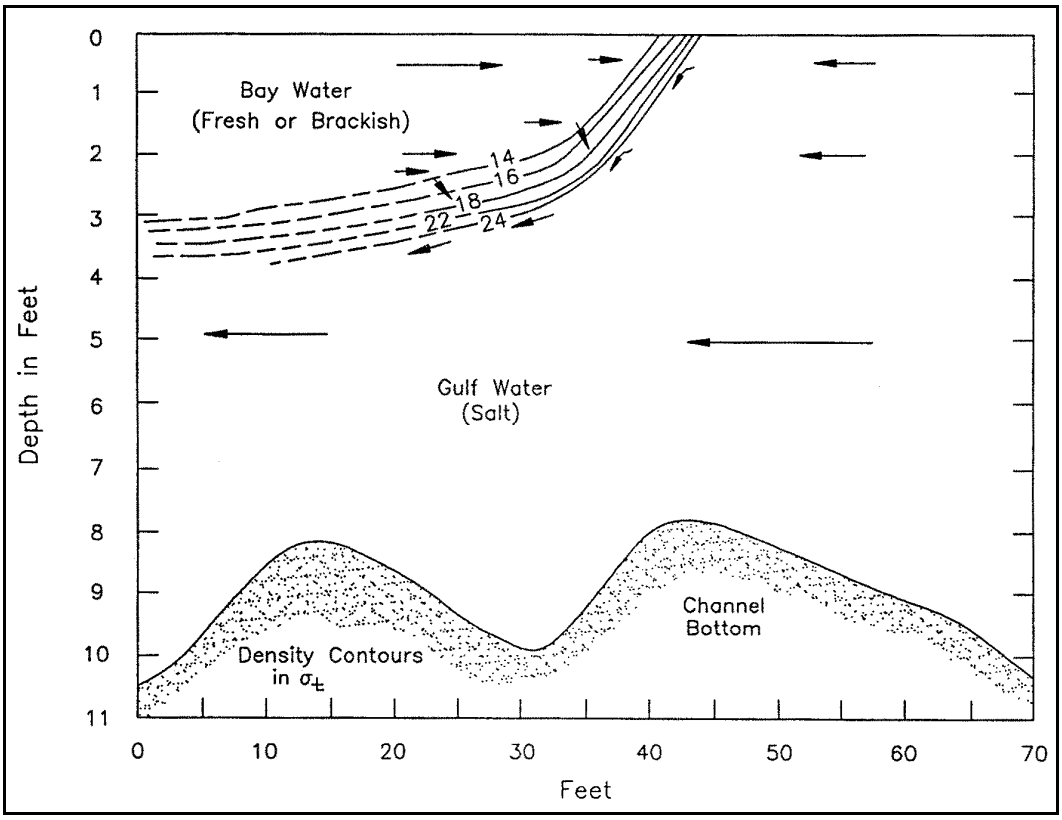

Figure IV-3-22. At the bay opening of East Pass, Florida, stratified flow occurs during flood tide in Choctawhatchee Bay as a wedge of sea water dives underneath the lower density bay water (after Wright, Sonu, and Kielhorn (1972)). A similar phenomenon often occurs in estuaries

(2) Inlet migration and spit breaching.

(a) The first model describes the tendency of many inlets to migrate downdrift and then abruptly shift their course by breaching a barrier spit. The migration occurs because sediment supplied by the longshore current causes the updrift barrier to grow (spit accretion). The growth occurs in the form of low, curved beach ridges, which weld to the end of the spit, often forming a bulbous-tipped spit known as a "drumstick." The ridges are often separated by low, marshy swales. As the inlet becomes narrower, the opposite (downdrift) shore erodes because tidal currents attempt to maintain an opening.

(b) In environments where the back bay is largely filled with marshes or where the barrier is close to the mainland, migration of the inlet causes an elongation of the tidal channel. Over time, the tidal flow between bay and ocean becomes more and more inefficient. Under these conditions, if a storm breaches the updrift barrier, the newly opened channel is a more direct and efficient pathway for tidal exchange. This new, shorter channel is likely to remain open while the older, longer route gradually closes. The breaching is most likely to occur across an area where the barrier has eroded or where some of the inner-ridge swales have remained low. The end result of spit accretion and breaching is the transfer of large quantities of sediment from one side of the inlet to the other. An example of this process is Kiawah River Inlet, South Carolina, whose migration between 1661 and 1978 was documented by FitzGerald, Hubbard, and Nummedal (1978). After a spit is breached and the old inlet closes, the former channel often becomes an elongated pond that parallels the coast.

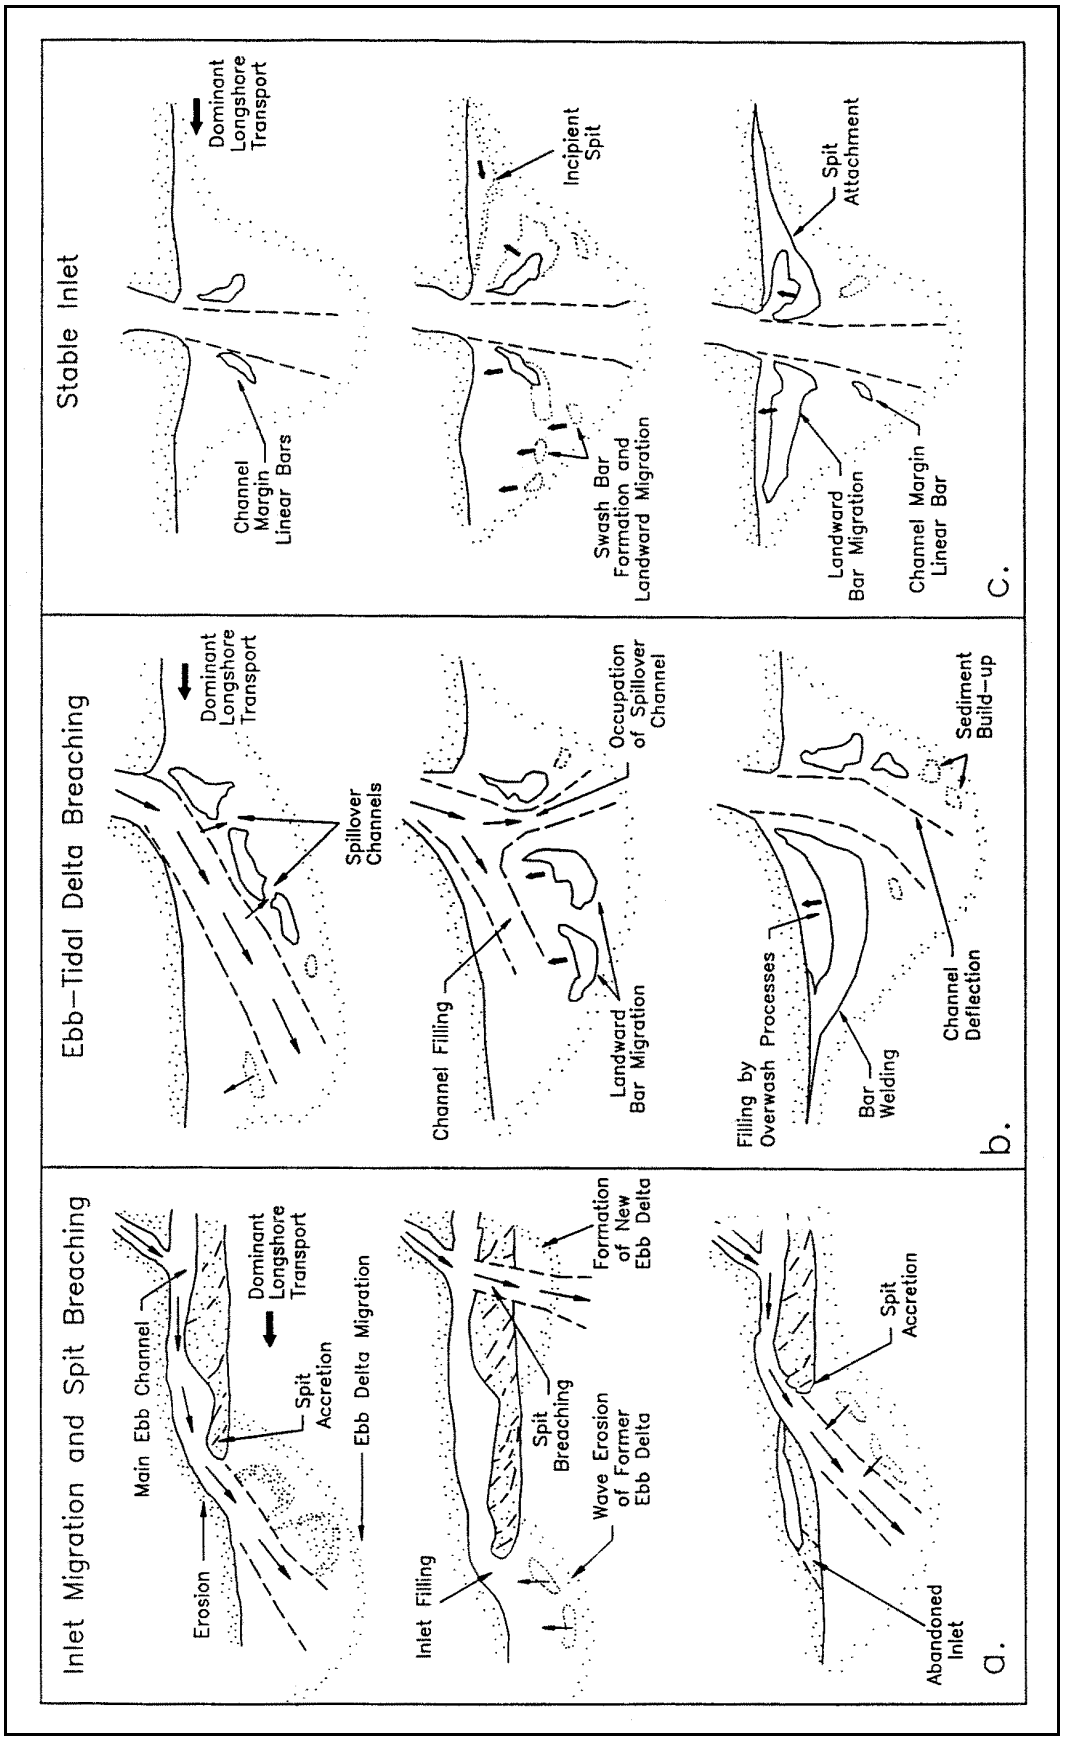

Figure IV-3-23. Three models of inlet behavior and sediment bypassing for mixed-energy coasts (from FitzGerald (1988))

(c) Several notes apply to the inlet migration model: First, not all inlets migrate. As discussed earlier, some inlets on microtidal shores are ephemeral, remaining open only a short time after a hurricane forces a breach through the barrier. If the normal tidal prism is small, these inlets are soon blocked by littoral drift. Short-lived inlets were documented along the Texas coast by Price and Parker (1979). The composition of the banks of the channel and the underlying geology are also critical factors. If an inlet abuts resistant sediment or bedrock, migration is restricted (for example, Hillsboro Inlet, on the Atlantic coast of Florida, is anchored by rock reefs). The gorge of deep inlets may be cut into resistant sediment, which also will restrict migration.

(d) Second, some inlets migrate updrift, against the direction of the predominate drift. Three mechanisms may account for updrift migration (Aubrey and Speer 1984):

- Attachment of swash bars to the inlet's downdrift shoreline.
- Breaching of the spit updrift of an inlet.
- Cutbank erosion of an inlet's updrift shoreline caused by back-bay tidal channels that approach the inlet throat obliquely.

(3) Ebb-tidal delta breaching.

(a) At some inlets, the position of the throat is stable, but the main ebb channel migrates over the ebb delta (Figure IV-3-23b). This pattern is sometimes seen at inlets that are naturally anchored by rock or have been stabilized by jetties. Sediment supplied by longshore drift accumulates on the updrift side of the ebb-tidal delta, which results in a deflection of the main ebb channel. The ebb channel continues to deflect until, in some cases, it flows parallel to the downdrift shore. This usually causes serious beach erosion. In this orientation, the channel is hydraulically inefficient, and the flow is likely to divert to a more direct seaward route through a spillover channel. Diversion of the flow can occur gradually over a period of months or can occur abruptly during a major storm. Eventually, most of the tidal exchange flows through the new channel, and the abandoned old channel fills with sand.

(b) Ebb delta breaching results in the bypassing of large amounts of sand because swash bars, which had formerly been updrift of the channel, become downdrift after the inlet occupies one of the spillover channels. Under the influence of waves, the swash bars migrate landward. The bars fill the abandoned channel and eventually weld to the downdrift beach.

(4) Stable inlet processes.

(a) These inlets have a stable throat position and a main ebb channel that does not migrate (Figure IV-3-23c). Sand bypassing occurs by means of large bar complexes that form on the ebb delta, migrate landward, and weld to the downdrift shoreline. The bar complexes are composed of swash bars that stack and merge as they migrate onshore. Swash bars are wave-built accumulations of sand that form on the ebb delta from sand that has been transported seaward in the main ebb channel. The swash bars move landward because of the dominance of landward flow across the swash platform. The reason for landward dominance of flow is that waves shoal and break over the terminal lobe (or bar) that forms along the seaward edge of the ebb delta. The bore from the breaking waves augments flood tidal currents but retards ebb currents.

(b) The amount of bypassing that actually occurs around a stable inlet depends upon the geometry of the ebb-tidal shoal, wave approach angle, and wave refraction around the shoal. Three sediment pathways can be identified:

- Some (or possibly much) of the longshore drift accumulates on the updrift side of the shoal in the form of a bar that projects out from the shore (Figure IV-3-23c). As the incipient spit grows, it merges with growing bar complexes near the ebb channel. Flood currents move some of the sand from the complexes into the ebb channel. Then, during ebb tide, currents flush the sand out of the channel onto the delta (both the updrift and downdrift sides), where it is available to feed the growth of new swash bars.

- Depending on the angle of wave approach, longshore currents flow around the ebb shoal from the updrift to the downdrift side. Some of the drift is able to move past the ebb channel, where it either continues moving along the coast or accumulates on the downdrift side of the ebb shoal. The sediment probably moves as large bed forms (Figure IV-3-4).

- Wave refraction around some ebb shoals causes a local reversal of longshore current direction along the downdrift shore. During this time, presumably, little sediment is able to escape the confines of the ebb-tidal shoal.

(5) Extension of bypassing models to other environments. The inlet migration models described above were originally based on moderate- to high-energy shores. However, research along the Florida Panhandle suggests that the models may be applicable to much lower energy environments than the original authors had anticipated. For example, between 1870 and 1990, the behavior of East Pass inlet, located in the low-wave-energy Florida Panhandle, followed all three models at various times (Figure IV-3-24; Morang (1992b)). It would be valuable to conduct inlet studies around the world to further refine the models and evaluate their applicability to different shores.

g. Inlet response to jetty construction and other engineering activities.

(1) Introduction. Typically, jetties are built to stabilize a migrating inlet, to protect a navigation channel from waves, or to reduce the amount of dredging required to maintain a specified channel depth. However, jetties can profoundly affect bypassing and other processes at inlets. Some of these effects can be predicted during the design phase of a project. Unfortunately, unanticipated geological conditions often arise, which lead to problems such as increased shoaling or changes in the tidal prism. Several classes of man-made activities affect inlets:

(a) Jetties stabilize inlets and prevent them from migrating.

(b) Jetties can block littoral drift.

(c) Walls or revetments can change the cross section of an inlet.

(d) Dredging can enlarge the cross section of a gorge.

(e) Dam construction and freshwater diversion reduce fluvial input.

(f) Weir sections (low portions of a jetty) allow sediment to pass into an inlet, where it can accumulate in a deposition basin and be bypassed.

(g) Landfilling and development in estuaries and bays can reduce tidal prism.

(2) Technical literature. Many reports have documented the effects of jetties on littoral sediment transport. Early works are cited in Barwis (1976). Dean (1988) discussed the response of modified Florida inlets,

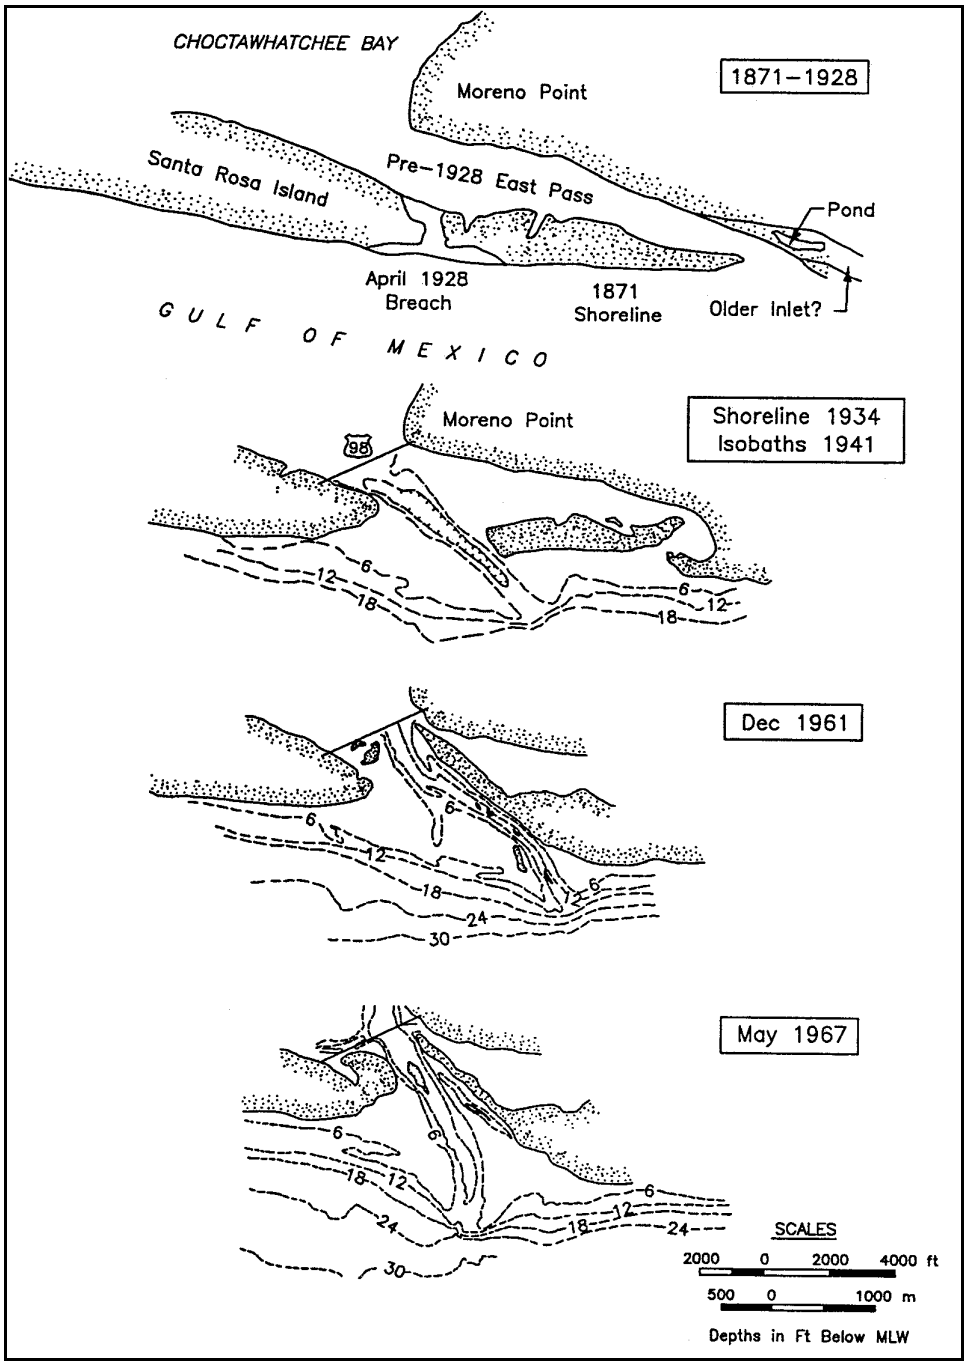

Figure IV-3-24. Spit breaching and inlet migration at East Pass, Florida (from Morang (1992a))

and many other case studies are reviewed in Aubrey and Weishar (1988). Examples of monitoring studies that assess the effects of jetties include:

(a) Shinnecock Inlet, Long Island, New York (Morang, 1999; Pratt and Stauble 2001; Williams, Morang, and Lillycrop 1998)

(b) Ocean City Inlet, Maryland (Bass et al. 1994).

(c) Little River Inlet, North and South Carolina (Chasten 1992, Chasten and Seabergh 1992).

(d) Murrells Inlet, South Carolina (Douglass 1987).

(e) Manasquan Inlet, New Jersey (Bruno, Yavary, and Herrington (1998).

(f) St. Marys Entrance, Florida and Georgia (Kraus, Gorman, and Pope 1994, 1995).

(g) East Pass, Florida (Morang 1992a).

(h) Port Mansfield Channel, Texas (Kieslich 1977).

(3) Weirs and other structures and their effects on sediment movement in and around inlets are discussed in Part V-6.

h. Case study of inlet formation and growth: Shinnecock Inlet, Long Island, New York.[1]

(1) Background and inlet breaching (1938).

(a) Shinnecock Inlet is located on the south shore of Long Island, 136 km east of New York Harbor. It is the easternmost of six inlets that cut the south shore barrier islands and allow boat passage between the Atlantic Ocean and the coastal bays. The present inlet was breached during the Great New England Hurricane of 21 September 1938. Inlets had periodically existed in this area before, but immediately before the 1938 hurricane, the barrier was intact and there was a paved road along the beach (Nersesian and Bocamazo 1992) (Figure IV-3-25).

(b) The first aerial photographs of the new inlet were taken by the U.S. Army Air Corps three days after the hurricane (Figure IV-3-26). The seas had calmed, but the large number of overwash deposits attest to the violence of the storm. All the open breaches in this area trended left of perpendicular to the shoreline trend. Drift was to the east (opposite to the normal prevailing direction) because spits had grown from west-to-east across the mouths of the new openings. Two months after the hurricane (29 November 1938) an oval ebb-tide delta had already formed in the Atlantic Ocean, and there was a small shoal in Shinnecock Bay, showing the initial development of a flood shoal (Figure IV-3-27).

(c) There are no eye-witness accounts of exactly how this inlet was cut. One possibility is that storm waves from the ocean cut across the barrier. The overwash fans to the left and right of the inlet support this option. The other possibility is that Shinnecock Bay elevated due to rainwater and runoff. This is supported by a water level of 2.2 (7.2 ft) above mlw estimated at the south end of the Shinnecock canal, across Shinnecock Bay from the barrier island (U.S. Army Corps of Engineers 1958)). At a low or narrow place in the barrier, a torrent of bay water might have burst through the dunes and run out to sea, scouring a channel that later widened and became the inlet shown in the photograph. This latter hypothesis seems most likely because, only two months after the storm, a prominent ebb shoal already existed, while there was only minimal deposition in Shinnecock Bay. The ebb shoal likely consisted of sand eroded from the barrier.

(2) Semi-stabilized inlet (1947). After 1938, the inlet migrated steadily to the west. In 1939-40, Suffolk County erected timber pile bulkhead and short groins on the west side of the channel to prevent westward migration (Nersesian and Bocamazo 1992). However, a 1947 photograph shows that the inlet had moved

[1] Condensed from Morang (1999).

Figure IV-3-25. Shinnecock Bay, Long Island, New York, 30 June 1938. Photograph taken before the Great New England Hurricane of 21 September cut the barrier island in several locations. The present Shinnecock Inlet was cut where a channel crosses from the bay to the road. The channel may be a remnant of an artificial cut that was dug by the Shinnecock and Peconic Canal Company in 1896. Shoal areas in the bay near the barrier attest to former inlets that had been open long enough to form flood shoals. North is to the top, the water body in the center of the image is Shinnecock Bay, and the Atlantic Ocean is on the bottom. The image is part of a mosaic prepared by the Beach Erosion Board

east, leaving the bulkhead behind a sand beach (Figure IV-3-28). A spit extended out to sea from the west shore, suggesting that longshore transport, at least temporarily, had been to the east (possibly a local reversal). Some small shoals existed in the mouth of the inlet, but sediment transport was largely directed into the bay after 1938. The ebb shoal was a flat oval that hugged the shore. The shoreline in this area trends about 65° (approx NE-SW). The 1947 channel extended out to sea at about 120°, more eastward than perpendicular to the shore. In the following years, the inlet rotated clockwise, until by 1951, the channel was pushing up against the bulkhead and the flood shoal deposition was occurring east of its earlier location.

(3) Stabilized inlet (1996). East and west jetties were built in 1952-54 by Suffolk County and the State of New York and rebuilt in 1992-93 by the Corps of Engineers. A photograph from 24 October 1996 (Figure IV-3-29) shows that the channel inlet was aligned north-south, about 40° clockwise from the orientation in 1947. The jetties were 240 m (800 ft) apart. The updrift beach had advanced almost to the tip of the east jetty. During the 1970's and 1980's, the bay shoreline east of the inlet eroded about 500 ft (150 m) due to scour from the east ebb channel. To the west, the shore has suffered chronic erosion, requiring frequent emergency repair by the highway department to prevent the road from being breached. The ebb shoal (only partially shown in this photograph) is an unsymmetric oval that attaches to the downdrift beach about 1,200 m west of the west jetty.

Figure IV-3-26. Shinnecock Inlet, Long Island, New York, 24 September 1938. Taken three days after Great New England Hurricane breached the barrier, this image shows the new Shinnecock Inlet and many overwash fans along the adjacent shore. Immediately after the storm, all the inlets along this stretch of the coast trended left of the shore-perpendicular. (Photograph mosaic from Beach Erosion Board archives)

(4) Ebb shoal growth. The ebb shoal at Shinnecock Inlet has continued to grow in volume since the inlet was formed. Figure IV-3-30 shows that in 1998, the shoal contained about 6,000,000 m^3 (8,000,000 yd^3) of sand. It appears that the shoal is still growing, but the latest three surveys were spaced only 1 year apart (1996, 1997, and 1998), so another survey will be needed in several years to verify this conclusion. However, present evidence indicates that the shoal is a sediment sink, although some of the littoral drift is probably bypassing.

IV-4-5. Morphodynamics and Shoreface Processes of Clastic Sediment Shores

a. Overview.

(1) Introduction. This section discusses morphodynamics - the interaction of physical processes and geomorphic response - of clastic sediment shores. The topic covers beach features larger than a meter (e.g., cusps and bars) on time scales of minutes to months. Details on grain-to-grain interactions, the initiation of sediment motion, and high frequency processes are not included. A principle guiding this section is that the overall shape of beaches and the morphology of the shoreface are largely a result of oscillatory (gravity) waves, although tide range, sediment supply, and overall geological setting impose limits. We introduce basic relationships and formulas, but the text is essentially descriptive. Waves are discussed in detail in Part II of the *Coastal Engineering Manual*, while sediment properties are covered in Part III-1.

(2) Literature. Beaches and sediment movement along the shore have been subjects of popular and scientific interest for over a century. A few of the many textbooks that cover these topics include Carter (1988), Davis (1985), Davis and Ethington (1976), Greenwood and Davis (1984), Komar (1998), and Zenkovich (1967). Small-amplitude (Airy) and higher-order wave mechanics are covered in EM 1110-2-1502; more detailed treatments are in Kinsman (1965), Horikawa (1988), and Le Méhauté (1976). Interpreting and applying wave and water level data are covered in EM 1110-2-1414.

Figure IV-3-27. Shinnecock Inlet, New York, 29 November 1938, photographed only 2 months after the barrier island was breached during the Great New England Hurricane of 21 September 1938. North is to the top of the image. The body of water to the top is Shinnecock Bay, and the Atlantic Ocean is on the bottom. The inlet already displays an oval ebb-tidal shoal. A small shoal in Shinnecock Bay indicated development of a flood shoal. Washover fans, remnants of the storm, can be seen on both sides of the inlet. (Photograph from Beach Erosion Board archives)

Figure IV-3-28. Shinnecock Inlet, New York, 1 April 1947. The inlet was much wider than in 1938, and a large flood shoal had accumulated. Some small shoals existed in the mouth of the inlet, but sediment transport had been largely directed into the bay since 1938. (Photograph from Beach Erosion Board archives)

(3) Significance of clastic coasts. It is important to examine and understand how clastic shores respond to changes in wave climate, sediment supply, and engineering activities for economic and management reasons:

(a) Many people throughout the world live on or near beaches. Beaches are popular recreation areas and of vital economic importance to many states (Houston 1995, 1996a, 1996b).

Figure IV-3-29. Shinnecock Inlet, New York, 24 October 1996. The inlet has been stabilized with stone jetties 800 ft apart. The beach east of the inlet has advanced to the end of the east jetty. To the west, the shore has suffered chronic erosion, requiring frequent emergency repair by the highway department to prevent the road from being breached. The ebb shoal (only partially shown in this photograph) is an unsymmetric oval that attaches to the downdrift beach about 1,200 m west of the west jetty (Photograph courtesy of USAED, New York)

(b) Beaches are critical buffer zones protecting wetlands and coastal plains from wave attack.

(c) Beaches are habitat or nesting ground for many animal species, some of which are endangered (e.g., turtles).

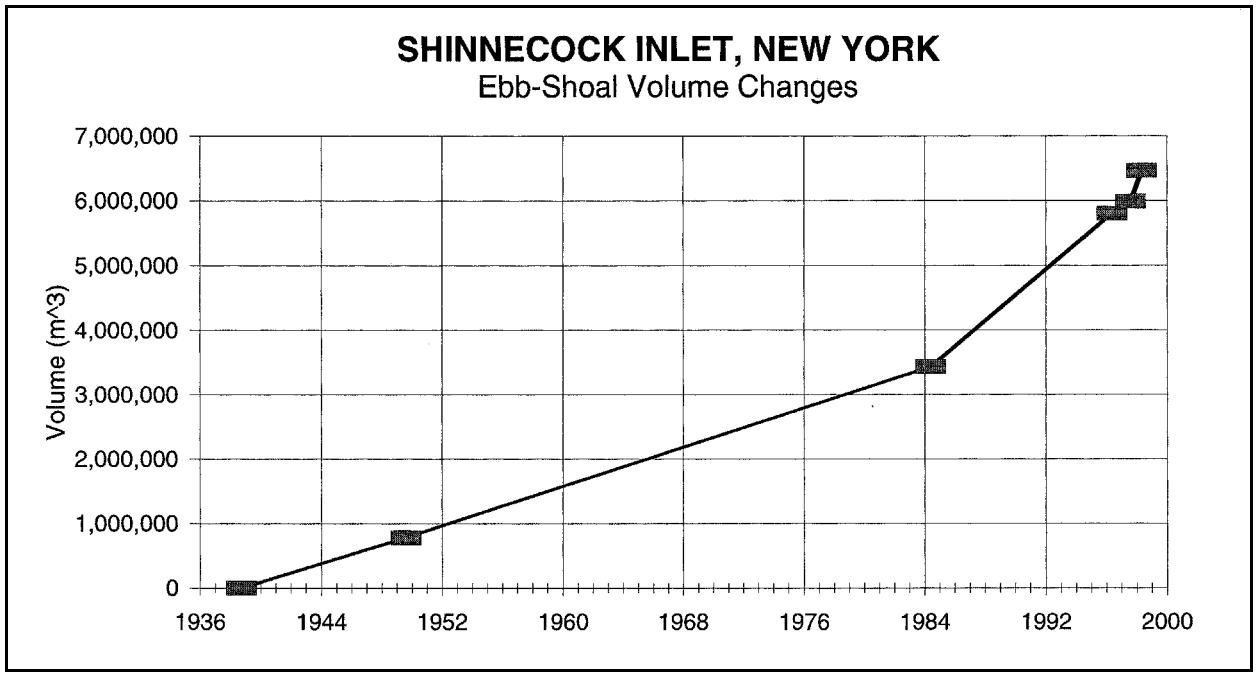

Figure IV-3-30. Ebb-shoal volume changes, Shinnecock Inlet, New York. Volumes were based on subtracting the 1933 U.S. Coast and Geodetic Survey data (pre-inlet) from more recent surveys: 1949, 1985, 1996, 1997, and 1998. The ebb shoal is still growing, indicating that it is a sediment trap, although some of the littoral drift probably bypasses. Hydrographic data courtesy of U.S. Army Engineer District, New York

(d) Much engineering effort and large amounts of funding are expended on planning and conducting beach renourishment.

(e) Sediment supply and, therefore, beach stability, are often adversely affected by the construction of navigation and shore-protection structures.

(f) Sand is a valuable and increasingly rare mineral resource in most of the coastal United States.

(4) Range of coastal environments. Around the world, coasts vary greatly in steepness, sediment composition, and morphology. The most dynamic shores may well be those composed of unconsolidated clastic sediment because they change their form and state rapidly. Clastic coasts are part of a geologic continuum that extends from consolidated (rocky) to loose clastic to cohesive material (Figure IV-3-31). Waves are the primary mechanisms that shape the morphology and move sediment, but geological setting imposes overall constraints by controlling sediment supply and underlying rock or sediment type. For example, waves have little effect on rocky cliffs; erosion does occur over years, but the response time is so long that many rocky shores can be treated as being geologically controlled. At the other end of the continuum, cohesive shores respond very differently to wave action because of the electrochemical nature of the sediment (see Part III-5).

b. Tide range and overall beach morphology.

Most studies of beach morphology and processes have concentrated on microtidal (< 1 m) or low-mesotidal coasts (1-2 m). To date, many details concerning the processes that shape high-meso- and macrotidal beaches (tide range > 2 m) are still unknown. Based on a review of the literature, Short (1991) concluded that

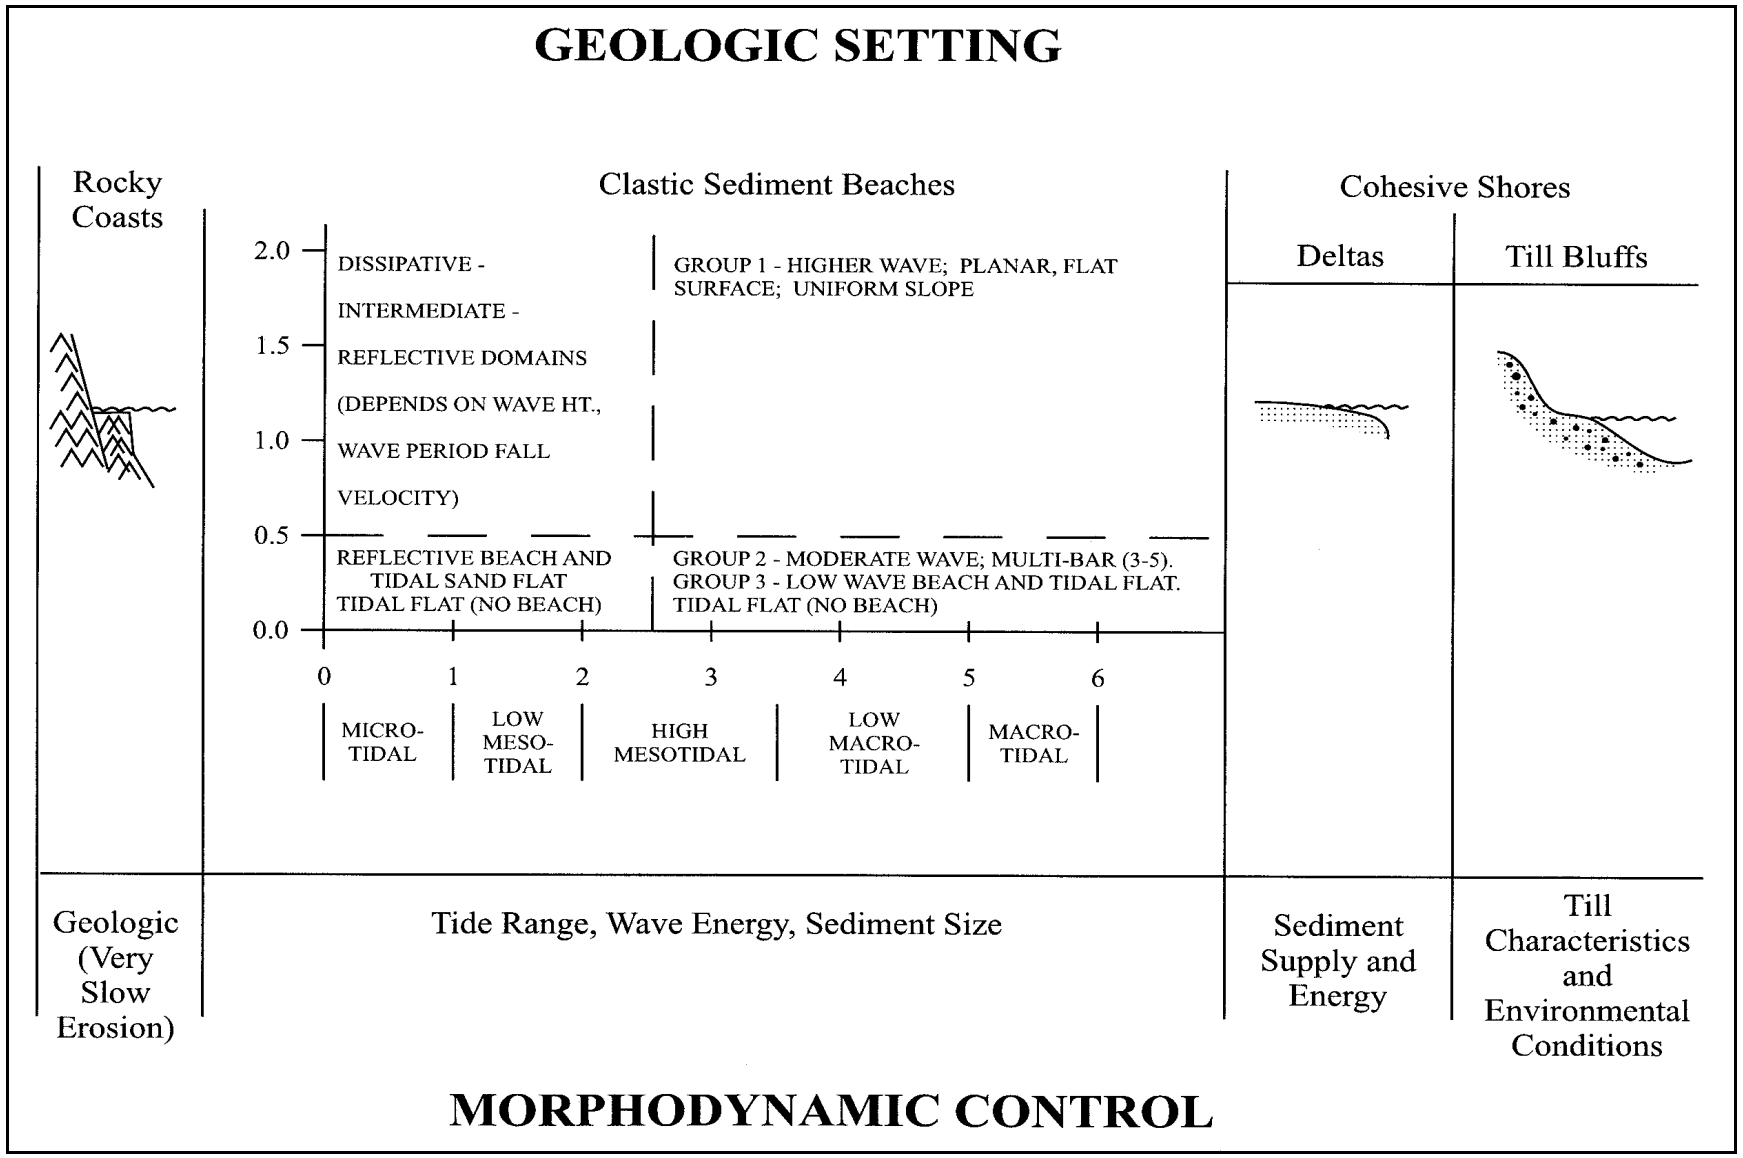

Figure IV-3-31. Summary of factors controlling morphodynamics along a range of coastal environments. Clastic shore processes are detailed in Figure IV-3-26 and discussed in the text

wave-dominated beaches where tide range is greater than about 2 m behave differently than their lower-tide counterparts. Short underscored that high-tide beaches are also molded by wave and sediment interactions. The difference is the increasing impact of tidal range on wave dynamics, shoreface morphodynamics, and shoreline mobility. Short developed a tentative grouping of various beach types (Figure IV-3-32). Discussion of the various shoreface morphologies follows.

c. High tidal range (> 2 m) beach morphodynamics.

(1) Review. Based on a review of research on macrotidal beaches, Short (1991) summarized several points regarding their morphology:

(a) They are widespread globally, occurring in both sea and swell environments.

(b) Incident waves dominate the intertidal zone.

(c) Low-frequency (infragravity) standing waves may be present and may be responsible for multiple bars.

(d) The intertidal zone can be segregated into a coarser, steeper, wave-dominated high tide zone, an intermediate zone of finer sediment and decreasing gradient, and a low-gradient, low-tide zone. The highest zone is dominated by breaking waves, the lower two by shoaling waves.

(e) The cellular rip circulation and rhythmic topography that are so characteristic of microtidal beaches have not been reported for beaches with tide range greater than 3 m.

(2) Macrotidal beach groups. Using published studies and field data from Australia, Short (1991) divided macrotidal beaches into three groups based on gradient, topography, and relative sea-swell energy:

(a) GROUP 1 - High wave, planar, uniform slope. Beaches exposed to persistently high waves ($H_b > 0.5$ m) display a planar, flat, uniform surface. Shorefaces are steep, ranging from 1 to 3 deg, and have a flat surface without ripples, bed forms, or bars. The upper high tide beach is often relatively steep and cuspid and contains the coarsest sediment of the system. On both sand and gravel beaches, the high tide, upper foreshore zone is exposed to the highest waves. Plunging and surging breakers produce asymmetric swash flows, which maintain the coarse sediment and steep gradient. Further seaward, wave shoaling becomes a more important factor than wave breaking because waves are attenuated at low tide (due to shallower water and greater friction). Tidal currents also increase in dominance seaward. Wright (1981) found that tidal currents left no bed forms visible at low tide but were an important factor in longshore sediment transport.

(b) GROUP 2 - Moderate wave, multi-bar. Multi-bar, macrotidal beaches are formed in fetch-limited environments with high tide range and abundant fine sand (King 1972b). The common characteristic of these beaches is a relatively uniform 0.5- to 0.6-deg intertidal gradient and the occurrence of multiple bars (two to five sets) between msl and mlw (Short 1991). Bar amplitude is usually below 1 m and spacing ranges from 50 to 150 m, with spacing increasing offshore. Field observations indicate that the bars are formed by a wave mechanism, particularly during low wave, post-storm conditions. The bars appear to build up onsite rather than migrate into position. These multi-bar beaches probably cause dissipative conditions during most wave regimes, possibly resulting in the development of infragravity standing waves. This would account for the spacing of the bars; however, this hypothesis has not been tested with rigorous field measurements (Short 1991).

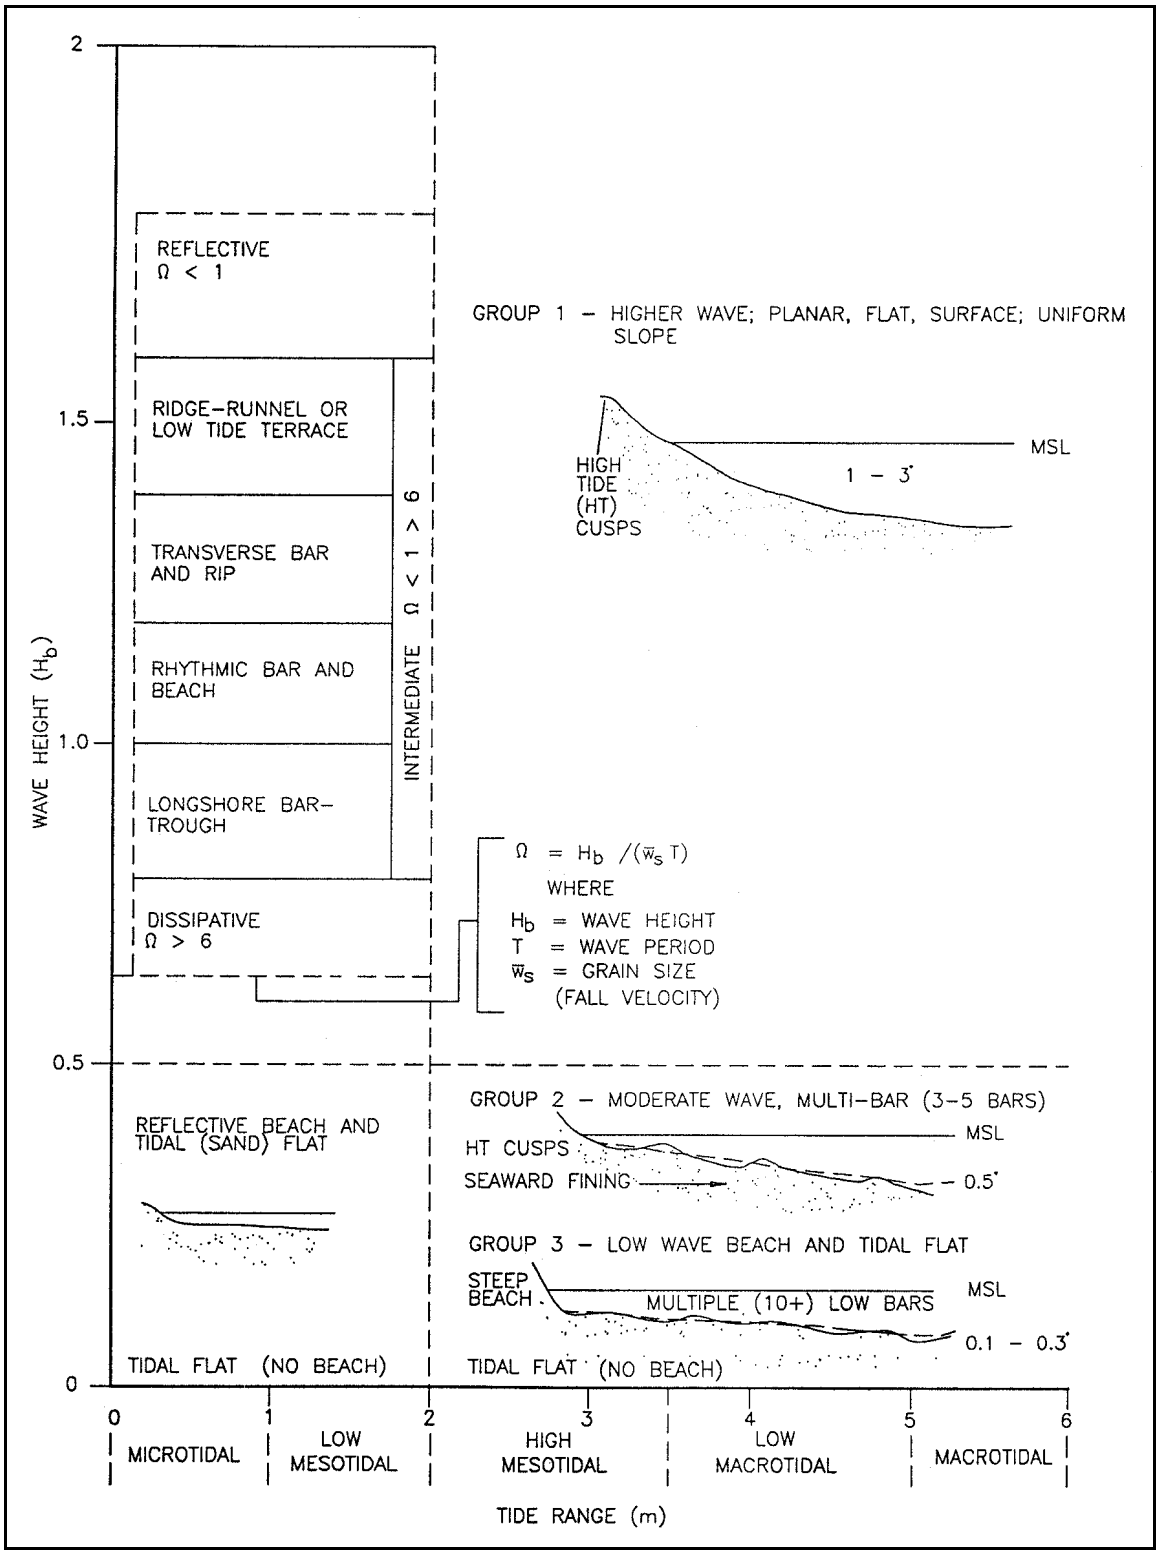

Figure IV-3-32. Micro- to macrotidal beach and tidal flat systems (adapted from Short (1991)). Dimensionless parameter Ω discussed in the text

(c) GROUP 3 - Low wave beach and tidal flat. As wave energy decreases, macrotidal beaches eventually grade into tide-dominated tidal flats. Between the two regimes, there is a transition stage that contains elements of both morphologies. These beach-tidal flat systems are usually characterized by a steep, coarse-grained reflective beach (no cusps usually present) which grades abruptly at some depth below msl into a fine-grained, very low gradient (0.1 deg), rippled tidal flat (Figure IV-3-33). The tidal flat may be uniform or may contain low, multiple bars. Beach-tidal flat shores are found in low-energy environments that are only infrequently exposed to wave attack, but the energy must be sufficient to produce the morphologic zonation.

Figure IV-3-33. View west from Tarskavaig, Isle of Skye, Scotland, August 1983. Photograph taken at low tide. At this macrotidal beach, facing the Sea of the Hebrides, the upper shoreface consists of coarse cobble, while the low foreshore is low gradient and almost featureless

(3) Spatial and temporal variations. Beaches on macro-tidal coasts vary morphologically as important environmental parameters change. Short (1991) cites one setting where the shoreface varies from high-energy, uniform steep beach (Group 1) to beach-tidal flat (Group 3) within 2 km. He suggests that the changes in morphology are due to variations in wave energy: as energy changes alongshore, important thresholds are crossed which result in different ratios of wave versus tide domination. In addition, there may be temporal variations throughout the lunar cycle. As tide range varies during the month, the transitions where one morphologic group merges into another may migrate cyclically along the coast. More field studies are needed to document this phenomenon.

(4) Summary. On tideless beaches, morphology is determined by waves and sediment character. On microtidal beaches, waves still dominate the morphodynamics, but tide exerts a greater influence. As tide range increases beyond 2-3 m, the shape of beaches becomes a function of waves coupled with tides. On the higher tide coasts, as water depth changes rapidly throughout the day, the shoreline and zone of wave breaking move horizontally across the foreshore and tidal currents move considerable sediment.

d. Morphodynamics of micro- and low-mesotidal coasts.

(1) Morphodynamic variability of microtidal beaches and surf zones. Based on field experiments in Australia, Wright and Short (1984) have presented a model of shoreface morphology as a function of wave parameters and sediment grain size. This model is a subset of Figure IV-3-31 that occupies the zone where tide range is between 0 and 2 m and H_b (breaker height) is greater than about 0.5 m.

(a) Wright and Short (1984) determined that the morphodynamic state of sandy beaches could be classified on the basis of assemblages of depositional forms and the signatures of associated hydrodynamic processes. They identified two end members of the morphodynamic continuum:

- Fully dissipative.
- Highly reflective.

Between the extremes were four intermediate states, each of which possessed both reflective and dissipative elements (Figure IV-3-32).

(b) The most apparent differences between the beach states are morphological, but distinct process signatures, representing the relative velocities of different modes of fluid motion, accompany the characteristic morphology. As stated by Wright and Short (1984):

> Although wind-generated waves are the main source of the energy which drives beach changes, the complex processes, which operate in natural surf zones and involve various combinations of dissipation and reflection, can lead to the transfer of incident wave energy to other modes of fluid motion, some of which may become dominant over the waves themselves.

(c) Wright and Short grouped fluid motion into four categories (Table IV-3-1):

- Oscillatory flows.
- Oscillatory or quasi-oscillatory flows.
- Net circulations.
- Non-wave-generated currents.

Table IV-3-1
Modes of Fluid Motion Affecting Clastic Shorelines

Modes	Notes	Frequencies of flows	Examples
Oscillatory	Corresponds directly to incident waves	Frequency band of deep-water incident waves	Sediment-agitating oscillations
Oscillatory or quasi-oscillatory	Shore-normal oriented standing and edge waves	Wide range of frequencies	Trapped edge waves, "leaky" mode standing waves
Net circulations	Generated by wave energy dissipation	Minutes to days	Longshore currents, rip currents, rip feeder currents
Non-wave-generated currents	Generated by tides and wind shear	Minutes to hours (?)	Tidal currents

(Based on Wright and Short (1984))

(d) From repeated observations and surveys of beaches, Wright and Short (1984) concluded that beach state is clearly a function of breaker height and period and sediment size. Over time, a given beach tends to exhibit a *modal* or most frequent recurrent state, which depends on environmental conditions. Variations in shoreline position and profile are associated with temporal variations of beach state around the modal state. Wright and Short found that a dimensionless parameter Ω could be used to describe the modal state of the beach:

$$\Omega = \frac{H_b}{\overline{w_s} T} \tag{IV-3-3}$$

where H_b is breaker height, $\overline{w_s}$ is sediment fall velocity, and T is wave period. For the following values of Ω (Figure IV-3-32):

- Ω about 1: defines the reflective/intermediate threshold
- $1 < \Omega < 6$: intermediate beaches
- $\Omega \cong 6$: marks the threshold between intermediate and dissipative conditions

(e) Beaches take time to adjust their state, and a change of Ω across a threshold boundary does not immediately result in a transformation from reflective to intermediate or from intermediate to dissipative. On the Pacific coasts of Australia and the United States, storms can cause a shift of beach state from reflective or intermediate to dissipative in a few days because the energy is high. The return to reflective conditions under low energy may require weeks or months or longer (the sequence of beach recovery is illustrated in stages *a* through *f* in Figure IV-3-34). In environments where the dominant variation in wave energy occurs on an annual cycle (e.g., high storm waves in winter and low swell in summer), the full range from a dissipative winter profile to a reflective summer profile may be expected.

(f) Wright and Short (1984) concluded that large temporal variations in Ω are accompanied by large changes in state. However, when the variations in Ω take place in the domains of $\Omega < 1$ or $\Omega > 6$, no corresponding changes in *state* result. Intermediate beaches, where Ω is between 1 and 6, are spatially and temporally the most dynamic. They can undergo rapid changes as wave height fluctuates, causing reversals in onshore/offshore and alongshore sediment transport.

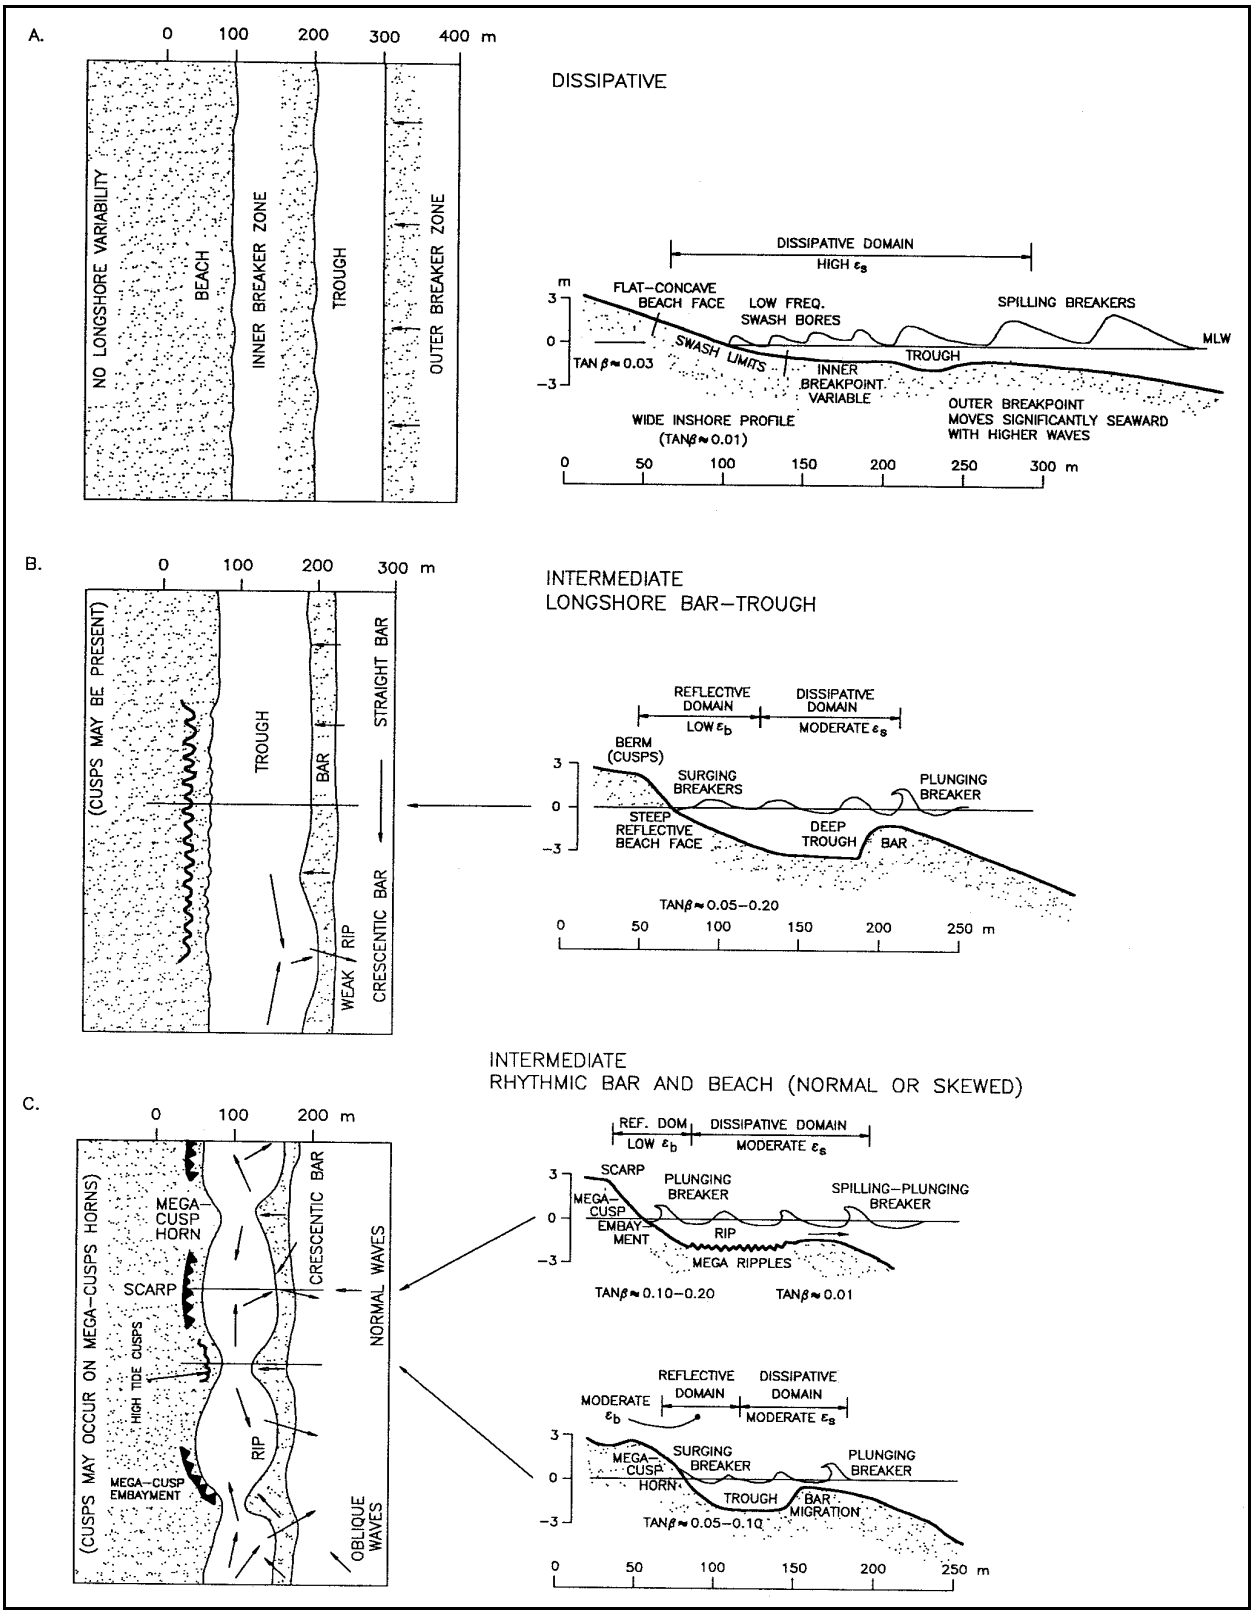

Figure IV-3-34. Plan and profile views of six major beach stages (adapted from Wright and Short (1984)). Surf-scaling parameter ε is discussed in the text; β represents beach gradient. Dimensions are based on Australian beaches, but morphologic configurations are applicable to other coastlines (Continued)

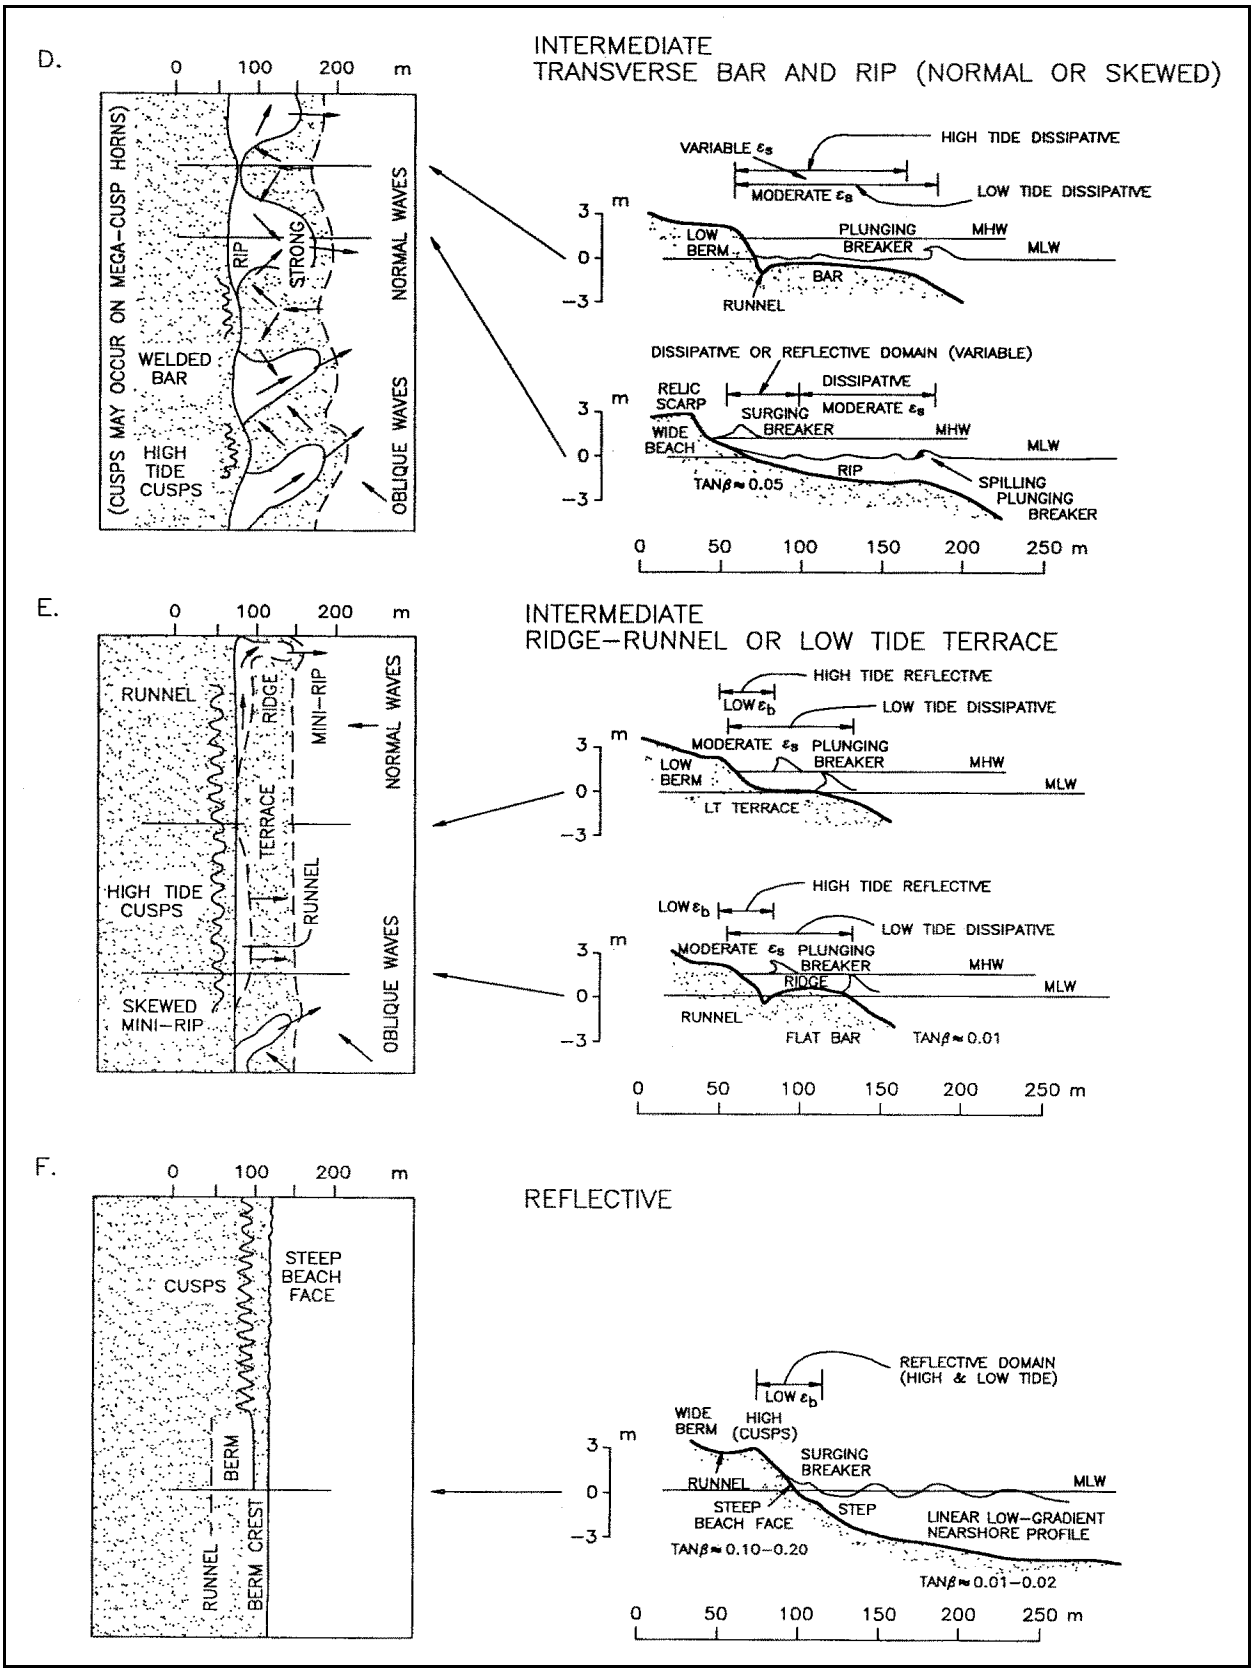

Figure IV-3-34. (Concluded)

(g) The parameter Ω depends critically upon $\overline{w_s}$, the sediment fall velocity. It is unclear how the relationships described above apply to shorefaces where the grain size varies widely or where there is a distinct bimodal distribution. For example, many Great Lakes beaches contain material ranging in size from silt and clay to cobble several centimeters in diameter. During storms, not only do wave height and period change, but fine-grain sediment is preferentially removed from the shoreface; therefore, the effective $\overline{w_s}$ may change greatly within a few hours. Further research is needed to understand how Great Lakes beaches change modally and temporally.

(2) Highly dissipative stage (Figure IV-3-34a). The dissipative end of the continuum is analogous to the "storm" or "winter beach" profile described by Bascom (1964) for shores that vary seasonally. The characteristic feature of these beaches is that waves break by spilling and dissipating progressively as they cross a wide surf zone, finally becoming very small at the upper portion of the foreshore (Figure IV-3-35) (Wright and Short 1984). A dissipative surf zone is broad and shallow and may contain two or three sets of bars upon which breakers spill. Longshore beach variability is minimal.

Figure IV-3-35. Example of a dissipative beach: Southern California near San Diego

(3) Highly reflective stage (Figure IV-3-34f). On a fully reflective beach, breakers impinge directly on the shore without breaking on offshore bars (Figures IV-3-36 and 37). As breakers collapse, the wave uprush surges up a steep foreshore. At the bottom of the steep, usually linear beach is a pronounced step composed of coarser material. Seaward of the step, the slope of the bed decreases appreciably. Rhythmic beach cusps are often present in the swash zone. The fully reflective stage is analogous to the fully accreted "summer profile."

(4) Surf-scaling parameter. Morphodynamically, the two end members of the beach state model can be distinguished on the basis of the surf-scaling parameter (Guza and Inman 1975):

Figure IV-3-36. Example of a reflective sand beach: Newport Beach, California, April 1993

$$\varepsilon = \frac{a_b \omega^2}{g \tan^2 \beta} \tag{IV-3-4}$$

where

a_b = breaker amplitude

ω = incident wave radian energy ($2\pi/T$ where T = period)

g = acceleration of gravity

β = the gradient of the beach and surf zone

Strong reflection occurs when $\varepsilon \leq 2.0\text{-}2.5$; this situation defines the highly reflective extreme. When $\varepsilon > 2.5$, waves begin to plunge, dissipating energy. Finally, when $\varepsilon > 20$, spilling breakers occur, the surf zone widens, and turbulent dissipation of wave energy increases with increasing ε.

(5) Intermediate beach stages. These exhibit the most complex morphologies and process signatures.

(a) Longshore bar-trough state (Figure IV-3-34b). This beach form can develop from an antecedent dissipative profile during an accretionary period. Bar-trough relief is higher and the shoreface is much steeper than on the dissipative profile. Initial wave breaking occurs over the bar. However, in contrast to

Figure IV-3-37. Example of a reflective cobble beach: Aldeburgh, Suffolk (facing the North Sea), August 1983. Note the steep berm and the lack of sand-sized sediment. In the background is part of the town of Aldeburgh, which has lost many buildings and churches since the Middle Ages due to erosion

the dissipative beach, the broken waves do not continue to decay after passing over the steep inner face of the bar, but re-form in the deep trough. Low-steepness waves surge up the foreshore; steeper waves collapse or plunge at the base of the foreshore, followed by a violent surge up the subaerial beach (Wright and Short 1984). Runup is relatively high and cusps often occur in the swash zone.

(b) Rhymthic bar and beach (Figure IV-3-34c). Characteristics are similar to the longshore bar-trough state (described above). The distinguishing features of the rhymthic bar and beach state are the regular longshore undulations of the crescentic bar and of the subaerial beach (Figures III-2-23 (ocean) and IV-3-38 (lake)). A weak rip current circulation is often present, with the rips flowing across the narrow portions of the bar. Wright and Short (1984) state that incident waves dominate circulation throughout the surf zone, but subharmonic and infragravity oscillations become important in some regions.

(c) Transverse-bar and rip state (Figure IV-3-34d). This morphology commonly develops in accretionary sequences when the horns of crescentic bars weld to the beach. This results in dissipative transverse bars (sometimes called “mega-cusps”) that alternate with reflective, deeper embayments. The dominant dynamic process of this beach state is extremely strong rip circulation, with the seaward-flowing rip currents concentrated in the embayments.

(d) Ridge and runnel/low tide terrace state (Figures IV-3-34e, IV-2-31 (ocean), and IV-3-39 (lake)). This beach state is characterized by a flat accumulation of sand at or just below the low tide level, backed by a steeper foreshore. The beach is typically dissipative at low tide and reflective at high tide.

Figure IV-3-38. Gravel cusps at St. Joseph, Michigan, November 1993. This is an example of a rhythmic bar and beach on a freshwater coast without tides but subject to irregular seiching

e. Processes responsible for shoreface sediment movement.

(1) Despite intense study for over a century, the subject of sand movement on the shoreface is still poorly understood. Sand is moved by a combination of processes including the following (Pilkey 1993, Wright et al. 1991):

(a) Wave orbital interactions with bottom sediments and with wave-induced longshore currents.

(b) Wind-induced longshore currents.

(c) Turbidity currents.

(d) Rip currents.

(e) Tidal currents.

(f) Storm surge ebb currents.

(g) Gravity-driven currents.

(h) Wind-induced upwelling and downwelling.

(i) Wave-induced upwelling and downwelling.

Figure IV-3-39. Ridge and runnel north of St. Joseph, Michigan, November 1993. This example shows that these features can be found on lake shores that do not have regular tides

(j) Gravity-induced downslope transport.

(2) Additional complications are imposed by constantly changing shoreface conditions, as follows:

(a) The relative contributions made by the different transport mechanisms vary over time.

(b) Because of differing regional geological configuration and energy climate, the frequencies of occurrence of the different mechanisms vary with location.

(c) Oscillatory flows normally occur at many frequencies and are superimposed on mean flows and other oscillatory flows of long period.

(3) Middle Atlantic Bight experiments of Wright et al. (1991).

(a) Wright et al. (1991) measured suspended sediment movement, wave heights, and mean current flows at Duck, North Carolina, in 1985 and 1987 and at Sandbridge, Virginia, in 1988 using instrumented tripods. During their study, which included both fair weather and moderate energy conditions, onshore mean flows (interpreted to be related to tides), were dominant over incident waves in generating sediment fluxes. In contrast, during a storm, bottom conditions were strongly dominated by offshore-directed, wind-induced mean flows. Wright et al. attributed this offshore-directed flow to a rise of 0.6 m in mean water level (during this particular storm) and a resultant strong seaward-directed downwelling flow.

(b) Wright et al. (1991) examined the mechanisms responsible for onshore and offshore sediment fluxes across the shoreface. They related two factors explicitly to incoming incident waves:

- Sediment diffusion arising from gradients in wave energy dissipation.
- Sediment advection caused by wave orbital asymmetries.

They found that four other processes may also play important roles in moving sediment:

- Interactions between groupy incident waves and forced long waves.
- Wind-induced upwelling and downwelling currents.
- Wave-current interactions.
- Turbidity currents.

Overall, Wright et al. found that incoming incident waves were of primary importance in bed agitation, while tide- and wind-induced currents were of primary importance in moving sediment. The incoming wave orbital energy was responsible for mobilizing the sand, but the unidirectional currents determined where the sand was going. Surprisingly, cross-shore sediment fluxes generated by mean flows were dominant or equal to sediment fluxes generated by incident waves in all cases and at all times.

(c) Based on the field measurements, Wright et al. (1991) concluded that "near-bottom mean flows play primary roles in transporting sand across isobaths on the upper shoreface" (p. 49). It is possible that this dominance of mean flows is a feature that distinguished the Middle Atlantic Bight from other shorefaces. The oscillatory (wave) constituents may be proportionately much more important along coasts subject to persistent, high-energy swell, such as the U.S. west coast. Wright et al. also concluded that the directions, rates, and causes of cross-shore sediment flux varied temporally in ways that were only partly predictable with present theory.

f. Sea level change and the Bruun rule.

(1) General coastal response to changing sea level.[1] Many barrier islands around the United States have accreted vertically during the Holocene rise in global sea level, suggesting that in these areas the supply of sediment was sufficient to allow the beaches to keep pace with the rise of the sea. It is not clear how beaches respond to short-term variations in sea level. Examples of shorter processes include multi-year changes in Great Lakes water levels and multi-month sea level rises associated with the El Niño-Southern Oscillation in the Pacific.

[1] Part IV-1 reviewed sea level change and outlined some of the associated coastal effects and management issues. Table IV-1-7 outlined how shoreline advance or retreat at any particular location is a balance between sediment supply and the rate of sea level change. In this section, sea level change is meant in a general sense to be caused by a combination of factors, including eustatic (global) changes and local effects due to vertical movements of the coastal land.

(2) Storm response.

(a) Based on his pioneering research of southern California beaches in the 1940's, Shepard (1950) developed the classic model that there is an onshore-offshore exchange of sediment over winter-summer cycles. Studies since then have shown that this model applies mostly to beaches on swell-dominated coasts where the wave climate changes seasonally (particularly Pacific Ocean coasts) (Carter 1988). Many beaches do *not* show an obvious seasonal cycle. Instead, they erode during storms throughout the year and rebuild during subsequent fair weather periods. Some coasts, like New Jersey, have a seasonal signature, but storms cause such great perturbations that it can take repetitive surveys over many years to extract the seasonal signature.

(b) In some locations, such as the Gulf Coast, infrequent and irregular hurricanes may be the most important dynamic events affecting beaches. Following one of these storms, beach and dune rebuilding may take years (Figure IV-2-10 shows a portion of the Florida/Alabama shore that was damaged by Hurricane Frederic in 1979 and is slowly recovering). Recently, the popular belief that hurricanes are the most important morphodynamic events causing Gulf Coast beach erosion is being reevaluated with the benefit of new field data. Scientists have learned that, cumulatively, winter cold fronts produce significant annual barrier island retreat. Dingler, Reiss, and Plant (1993) monitored Louisiana's Isles Dernieres and found that Hurricane Gilbert (September 1988) produced substantial beach retreat initially, but it actually reduced the average erosion rate by modifying the slope of the shoreface from that produced by cold-front-generated storms. The different responses were related to the scale of the storms. Cold fronts, which individually were small storms, eroded the entire beach to the same degree. Most sand and mud was deposited offshore and only a small percentage of eroded sand was deposited on the backshore because the fronts usually did not raise the sea enough to cause overtopping. Hurricane Gilbert, in contrast, raised sea level substantially such that the primary erosion occurred on the upper beach, and much of the sand was deposited behind the island via overwash processes. Over a 5-year period, the overall effect of this hurricane on the Isles Dernieres was to retard the retreat rate of the island by about 50 percent over that produced by cold fronts alone.

(3) Bruun Rule beach response model.

(a) One of the best-known shoreface response models was proposed by Bruun in 1962 (rederived in Bruun (1988)). Bruun's concept was that beaches adjust to the dominant wave conditions at the site. He reasoned that beaches had to respond in some manner because clearly they had adjusted and evolved historically as sea level had changed. Beaches had not disappeared, they had moved. How was this translation accomplished? Earlier studies of summer/winter beach morphology provided clues that beaches responded even to seasonal changes in wave climate. The basic assumption behind Bruun's model is that with a rise in sea level, the equilibrium profile of the beach and the shallow offshore moves upward and landward. Bruun made several assumptions in his two-dimensional analysis:

- The upper beach erodes because of a landward translation of the profile.
- Sediment eroded from the upper beach is deposited immediately offshore; the eroded and deposited volumes are equal (i.e., longshore transport is not a factor).
- The rise in the seafloor offshore is equal to the rise in sea level. Thus, offshore, the water depth stays constant.

(b) The Bruun Rule can be expressed as (Figure IV-3-40a):

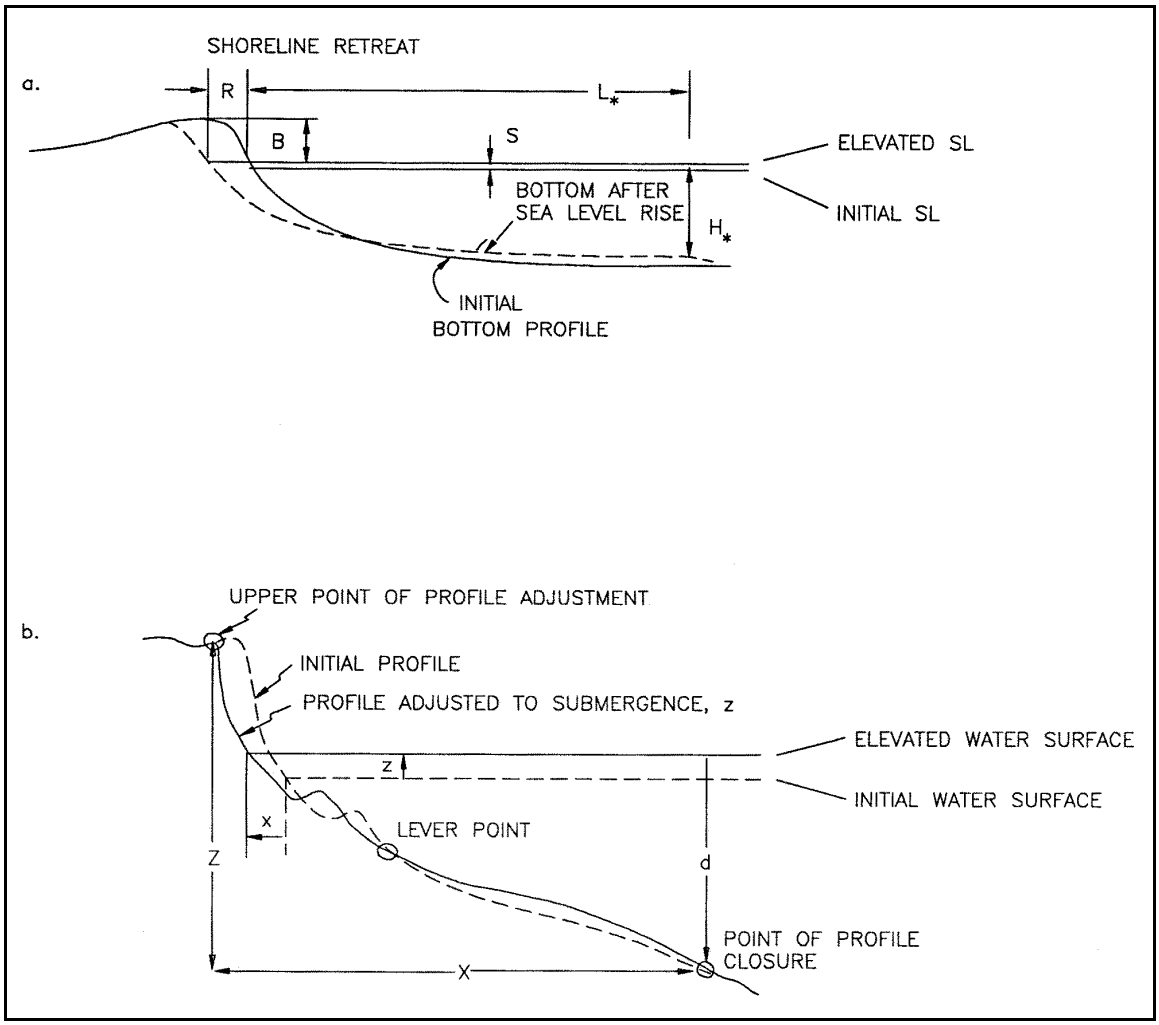

Figure IV-3-40. (a) Shoreline response to rising sea level (SL) depicted by the Bruun Rule. (b) Simplified nomenclature used by Hands (1983). The sandbar shows that the model is valid for complicated profile shapes

$$R = \frac{L_*}{B + H_*} S \tag{IV-3-5}$$

where

R = shoreline retreat

S = increase in sea level

L_* = cross-shore distance to the water depth H_*

B = berm height of the eroded area

Hands (1983) restated the Bruun Rule in simplified form:

$$x = \frac{zX}{Z} \qquad \text{(IV-3-6)}$$

where z is the change in water level. The ultimate retreat of the profile x can be calculated from the dimensions of the responding profile, X and Z, as shown in Figure IV-3-40b. Other expressions for the Bruun Rule are presented in Part III-3-h.

(c) Despite the continued interest in Bruun's concept, there has been only limited use of this method for predictive purposes. Hands (1983) listed several possible reasons for the reluctance to apply this approach:

- Skepticism as to the adequacy of an equilibrium model for explaining short-term dynamic changes.
- Difficulties in measuring sediment lost from the active zone (alongshore, offshore to deep water, and onshore via overwash).
- Problems in establishing a realistic closure depth below which water level changes have no measurable effect on the elevation or slope of the seafloor.
- The perplexity caused by a discontinuity in the profile at the closure depth which appeared in the original and in most subsequent diagrams illustrating the concept.

An additional, and unavoidable, limitation of this sediment budget approach is that it does not address the question of *when* the predicted shore response will occur (Hands 1983). It merely reveals the horizontal distance the shoreline must *ultimately* move to reestablish the equilibrium profile at its new elevation under the assumptions stated in Bruun's Rule.

(d) Hands (1983) demonstrated the geometric validity of the Bruun Rule in a series of figures which show the translation of the profile upward and landward (the figures are two-dimensional; volumes must be based on unit lengths of the shoreline):

- Figure IV-3-41a: The equilibrium profile at the initial water level.
- Figure IV-3-41b: The first translation moves the active profile up an amount z and reestablishes equilibrium depths below the now elevated water level. Hands defines the *active profile* as the zone between the closure depth and the upper point of profile adjustment. The volume of sediment required to maintain the equilibrium water depth is proportional to X (width of the active zone) times z (change in water level).
- Figure IV-3-41c: The required volume of sediment is provided by the second translation, which is a recession (horizontal movement) of the profile by an amount x. The amount of sediment is proportional to x times Z, where Z is the vertical extent of the active profile from the closure depth to the average elevation of the highest erosion on the backshore.
- Figure IV-3-41d: Equating the volume required by the vertical translation and the volume provided by the horizontal translation yields Equation 3-6. In reality, both translations occur simultaneously, causing the closure point to migrate upslope as the water level rises.

(e) One of the strengths of the Bruun concept is that the equations are valid regardless of the shape of the profile, for example, if bars are present (Figure IV-3-40b). It is important that an offshore distance and depth of closure be chosen that incorporate the entire zone where active sediment transport occurs. Thereby,

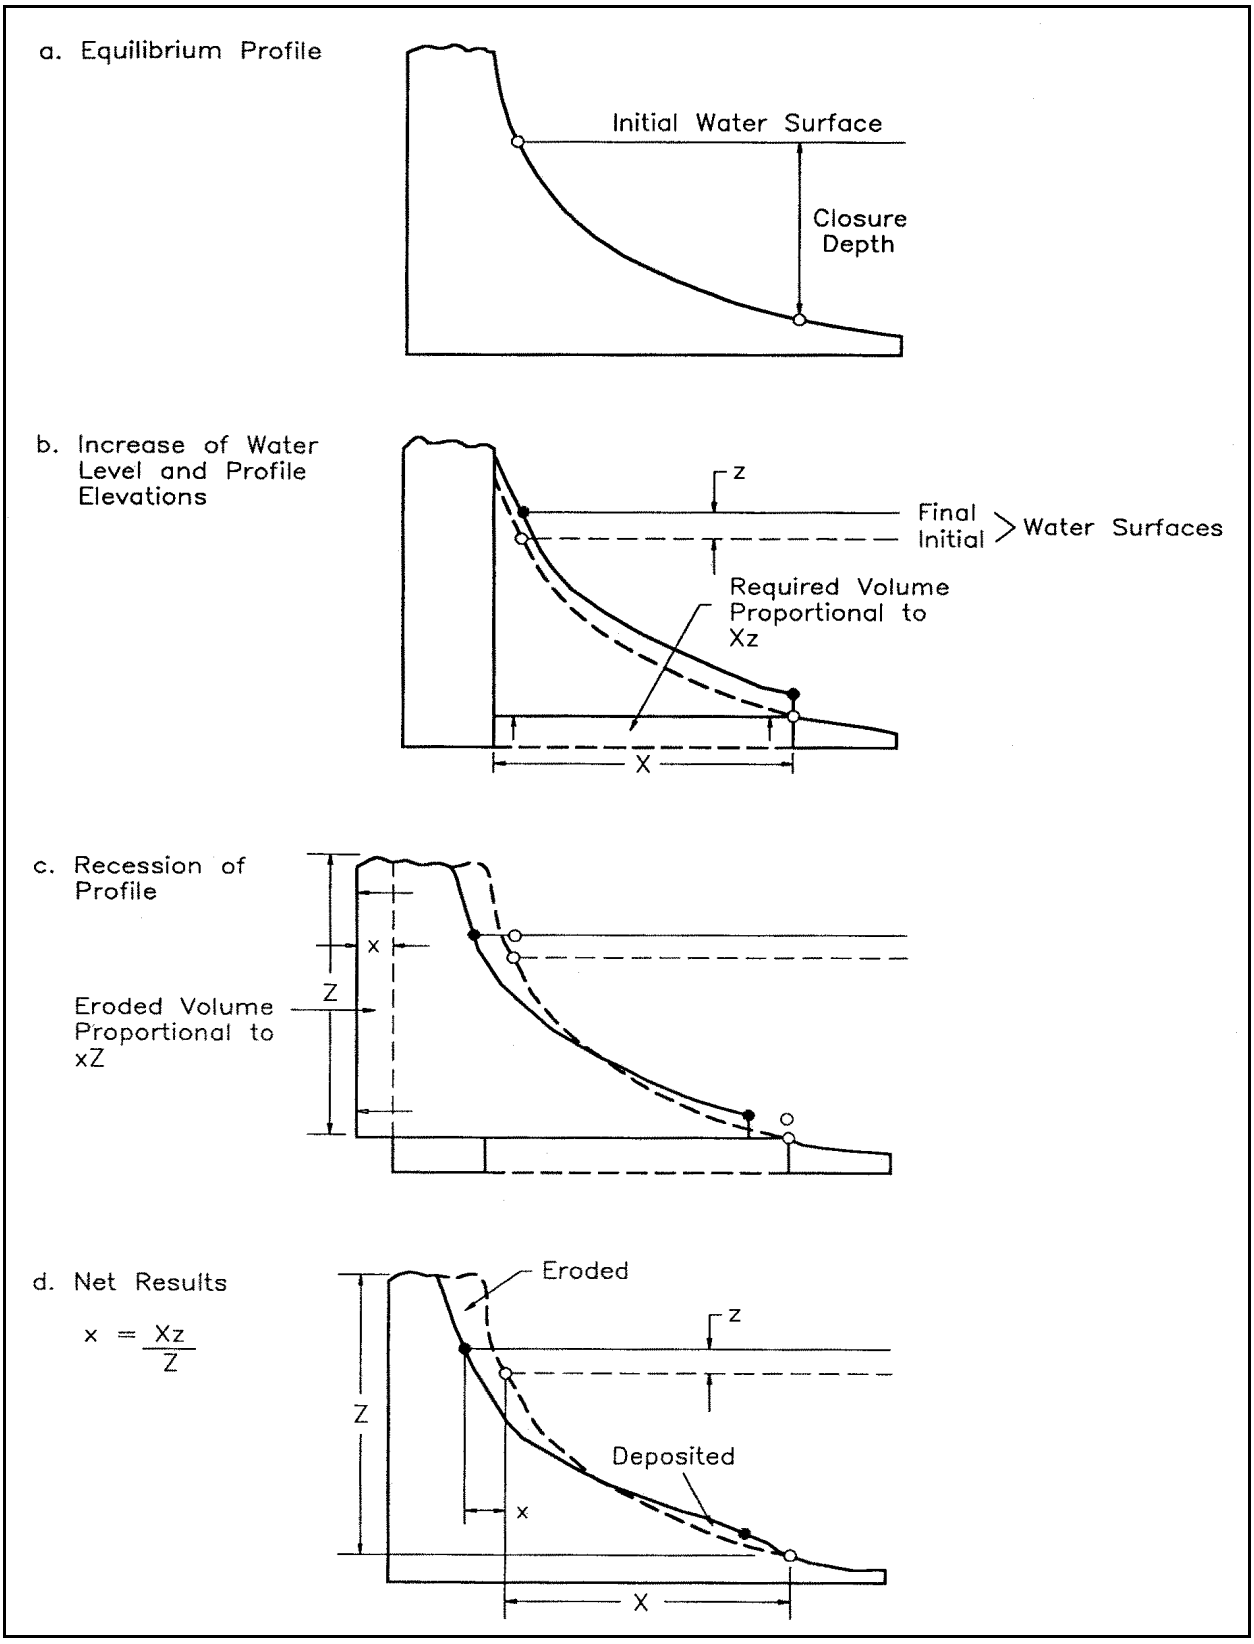

Figure IV-3-41. Profile adjustment in two stages, first vertical, then horizontal, demonstrating the basis for the Bruun Rule (Equation 3-6) (from Hands (1983)). Details discussed in the text

sediment is conserved in spite of the complex processes of local erosion versus deposition as bars migrate (Komar et al. 1991). Another strength is that it is a simple relationship, a geometric conclusion based only on water level. Despite its simplicity and numerous assumptions, it works remarkably well in many settings. Even with its shortcomings, it can be used to predict how beaches can respond to changes in sea level.

(4) Use of models to predict shoreline recession. Although field studies have confirmed the assumptions made by Bruun and others concerning translations of the shoreface, there has been no convincing demonstration that the models can predict shoreline recession rates. Komar et al. (1991) cite several reasons for the inability to use the models as predictive tools:

(a) Existence of a considerable time lag of the beach response following a sustained water level rise (as shown by Hands (1983) for Lake Michigan).

(b) Uncertainty in the selection of the parameters used in the equations (in particular, closure depth).

(c) Local complexities of sediment budget considerations in the sand budget.

(5) Recommendations. More field and laboratory studies are needed to better evaluate the response of beaches to rising (and falling) sea level. For example, it would be valuable to reoccupy the profile lines monitored by Hands (1976, 1979, 1980) in Lake Michigan in the 1970's to determine how the shores have responded to the high water of the mid-1980's and to the subsequent drop in the early 1990's. In addition, conceptual advances need to be incorporated in the theoretical models. How sediment has moved onshore in some locations following sea level rise also needs to be evaluated, because there is evidence that in some areas beach sand compositions reflect offshore rather than onshore sources (Komar et al. 1991).

g. Equilibrium profiles on sandy coasts.

(1) General characteristics and assumptions. The existence of an equilibrium shoreface profile (sometimes called equilibrium *beach* profile) is a basic assumption of many conceptual and numerical coastal models. Dean (1990) listed characteristic features of profiles:

(a) Profiles tend to be concave upwards.

(b) Fine sand is associated with mild slopes and coarse sand with steep slopes.

(c) The beach (above the surf zone) is approximately planar.

(d) Steep waves result in milder inshore slopes and a tendency for bar formation.

The main assumption underlying the concept of the shoreface equilibrium profile is that the seafloor is in equilibrium with *average* wave conditions. Presumably, the term *equilibrium* is meant to indicate a situation in which water level, waves, temperature, etc., are held constant for a sufficient time such that the beach profile arrives at a final, stable shape (Larson and Kraus 1989a). Larson (1991) described the profile as: "A beach of specific grain size, if exposed to constant forcing conditions, normally assumed to be short-period breaking waves, will develop a profile shape that displays no net change in time." This concept ignores the fact that, in addition to wave action, many other processes affect sediment transport. These simplifications, however, may represent the real strength of the concept because it has proven to be a useful way to characterize the shape of the shoreface in many locations around the world.

(2) Shape. Based on studies of beaches in many environments, Bruun (1954) and Dean (1976, 1977) have shown that many ocean beach profiles exhibit a concave shape such that the depth varies as the two-thirds power of distance offshore along the submerged portions:

$$h = Ay^{2/3} \tag{IV-3-7}$$

where

h = water depth (m) at distance y (m) from the shoreline

A = a scale parameter that depends mainly on sediment characteristics

This surprisingly simple expression asserts, in effect, that beach profile shape can be calculated from sediment characteristics (particle size or fall velocity) alone. Moore (1982) graphically related the parameter A, sometimes called the *profile shape parameter,* to the median grain size d_{50}. Hanson and Kraus (1989) approximated Moore's curve by a series of lines grouped as a function of the median nearshore grain size d_{50} (in mm):

$$\begin{aligned} A &= 0.41(d_{50})^{0.94} \quad , \quad d_{50} < 0.4 \\ A &= 0.23(d_{50})^{0.32} \quad , \quad 0.4 \le d_{50} < 10.0 \\ A &= 0.23(d_{50})^{0.28} \quad , \quad 10.0 \le d_{50} < 40.0 \\ A &= 0.46(d_{50})^{0.11} \quad , \quad 40.0 \le d_{50} \end{aligned} \tag{IV-3-8}$$

Note that A has unit dependence ($m^{1/3}$). Equation 3-8 is for SI (metric) values only. Different equations must be used for English units.

Table III-3-3 is a summary of recommended A values, and a more detailed discussion of methods to compute equilibrium profiles is provided in Part III-3.

(3) Discussion of assumptions. Pilkey et al. (1993), in a detailed examination of the concept of the equilibrium shoreface profile, contended that several assumptions must hold true for the concept to be valid:

(a) *Assumption 1: All sediment movement is driven by incoming wave orbitals acting on a sandy shoreface.*

This assumption is incorrect because research by Wright et al. (1991) showed that sediment movement on the shoreface is an exceedingly complex phenomenon, driven by a wide range of wave, tidal, and gravity currents. Even in locations where the wave orbitals are responsible for mobilizing the sand, bottom currents frequently determine where the sand will go.

(b) *Assumption 2: Existence of closure depth and no net cross-shore (i.e., shore-normal) transport of sediment to and from the shoreface.*

Pilkey et al. (1993) state that this assumption is also invalid because considerable field evidence has shown that large volumes of sand may frequently move beyond the closure depth. Such movement can occur during

both fair weather and storm periods, although offshore-directed storm flows are most likely the prime transport agent. Pilkey et al. cite studies in the Gulf of Mexico that measured offshore bottom currents of up to 200 cm/sec and sediment transport to the edge of the continental shelf. The amount of sediment moved offshore was large, but it was spread over such a large area that the change in sea bed elevation could not be detected by standard profiling methods.[1] Wright, Xu, and Madsen (1994) measured significant across-shelf benthic transport on the inner shelf of the Middle Atlantic Bight during the Halloween storm of 1991.

(c) *Assumption 3: There exists a sand-rich shoreface; the underlying and offshore geology must not play a part in determining the shape of the profile.*

Possibly the most important of the assumptions implicit in the equilibrium profile concept is that the entire profile is sand-rich, without excessive areas of hard bottom or mud within the active profile. Clearly these conditions do not apply in many parts of the world. Coasts that have limited sand supplies, such as much of the U.S. Atlantic margin, are significantly influenced by the geologic framework occurring underneath and in front of the shoreface. Many of the east coast barriers are perched on a platform of ancient sediment. Depending upon the physical state, this underlying platform can act as a subaqueous headland or hardground that dictates the shape of the shoreface profile and controls beach dynamics and the composition of the sediment. Niederoda, Swift, and Hopkins (1985) believed that the seaward-thinning and fining veneer of modern shoreface sediments is ephemeral and is easily removed from the shoreface during major storms. During storms, Holocene and Pleistocene strata cropping out on the shoreface provide the immediate source of the bulk of barrier sands. Swift (1976) used the term *shoreface bypassing* to describe the process of older units supplying sediment to the shoreface of barrier islands. Pilkey et al. (1993) contend that:

> ...a detailed survey of the world's shorefaces would show that the sand rich shoreface required by the equilibrium profile model is an exception rather than the rule. Instead, most shorefaces are underlain by older, consolidated or semi-consolidated units covered by only a relatively thin veneer of modern shoreface sands. These older units are a primary control on the shape of the shoreface profile. The profile shape is not determined by simple wave interaction with the relatively thin sand cover. Rather, the shape of the shoreface in these sediment poor areas is determined by a complex interaction between underlying geology, modern sand cover, and highly variable (and often highly diffracted and refracted) incoming wave climate. (p. 271)

(d) *Assumption 4: If a shoreface is, in fact, sand-rich, the smoothed profile described by the equilibrium profile equation (ignoring bars and troughs) must provide a useful approximation of the real shoreface shape.*

In addressing this assumption, Pilkey et al. (1993) cited studies conducted on the Gold Coast, in Queensland, Australia. The Gold Coast shoreface is sand-rich to well beyond a depth of 30 m. Without being directly influenced by underlying geology, the shoreface is highly dynamic. As a consequence, the Gold Coast shoreface shape cannot be described by one equilibrium profile; rather, it is best described by an ever-changing regime profile. Pilkey et al. concluded:

> The local shoreface profile shapes are entirely controlled by relative wave energy "thresholds"; for the sediment properties have not changed at all. Thus principal changes to the shoreface profiles of the Gold Coast are driven by wave power history with some modification by currents, and not by sediment size, or its parameter *A*, as defined within the equilibrium profile concept. (p. 272).

---

[1] This latter statement underscores how important it is to develop improved methods to detect and measure sediment movement in deep water.

(4) General comments.

(a) The idea of a profile only adjusting to waves is fundamentally wrong as shown by Wright et al. (1991) and others. However, although the physical basis for the equilibrium profile concept is weak, critics of this approach have not proven that it always results in highly erroneous answers.

(b) Before the use of the equilibrium profile, coastal engineers had no way to predict beach change other than using crude approximations (e.g., sand loss of 1 cu yd/ft of beach retreat). The approximations were inadequate. Surveys from around the world have shown that shoreface profiles display a characteristic shape that differs with locality but is relatively stable for a particular place (i.e., Duck, North Carolina). With many caveats (which are usually stated, then ignored), a profile can be reasonably represented by the equilibrium equation. The fit between the profile and the real seafloor on a daily, seasonal, and storm variation basis may not be perfect, but the differences may not matter in the long term.

(c) One critical problem for coastal engineers is to predict what a sequence of waves (storm) will do to a locality when little is known about the particular shape of the pre-storm beach. For this reason, numerical models like SBEACH (Larson and Kraus 1989a), despite their reliance on the equilibrium profile concept, are still useful. The models allow a researcher to explore storm impact on a location using a general approximation of the beach. The method is very crude - however, the resulting numbers are of the right order of magnitude when compared with field data from many locations.

(d) Answers from the present models are not exact, and researchers still have much to learn about the weakness of the models and about physical processes responsible for the changes. Nevertheless, the models do work and they do provide numbers that are of the correct magnitudes when run by careful operators. Users of shoreface models must be aware of the limitations of the models and of special conditions that may exist at their project sites. In particular, profile-based numerical models are likely to be inadequate in locations where processes other than wave-orbital transport predominate.

h . Depth of closure.

(1) Background.

(a) *Depth of closure* is a concept that is often misinterpreted and misused. For engineering practice, depth of closure is commonly defined as the minimum water depth at which no measurable or significant change in bottom depth occurs (Stauble et al. 1993). The word *significant* in this definition is important because it leaves considerable room for interpretation. “Closure” has erroneously been interpreted to mean the depth at which no sediment moves on- or offshore, although numerous field studies have verified that much sediment moves in deep water (Wright et al. 1991). Another complication is introduced by the fact that it is impossible to define a single depth of closure for a project site because “closure” moves depending on waves and other hydrodynamic forces. Therefore, it is invalid to assume that “closure” is a single fixed depth at a project site or a stretch of coastline.

(b) Closure depth is used in a number of applications such as the placement of mounds of dredged material, beach fill, placement of ocean outfalls, and the calculation of sediment budgets.

(2) Energy factors. As discussed above, the primary assumption behind the concept of the shoreface equilibrium profile is that sediment movement and the resultant changes in bottom elevation are a function of wave properties and sediment grain size. Therefore, the active portion of the shoreface varies in width throughout the year depending on wave conditions. In effect, “closure” is a time-dependent quantity that may be predicted based on wave climatology or may be interpreted statistically using profile surveys.

(3) Time considerations. The energy-dependent nature of the active portion of the shoreface requires us to consider return period. The closure depth that accommodates the 100-year storm will be much deeper than one that merely needs to include the 10-year storm. Therefore, a closure depth must be chosen in light of a project's engineering requirements and design life. For example, if a berm is to be built in deep water where it will be immune from wave resuspension, what is the minimum depth at which it should be placed? This is an important question because of the high costs of transporting material and disposing of it at sea. It would be tempting to use a safe criterion such as the 100- or 500-year storm, but excessive costs may force the project engineer to consider a shallower site that may be stable only for shorter return period events.

(4) Predictive methods.

(a) Hallermeier (1977, 1978, 1981a, 1981b, 1981c), using laboratory tests and limited field data, introduced equations to predict the limits of extreme wave-related sediment movement. He calculated two limits, d_ℓ and d_i, that included a buffer region on the shoreface called the shoal zone. Landward of d_ℓ, significant alongshore transport and intense onshore-offshore sediment transport occur (the littoral zone). Within the shoal zone, expected waves have neither a strong nor a negligible effect on the sandy bed during a typical annual cycle of wave action. Seaward of d_i, only insignificant onshore-offshore transport by waves occurs. The deeper limit was based on the median nearshore storm wave height (and the associated wave period). The boundary between the shoal zone and the littoral zone (d_ℓ) as defined represents the annual depth of closure. Hallermeier (1978) suggested an analytical approximation, using linear wave theory for shoaling waves, to predict an *annual* value of d_ℓ:

$$d_\ell = 2.28H_e - 68.5\left(\frac{H_e^2}{gT_e^2}\right) \tag{IV-3-9}$$

where

d_ℓ = annual depth of closure below mean low water

H_e = non-breaking significant wave height that is exceeded 12 hr per year (0.137 % of the time)

T_e = associated wave period

g = acceleration due to gravity

According to Equation 3-9, d_ℓ is primarily dependent on wave height with an adjustment for wave steepness. Hallermeier (1978) proposed using the 12-hr exceeded wave height, which allowed sufficient duration for "moderate adjustment towards profile equilibrium." Equation 3-9 is based on quartz sand with a submerged density of $\gamma' = 1.6$ and a median diameter between 0.16 and 0.42 mm, which typifies conditions in the nearshore for many beaches. If the grain size is larger than 0.42 mm, Equation 3-9 may not be appropriate. Because d_ℓ was derived from linear wave theory for shoaling waves, d_ℓ must be seaward of the influence of intense wave-induced nearshore circulation. However, because of various factors, Hallermeier (1978) "proposed that the calculated d_ℓ be used as a minimum estimate of profile close-out depth with respect to low(er) tide level." Because tidal or wind-induced currents may increase wave-induced near-bed flow velocities, Hallermeier suggested using mean low water (mlw) as a reference water level to obtain a conservative depth of closure. Note that Hallermeier's equations critically depend on the quality of wave data at a site. The reader is cautioned that Hallermeier's equations can be expressed in various forms depending on the assumptions made, the datums used as reference levels, and available wave data. The reader is referred

to his original papers for clarification and for details of his assumptions. The equations may not be applicable at sites where currents are more important at moving sand than wave-induced flows.

(b) At the Lake Michigan sites that Hands (1983) surveyed, the closure depth was equal to about twice the height of the 5-year return period wave height (H_5):

$$Z \simeq 2H_5 \tag{IV-3-10}$$

In the absence of strong empirical evidence as to the correct closure depth, this relationship is recommended as a rule of thumb to estimate the 5-year profile response under Great Lakes conditions. The return period of the wave height should approximate the design life of interest. For example, the 20-year closure depth would be estimated by doubling the 20-year return period wave height ($Z \simeq 2H_{20}$).

(5) Empirical determination.

(a) When cross-shore surveys covering several years are available for a project site, closure is best determined by plotting and analyzing the profiles. The closure depth computed in this manner reflects the influence of storms as well as of calmer conditions. Kraus and Harikai (1983) evaluated the depth of closure as the minimum depth where the standard deviation in depth change decreased markedly to a near-constant value. Using this procedure, they interpreted the landward region where the standard deviation increased to be the active profile where the seafloor was influenced by gravity waves and storm-driven water level changes. The offshore region of smaller and nearly constant standard deviation was primarily influenced by lower frequency sediment-transporting processes such as shelf and oceanic currents (Stauble et al. 1993). It must be noted that the smaller standard deviation values fall within the limit of measurement accuracy. This suggests that it is not possible to specify a closure depth unambiguously because of operational limits of offshore profiling hardware and procedures.

(b) An example of how closure was determined empirically at Ocean City, Maryland, is shown in Figure IV-3-42 (from Stauble et al. (1993)). A clear reduction in standard deviation occurs at a depth of about 5.5 - 6 m. Above the ~5.5 m depth, the profile exhibits large variability, indicating active wave erosion, deposition, and littoral transport. Deeper (and seaward) of this zone, the lower and relatively constant deviation of about 7 - 10 cm is within the measurement error of the sled surveys. Nevertheless, despite the inability to precisely measure seafloor changes in this offshore region, it is apparent that less energetic erosion and sedimentation take place here than in water shallower than ~5.5 m. This does not mean that there is no sediment transport in deep water, just that the sled surveys are unable to measure it. For the 5.6 km of shore surveyed at Ocean City, the depth of closure ranged between 5.5 and 7.5 m. Scatter plots indicated that the average closure depth was 6 m.

(c) Presumably, conducting surveys over a longer time span at Ocean City would reveal seafloor changes deeper than ~6 m, depending on storms that passed the region. However, Stauble et al. (1993) noted that the "Halloween Storm" of October 29 to November 2, 1991 generated waves of peak period (T_p) 19.7 sec, extraordinarily long compared to normal conditions along the central Atlantic coast. Therefore, the profiles may already reflect the effects of an unusually severe storm.

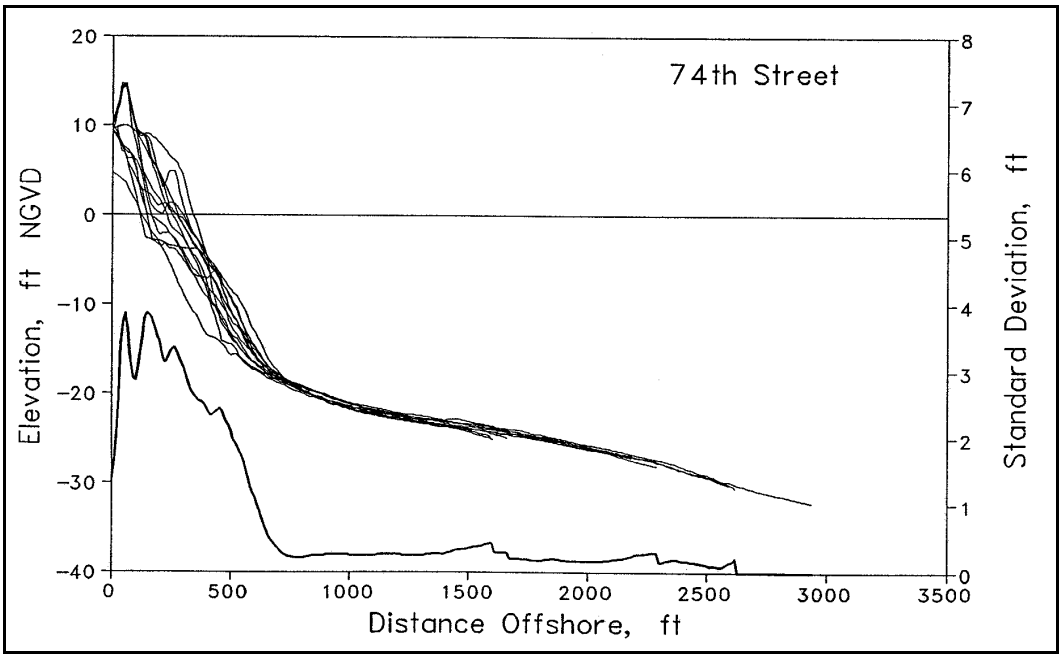

Figure IV-3-42. Profile surveys and standard deviation of seafloor elevation at 74th Street, Ocean City, Maryland (from Stauble et al. (1993)). Surveys conducted from 1988 to 1992. Large changes above the datum were caused by beach fill placement and storm erosion. Figure discussed in the text

(d) Figure IV-3-43 is an example of profiles from St. Joseph, Michigan, on the east shore of Lake Michigan. Along Line 14, dramatic bar movement occurs as far as 760 m offshore to a depth of 7.6 m with respect to International Great Lakes Datum (IGLD) 1985. This is where an abrupt decrease in standard deviation of lake floor elevation occurs and can be interpreted as closure depth. In September 1992, the mean water surface was 0.51 m above IGLD 85. Therefore, closure was around 7.9 - 8.2 m below *water* level.

(e) In the Great Lakes, water levels fluctuate over multi-year cycles. This raises some fundamental difficulties in calculating closure based on profile surveys. Presumably, during a period of high lake level, the zone of active sand movement would be higher on the shoreface than during a time of low lake level (this assumes similar wave conditions). Therefore, the depth where superimposed profiles converge should reflect the *deepest* limit of active shoreface sand movement. This would be a conservative value, but *only with respect to the hydrologic conditions that occurred during the survey program*. Presumably, if lake level dropped further at a later date, sediment movement might occur deeper on the shoreface. This suggests that closure on the lakes should be chosen to reflect the *lowest* likely water level that is expected to occur during the life of a project. (Note that this consideration does not arise on ocean coasts because year-to-year changes in relative sea level are minor, well within the error bounds of sled surveys. Sea level does change throughout the year because of thermal expansion, freshwater runoff, and other factors as discussed in Part IV-1, but the multi-year mean is essentially stable.) In summary, determining closure depth in the Great Lakes is problematic because of changing water levels, and more research is needed to develop procedures that accommodate these non-periodic lake level fluctuations.

(f) The variation of closure depth at approximately 100 profile lines along the south shore of Long Island is plotted in Figure IV-3-44. Generally the depth increases towards the east, with Rockaway Beach averaging 5.0 m below NGVD and the Montauk zone averaging 7.6 m. These values were based on

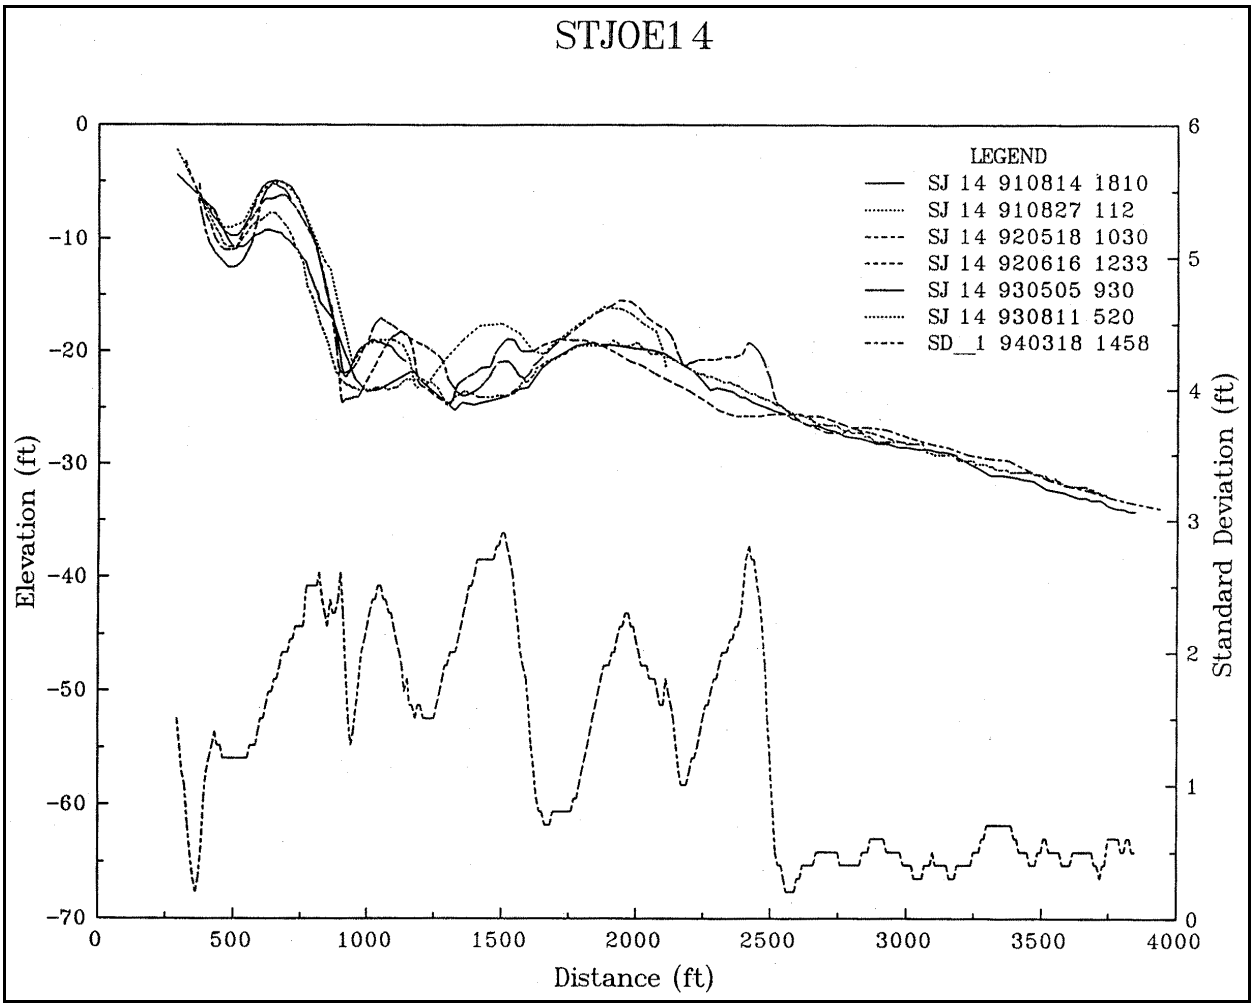

Figure IV-3-43. Profile surveys and standard deviation of lake floor elevation at St. Joseph, Michigan, on the east shore of Lake Michigan. Profiles are referenced to International Great Lakes Datum (IGLD) 1985. Surveys conducted between 1991 and 1994 (Nairn et al. 1997). Figure discussed in the text

surveys in 1995 and 1996 (Morang 1998). The depth increase toward the east is expected because wave energy is greater there than at the west end of Long Island.

i. Longshore sediment movement.

The reader is referred to Part III-2 and to *Coastal Sediment Transport* (EM 1110-2-1502) for a detailed treatment of longshore transport.

j. Summary.

(1) A model of shoreface morphodynamics for micro- and low-mesotidal sandy coasts has been developed by Wright and Short (1984). The six stages of the model (Figure IV-3-34) illustrate the response of sandy beaches to various wave conditions.

(2) Sediment movement on the shoreface is a very complicated phenomenon. It is a result of numerous hydrodynamic processes, among which are: (a) wave orbital interactions with bottom sediments and with

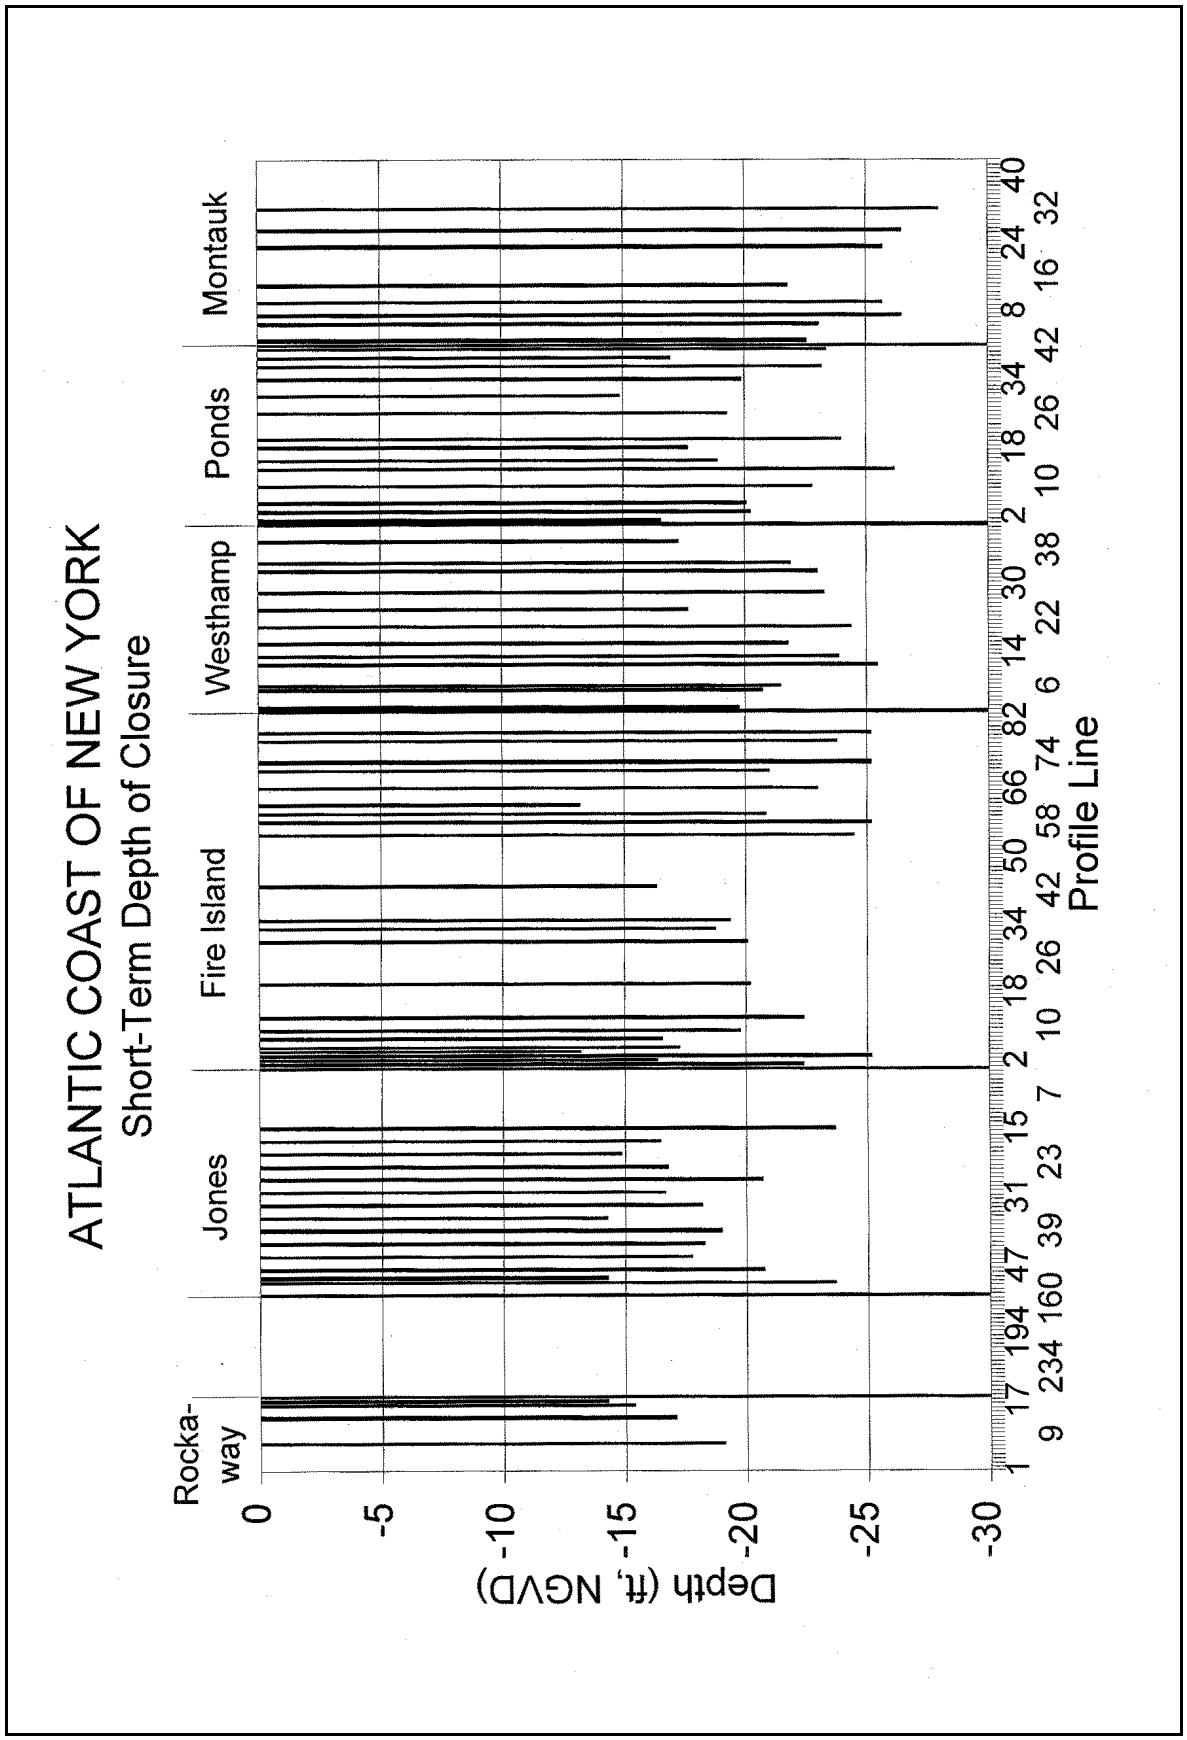

Figure IV-3-44. Variation in short-term closure depth along the south shore of Long Island, New York, computed for four survey dates in 1995 and 1996

wave-induced longshore currents; (b) wind-induced longshore currents; (c) rip currents; (d) tidal currents; (e) storm surge ebb currents; (f) gravity-driven currents; (g) wind-induced upwelling and downwelling; (h) wave-induced upwelling and downwelling; and (i) gravity-induced downslope transport.

(3) The Bruun Rule (Equation 3-5 or 3-6) is a model of shoreface response to rising sea level. Despite the model's simplicity, it helps explain how barriers have accommodated rising sea level by translating upward and landward. A limitation is that the model does not address *when* the predicted shore response will occur (Hands 1983). It merely reveals the horizontal distance the shoreline must *ultimately* move to reestablish the equilibrium profile at its new elevation under the stated assumptions.

(4) The concept of the equilibrium shoreface profile applies to sandy coasts primarily shaped by wave action. It can be expressed by a simple equation (Equation 3-7) which depends only on sediment characteristics. Although the physical basis for the equilibrium profile concept is weak, it is a powerful tool because models based on the concept produce resulting numbers that are of the right order of magnitude when compared with field data from many locations.

(5) *Closure* is a concept that is often misinterpreted and misused. For engineering practice, depth of closure is commonly defined as the minimum water depth at which no measurable or significant change in bottom depth occurs (Stauble et al. 1993). Closure can be computed by two methods: (a) analytical approximations such as those developed by Hallermeier (1978), which are based on wave statistics at a project site (Equation 3-10); or (b) empirical methods based on cross-shore survey profile data. When profiles are superimposed, a minimum value for closure can be interpreted as the depth where the standard deviation in depth change decreases markedly to a near-constant value. Both methods have weaknesses. Hallermeier's analytical equations depend on the quality of wave data. Empirical determinations depend on the availability of several years of profile data at a site. Determining closure in the Great Lakes is problematic because lake levels fluctuate due to changing hydrographic conditions.

IV-3-7. Definition of Symbols

β	Gradient of the beach and surf zone
ε	Surf-scaling parameter (Equation IV-3-4) [dimensionless]
ρ_f	Mass density of fresh water (= 1,000kg/m^3 or 1.94 slugs/ft^3) [force-time^2/length^4]
ρ_s	Mass density of salt water (= 1,025 kg/m^3 or 2.0 slugs/ft^3) [force-time^2/length^4]
ω	Wave angular or radian frequency (= $2\pi/T$) [time^{-1}]
Ω	Modal state of the beach (Equation IV-3-3) [dimensionless]
A	Sediment scale or equilibrium profile parameter or profile shape parameter (Table III-3-3) [length$^{1/3}$]
a_b	Breaker amplitude [length]
B	Berm height of the eroded area [length]
d_ℓ	Annual depth of closure below mean low water (Equation IV-3-9) [length]
F'	Froude number
g	Gravitational acceleration (32.17 ft/sec^2, 9.807m/sec^2) [length/time^2]
h	Equilibrium beach profile depth (Equation IV-3-7) [length]
H_*	Water depth [length]
H_b	Wave height at breaking [length]
H_e	Non-breaking significant wave height that is exceeded 12 hr per year [length]
H_x	Wave height of the x-year return period [time]
h'	Depth of density interface [length]
L_*	Cross-shore distance to the water depth H_* [length]
R	Shoreline retreat (Equation IV-3-5) [length]
S	Increase in sea level [length]
T	Wave period [time]
T_e	Wave period associated with H_e [time]
U	Mean outflow velocity of upper layer (in case of stratified flow) [length/time]
$\overline{w_s}$	Sediment fall velocity [length/time]
x	Retreat of the profile, Bruun Rule (Equation IV-3-6) [length]
X	Horizontal distance of responding profile {Equation IV-3-6 and Figure IV-3-40) [length]

y	Equilibrium beach profile distance offshore (Equation IV-3-7) [length]
z	Change in water level [length]
Z	Closure depth (Equation IV-3-10) [length]
Z	Vertical distance of responding profile {Equation IV-3-6 and Figure IV-3-40) [length]

IV-3-8. Acknowledgments

Engineering and Design
COASTAL ENGINEERING MANUAL

1. Purpose. The purpose of the *Coastal Engineering Manual* (CEM) is to provide a comprehensive technical coastal engineering document. It includes the basic principles of coastal processes, methods for computing coastal planning and design parameters, and guidance on how to formulate coastal flood studies, shore protection, and navigation projects.

2. Applicability. This manual applies to all HQUSACE elements and all USACE commands having Civil Works and military design responsibilities.

3. Discussion. The CEM is divided into two major subdivisions: science-based and engineering-based. The science subdivision is further divided into three parts. The first part, "Coastal Hydrodynamics," leads the reader from the fundamental principles of wave theory and ocean wave generation through the process of wave transformation as the wave form approaches and reacts with the shore including water-level variations and currents. The second part, "Coastal Sediment Processes," addresses longshore and cross-shore transport as well as shelf, and wind transport processes. The third part, "Coastal Geology," covers geomorphology, coastal classification, and morphodynamic processes on sandy shores.

The engineering-based subdivision is oriented toward a project-type approach, rather then the individual structure design and is divided into two parts. The first one, "Coastal Planning and Design," provides information on the design process and selection of appropriate type of solution to various coastal problems. The second part, "Design of Coastal Project Elements," provides engineering guidance on materials, fundamentals of design, and reliability.

4. Distribution Statement. Approved for public release, distribution unlimited.

Engineering and Design
COASTAL ENGINEERING MANUAL

1. Purpose. The purpose of the *Coastal Engineering Manual* (CEM) is to provide a comprehensive technical coastal engineering document. It includes the basic principles of coastal processes, methods for computing coastal planning and design parameters, and guidance on how to formulate coastal flood studies, shore protection, and navigation projects.

2. Applicability. This manual applies to all HQUSACE elements and all USACE commands having Civil Works and military design responsibilities.

3. Discussion. The CEM is divided into six parts in two major subdivisions: science-based and engineering-based. The first four parts of the CEM and an appendix were issued in 30 April 2002 and subsequently updated by change dated 31 July 2003. These included:

Part I, "Introduction"
Part II, "Coastal Hydrodynamics"
Part III, "Coastal Sediment Processes"
Part IV, "Coastal Geology"
Appendix A, "Glossary"

The engineering-based subdivision is oriented toward a project-type approach and is divided into two parts. Part V, "Coastal Project Planning and Design," is included in this transmittal. The text and figures provide information on the design process and selection of appropriate types of solution to various coastal problems. Part VI, "Design of Coastal Project Elements," which provides engineering guidance on materials, fundamentals of design, and reliability, is in preparation.

4. Distribution Statement. Approved for public release, distribution unlimited.

Chapter V-1
Planning and Design Process

V-1-1. Background

a. Introduction.

(1) Purpose. This chapter provides a comprehensive description of definitions and procedures needed in the planning and design process for coastal projects. The goal of the following sections is to provide the planner/designer with sufficient engineering guidance to accomplish the level of detail necessary to produce an acceptable finished product.

(2) Applicability. Although the information on procedures presented here is directly applicable to the reconnaissance and feasibility studies of the U.S. Army Corps of Engineers (USACE), it is also applicable to all other planning and design efforts because the process is generic. The process of developing a coastal project must be iterative to ensure that the final product is optimum from both the technical and economic viewpoints and will be acceptable to the various levels of decision makers and all project partners.

b. The planning process.

(a) The solution to coastal engineering problems begins with understanding the roles of the engineer as a planner and designer. These roles may be, and often are, embodied in the same person doing sequential tasks. This chapter presents the planning and design processes, the umbrella under which the project evolves from conception through functional detailed technical design phases. Examples of detailed technical designs are found in Part VI of this manual. Although the procedures and examples are those of the USACE, the principles apply to whomever is doing the planning and designing and follow a logical engineering process regardless of project type, scale, geographic siting, or sponsor.

(b) The planning process begins with the questions “What is the problem?” and “What exactly is the project trying to accomplish?” As trite as this sounds, these are the most important and the most difficult questions to answer. To achieve a successful coastal project plan and design requires that the engineer must have a completely open mind, one without preconceived notions of the ultimate form of the project or a specific solution to advocate. An example of a pitfall of the planning process is to answer the second question with “To design a breakwater” without first clearly stating the problem. Is the problem one of navigation difficulties in the vicinity of a harbor, or potential damage to buildings near the shorefront, or water quality problems in a bay? These are symptoms of a problem, but they do not define the problem.

(c) An interdisciplinary team approach is recommended in planning coastal projects to ensure the involvement of physical, natural, and social sciences personnel. The disciplines of the coastal project planners should be appropriate to the problems and opportunities identified in the planning process, and range from coastal, geotechnical, structural, and hydraulic engineers through meteorologists, oceanographers, biologists, and geologists, to economists, urban planners, and transportation specialists. Not all disciplines are needed on all studies, but the team leader needs to be cognizant of the possible need for such talents during the project development.

(d) Interested and affected agencies, groups, coast-sharing partners, and individuals (collectively termed the public) should be provided opportunities to participate with USACE throughout the planning, design, construction, and operation of a Federal project. The purpose of public involvement is to ensure that the project is responsive to the needs and concerns of the public. The objectives of public involvement are to

provide the public with information about proposed Federal activities; to make the public's desires, needs, and concerns known to the decision makers; and to consult with the public and consider the public's views before a decision is reached.

(e) In responding to the question of *problem definition*, the more detailed the engineer can make the statement, the more likely a solution can be found which will satisfy all the numerous stakeholders. A stakeholder is defined as anyone who will be affected by a problem and its potential solution, including a segment of the public. This includes the planner, designer, constructor, manager, all probable sponsors, riparian owners, project users, the political, legal, financial, and environmental entities with interests, and of course the populations that pay the taxes to support the enterprise.

(f) USACE has two levels of planning: one that looks at the problem in a relatively cursory way for a *reconnaissance* level study, and the other for a detailed study of all the factors, conditions, and alternatives for a *feasibility* level study. These terms are equivalent to conceptual design and final design as used in private practice. In the reconnaissance study, the objective is to determine if there is a Federal interest; that is, to determine if the Federal Government should invest in the solution to the problem. Responses are needed to three questions to make this determination: (a) is there a technically doable solution, (b) is it economically and politically feasible, and (c) is it environmentally sound? These are often difficult to answer, but keeping in mind all the stakeholders and the detailed problem definition, the coastal planner can proceed.

(g) Under present laws and regulations (as of the publication date of this manual), a reconnaissance level study is funded entirely by the Federal Government. To be "in the Federal interest," at least one technically adequate solution to the problem must be identified, a cost-sharing sponsor who will pay for one half of the feasibility study costs must be identified, and the economics of the potential solution must be such that the National Economic Development (NED) benefits are larger than the costs. More details of the planning process are found in ER 1105-2-100.

(h) Since reconnaissance and feasibility studies differ in their level of detail, the following discussion concentrates on feasibility requirements. The requirements of a feasibility study differ from those of a reconnaissance study in degree, not kind. A diagram is presented later in this chapter to assist the engineer planner/designer in going through all the steps needed for successful solution of a coastal engineering problem.

(i) In the case where a coastal project is planned and designed by other than USACE, Federal and state permits are usually required before construction can begin. (Requirements for USACE projects are discussed later in the chapter.) The USACE must ascertain that the proposed project would not harm the environment or adjacent property owners, that it would not interfere with navigation, and that water quality would not be impaired. Federal, state, and possibly local permits are required for construction in, across, under, or on the banks of navigable waters of the United States. Federal permits are coordinated by the applicant through the USACE District offices. Permit authorities are Section 10 of the River and Harbor Act of 1899 and Section 404 of the Clean Water Act of 1977, as amended.

Section 10 of the 1899 act requires permits for structures and dredging in navigable waters, which are those coastal waters subject to tidal action and inland waters used for interstate or foreign commerce. In tidal areas, this includes all land below the mean high-water line.

Section 404 of the Clean Water Act mandates a Federal permit for discharges of dredged or fill material in waters of the United States, which include tributaries and wetlands adjacent to navigable waters, and extends to headwaters of streams with flows greater that 0.142 m^3/sec (5 ft^3/sec). Wetlands are defined as "those areas inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal conditions do support, a prevalence of

vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas."

More detailed requirements for the permit process are found in Chapter 33 of the Code of Federal Regulations, paragraphs 320-330 (33 CFR 320-330).

(j) Still, the first question to be answered is: Exactly what is the problem? The more detailed the response, the easier it becomes to be sure all the important factors are considered. A more precise answer to the question posed earlier in this section might be: "The waves and currents in a harbor berthing area are of such magnitude that 30,000-ton tankers find it unsafe to berth there approximately 50 percent of the time." A statement of what the project is trying to accomplish might be "to provide safe berthing for 30,000-ton tankers at least 90 percent of the time." If this is an exact statement of the problem, then investigation is necessary to determine that the engineering, economic, and environmental conditions and constraints can all be resolved satisfactorily.

c. Six major planning steps. The planning process consists of six major steps:

(1) Specify problems and opportunities.

(2) Inventory and forecast conditions if no action is taken.

(3) Formulate alternative plans.

(4) Evaluate effects.

(5) Compare alternative plans.

(6) Select a plan.

The following paragraphs describe these steps in more detail.

(1) Specify problems and opportunities.

(a) The identification of a problem usually begins with a unit of local Government requesting, through its local congressional representative, that USACE investigate and solve a problem. The Senator or Representative then introduces a resolution, which when passed by the Senate or House of Representatives, authorizes USACE to study the problem. The problem and opportunity statements are framed in terms of Federal objectives as well as identifying state and local objectives. The statements are fashioned to ensure that a wide range of alternative solutions can be considered with identifiable levels of achievement.

(b) In the case of a small project, the Secretary of the Army, acting through the Chief of Engineers, may plan, design, and construct certain water resource improvements without specific congressional authorization. This authority is found in the six legislative authorities collectively called the Continuing Authorities Program. The per-project limit on Federal expenditures under the CAP is currently $2,000,000 for a small beach erosion control project (Section 103 of Public Law (PL) 87-874, as amended) and $4,000,000 for a small navigation project (Section 107 of PL 86-645, as amended). A complete discussion of the six legislative authorities, including that for the mitigation of shoreline erosion damage caused by Federal navigation works (Section 111 of PL 90-483, as amended), is found in ER 1105-2-100 Chapter 3.

(2) Inventory and forecast conditions if no action is taken. The next step is to identify the initial site characteristics. These include not only the physical dimension of the site and environs, but also the

biological, cultural, social, safety, political, economic, endangered species, and other environmental aspects such as auditory, olfactory, visual, etc. The complete description of these elements will help to define the positions of the various stakeholders and how they might influence the success of any proposal. If these concerns can be accommodated early on, and the parties made to feel a part of the process, then any compromises that might be called for later are easier to obtain. All alternative schemes are measured against the *without-project plan* (the conditions that would prevail in the future if no plan is constructed), in order to quantify the benefits that would accrue from the various alternative plans examined. This is an important step in the planning process since it is the foundation for evaluating potentials for alleviating the problems and realizing the opportunities. It sets a consistent base upon which alternative plans are formulated, from which all benefits are measured, against which all impacts are assessed, and from which plans are compared and selected.

(3) Formulate alternative plans. Alternative plans are formulated in a systematic manner during both the reconnaissance and feasibility studies to ensure that all reasonable alternative solutions are identified early in the planning process and are refined in subsequent iterations. Alternatives are not merely slight variations; for example, breakwater lengths of 200, 300, or 400 m, but significant ones, such as a breakwater construction, a saltwater barrier, or a harbor realignment. As the process is under way, additional alternatives may be introduced as the need or opportunity presents itself. A plan that reasonably maximizes the net NED benefits and is consistent with protecting the nation's environment, is identified as the NED Plan in the feasibility report. Other plans that reduce net NED benefits in order to further address other Federal, state, local, or international concerns should also be formulated. Each alternative plan is formulated considering the four criteria described in the Water Resources Council's Principles and Guidelines: completeness, efficiency, effectiveness, and acceptability (ER 1105-2-100). The period of analysis must be the same for each alternative plan and appropriate mitigation of adverse effects is an integral part of each alternative plan. It is usual for an economic life of 50 years to be selected for analysis. This does not imply that a coastal structure, such as a breakwater, would only last 50 years, but that analysis of benefits and costs is limited to that period. Alternative plans may include significant nonstructural components or may be completely nonstructural. It should be noted that this step usually involves many iterations in the development of the alternatives, and may also require a restatement of the problem if it is found that the functional needs are not completely met.

(4) Evaluate effects. The evaluation of effects is a comparison of the *with-* and *without-plan* conditions for each alternative plan. Differences between each with- and without-plan condition are measured or assessed, and the differences are appraised or weighted. Four accounts are established to facilitate the evaluation and display the effects of the alternative plans: NED, EQ, RED, and OSE.

NED: The *National Economic Development* account displays changes in the economic value of the national output of goods and services. A comprehensive treatment of analysis required for determining the economic benefits of coastal projects is found in U.S. Army Corps of Engineers (1991).

EQ: The *environmental quality* account displays the nonmonetary effects on ecological, cultural, and aesthetic resources.

RED: The *regional economic development* account registers the changes in regional economic activity. Regional effects are evaluated using nationally consistent projections of income, employment, output, and population.

OSE: The *other social effects* account registers plan effects from perspectives that are relevant to the planning process, but are not reflected in the other three accounts.

Display of the NED account is required. Since technical data concerning benefits and costs in the NED account are expressed in monetary units, the NED account already contains a weighting of the effects; therefore, appraisals are applicable only to the EQ, RED, and OSE account evaluations. Planners must also identify areas of risk and uncertainty in these analyses and describe them clearly so that decisions can be made with knowledge of the degree of reliability of the estimated benefits and costs, and of the effectiveness of the alternative plans (see Section V-1-3).

(5) Compare alternative plans. Plan comparison focuses on the differences among the alternative plans as determined in the preceding step. Both monetary and nonmonetary effects are compared. Again, if the functional requirements of a project are not met, it is time to go back and iterate the formulation step.

(6) Select a plan. After consideration of the various alternative plans, their effects, and public comments, the *NED Plan* is selected as the one to recommend for implementation, unless a justified exception is granted by the Assistant Secretary of the Army for Civil Works (ASA(CW)). The USACE feasibility report, along with expressions of related views by the ASA(CW) and the Office of Management and Budget, is then sent to Congress with a recommendation for authorization for construction.

d. Planning coordination requirements.

(1) Table V-1-1 lists some of the laws enacted to ensure that environmental effects of projects are fully taken into account in the planning process. These laws are briefly described below.

Table V-1-1
Major Coordination Requirements

National Environmental Policy Act, 1970, 33USC234.4
Fish and Wildlife Coordination Act, 1958, 16USC460-1(12) et seq
Coastal Zone Management Act, 1972, 16USC1451 et seq
Clean Water Act, 1977, 33USC1344 et seq
National Historic Preservation Act, 1966, 16USC470a et seq
Coastal Barrier Resources Act, 1982, 16USC3501

(2) The National Environmental Policy Act (NEPA) of 1970, as amended, ensures that all proposed Federal actions take full cognizance of the environmental effects of those actions. This act defines the NEPA process by which an environmental impact statement (EIS) [or an environmental impact assessment (EIA) for a lesser impact activity that does not require a statement] is prepared. (An EIA is sometimes prepared to determine whether an EIS is required.) The EIS is given wide circulation and the public comment and the Federal agency's response are incorporated in the USACE report of its proposed activity. It is through this process that any unforeseen impacts are uncovered and mitigation measures are proposed.

(3) The Fish and Wildlife Coordination Act of 1958, as amended, ensures that fish and wildlife conservation receives equal consideration with other project purposes and is coordinated with other features of any coastal development project. USACE consults with the Regional Director, U.S. Fish and Wildlife Service (FWS), the Regional Director, National Marine Fisheries Service (NMFS), and the head of the state agency responsible for fish and wildlife for the state in which the proposed work is to be performed. Funds are transferred to the FWS and NMFS to accomplish the investigations, and a Fish and Wildlife Report is made part of the USACE report.

(4) The Coastal Zone Management Act of 1972, as amended, ensures that all Federal activities are consistent with an approved coastal zone management plan for that state. If the Secretary of Commerce has approved a state's plan (all but five coastal states have approved plans), then USACE must receive state certification that its proposed activity is consistent with the state's plan.

(5) The Federal Water Pollution Control Act was enacted to regulate the discharge of pollutants. Subsequently the Clean Water Acts, as amended, required water quality certification by the Environmental Protection Agency or a designated state agency to ensure that the USACE-proposed project does not degrade the state's water quality, particularly through any dredge and fill activities.

(6) The National Historic Preservation Act of 1966, as amended, provides for the consideration of the effects of a proposed project on the cultural resources (including archeological and Indian religious and cultural sites) of the area. Studies are coordinated with the National Park Service, the Advisory Council on Historic Preservation, and the appropriate State Historic Preservation Officer.

(7) The Coastal Barrier Resources Act of 1982, as amended, requires that no Federal funds (with some exceptions) are expended in any undeveloped region designated as a unit of the coastal barrier resource system (CBRS). Most notable for coastal projects, a major exception is for beach nourishment since it mimics the natural processes; hard structures in conjunction with beach nourishment are prohibited on areas identified in this Act. Also, maintenance dredging in waters within the CBRS unit is allowed, but new work dredging is not; using sand for beach nourishment that comes from a borrow area within a CBRS unit is not generally permitted. Coordination with the Regional Director, FWS is required for all cases involving the CBRS.

e. Criteria development. The criteria needed to be established are those that must be used to determine at each step of the process whether the objectives of that step are met. This is quite site-specific, and as will be seen in the section describing the generic design chart, the questions are answered either "*yes*, it meets the objective" (go on to the next step) or "*no*, it does not meet the objective" (go back and either refine the question or pick another alternative.) The importance of adequately posing the problem in the first place is readily seen in this approach. The advantage of this method of defining the criteria is that as long as all the questions are answered, the result will be the optimum project that meets the originally stated problem.

f. The design process.

(1) Final design. To produce a final design, it is necessary to continue the iterative process begun in the planning of the project. The project is said to be at final design status when all of the objectives are met, and all the stakeholders are satisfied that an optimum design has been reached. If there are any unanswered questions, then the final design has not been reached, and another iteration is necessary. It is current USACE practice to include the final recommended design in the feasibility report, and if approved for construction, no further design work is needed. The engineer can proceed directly to plans and specifications when the project is approved for construction and funds for construction are appropriated.

(2) Plans and specifications. The documents required for a contract for construction to be awarded include the *plans and specifications* for the job. These incorporate any restrictions or other constraints on the contractor, and spell out the accuracy and tolerances appropriate to the job. The procedures for plans and specifications for construction of USACE projects are found in ER 1110-2-1200, and no further discussion is warranted here.

g. Construction and monitoring.

Although construction and monitoring are not part of the planning and design process, they must be considered before the design process is complete.

(1) Construction. In order to have a successful project, the work to be accomplished must be capable of construction, i.e., have bidability, constructibility, and operability (see ER 415-1-11). If no equipment is available that can do the work prescribed (for example, a crane capable of lifting breakwater armor units into place), then the project is not constructible. If sand for a beach nourishment job is found to be outside the limits of available dredging equipment capability, then the job is not constructible. Guidance for construction management of USACE projects is found in EP 415-1-260, and no further discussion is warranted here.

(2) Post-construction inspection and monitoring. Monitoring is an essential element of a USACE project. The degree of monitoring depends on how the data are to be used. There are two basic types of monitoring: for conformance of construction to the design and for evaluation of performance of the project. The second type is often neglected, although ER 1110-2-1407 and ER 1105-2-100 clearly specify that a monitoring plan and an operation and maintenance plan are to be prepared as part of every project for which USACE has a continuing responsibility. This is especially important in beach nourishment projects to determine when a renourishment is needed. Also, data on project performance are needed for the continuing improvement and refinement of prediction models for coastal projects.

h. Generic design chart.

(1) Figures V-1-1 through V-1-3 show the thought processes that occur in the planning and design of a coastal project. The thought processes to successfully engineer a solution to a problem are basically the same as for the solution of any problem, but for the ease of presenting appropriate examples, will be limited here to the discussion of coastal engineering problems. The diagram is quite comprehensive and represents the steps followed by all engineers in developing successful solutions to coastal problems. It can be modified, however, to fit the needs of the planner and designer.

(2) Figure V-1-1 is generic in the sense that navigation, shore protection, coastal flooding, storm damage reduction, environmental enhancement, or any other set of problems can be treated by following the steps outlined in the diagram. As discussed earlier in this chapter, the project begins with a need, from which an accurate statement of the problem is derived. Figure V-1-1 illustrates the path (or paths) typically followed in developing a coastal project, from initiation to cost completion phases, including the reevaluation and feedback loops. There are ten major segments of the process, with several blocks in each segment. They are designated by the letters in circles, and are keyed to the following list:

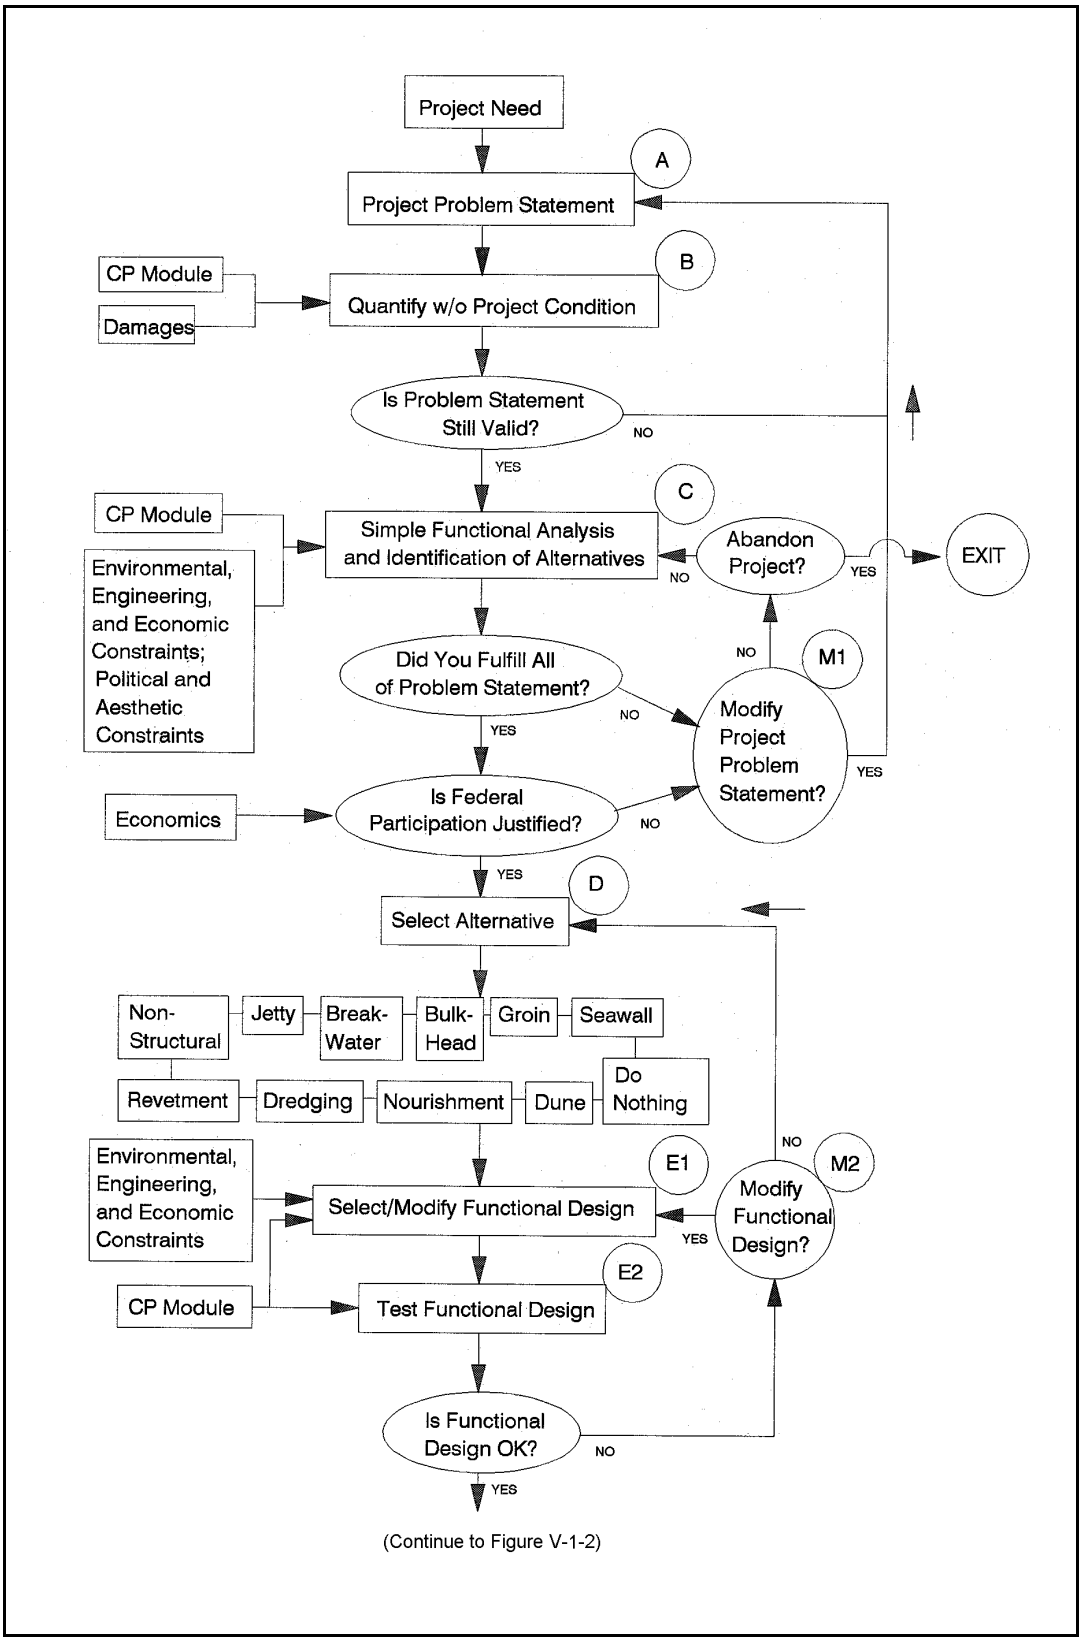

Figure V-1-1. Thought process in the planning and design of a coastal project, Part 1

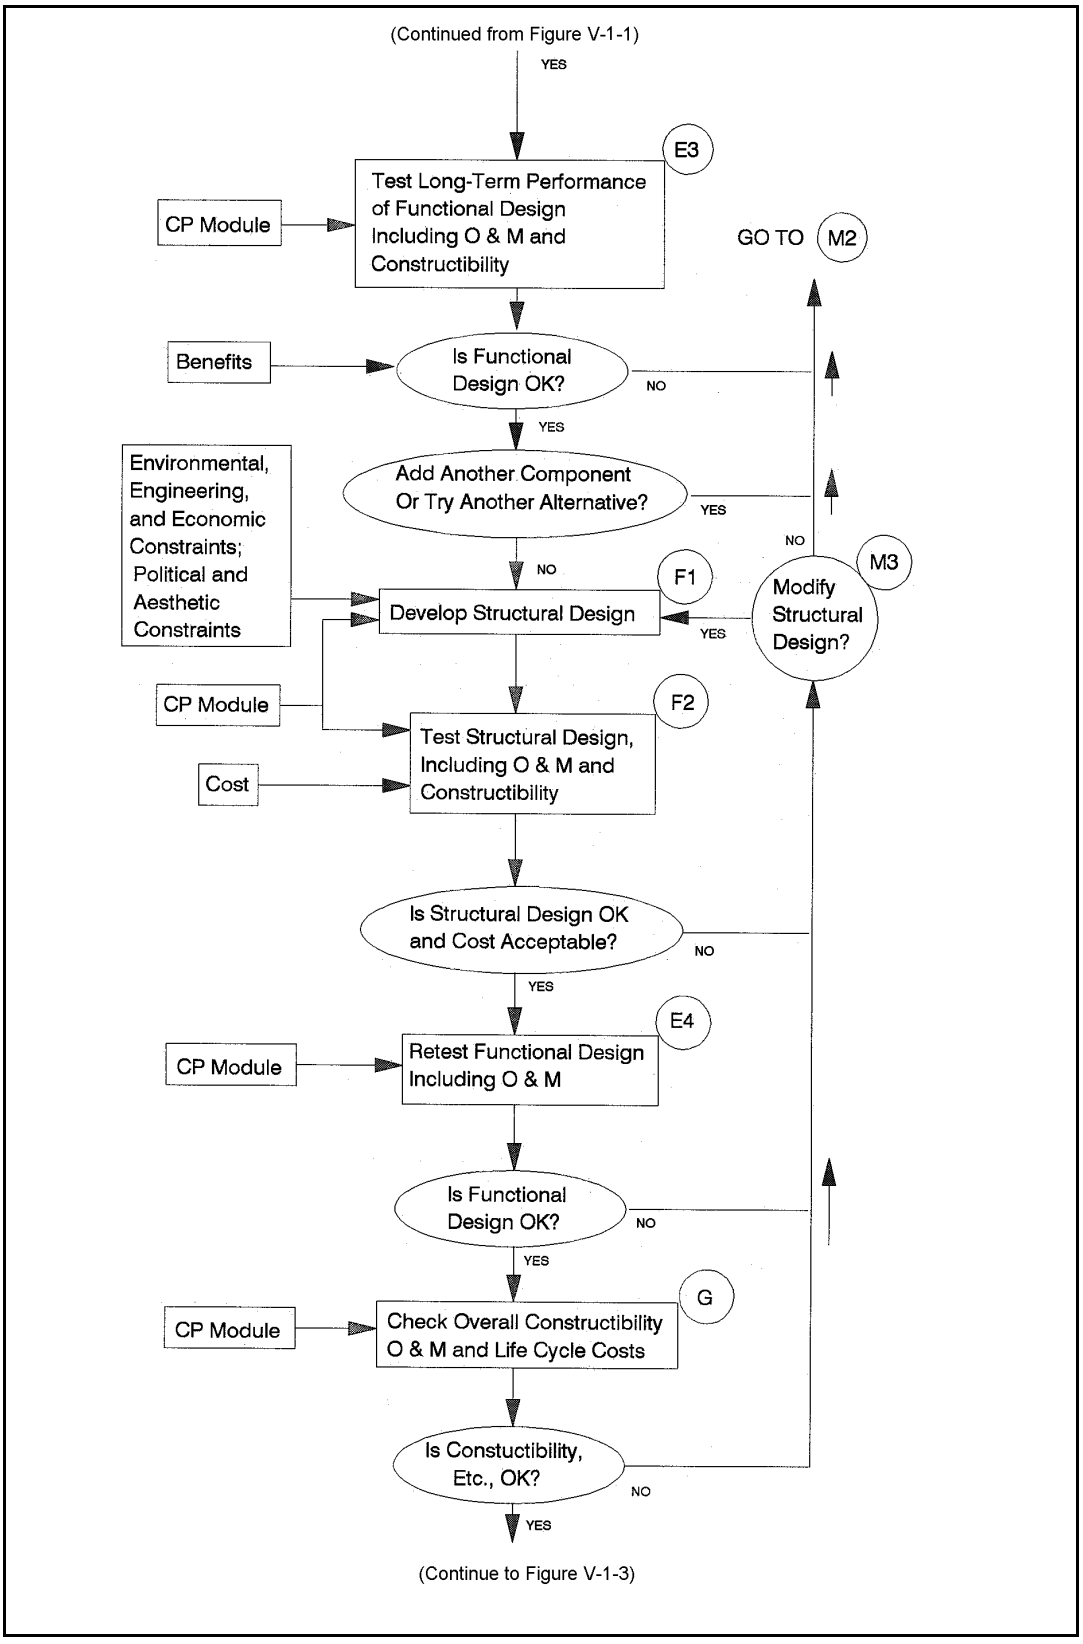

Figure V-1-2. Thought process in the planning and design of a coastal project, Part 2

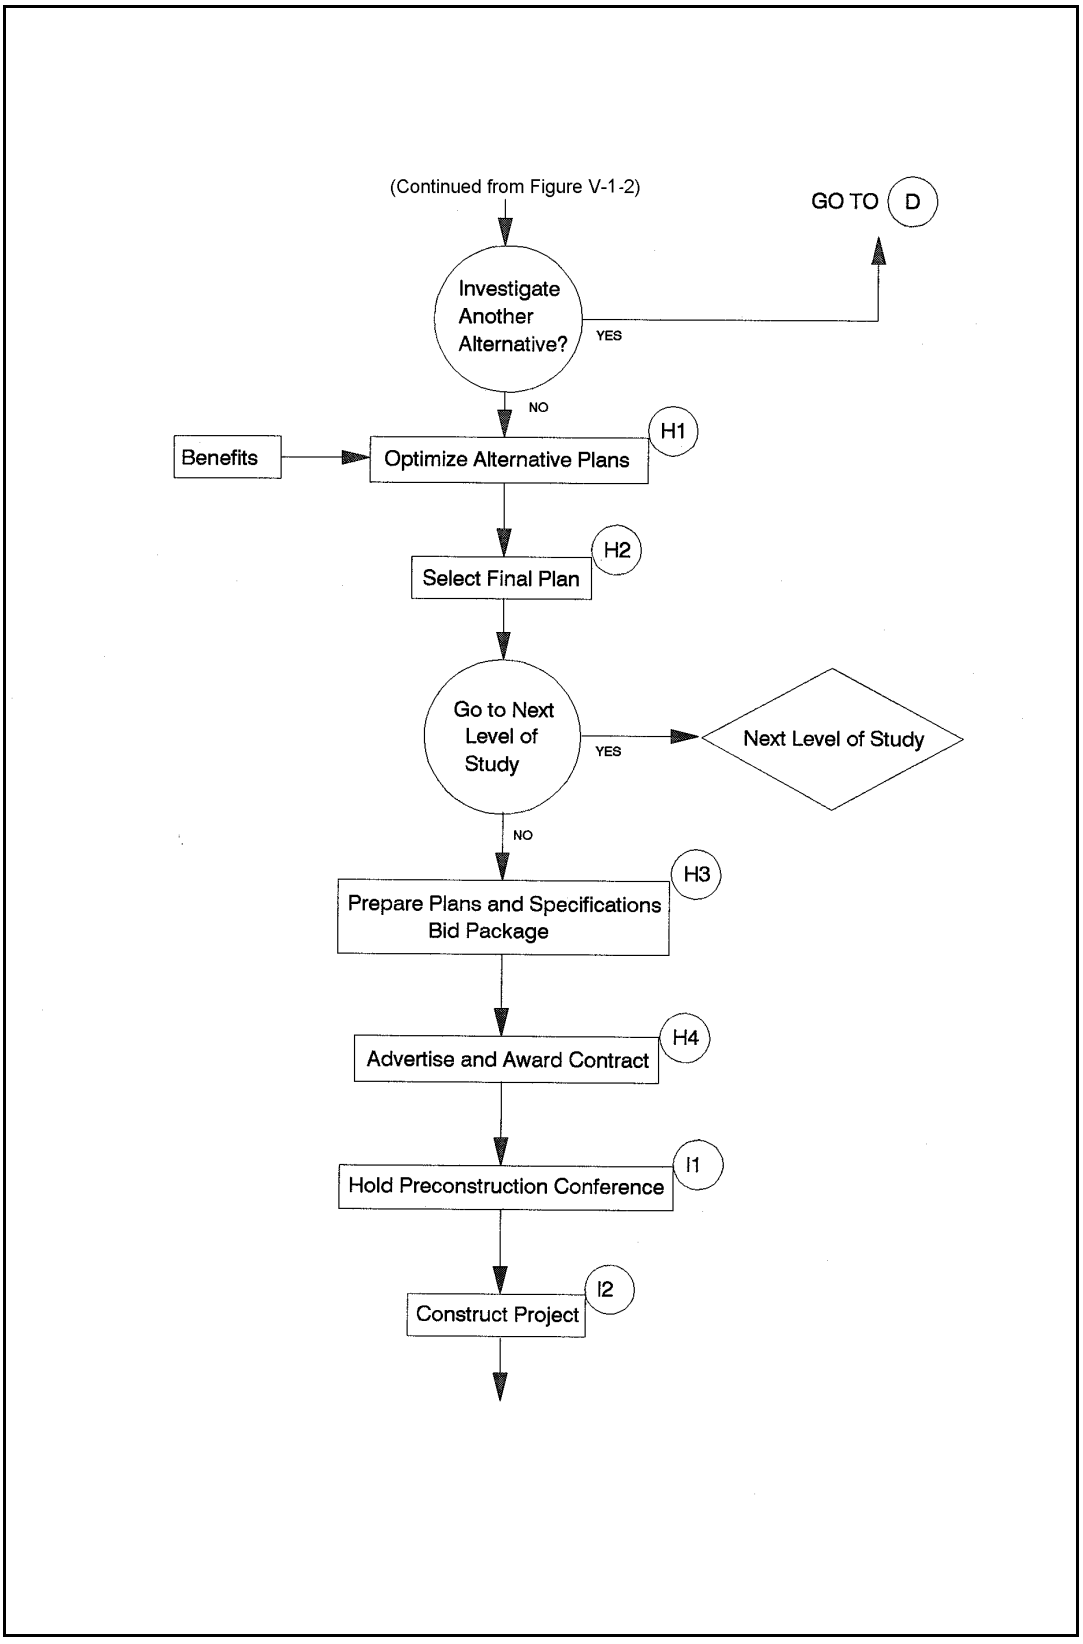

Figure V-1-3. Thought process in the planning and design of a coastal project, Part 3

(a) Clearly define project problem statement, including the project objective.

(b) Quantify existing and most likely future conditions (without project).

(c) Identify and analyze alternatives.

(d) Select alternative.

(e) Develop and test functional design.

(f) Develop and test structural design.

(g) Check for constructibility, operation and maintenance, and life-cycle costs.

(h) Select final plan, and prepare plans and specifications.

(i) Construct project.

(j) Monitor and evaluate project performance.

There are also several key segments concerning decisions about modifying various phases of the project; they are designated by the letter M.

(3) The term "functional design" refers to the effectiveness of a project at its intended function, such as the effectiveness of a breakwater at providing tranquil waters inside a harbor. "Structural design" refers to the ability of a structure to exist in the climate in which it is placed, such as the ability to withstand the effects of extreme storms without affecting its functional requirements. The term "constructibility" refers to the means, methods, and materials involved in successful project construction.

(4) In the diagram, the notation "CP Module" designates a generic concept of a Coastal Processes Module, a repository of physical data and analysis tools relevant to the coastal problem. The module includes information on wind, waves, currents, water levels, bathymetry, geomorphology, stratigraphy, sediment characteristics, sediment transport, ice processes, etc. The output from this module is needed at many points in the process. At the present time, portions of a module exist as limited databases and tools; however, a complete, integrated module, similar to the generic model, is under development, but is yet a long way from completion.

V-1-2. Design Criteria

a. Design criteria are the minimum parameters of design that are followed to ensure that the project function and structure (if any) meet the needs of a customer. A design is based on a number of design criteria that include: forcing function criteria, configuration criteria, materials criteria, geotechnical criteria, construction criteria, maintenance criteria, and economics criteria. These criteria are partly interrelated and partly independent of each other. Materials may depend on configuration, construction (including availability of equipment and manpower), and maintenance criteria. Construction may depend on configuration and materials (including availability). Maintenance depends on materials and construction.

b. Forcing function criteria must always be seen in relation to configuration, materials, and geotechnical criteria. For example, the "design storm" is an obsolete concept. Short- and long-term wave statistics are needed, and the hydrodynamics of wave interaction with its surroundings must be known in detail. The parameters of wave height, wave period, storm duration, and surge water level are quasi-independent

components of a storm whose effects on a design need to be understood to adequately examine the alternatives. The frequency of occurrence (or the return period) of an event (such as a storm) is a primary component of the wave criteria. These concepts are fully discussed in Part II of this manual.

c. Criteria that need to be considered in all coastal projects are: safety, accessibility (as defined by the American Disability Act), and environmental effects. All other effects are highly site-specific, and in addition to those cited above, include project area use, materials corrosion, ice, structural unit stability, subsurface foundations, and susceptibility to seismic events (i.e., earthquakes or tsunamis).

d. In every case, the criteria must be measured against the function to be satisfied by the proposed coastal project. If the alternative does not adequately address the need, then the function is not fully satisfied, and either the problem must be restated or another alternative must be investigated. As discussed in earlier sections of this chapter, the iterative process of planning and design requires the above-cited criteria be used to evaluate each step in the process. Design criteria relative to specific project types are discussed in the remaining chapters of Part V.

V-1-3. Risk Analysis and Project Optimization

a. Introduction.

(1) The approach for analyzing coastal projects is undergoing some fundamental changes, shifting from the traditional deterministic basis to a probabilistic, risk-based methodology. The changes strongly impact both planning and engineering phases of project formulation and design. Concepts of risk analysis and probabilistic optimization of project design are presented in this section. The remaining chapters in Part V include further information on the subject in relation to specific project types. As of this writing, risk-based analysis is a rapidly emerging tool, and significant advances can be expected during the next few years.

(2) The changes in analysis approach, which can be expected to be distilled into a new standard for coastal practice, are driven by several progressive developments. First, general understanding of probabilistic coastal processes continues to advance, particularly due to advances in field measurement, physical modeling, and numerical modeling. Second, standard computing capabilities are increasing rapidly, facilitating lengthy probabilistic calculations which would have been impractical in the past. Third, engineers, cognizant of limitations in the traditional approach, are often eager to implement better procedures, provided that they are well-founded and clearly improve the analysis. Finally, the public is becoming more aware and concerned about coastal project performance, and expects realistic project analyses. In the United States, public involvement in coastal projects is further intensified by legislation which increases the proportion of costs borne by the client (typically state or local Government) in Federal projects.

b. Traditional vs. Risk-based analysis.

(1) Traditional analysis treats a coastal project in deterministic terms. The forces of nature are often represented as a design significant wave height, period, and direction, a design water level, etc. Coastal response is described as *the* response if no project is implemented, *the* response if one plan is implemented, *the* response if another plan is implemented, etc., without much formal recognition of the wide variation in possible responses.

(2) In contrast to traditional analysis, some significant developments in probabilistic treatment of coastal projects have appeared during the 1990's. Most relate to coastal structure design (Construction Industry Research and Information Association/CUR 1991, International Conference on Coastal Engineering (ICCE) 1992). Within USACE, water resource planning guidance has moved from a deterministic to a risk-based

approach, which incorporates considerations of risk and uncertainty. Similar concepts are now being adapted to USACE coastal engineering studies.

c. Reasons for risk-based analysis.

(1) Introduction. There are a number of reasons why coastal projects in the broader sense, not just structural design, may be effectively analyzed from a risk-based point of view (Table V-1-2).

Table V-1-2
Reasons for Risk-Based Analysis of Coastal Projects

(1) Forcing is probabilistic.
(2) Major uncertainties in behavior.
(3) Damage & functional performance change incrementally.
(4) Benefits and risks not fully represented in deterministic terms.
(5) Uncertain effects on adjacent areas.

(a) Coastal forcing is probabilistic. Wave characteristics vary greatly over both short-term (individual waves) and long-term (from one sea state to another). Similar considerations arise with winds, water levels, infragravity waves, and currents.

(b) Coastal engineering embodies major uncertainties. Knowledge of both the forcing processes and coastal response usually involves major uncertainties. Deterministic representations mask the uncertainties and can be misleading.

(c) Damage and functional performance change incrementally. Coastal projects rarely progress from the design condition to total failure during a single storm event. Damage usually occurs incrementally. For example, damage to a rubble-mound breakwater (when it occurs) typically begins during an unusually severe storm and progresses during subsequent severe storms until repairs are done. Similarly, beach fills erode incrementally in response to storms over a period of years. Coastal projects often continue to provide some measure of functional benefit even in a damaged state. A damaged breakwater continues to provide some protection from incident waves; a partially eroded beach fill continues to reduce coastal flooding risks.

(d) Benefits and risks not fully represented in deterministic terms. Because of the above factors, positive impacts and risks of coastal projects cannot be fully represented in deterministic terms. Some projects provide benefits beyond the design configuration, which are generally ignored in traditional practice. For example, a nearshore berm which is overbuilt to allow for progressive deterioration provides increased coastal protection during its early life. Another example is an overdredged entrance channel giving increased vessel access depths until it shoals to the design depth.

(e) Uncertain effects on adjacent areas. In addition to the uncertainties associated directly with coastal projects, the projects can introduce significant possibilities for changing adjacent areas. While projects are designed with the intent of minimizing adverse impacts on adjacent areas, it is important to recognize that uncertainties and risks can increase beyond the without-project condition. In effect, a project can transfer risk from one area or party to another. When the risks of *all* major aspects of a project are represented as best they can be determined, better-informed final decisions can be made.

(2) Professional judgement. Experienced coastal engineers are well aware of the concerns in Table V-1-2. Even with deterministic methods, they can be expected to produce project plans that include a large measure of professional judgement to ensure a technically successful project. However, the ultimate fate of a project can depend upon higher level decision makers who must weigh technical concerns against economic, environmental, aesthetic, social, and political concerns. By quantifying risks, the coastal engineer can better pass his or her experience and judgement on to other decision makers, who may not have coastal expertise.

d. Considerations for including risk-based analysis in project design

(1) Objectives. The main objectives of adopting a risk-based analysis approach rather than a traditional approach are to explicitly identify uncertainties, provide improved information for assessing tradeoffs between risks and cost, and improve decision-making for project optimization.

(2) Key variables. Although a large number of variables affect any coastal project, a small subset can usually be identified as *key variables*; that is, variables that strongly relate to project performance. The key variables will embody the main forcing mechanisms, project sizing, and project response. For example, some of the key variables for a beach nourishment project might be significant wave height (forcing), beach fill width (project size), and erosion width (response).

(3) Professional judgement. Coastal engineering requires an unusually large measure of professional judgement because of the number and complexity of processes and responses involved. Analytical and modeling tools help to represent the variability affecting coastal projects, but the judgement of an experienced engineer is a vital ingredient in risk assessment and project optimization.

(4) Resistance and functional performance vary with time. Both the resistance to damage and functional performance often vary significantly over a coastal project's design life. For example, the resistance (or structural strength) of a rubble-mound breakwater may decrease in time due to deterioration of stone such as loss of angular corners, cracking, and breaking. Resistance may also decrease due to displacement of stone and exposure of underlayers to wave attack, which would also decrease protection provided by the breakwater (functional performance). For a beach nourishment project, loss of material to storms decreases the resistance of the beach to future storms. The effectiveness of the beach as a deterrent to coastal flooding is also decreased (functional performance). In some cases, resistance *increases* with time, as in the progressive growth of protective vegetation on coastal dunes and natural cementation of beach sediments rich in calcium carbonate.

(5) Construction season and mobilization concerns. Often maintenance of coastal projects requires major mobilization efforts and is confined to a *construction season* dictated by climate and environmental factors. Therefore the risk during the *interval between construction seasons* rather than during a single storm becomes a key concern. During an unusually stormy winter (such as the winter of 1987-88 in southern California), this risk can be significantly greater than that for individual storms.

(6) Environmental, aesthetic, social, and political concerns. The role of environmental, aesthetic, social, and political factors in the ultimate planning and design of a coastal project is often at least as important as the technical engineering factors. An optimized final design includes appropriate consideration of these factors and their associated risks and uncertainty.

e. Frequency-based vs. life cycle approach.

(1) Risk-based analysis of coastal projects can be done by either of two fundamentally different approaches. The *frequency-based approach* deals with frequency-of-occurrence relationships among the key variables. By combining key forcing variables with various occurrence frequencies, information about the

frequency-of-occurrence of key project responses can be developed. For example, a traditional stage- (water level)-versus frequency curve and a stage-damage curve can be combined to generate a damage-versus-frequency curve. This approach can be applied as an add-on to traditional planning and design procedures.

(2) The *life cycle approach* deals with multiple realizations of possible evolution of the project with *time* during the span of its design life. The suite of life cycle realizations is constructed with consideration of the probabilities of key variables. For example, the realistic time variation of key forcing and response variables during a 50-year life cycle can be generated for 1,000 different possible life cycles. Probabilities and risks associated with the project are then compiled by analyzing project performance over the 1,000 life cycles.

(3) The life cycle approach appears better suited to most coastal engineering applications. Variation with time is an essential ingredient in most coastal projects, and it is directly incorporated into the life cycle approach. Time variation of resistance and functional performance, constraints imposed by construction season and mobilization, even some economic, environmental, and political factors, can be conveniently and flexibly introduced into the life cycle approach. This approach leads to a unified analysis of technical performance and many economic factors which are critical to project success. In addition to its technical and economic strengths, the life cycle approach is more easily understood by nontechnical parties involved with a project. This type of approach is evident in the Empirical Simulation Technique (Chapter II-5).

(4) The life cycle approach adapted to shore protection projects is particularly instructive (U.S. Army Corps of Engineers 1997). The life cycle embodies sequences of storms (including provisions for multiple storms of varying intensity during each year of the life cycle), erosion and post-storm recovery during each event, partial and complete property damage during each event (depending on water level, waves, extent of storm erosion, and type of building construction), cumulative property damage due to a succession of storms, optional repair or rebuilding after a suitable time lag (with conformance to any stricter building codes in effect), and periodic renourishment of the beach when needed and feasible during the life cycle. Typically, a key result from this analysis is the renourishment required during each life cycle, which can be converted to an economic present-worth dollar value. The expected cost and economic risks associated with maintaining the beach can then be realistically assessed by combining information from many different life cycle simulations.

f. Typical project elements. Risk-based analysis can be integrated into the six major planning steps (Section V-1-1b(2). Typical project elements which are especially well-suited to risk-based analysis include the following.

(1) Site characterization. Significant uncertainty can arise in documenting past and present behavior at a site. The uncertainty can be estimated based on data quality and quantity, methodologies used, observed variability, etc. (Chapter V-3).

(2) *Without-plan* alternative. Evaluation of what would happen in the future if no Federal project were built involves speculation about the natural processes and human interventions that would affect the site during the proposed project life. The impact of the *without-plan* alternative is conveniently described in probabilistic terms.

(3) Formulate, evaluate, and compare alternative plans. Risk-based analysis can be a powerful tool for formulating and comparing alternative plans. It enables decision makers to intercompare not only the expected level of performance, but also the probabilities of enhanced or reduced performance levels, which can differ greatly among alternatives. Typically, alternatives involve hard structures (such as walls, revetments, breakwaters, and jetties) and/or soft structures (such as beach nourishment projects, coastal dunes, and nearshore berms). Risk-based analysis of hard structures is discussed in Part VI. Soft structures (Chapter V-4) involve calculated risks about the movement of sediment through time and the need for future

maintenance. Uncertainties arise in forcing processes, sequencing of storms, initial state of nearshore profile when storms occur, and evolution and recovery of storm profiles (especially three-dimensional aspects). The life cycle approach to risk analysis has been shown to be a powerful tool in this type of application.

Chapter V-2
Site Characterization

V-2-1. Introduction

a. Many coastal failures can be traced back to inadequate site characterization analyses. Site characterization involves identifying distinguishing qualities and features of a region that have a direct and indirect impact on the conception, design, economics, aesthetics, construction, and maintenance of a coastal project. The coastal environment varies spatially and temporally and therefore a design that is functionally, economically, and environmentally appropriate at one location may be inappropriate at another. Physical, biological, and cultural attributes need to be delineated so that an acceptable project is adopted and potential effects of the project are determined.

b. Waves bring an enormous amount of energy to the coast that is dissipated through wave breaking, generation of currents, water level changes, movement of sediment, turbulence, and heat. Incident waves vary spatially and temporally, with their properties changing with movement over the bottom. The beach is composed of sediment particles of various types, sizes, and shapes which move along and across the shore. The beach and backshore exhibit different textural properties that vary alongshore, across-shore, and with time. The coastal region supports a diverse biological community of aquatic, terrestrial, and avian organisms. It also must continue to enhance the quality of human existence by providing commercial and recreational benefits. In light of the profound diversity of the coastal zone, it is imperative that the coastal designer have a full understanding of potential impacts of engineering activities on the regional environment.

c. This chapter enumerates important physical and engineering factors that should be identified. Readers are directed to other pertinent sections of this manual for specific details on monitoring the coastal environment and for information on the physics of coastal processes. Not all factors described in this chapter pertain to all coasts. For example, ice and volcanic hazards are not applicable to a Gulf Coast project design. However, most factors should be included in all other site characterizations.

d. General Design Memorandums (GDMs) and monitoring reports (Table V-2-1) prepared by U.S. Army Corps of Engineer (USACE) Districts may be consulted for examples of site characterization studies. The Alaska Coastal Design Manual (U.S. Army Corps of Engineers 1994) also summarizes important site characterization features.

e. In summary, it is important when characterizing a site to:

(1) Include **all components** of the system.

(2) Recognize the extreme **temporal variability** in most physical and biological processes.

(3) Be cognizant of the **spatial variability** of processes, climate, land forms, underlying geology, biological habitat, and cultural resources. Process measurements made at one site may not be valid at another site only a short distance away.

f. In conclusion, the designer must think globally and engineer locally.

V-2-2. Defining Project Area and Boundary Conditions

a. The total project area encompasses not only the physical limits of the project but also the area in which the project has an effect upon littoral processes. The physical limits of a proposed project usually are predetermined by the local sponsor for the area of interest. Often this is defined by property limits (municipal park, business district, navigation inlet, etc.) and legislative authority. Project boundaries are sometimes defined by the limits of available historic data - particularly bathymetric data. Economic analysis of the project may lead to modification of these limits if a project along the entire reach cannot be economically justified, or is not technically feasible or environmentally acceptable.

b. It is imperative that a project designer be cognizant of potential impacts of the project on the adjoining coast. Mitigation due to disruption of littoral movement is often necessary. Legal requirements for replacement of sediment loss using bypassing or introduction of an equivalent quantity downdrift vary with locality. For example, the state of Florida (1987) requires:

(1) *All construction and maintenance dredging of beach-quality sand should be placed on the downdrift beaches: or, if placed elsewhere, an equivalent quality and quantity of sand from an alternate location should be placed on the downdrift beaches.*

(2) *On an average annual basis, a quantity of sand should be placed on the downdrift beaches equal to the natural net annual longshore sediment transport.*

The lack of legal requirements does not absolve the project designer of responsibility to mitigate project impacts.

c. In order to establish the potential physical impact of the project, a sediment budget for the entire littoral cell in which the project will reside must be determined. A sediment budget quantifies the amount of sediment moving within a littoral cell. A littoral cell is a self-contained reach of coast with its own sand sources and losses or sinks. Updrift and downdrift boundaries (the location at which most, if not all, sediment enters or leaves the cell) may be formed by natural barriers such as a headland or prominent protruding structures. In developing a sediment budget, information on the sources and characteristics of materials, modes and direction of transport in the littoral zone, rates of sediment supply, and transport and loss is required. Complete understanding of the boundaries, significance of individual sources, littoral drift direction and volumes, and sinks is crucial to estimating the effect of any engineering intervention in the littoral system and helps define the project area. Part III presents a complete description of sediment transport processes.

d. Development of the sediment budget will assist in establishing the amount of mitigation required. If no mitigative measures are enacted, the more difficult question will be to determine how erosion, due to loss of sediment, is distributed downdrift as a function of time. To answer this question, the three parameters that need to be identified are (a) length of the adversely affected shore; (b) cross-sectional retreat of the erosion cut; and (c) rate of expansion of erosion, and its distribution downdrift as a function of time (Bruun 1995). It has been observed that a littoral drift barrier has a short- and long-distance influence on the downdrift shoreline as briefly discussed in Section V-2-8. The reader is directed to Bruun (1995) for a discussion on examples of downdrift shoreline impacts and the short- and long-distance influence of a littoral barrier.

V-2-3. Storm Characteristics/Meteorology

a. Storm types.

(1) A storm is an atmospheric disturbance characterized by high winds that may or may not be accompanied by precipitation. Two distinctions are made in classifying storms: a storm originating in the tropics (5 to 350 deg in both hemispheres) is a tropical storm, a storm resulting from a cold or warm front in the middle and high latitudes (30 to 60 deg) is an extratropical storm (Silvester and Hsu 1993). Both storms can generate large waves and produce abnormal rises in water level in shallow water near the edge of water bodies.

(2) A hurricane is a severe tropical storm with maximum sustained wind speeds of 120 km/hour (75 mph or 65 knots). These low pressure centers are known by different names geographically: hurricanes on the east coast of the Americas, typhoons in the western Pacific, monsoons in the Indian Ocean, and tropical cyclones in Australia (Silvester and Hsu 1993). Hurricanes, unlike less severe tropical storms, generally are well-organized and have a circular wind pattern with winds revolving around a center or eye. The eye is an area of low atmospheric pressure and light winds. The Coriolis force causes the radial inflow to rotate counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere. Atmospheric pressure and wind speed increase rapidly with distance outward from the eye to a zone of maximum wind speed, which may range from 7 to 110 km (4 to 70 statute miles) from the center. From the zone of maximum

wind to the periphery of the hurricane, pressure continues to increase; however, wind speed decreases. Atmospheric pressure within the eye is the best single index for estimating surge potential of a hurricane. This index is called the Central Pressure Index (CPI). Central pressures of 950-960 mb (28.0 - 28.3 in.) are common. Hurricane Ida in the Philippines in 1958 had an extremely low pressure of 877 mb (25.9 in.) (Eagleman 1983). Generally, for hurricanes of fixed size, the lower the CPI, the higher the wind speeds.

(3) Unlike tropical storms, which generally occur in summer, extratropical storms generally occur in winter. These depressions in the middle latitudes consist of warm and cold air fronts which rotate about a low pressure center. Winds are not as intense as hurricanes since their horizontal scale is greater with a lesser pressure gradient. However, extratropical storms tend to have a longer duration and their destruction effects may be felt over large areas. Extratropical storms that occur along the northern part of the east coast of the United States, when accompanied by strong winds blowing from the northeast quadrant, are called nor'easters. Nearly all destructive nor'easters have occurred between November and April. Extratropical storms produce the dominant large wave conditions in the Great Lakes and generally occur between mid-October and April. The size of a typical storm of this type is shown in Figure V-2-1 (Resio and Vincent 1976).

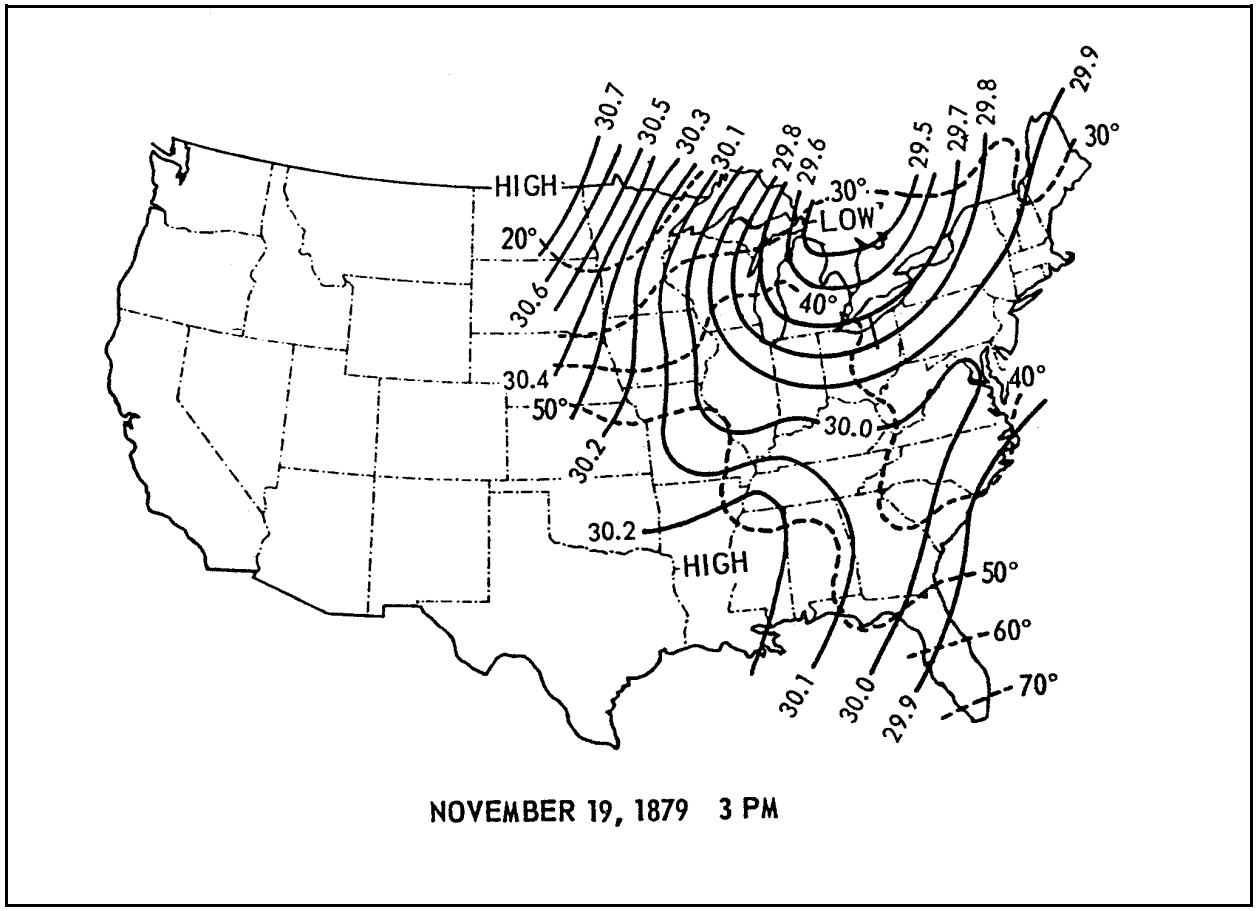

Figure V-2-1. Isobaric pattern of a typical extratropical low in the Great Lakes Region (Resio and Vincent 1976)

b. Storm characteristics. Depending upon availability of observed hurricane data for the open ocean coast, the design analysis for coastal structures may not be based on measured water levels and waves. A statistical approach has evolved that takes into account the expected probability of occurrence of a hurricane with a specific CPI at any particular coastal location. Statistical evaluations of hurricane parameters, based on detailed analysis of many hurricanes, have been compiled for coastal zones along the Atlantic and U.S. Gulf coasts. Parameters that need to be evaluated are radius of the maximum wind, minimum central pressure of the hurricane, forward speed of the hurricane while approaching or crossing the coast, and maximum sustained wind speed at 10 m (33 ft) above the mean water level. Table V-2-2 presents extreme pressure and wind data for hurricanes recorded along the Alabama coast between 1892 and 1969 (U.S. Army Engineer District, Mobile 1978).

Table V-2-2
Extreme Pressure and Wind Data of Hurricanes Recorded along the Alabama Coast between 1892 and 1969 (U.S. Army Engineer District, Mobile 1978).

c. Hypothetical hurricanes. The National Weather Service and the U.S. Army Corps of Engineers have jointly established specific storm characteristics developed from statistical consideration. Since parameters characterizing these storms were statistically derived, they are known as hypothetical storms. Parameters for such storms are assumed constant during the entire surge generation period. The Standard Project Hurricane is defined as a hypothetical hurricane that is intended to represent the most severe combination of hurricane parameters that is reasonably characteristic of a region excluding rare combinations. The Probable Maximum Hurricane is defined as a hypothetical hurricane having that combination of characteristics which will make the most severe storm that is reasonably possible in the region involved if the hurricane should approach the

point under study along a critical path and at an optimum rate of movement. The reader is directed to Part II, Chapter 2 for further discussions on meteorological systems and waves.

V-2-4. Hydrodynamic Processes (Design Sea State, Water Levels, Currents)

a. Design condition.

(1) In selection of design water levels and waves for a project, critical conditions must be considered. These represent critical threshold combinations of tide level, surge (or setup) level, wave conditions and local runoff, which, if surpassed, would endanger the project and/or make the project nonfunctional during their occurrence. It should be recognized that water levels have a direct impact on wave conditions in shallow water. Conversely, waves can have some impact on the water level through wave-induced setup.

(2) In selection of the design condition for the project, it is important to consider the intended structural integrity, and functional performance. Structural integrity relates to the structure's ability to withstand effects of extreme storms without sustaining significant damage. Structural integrity criteria determine the structure's life-cycle costs to the extent that a certain level of investment is necessary to prevent damages from an extreme event. Functional performance determines the incremental economic benefits of a project since it defines the structure's level of effectiveness. For example, the crest height of a shore dike to prevent flooding should be optimized for different storm frequencies with consideration of interior ponding elevations (and damages) in comparison to costs of different structure heights. In performing analyses, one must be aware of the risk and uncertainty inherent in the design process. See U.S. Army Corps of Engineers (1992) for a discussion on risk and uncertainty analysis in water resources planning.

b. Design wave height and period.

(1) Most coastal projects require an estimate of characteristics (height, period, direction and frequency of occurrence) of wind-generated gravity waves at the project site. In the Pacific basin, tsunamis also may need to be considered. Wave characteristics are determined outside the surf zone and then transferred to the project site by considering refraction, diffraction, reflection, shoaling, and breaking effects. Part II, Chapter 3 discusses methods to estimate nearshore waves with guidance for performing wave transformation studies.

(2) Wave data sets are available as summaries of visual observations, wave hindcasts and wave gauge statistics. Shipboard observations generally represent deepwater wave conditions over large areas. For coastal areas of the United States, summaries have been published in Department of the Navy (1976). The USACE's Wave Information Study (WIS) has developed wave hindcasts along U.S. coasts, the Great Lakes, and some international locations. These hindcasts generally consist of wave height, period, and direction time series and summary statistics. WIS data are available on the World Wide Web (WWW) at:
http://chl.erdc.usace.army.mil/CHL.aspx?p=s&a=DATA;1
or at:
http://frf.usace.army.mil/wis/

(3) Wave data can be measured by various forms of floating and bottom-mounted wave gauges. If available for a project site, actual measured data are preferred to hindcasts because these data are obtained by physical measurement. While the amount of wave gauge data may be spatially and temporally limited, they can be used to confirm hindcasts. If the physical measurements include significant storms (Figure V-2-2), this data can confirm hypothetical design storm size and effects. Wave gauge data collected by the Coastal and Hydraulics Laboratory (CHL) can be accessed at:
http://sandbar.wes.army.mil/public_html/pmab2web/htdocs/dataport.html

Wave data, extremal analyses, climatic summaries, buoy data, and aerial photographs, arranged geographically, can be found at the CHL web page:
http://chl.erdc.usace.army.mil/chl.aspx?p=s&a=Data;0
Wave data from the west coast is available from the Coastal Field Data Information Program:
http://cdip.ucsd.edu/
Buoy wave data and meteorological observations can be found at the National Data Buoy Center's web page:
http://www.ndbc.noaa.gov/

c. Design water level.

(1) Storm surge at the shoreline due to a rise in water level above the still-water level is of more interest to the design engineer. Peak surge is generally used to establish design water levels at a site. The highest water levels that occur along the Gulf Coast, the east coast of the United States from Cape Cod to south Florida, and the Hawaiian Islands are generally the result of tropical storms. At most other U.S. locations, high water levels result from extratropical storms. The state of Alaska has experienced peak storm surges over 4 m (13 ft) high. (State of Alaska 1994). Storm surge interaction with tidal elevations is discussed in Chapter II-5, along with methods to determine storm event frequency-of-occurrence relationships.

(2) While large inland water bodies such as the Great Lakes experience negligible tidal fluctuations, they encounter fluctuating water levels due to variations in the hydrologic cycle coupled with storm surges (wind setup) resulting from extratropical storms. Significant water level setup is possible on large shallow inland water bodies, such as Lake Okeechobee, Florida, and Lake Erie of the Great Lakes. Peak water level relationships have been determined for various locations along the Great Lakes coast (U.S. Army Engineer District, Detroit 1993a). Figure V-2-3 presents a lake elevation hydrograph for the December 2, 1985 event on Lake Erie (National Oceanic and Atmospheric Administration (NOAA) 1985).

(3) A complete discussion on tides, surges, and seiches is presented in Chapter II-5. This chapter should be reviewed to determine the type of data required for the study being performed. NOAA is the most comprehensive source of global tide predictions in tables of time and heights of high and low tides, tidal current tables for U.S. coasts, tidal current charts for selected harbors, and other summaries of tidal predictions for selected areas. They may be contacted at:

NOAA National Ocean Service
Tidal Datums and Information Section
6001 Executive Boulevard
Rockville, MD 20852

NOAA'S WWW site lists availability of tide data, charts, and other material.

V-2-5. Seasonal Variability

Recognizing seasonal variability of waves and currents along the coast is important to appropriately interpret historic data and predict a project's response. This variability has effects on littoral transport quantities and direction, and gross profile shape. Alternate erosion and accretion may be seasonal on some beaches; winter storm waves erode the beach and summer swell waves rebuild it. Just as insufficient data can lead to erroneous conclusions, information obtained only during a particular season can lead to similar results. Most ocean coasts experience periods during which storm or swell waves dominate, although both can occur simultaneously. As mentioned in Section V-2-3.a, tropical and extratropical storms occur only during a portion of the year. The WIS wave hindcast (Section V-2-4.b) is a source of storm and swell wave conditions along the U.S. coasts and Great Lakes.

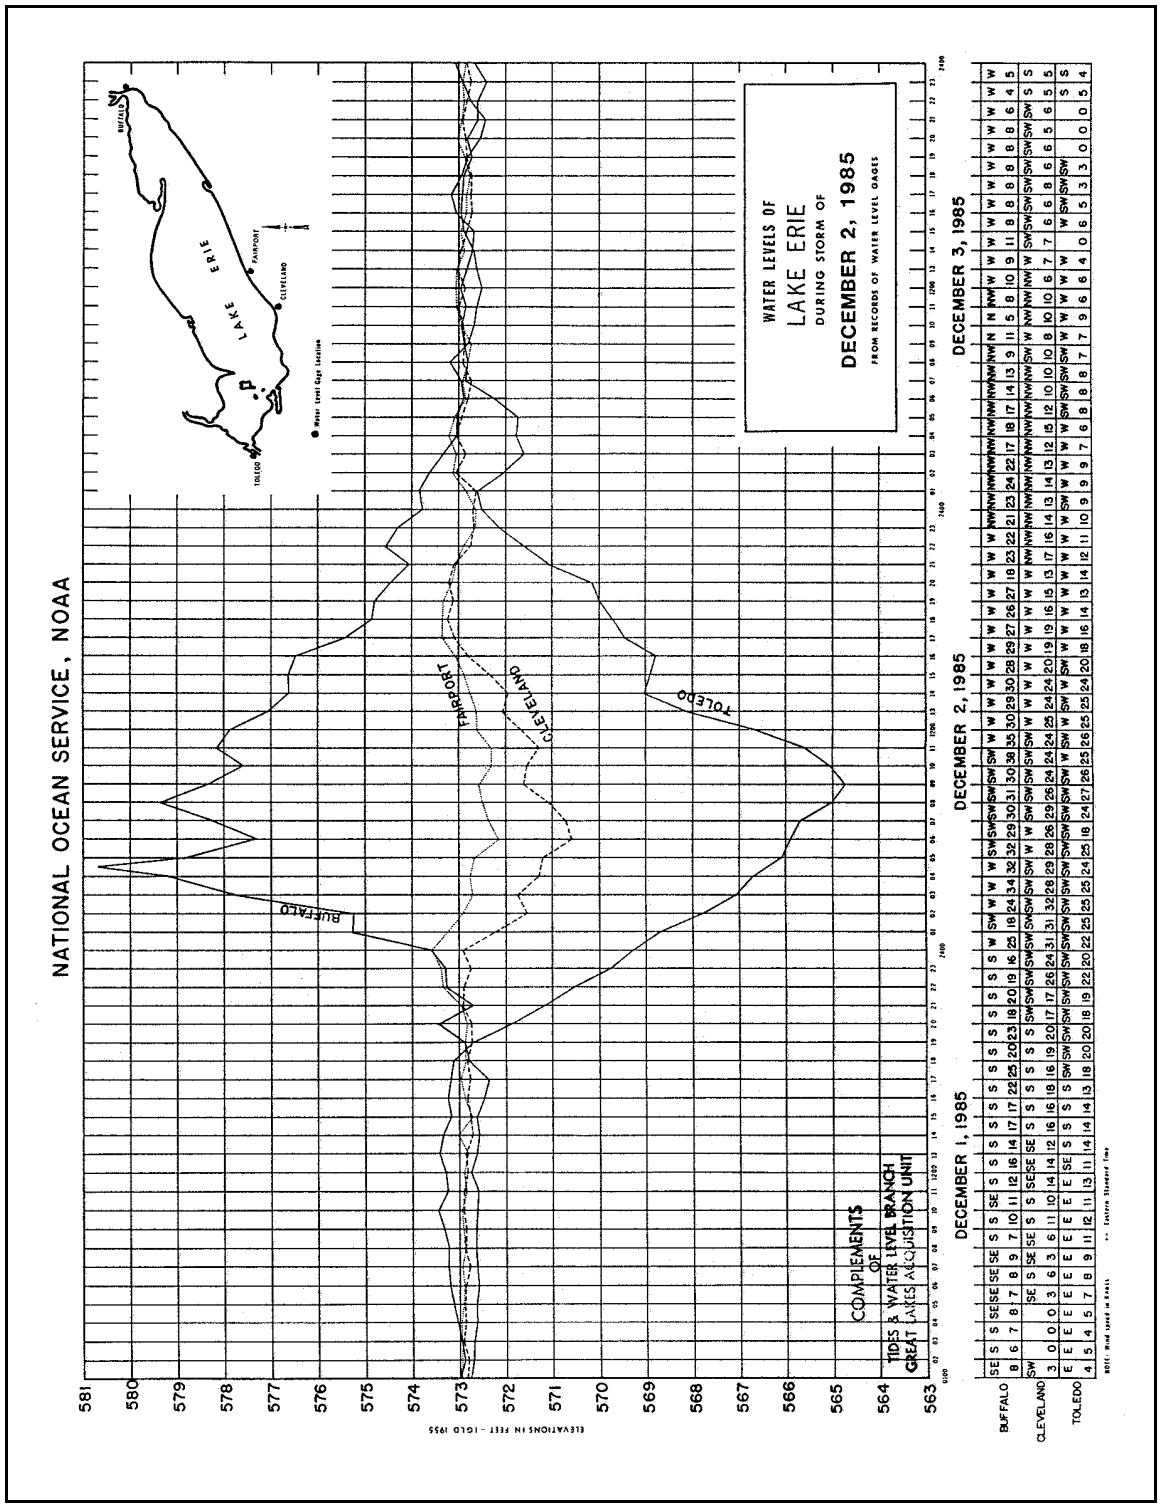

Figure V-2-3. Water levels of Lake Erie during storm of December 2, 1985 (NOAA 1985)

V-2-6. Topography and Bathymetry (Map Data)

a. Data needs.

(1) The amount of data needed for each project varies with the scope and type of project. Maps of the study area should include the updrift coastal zone which may affect the project and the downdrift area that will be affected by the project. Cadastral, topographic, and bathymetric information obtained from different sources should be combined into one or a series of maps. Computer Aided Drafting and Design (CADD) or Geographic Information System (GIS) programs facilitate the consolidation of map information. The advantage of a CADD or GIS drawing is that different types of information can be placed on different levels, allowing the user to access different layers for presentations, and 2- and 3-D illustrations are possible. Calculation of linear, areal, and volumetric change between elevations and distances (profiles) is possible.

(2) Recent surveys will be required to provide data in sufficient detail for cut/fill computations, sediment budgets, shoreline change, existing features, and property boundaries. Comparison with historic data will serve to illustrate shoreline and profile change and development. A review of historic maps and photographs is mandatory to fully understand the nature and processes at work, evolutionary trends, and natural ranges of variability. As windows to the past, they can present information which was at one time common knowledge, but has been lost with the passing of generations. Figure V-2-4 presents a portion of the 1836 shoreline map for Presque Isle, Pennsylvania. The location and extent of the breach along the neck (which afterward healed) give a glimpse of the shoreline position from another era. Most historic information, at least in the United States, only spans a century or less.

(3) Cadastral information relates to the showing or recording of property boundaries, subdivision lines, buildings, utilities, and related data. Topographic data presents the relief of land and the position of natural and man-made features. Often, topographic surveys with a contour interval of 0.3 m (1.0 ft) are required. Hydrographic surveys present the subsurface relief of water bodies and their shoreline position. Hydrographic survey techniques have been experiencing a renaissance. While the use of a lead line or other direct measure surveying procedures are still common, most hydrographic surveys are presently conducted using acoustical echo sounders. Other means such as the Scanning Hydrographic Operational Airborne Lidar Survey (SHOALS), a helicopter-mounted hydrographic surveying system for bathymetric measurement, are being introduced. SHOALS uses Light Detection and Ranging (LIDAR), a technology that uses a laser transmitter and receiver for water surface and water bottom detection. Because SHOALS is airborne, data can be obtained over ten times faster than shipboard echo soundings.

b. Available sources. Existing map data for the United States may be obtained from the following sources:

Cadastral: City, county, and state real estate records.
Topographic: State Department of Transportation, United States Geological Survey (USGS) and the U.S. Army Corps of Engineers (USACE).
Hydrographic: NOAA and USACE.

USACE District offices prepare annual reports on their activities. Review of these historic documents presents a narrative summary of coastal activities at U.S. Government installations. Maps also may be attached to these reports. The reader is referred to Part II, Chapter 8.

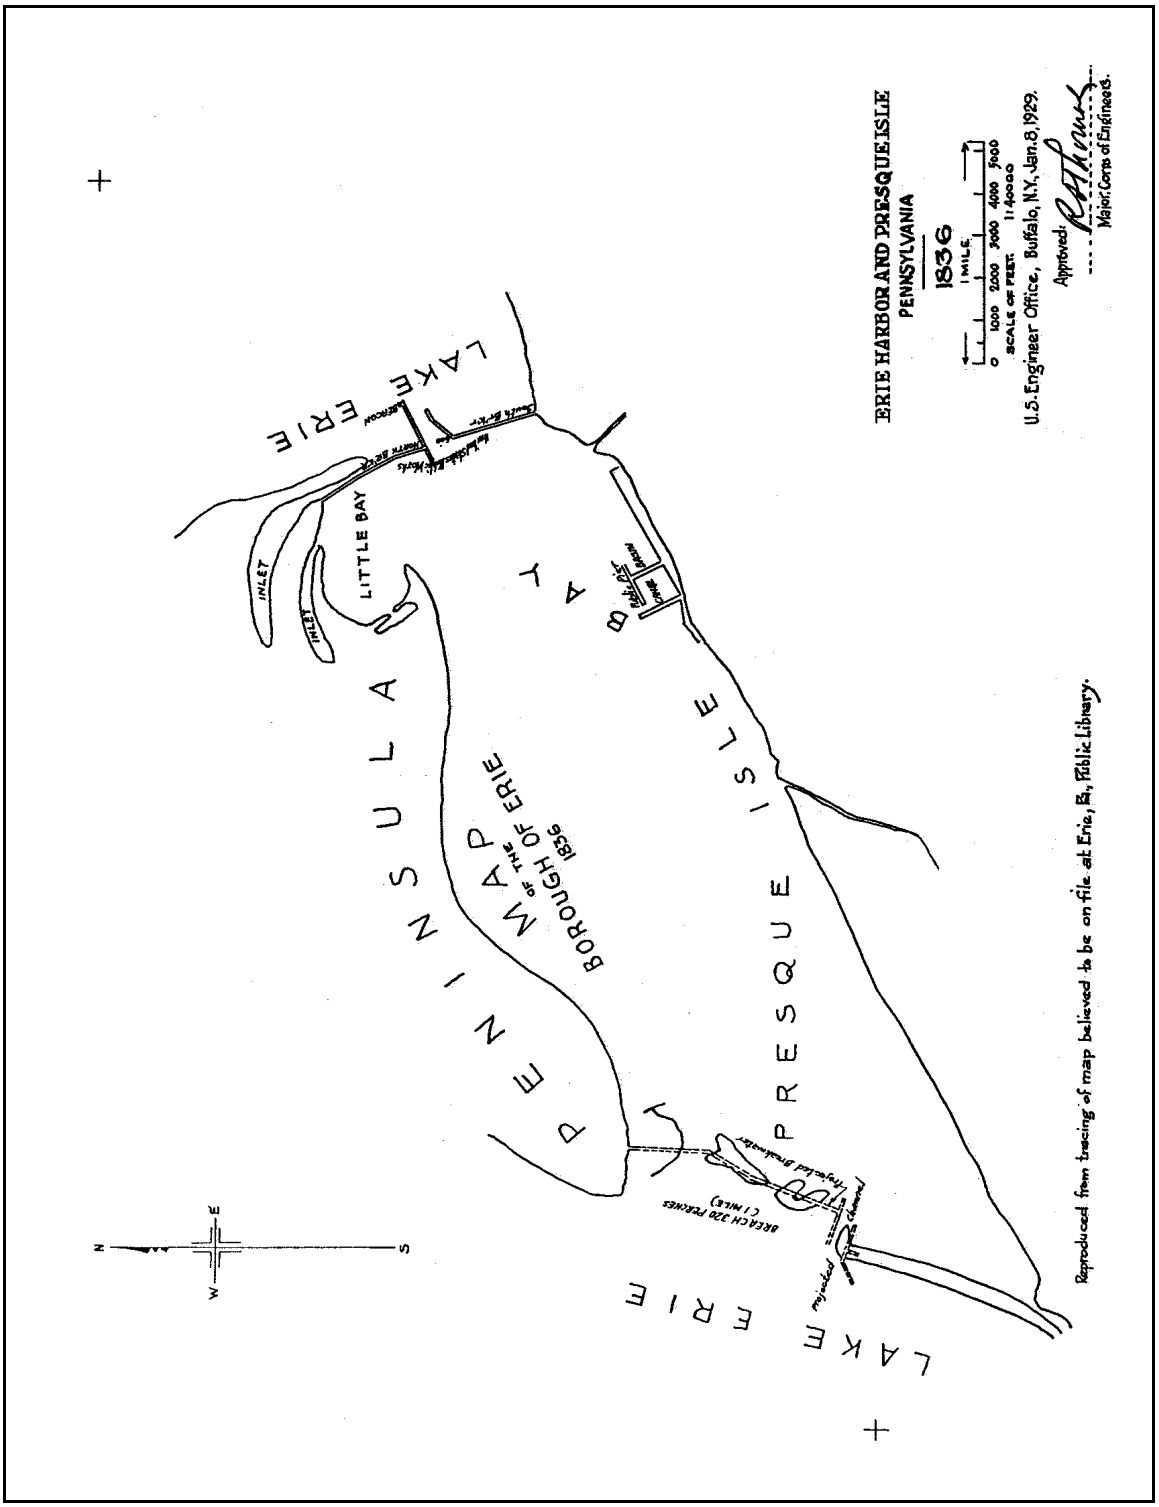

Figure V-2-4. The 1836 shoreline at Presque Isle, Pennsylvania

c. Reliability.

(1) All maps should have a north arrow (or south arrow in the Southern Hemisphere), a scale, and reference to the horizontal and vertical datum planes used. When using a historic map, one should be aware that magnetic north varies with time and one must align the map using true north. A map with a bar scale indicating the actual length is preferred. Be wary of maps that only report the scale, such as 1 cm = 1 km, unless the map is the original. The scale may be different if it is a copy, either due to slight paper shrinkage or reduction or enlargement when the copy was made. Also be aware that the datum plane can change with time or that a different datum plane may have been used. The datum used for topographic surveys may be different than that used for hydrographic work. Also, individual localities, such as cities, may have their own datum planes (Part II, Chapter 5 discusses datums). When comparing historic maps, at least two points of reference will be necessary in order to align the maps.

(2) The accuracy of hydrographic data is affected by four types of error: sounding, spacing, closure, and error due to temporal fluctuations in the lake or sea bottom. These errors may be more significant (greater) for nearshore profiles than for beach or topographic surveys since land surveys are not affected by the latter error and measurement techniques are more precise for topographic work. The presence of errors suggests a need for caution in interpreting differences obtained from two surveys of the same profile. In other words, be sure that different profiles truly represent differences in the sea bottom and do not merely reflect survey or plotting errors. Since the nearshore seafloor can change rapidly in response to changing wave conditions, differences between successive surveys may reflect bottom differences caused by storms and seasonal wave climate changes. These fluctuations may actually be greater than long-term trends. Reviewing available historic bathymetric charts will assist in interpreting long-term trends as short-term changes are often larger than net changes.

V-2-7. Geomorphology/Geometry and Sediment Characteristics

a. The coast is a diverse and dynamic environment. Many geologic, biological, and natural and human-made physical factors are responsible for shaping the coast and keeping it in a constant state of flux. Ancient geological events created, modified, and molded the rock and sediment bodies that form the foundation of the modern coastal zone. Over time, various physical processes have acted on this preexisting geology, subsequently eroding, shaping, and modifying the landscape.

b. Lithology deals with the general characteristics of rock and sediment deposits and is an important factor in shaping the present coast. The most crucial lithologic parameters responsible for a rock's susceptibility to erosion or dissolution are the mineral composition and degree of consolidation. Marine processes are most effective when acting on uncemented material, which is readily sorted, redistributed, and sculpted into forms that are in a state of dynamic equilibrium with incident energy. Part IV describes coastal geomorphology/sediment characteristics.

a. Types of coasts/principal features.

(1) Upon initiation of a study in a coastal area, the investigator needs to be aware of the type of coast being examined. Coasts may generally be classified as consolidated, unconsolidated, tectonic, or volcanic. Consolidated rock consists of firm and coherent material with coasts of this type typically found in hilly or mountainous terrain such as that in Maine (Figure V-2-5). In contrast, depositional and erosional processes dominate unconsolidated coasts, which are normally found on low relief coastal plains or river deltas. The Atlantic and Gulf of Mexico coasts of the United States are mostly unconsolidated depositional environments (except locations like the rocky New England shores). Figure V-2-6 is a photo of an unconsolidated coast.

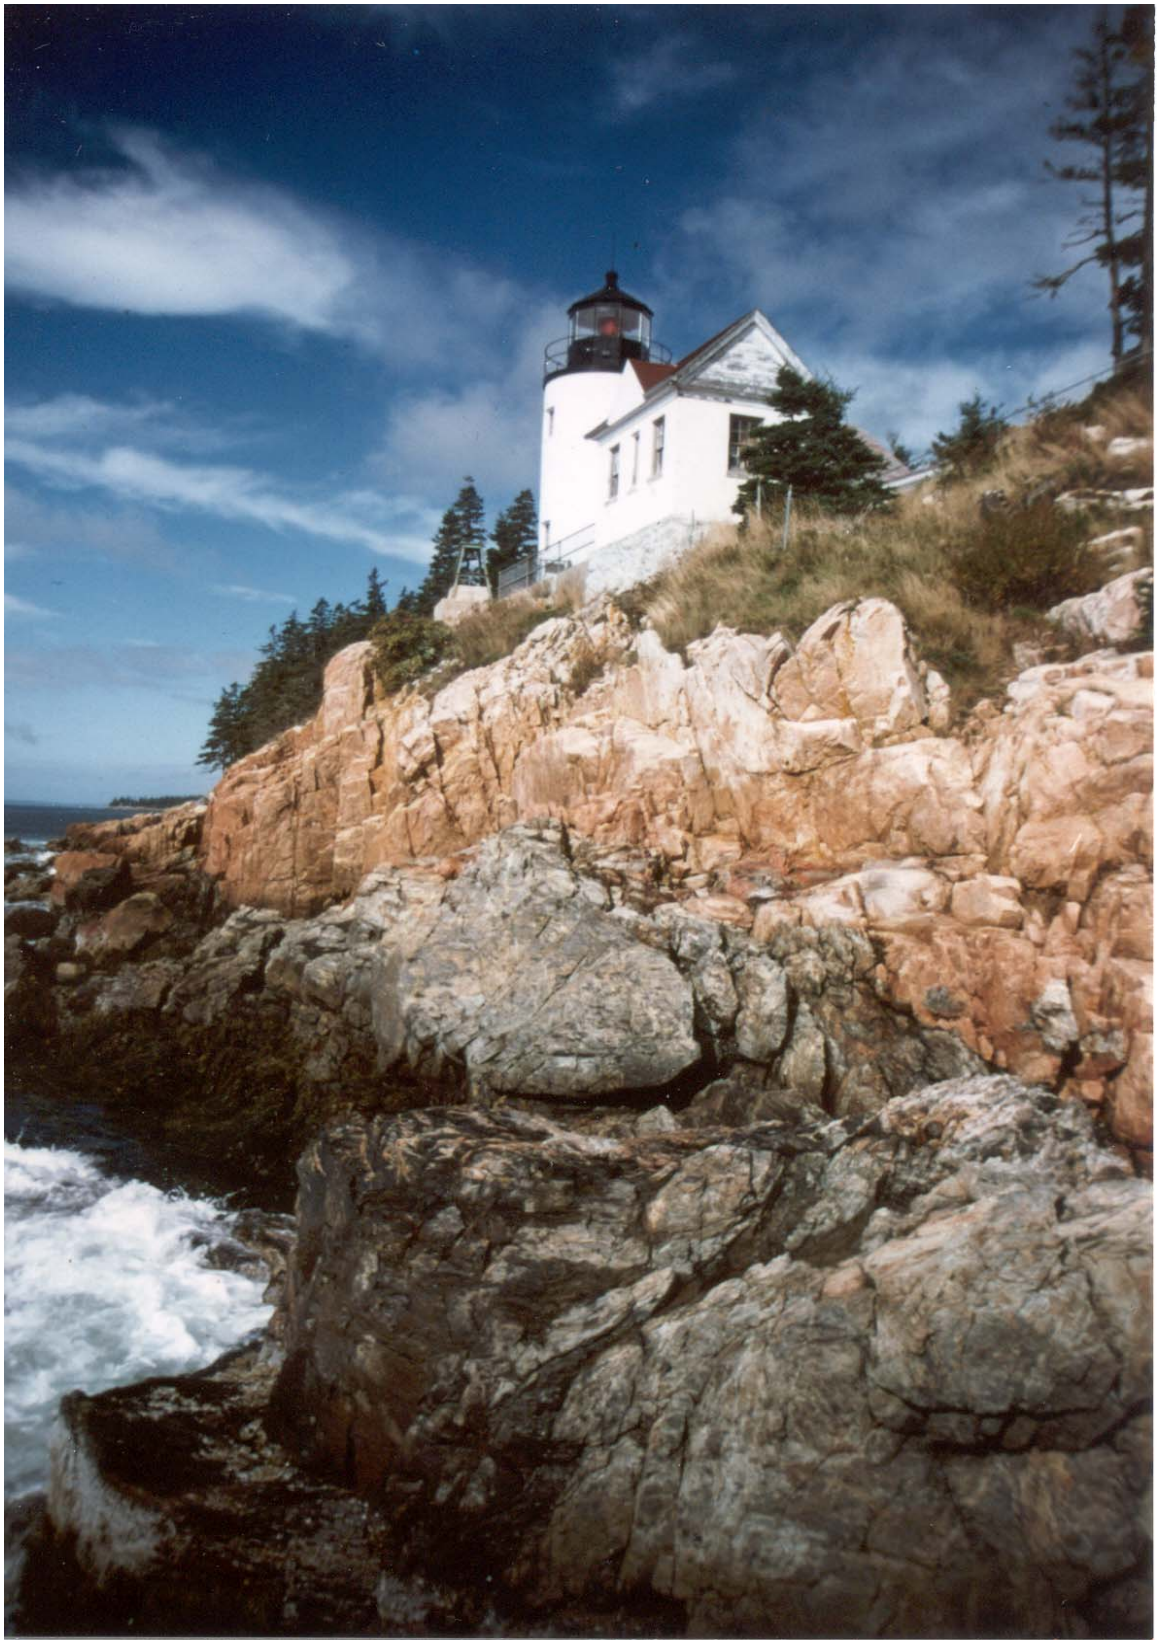

Figure V-2-5. Example of resistant rock-bound coast of Maine (Bass harbor Head Light, Maine, south of Acadia National Park)

Figure V-2-6. Beach near entrance to North Sand Pond, Lake Ontario, NY. This is a relict dune environment at the eastern end of Lake Ontario

Forces within the earth's crust and mantle deform, destroy, and create crustal material. These tectonic activities produce large-scale uplift and subsidence of land masses. The west coast of the United States is an example of a tectonically dominated coast. Sea stacks are prevalent along the U.S. Pacific coast. Sea stacks are steep-sided rocky projections above sea level near the coast. They are formed by wave cutting back on the two sides of a promontory. With the aid of weathering and further cutting behind it, it is left as an island. Sea stacks may be located onshore (Figure V-2-7) or further offshore, are of varied sizes and locally affect the wave patterns near them. The Great Lakes were created by glacial action, and physical characteristics of the shorelands are very diverse. They vary from high bluffs of consolidated or unconsolidated (Figure V-2-8) material to low bluffs and plains, dunes and wetlands. The eruption of lava and the growth of volcanoes may result in large masses of new crustal material, such as in the Hawaiian Islands.

(2) Principal coastal features which have been formed by local processes give indications of the types of coast under investigation. For example, the presence of a barrier island is indicative of a coast consisting primarily of unconsolidated sediments. In contrast, the most prominent feature exhibited by a fault coast is a scarp where normal faulting has recently occurred, dropping a crustal block so that it is completely submerged and leaving a higher block standing above sea level.

b. Sources and sinks. Recognition of the many sources (gains) and sinks (losses) in the coastal zone is important during development of the sediment budget for the region. In general, sand supply from rivers, cliff/bluff erosion, onshore transport from the shelf, biogenic sources (such as reefs), and alongshore sediment transport into the area constitute the major natural sources. Beach nourishment represents a human-induced gain to the budget. Natural losses can include sediment blowing inland to form dunes, offshore transport to deeper water, losses down submarine canyons, and the longshore transport that carries littoral

Figure V-2-7. Coast at Orick, CA. This is a pocket beach between resistant headlands

Figure V-2-8. Shore at Chimney Bluffs State Park, Lake Ontario, NY. Chimneys consist of glacial till more weather resistant than surrounding material

sediments out of the study area. Sand mining or direct removal (e.g., channel dredging with disposal outside of the littoral system) is a human-induced deficit to the budget.

c. Prevailing sediment characteristics.

(1) The geology of the coast and the source of littoral materials ultimately determine the prevalent shape of the shore and the composition of the beach at a specific locality. Littoral materials are classified by size, composition, shape, and other properties such as color. Littoral materials are classified by grain size in clay, silt, sand, gravel, cobble, and boulder. Several size classifications exist, with the Unified Soil Classification being the primary classification used by engineers and the Wentworth by geologists. Part III, Chapter 1 discusses sediment properties and classification.

(2) Littoral material is composed of materials specific to that region. While beach material is most commonly composed of quartz or feldspar particles, it also can be volcanic debris, as in the Hawaiian and Aleutian Islands, shell and coral, organics (peat), silts and clays. Littoral sands, gravel, and cobbles are usually rounded (Figure V-2-9), while departures from this shape are attributed to contributions from shell fragments and sedimentary rock such as shale. These departures from a spherical shape affect sediment motion initiation.

Figure V-2-9. Cobble Beach along Lake Ontario, Oswego, NY. Origin of cobble is bluff and glacial drumlin erosion

Sediment color may be used to trace the source of littoral material. It also is an indication of the relative density of the material. "Light minerals" such as quartz and feldspar, which have specific gravities ranging from 2.65 to 2.76 are generally tan, cream, or transparent. The famous white sands of the Florida panhandle are a very clean, uniformly sized quartz. "Heavy minerals," such as hornblende, garnet, and magnetite, which have specific gravities ranging from 3.0 to 5.2, are dark (black, red, dark green, etc.) in color. Littoral sediments of volcanic islands are dark, often green and black (Figure V-2-10).

Figure V-2-10. Black Sand Beach, Kalapana, HI. Sand is of volcanic origin

d. Sediment layering. It is important to recognize that variation in beach material may occur with depth. Classification of the surficial material only may lead to erroneous interpretations of coastal activity. Underlying the beach material can be layers of cohesive material, peat or rock. These will have significant effects on beach profile response to storm activity and foundation conditions for proposed structures. An understanding of the geology of the area will indicate whether layering (stratigraphic variability) can be expected.

V-2-8. Littoral Drift and Sediment Transport Patterns

Littoral transport is the movement of material in the littoral zone by waves and currents. This includes movement parallel (longshore) and perpendicular (cross-shore). The littoral zone extends from the shoreline to just beyond the seawardmost breakers.

a. Longshore movement. Wave-generated currents tend to dominate water movements in the nearshore zone and are important in the movement of sediments. Wave-induced currents are superimposed on the wave-induced oscillatory motion of the water. When waves break with their crests at an angle to the shoreline, a current is generated parallel to the shore that is largely confined to the nearshore between the breakers and the shoreline. The volume rate of material transport along the shore is sensitive to the breaker angle and height. The longshore gradient in breaking wave height is also a generating mechanism for longshore sand transport. This contribution is usually much smaller than that from oblique wave incidence in an open coast situation. However, in the vicinity of structures, where diffraction produces substantial change in breaking wave height, its inclusion improves transport rate prediction (Hanson and Kraus 1989). Longshore sediment processes are discussed in Part III, Chapter 2.

b. Cross-shore movement.

(1) Wave breaking generates turbulent motion and provides the necessary mechanism for suspending sediment. Sediment transport in a direction perpendicular to the beach is known as cross-shore movement. The equilibrium profile is a profile of constant shape which is approached if exposed to fixed wave and water level conditions. Waters (1939) proved that the existence of an equilibrium profile was a valid concept under laboratory conditions. The concept of the equilibrium profile is discussed in Part IV.

(2) As a beach profile approaches an equilibrium shape, the net cross-shore transport rate decreases to approach zero at all points along the profile (Larson and Kraus 1989). The division of the profile into different transport regions has allowed empirically based relationships for the net transport rate to be formulated. The four transport zones across the profile are defined as:

Zone I: From the seaward depth of effective sand transport to the break point (prebreaking zone).

Zone II: From the break point to the plunge point (breaker transition zone).

Zone III: From the plunge point to the point of wave reformation or to the swash zone (broken wave zone).

Zone IV: From the shoreward boundary of the surf zone to the shoreward limit of runup (swash zone).

(3) The net transport rate in zones of broken waves, where the most active transport occurs, shows good correlation with the wave energy dissipation per unit water volume. The net transport rate in the prebreaking zone decreases exponentially with distance offshore. In the foreshore zone, the net transport rate shows an approximately linear behavior decreasing in the shoreward direction. The reader is referred to

Chapter III-3 for a discussion on cross-shore transport. Larson and Kraus (1989) present an excellent literature summary of the chronological investigations on profile change and the development of cross-shore transport modelling. Dean (1991) summarizes equilibrium profile responses for differing coastal conditions. Houston (1996) applies equilibrium profile responses to beach fill design. The reader is referred to Part III, Chapter 4.

c. Seasonal reversals.

(1) Section V-2-5 discussed the seasonal variability of storms and waves. This variability results in two distinct classes of waves, storm waves and swell waves, which have completely different effects on the beach profile. In general, storm waves remove the beach berm to place it along the offshore portion of the profile while swell waves replace it back onshore (Silvester and Hsu 1993). This occurs primarily along the oceanic coasts and to a reduced degree along inland seas. Recognition of this variability is important in interpreting existing beach change and during the establishment of a monitoring program for a beach.

(2) The following synopsis of this action is presented eloquently in Sylvester and Hsu (1993). In describing the action of swell waves on the beach profile,

> *The broken wave swashes up the beach face with its water percolating through it, so long as there is adequate time between each wave. ...this water soaks down to the water table some distance below the face, eventually to be returned back to the sea. The downrush, when a trough arrives, is smaller than the uprush due to this percolation and therefore cannot carry much of the sediment load back down the beach face. Also, the hydraulic jump associated with this flow reversal is small. The result is that swell waves, with several seconds between each crest, will leave material on the face and hence the beach accretes.*

(3) In contrast to swell waves, storm waves are steeper. Silvester and Hsu (1993) wrote,

> *Now consider what happens to this swell profile when storm waves arrive. These are very steep and contain much water above the mean sea surface. They comprise waves of many periods, or constitute a wide spectrum, with heights appropriate to each. A crest arrives almost every second instead of every few seconds and hence large volumes of water are thrown over the beach face, which is quickly saturated.* By this action, *the water table has become almost coincident with the face itself. The downrush now nearly equals the uprush so that much sand is dragged down the face into the hydraulic jump, which is increased in size. This is one mechanism by which the berm is eroded and its contents placed into suspension.*
>
> *Another factor, of equal if not greater importance, is the flow of the excess ground water returning to the sea. At the waterline, where the hydraulic jump is also located, it is moving vertically, thus causing liquefaction or a "quicksand" effect (Longuet-Higgins 1983). This aids suspension so helping to undermine the toe of the beach, which progressively retreats landward...*

(4) The above briefly described the effect on the profile type (accretion/erosion) and hence a net onshore or offshore cross-shore transport due to the presence of swell or storm waves, respectively. It also is important to recognize during development of the sediment budget that the net direction of the storm and swell waves may be different, resulting in a reversal of longshore drift with season. This can have a significant effect upon the location of accretionary/erosional zones adjacent to the project. The project design needs to tolerate a range of expected conditions. One must be able to change bypassing operations during a year to accommodate these seasonal reversals.

d. Long-term reversals. Recognition of changes in the sediment budget over the long term (years to decades) is important when evaluating historic changes or predicting potential changes due to a proposed project. Modifications of the sediment gains or losses through natural causes or human intervention can shift an accretionary shore to an erosional shore. For example, the construction of large harbor structures or the stabilization of an inlet along the coast have affected the amount of sediment reaching downdrift beaches. Without sediment bypassing around the harbor, downdrift beaches may erode severely. Cyclic climatic changes such as the El Ninõ can cause reversals for many months. Knowledge of these type of activities is necessary to properly interpret profile change.

e. Slug motion.

(1) Sediment movement along the shore rarely occurs at a temporally and spatially constant rate. The presence of large beach protuberances termed "sand slugs" or "longshore sandwaves" is a phenomenon that has been reported at numerous beaches around the world. Along Long Point on the Lake Erie shore, these features have been observed with alongshore lengths of 500 to 2,500 m (1,640 - 8,200 ft) and maximum widths of 50 to 90 m (164 - 295 ft) which migrate alongshore in the direction of net drift at 150 to 300 m/year (492 - 984 ft/year) (Stewart and Davidson-Arnott 1988; Davidson-Arnott and Stewart 1987). Similarly along the Dutch coast, they have been measured with an amplitude of 30 to 500 m (98 - 1,640 ft), a celerity of 50 to 200 m/year (164 - 656 ft/year), and a period of 50 to 150 years (Verhagen 1989).

(2) Bakker (1968) presents a mathematical theory on sandwaves and an application on the Dutch Wadden Isle of Vlieland. Stewart and Davidson-Arnott (1988) describe their formation by the onshore movement and welding of inner nearshore bars during nonstorm periods on areas of local sediment abundance. In addition, growth and downdrift extension and widening of the protuberance in the direction of net sediment transport results from attachment of an inner bar to the slug and infilling of the trough-runnel downdrift of the protuberance. The presence of sand waves results in a spatial pattern of erosion and accretion, with erosion occurring primarily in the embayments between the slugs and accretion occurring opposite the wide beach of the sand wave.

(3) The presence of this type of phenomenon can dwarf the effects of a relatively smaller shore project. At Presque Isle Peninsula, Pennsylvania, three prototype segmented offshore breakwaters were built in 1978. The intent was to study the effect of offshore distance, breakwater length, and gap width upon the shoreline. The movement of a sand wave through the project area a few years later totally covered the breakwaters. They began to emerge more than a decade later. Verhagen (1989) concluded that along the southern part of Holland, groin construction did not change linear long-term coastal erosion and did not change the cyclic behavior of the shore. He concluded that construction of groins on this coast did not have any effect at all.

f. Hot spots. Often at a beach nourishment project, there will be one or more areas that erode more rapidly than others. These areas are termed erosional hot spots. The location may correlate with areas which had previously experienced high erosion. Hot spots at new locations may be due to wave refraction and possibly wave focusing in response to bathymetric change from placed material (National Research Council 1995). Another cause may be a bottom composition change which affects the rate of movement. In any event, erosional hot spots may require renourishment earlier than the rest of the project. This unexpected work will place an additional financial strain on the project. Placement of a greater quantity of sand in hot spot areas may extend the time between renourishment.

V-2-9. Shoreline Change Trends

a. Evidence of cyclic processes.

(1) The presence of cyclic processes due to water levels and waves is observed in coastal features such as tidal inlets and seasonal bars. Inlets are the openings in coastal barriers through which water, sediments, nutrients, planktonic organisms and pollutants are exchanged between the open sea and the protected embayments behind the barriers. Inlets are not restricted to barrier environments or to shores with tides; on the west coast of the United States and in the Great Lakes, many river mouths are considered to be inlets, and in the Gulf of Mexico, the wide openings between the barriers, locally known as passes, are also inlets. Tidal inlets are analogous to river mouths but differ as they experience diurnal or semidiurnal flow reversals and they have two opposite-facing mouths (seaward/lakeward and lagoonward). Tidal inlets are characterized by large sand bodies that are deposited and shaped by tidal currents and waves. The ebb-tide shoal is a sand deposit that accumulates sea/lakeward of the inlet mouth. It is formed by ebb tidal currents and is modified by wave action. The flood-tide shoal is a sediment deposit at the landward opening that is mainly shaped by flood currents. Depending upon the size of the bay (lagoon), the flood shoal may extend into open water or may merge into a complex of meandering tributary channels, point bars, and muddy estuarine sediments.

(2) As indicated in Section V-2-8, seasonal variability of storms and waves results in seasonal reversals in cross-shore drift. The effect of the change from a swell-dominated to storm-dominated profile is clearly seen in the presence of seasonal bars. Storm waves remove the beach berm and place the material offshore as a bar. Swell waves attempt to reverse this action. Interpretation of long-term trends must account for these short-term changes.

b. Eustatic sea level changes. A worldwide change in sea level, referred to as eustatic sea level change, is caused by change in the relative volumes of the world's ocean basins and the total amount of ocean water (Sahagian and Holland 1991). The rise results in a slow, long-term recession of the shoreline, partly due to direct flooding and partly as a result of profile adjustment to the higher water level. Estimates of recent eustatic rise range from 15 cm/century (Hicks 1978) to 23 cm/century (Barnett 1984), although some researchers, after exhaustive studies of worldwide tide records, have not seen conclusive evidence of a continuing eustatic rise (Emery and Aubrey 1991). This topic is reviewed in greater detail in Part IV.

c. Subsidence. Subsidence is the sinking of land due to natural compaction of estuarine, lagoonal, and deltaic sediments resulting in large-scale disappearance of wetlands. This effect has been exacerbated in some areas by human intervention with groundwater and oil withdrawal. Significant subsidence occurs in and near deltas where large areas of fine-grain sediment accumulate. Land loss in the Mississippi delta has become an important issue because of loss of wetlands and rapid shoreline retreat. Along with the natural compaction of the deltaic sediments, groundwater and hydrocarbon withdrawal may have contributed to subsidence problems in southern Louisiana. The change in relative sea level in the Mississippi delta is about 15 mm/year, while the rate at New Orleans is almost 29 mm/year (data cited in Frihy (1992)).

V-2-10. Land/Shore Use

a. The present use of the shore and the area landward of the coast needs to be documented. The areal extent of information to be collected must be determined on a site-by-site basis. An understanding of the sediment budget will assist in defining limits. Information should be gathered not only for engineering purposes but also for environmental and economic documentation. For a project planned in the coastal zone, this information will assist in assessing environmental and economic effects of the project.

b. Information collected on structures will include the type, ownership (residential, commercial, public, and other), density, location, and value. The elevation-versus-damage relation may be required if there is a flooding problem. The distance of structures from the top of bluffs or high-water elevation may be needed for regulatory purposes (setbacks) or expected potential damage at the present recession rate. If a shoreline erosion protection project is proposed, infrastructure data will be needed to estimate damage reduction (project benefits) due to a lower recession rate. Structures which influence sediment supply or surface/groundwater drainage patterns may also be important.

c. In addition to the structure inventory, property boundaries have to be located. Identification of all lands, easements, and rights of way will be needed when assessing the required easements for construction limits and access to the site, as well as for future maintenance. The affected infrastructure (roads, utilities, etc.) also must be identified.

V-2-11. Potential for Project Impacts

a. Effects on natural tidal flushing.

(1) Dredging a channel through a tidal inlet usually results in increased shoaling. Channel dredging also can have a significant effect on adjacent shorelines, although the effect may be difficult to assess. A complete understanding of natural processes prior to dredging is required to discern the change due to dredging. Disposal of dredged material offshore may result in permanent removal from the littoral system if the depth is sufficient to prevent return to the nearshore littoral environment. Although the limiting depth for which material offshore will return to the beach is generally unknown, it is dependent on variables such as sediment size and wave climate. A few tests have suggested that material placed in water depths greater than 6 m (20 ft) in the ocean and about 2 m (6 ft) in the Great Lakes will not readily return to the nearshore littoral system (Harris 1954, Schwartz and Musialowski 1980).

(2) Jetties or breakwaters often are built to stabilize inlets. These structures serve to stop the entry of littoral drift into the channel, function as training walls for tidal currents, stabilize the position of the navigation channel, may increase tidal current velocities which flushes sediment from the channel, and reduce shoaling in the channel. Despite their positive engineering effects, jetties often form a barrier to longshore sediment movement. Where there is no predominant direction of longshore transport, jetties may stabilize nearby shores, but this effect is limited only to the sand impounded at the structures. At most sites the amount of sand available to downdrift shores is reduced, at least until a new equilibrium shore is formed at the jetties. Where longshore transport predominates in one direction, an accretionary fillet will occur on the updrift side of the channel and erosion will occur on the downdrift side. Again, bypassing or nourishment will be required to mitigate this imbalance.

(3) The increase in channel velocities also increases the potential for scour along the structure toe. This effect can be exacerbated by the presence of waves. This potential effect must be considered during project design.

b. Up/downdrift effects and need for bypassing.

(1) Construction of a coastal project that protrudes from the shore or is located nearshore and modifies the local wave climate may result in a change in sediment accretionary and erosional patterns. This perturbation of longshore drift movement will result in an accretionary zone immediately updrift or within the wave shadow of the structure and an erosion zone downdrift of the structure. The effect of the structure may be mitigated by prefilling the fillet (at a protruding structure) or salient (behind a shore-parallel structure). This preventative action may not be adequate. If the structure protrudes sufficiently to trap and deflect most of the littoral drift to deep water, bypassing of material may be required.

(2) Prediction of erosion downdrift of a barrier is challenging. Bruun (1995) presents a discussion, series of examples, and a good reference list on this problem. He notes that downdrift erosion may in some cases be composed of short (local) as well as long-distance effects which move downdrift at various rates. The presence of a 'zero-area' or location of a temporary reduction of erosion a short distance from the barrier does not necessarily indicate the extreme limit of leeside erosion. While the short distance effect is a geomorphological feature, the long-distance effect is due to a sediment deficit. Determination of the maximum recession and length of shore affected by downdrift erosion is further complicated by the presence of natural erosionary processes.

(3) Mitigation of shoreline damage due to the presence of an existing structure requires knowledge of recession rates (sediment budget) before and after its construction. The difference in sediment gain/loss downdrift of the structure is the minimum information required to mitigate effects of the structure. This value is used if bypassing of material is not practical or is politically infeasible (updrift owners enjoy the newly created or enlarged beach) and new material instead is introduced to the system.

c. Changes in wave climate.

(1) Construction of a protruding or an offshore shore-parallel structure will modify the local wave and current climate near the structure. A protruding structure, such as a groin or jetty, may cause development of a rip current along the updrift face. An offshore breakwater will reduce wave activity in the lee since wave energy behind the structure occurs from a combination of diffracted waves from the ends and transmission over/through the structure. This usually will result in deposition of littoral material in the breakwater shadow. Modification of the wave pattern may limit surfing but can enhance other recreational activities such as swimming.

(2) Reflection of incident waves from a natural or man-made structure also will affect local wave climate. The amount of wave reflection, expressed as the reflection coefficient (reflected wave height/incident wave height), is dependent upon the structure's surface roughness, structure height in relation to the wave runup (freeboard), structure slope and incident wave angle (especially as the wave direction approaches the structure orientation). Smooth, vertical, and high (no overtopping) structures (such as sheet-pile walls) reflect most incident wave energy. The resulting increase in wave height near the structure can induce additional scour at the structure toe, increase local transport rate, and result in unacceptable wave conditions within a harbor.

d. Impact on benthic organisms.

(1) Construction of shore protection measures usually produces short-term physical disturbances which directly affect biological communities and may result in long-term impacts. Coastal structures alter bottom habitats by physical eradication and in some cases scour or deposition. However, certain hard structures may create a highly productive, artificial reef-type habitat. Beach nourishment will cover nonmotile organisms.

(2) Species comprising marine bottom communities on most high-energy coastal beaches are adapted to periodic changes related to natural erosion and accretion cycles and storms. Burial of offshore benthic animals by nourishment material has a greater potential for adverse impacts than those in the intertidal and upper beach zone (Nagvi and Pullen 1982). Survival of vegetation and animals will depend upon the deposition depth, rate of deposition, length of burial time, season, particle size distribution and other habitat requirements.

(3) A biological survey of organisms living in and using the proposed project area must be completed before a project is initiated. This must include threatened and endangered species. This inventory and knowledge of habitat requirements will assist in defining potential impacts of the proposed project.

(4) Certain species are very sensitive to placement of beach nourishment. Moderate disturbance of a mature oyster reef can destroy it. Covering of mangrove prop roots can kill the entire plant (Odum, McIvor, and Smith 1982). Hard corals are more sensitive than soft corals to covering with fine sediments. Excessive sedimentation for a nourishment project which buries a reef results in permanent destruction or replacement by soft bottom habitat and community. Nourishment can affect sea turtles directly by burying their nests or by disturbing nest locating and digging during the spring and summer nesting season. Elimination of these adverse effects may be possible by timing of placement (to be discussed in Section V-2-12).

e. Changes in natural habitat. Construction of a project in the coastal zone can cause short- and long-term changes in the natural habitat. Placement or dragging dredge anchors and pipelines can damage environmentally sensitive habitats such as coral reefs, seagrass beds, and dunes. Short-term changes to the grain size and shape of the beach will occur depending on characteristics of the native and borrow material. Waves and currents will winnow and suspend finer sediments and deposit them in deeper water offshore. Eventually, the sediment size distribution will become comparable to the beach sediments prior to nourishment. An increase in compaction of the beach can result from beach nourishment. Burrowing animals such as crabs and sea turtles can have difficulty digging in compacted beaches. As with sediment sorting, the compaction increase will be temporary until the beach is softened by wave action, particularly storms. Construction of a hard structure can result in a permanent change locally by removal of bottom habitat. However, a rubble-mound structure may provide a different (reef-type) habitat. Scraping of the new beach fill face during its initial adjustment can also have an adverse effect on species such as sea turtles and crabs that transit the beach surface for nest building and reproduction.

V-2-12. Environmental Considerations

Selection of the best environmental and engineering solution to a coastal problem requires a thorough understanding of the complexity and diversity of the coastal zone. A clear definition and cause of the problem as well as a comprehensive review of potential solutions is required. In the previous sections, some potential impacts to be expected by a project were discussed. In this section, the principal environmental factors that should be considered in design and construction and techniques to attain environmental quality objectives are discussed briefly. The reader is directed to EM 1110-2-1204 for more detailed information.

a. Surveying the project area.

(1) An understanding of existing environmental conditions is vital to ensuring that the status quo is maintained or enhanced. An environmental survey of the project area is required in order to establish a baseline condition. As in any sampling program, the most critical aspect of data collection is identifying the proper parameters to sample and measure. The quality of information obtained will be dependent upon collecting representative samples, use of appropriate sampling techniques, protecting samples until they are analyzed, accuracy and precision of analysis, and correct interpretation of results.

(2) The purpose of collecting samples is to acquire adequate representation of the project area's characteristics. This requires that samples be taken in locations typical of ambient conditions found at the project site. The number and frequency of samples will need to be assessed. Sampling equipment should be selected based on reliability, efficiency, and the habitat to be sampled. In order to maintain the integrity of the results, preservation of samples is imperative. Preservation is intended to retard biological action and hydrolysis/oxidation of chemical constituents, and to reduce volatility of constituents.

(3) Habitat-based evaluation procedures are developed to document the quality and quantity of habitat. These procedures can be used to compare the relative value of different areas at the same time (baseline studies) or the relative value of one area with time (impact assessment). Two habitat assessment techniques available are the Habitat Evaluation Procedure (HEP) and the Benthic Resources Assessment Technique (BRAT).

(4) HEP has been computerized for use in habitat inventory, planning, management, impact assessment, and mitigation studies (U.S. Fish and Wildlife Service 1980). The method is comprised of a basic accounting procedure that computes quantitative information for each species evaluated. The inventory can pertain to all stages of a species, to a specific life stage, or to groups of species. An HEP analysis includes: scoping, development and use of Habitat Suitability Index models, baseline assessment, impact assessment, mitigation, and decision on course of action.

(5) BRAT procedures use benthic characterization information to produce semiquantitative estimates of potential trophic value of soft-bottom habitats. BRAT estimates the amount of benthos that is both vulnerable and available to target fish species that occur at a site. The utility of BRAT lies in the ability to provide meaningful information relevant to value decisions. While it does not provide an assessment of overall habitat status, it can be viewed as an in-depth assessment of a single habitat variable, that of trophic support. As such, it may contribute semiquantitative input to habitat-based assessments such as HEP.

b. Mitigation measures.

(1) During the design of a project, care must be taken to preserve and protect environmental resources, including important ecological, aesthetic and cultural values. Specific U.S. Army Corps of Engineer mitigation policy for fish and wildlife and historic and archaeological resources is included in Chapter 7 of Engineer Regulation (ER) 1105-2-100. Mitigation consists of avoiding, minimizing, rectifying, reducing, or compensating for impacts. The first elements often can be accomplished through their consideration during project design. The amount of compensation required for significant losses to important resources is quantified through documentation of the amount of actual/predicted losses. Justification must be based on significance of resource losses due to a project compared to costs necessary to carry out mitigation.

(2) Some examples of mitigative measures for the aforementioned mitigative elements are as follows:

(a) Avoid: Adjust the time of construction activities to avoid periods of fish migration, spawning, shorebird or turtle nesting; preserve a public access point.

(b) Minimize: Disturb an immature reef instead of a mature one; use rough-surface facing materials on a structure.

(c) Rectify: Replace a berm; restore flow to former wetland.

(d) Reduce: Control erosion (sedimentation control plan); place restrictions on equipment and movement of construction and maintenance personnel.

(e) Compensate: Use dredged material to increase beach habitat, create offshore islands, increase or develop new wetlands; construct an artificial reef.

c. Water quality. Water quality impacts consist of changes to the water column's characteristics which may have short- and long-term consequences. Construction processes often are responsible for short-term increases in local turbidity levels, releases of toxicants or biostimulants from fill materials, introduction of petroleum products and/or the reduction of dissolved oxygen levels. These impacts can be minimized by construction practices, fill material selection, and in some instances, construction scheduling. These impacts are temporary unless long-term changes in hydrodynamics have occurred. It is these long-term repercussions which must be identified during the design process. The size and type of structural alternatives will result in a range of potential impacts. For example, the design of a jetty or offshore breakwater will greatly influence its impact on circulation and flushing, which affect water quality.

d. Disposal of materials. Physical and chemical testing of the proposed material to be dredged is required in order to assess the appropriate disposal method. Local regulations also may dictate the manner in which material is to be disposed: open-water, upland or in a confined disposal facility. For material that is placed in open water, it may be necessary to predict long-term fate of the disposal mound. This assessment will entail determining whether the material is dispersive or nondispersive. If material is dispersive, rate of erosion and fate of the material should be computed from models or field studies.

V-2-13. Regional Considerations

a. Regulations.

(1) Construction of a shore erosion or navigation project in the coastal zone is governed by national and local regulations. Research of governing laws is an essential part of the planning process in order to determine potential limitations for constructing in the coastal zone. These stipulations may include physical structure limitations such as size, setback requirements, the need for buffer zones, restriction on hard structures (North Carolina, Massachusetts, and Maine), and ability to rebuild after sustaining damage; and environmental limitations such as season when construction can occur and required mitigation (i.e., bypassing, wetland creation, etc). These laws are the result of lessons learned from constructing along the coast (Figure V-2-11).

(2) The Coastal Barrier Resources Act (Public Law 97-348 1982) is an example of a national regulation affecting coastal regions of the United States. The purpose of the Act is to minimize loss of human life; wasteful expenditure of Federal revenues; and damage to fish, wildlife, and other natural resources associated with the coastal barriers of the United States by restricting future Federal expenditures and financial assistance which have the effect of encouraging development of coastal barriers. The Act established the Coastal Barrier Resources System, which identified undeveloped coastal barriers on a series of maps. A coastal barrier is a depositional geologic feature (such as a bay barrier, tombolo, barrier spit, or barrier island) which consists of unconsolidated sedimentary materials, is subject to wave, tidal, and wind energies and which protects landward aquatic habitats including adjacent wetlands, marshes, estuaries, inlets, and nearshore waters. It is considered undeveloped if it contains less than one structure per 0.02 km^2 (5 acres) that is "roofed and walled" and covers at least 18.6 m^2 (200 ft^2).

(3) Article 34 of the New York State Environmental Conservation Law (State of New York 1988) is an example of a state law that regulates the need for coastal erosion management permits and controls activities within defined structural hazard areas and natural protective feature areas. Maps of structural hazard areas are available for the entire state coastline which define a zone in which no new non-movable structures or non-movable major additions to existing structures can be built without formal approval. New public utilities must be located landward of the shore structures that they serve. Within natural protective feature areas, development is generally prohibited, only clean sand or gravel of an equivalent or slightly larger grain size may be deposited nearshore, and a permit is required for any new construction, modification, or restoration

Figure V-2-11. Structures threatened by erosion, Lake Ontario, Crescent Beach, NY

of coastal structures. Many other states and communities have similar regulations and set-back limits, which limit construction activities within a specified distance from the shore or bluff edge.

b. Seismic. Forces within the earth's crust and mantle deform, destroy, and create crustal blocks. These tectonic activities produce physical features such as faults and folds. Tectonic movements produce large-scale uplift and subsidence of land masses. The frequency and magnitude of seismic forces on foundations of marine structures is essential information along tectonically dominated coasts such as the west coast of North America. Rigid structures (e.g. piers and seawalls) and flexible structures (e.g. rubble-mound breakwaters and revetments) should be evaluated for seismic response, according to the same general practices used for building design (U.S. Army Corps of Engineers 1994).

c. Tsunami.

(1) Tsunamis, or seismic sea waves, are long-period waves generated by displacements of the seafloor by submarine earthquakes, volcanic eruptions, landslides and submarine slumps, and explosions. The term tsunami is derived from two Japanese words: "tsu," for harbor and "nami," meaning wave. The underwater disturbance results in uplifting the water surface over a large area, which forms a train of waves with periods exceeding 1 hr, in contrast to normally occurring wind-generated water waves which have periods less than 1 min. In the open ocean, amplitude of tsunamis is usually less than 1 m (3.3 ft) and hence may go unnoticed to passing ships. However, the wave height increases greatly as the shore is approached, resulting in potentially catastrophic flooding and damage. Tsunamis generated by volcanic activity or landslides result in the wave energy spreading along the wave crests and affect mainly the areas near their source. Those generated by tectonic uplifting may travel across an ocean basin, causing great destruction far from their source (Camfield 1980).

(2) Tsunamis can be generated in any large water body, including inland seas and large lakes. However, the majority of seismic activity that usually generates tsunamis occurs along the boundaries of the Pacific Ocean, and some strong activity is concentrated in the Caribbean and Mediterranean Seas. While earthquakes affect the eastern United States, these usually occur inland. The only major recorded tsunami along the east coast of North America was the one which devastated the Burin Peninsula along Placentia Bay, Newfoundland, in November 1929. The tsunami was enhanced by an exceptionally high tide and high storm waves.

(3) Because of the frequency and magnitude of tsunamis in the Pacific Ocean, a warning system has been developed. Although tsunamis travel at speeds as great as 800 km/hour (500 mph), transoceanic distances are sufficiently large to allow several hours warning prior to arrival of a distantly generated tsunami. The Tsunami Warning System (TWS) was founded in 1946 following the Aleutian tsunami of 1 April of that year that caused major damage and many casualties in the Hawaiian Islands. The TWS is a cooperative effort among Pacific Ocean nations with seismograph and tide data collected and communicated to the Pacific Tsunami Warning Center in Hawaii, which disseminates the appropriate warning.

(4) Tsunami flood elevation - frequency information is developed using historic data and numerical models. Unfortunately, good data are available for only a limited number of tsunamis. Cox and Pararas-Carayannis (1969) and Pararas-Carayannis (1969) present a catalog of tsunamis for Alaska and the Hawaiian Islands. Where data are available, the probability of tsunami flood elevations can be determined by the same methods used for the riverine environment. If insufficient information is available, a synthetic record of tsunami activity must be generated. The geophysical and tectonic setting of the area is used to synthesize a record of tsunamigenic, tectonic deformations on the seafloor. A numeric model is used to simulate the tsunamis resulting from each deformation. The resulting data are combined with tide information to produce the combined tsunami and tide elevation - frequency relationship. Houston (1979) presents a description of tsunami modeling, elevation prediction, and structural damage. Houston (1980) and Crawford (1987) present examples of tsunami elevation predictions for the southern California coast and coast of Alaska from Kodiak Island to Ketchikan, respectively.

d. Ice.

(1) An understanding of ice properties and the effect of ice on the shore and marine structures is important in the Great Lakes, in coastal estuaries experiencing significant freshwater inflow which may transport ice, and along the northern ocean coasts. Ocean coasts may be subject to sea ice or pans and floes of freshwater ice originating from river discharges. Northern lakes, such as the Great Lakes, experience significant accumulations of ice during the winter. Sea ice, also known as saline or brackish ice, freezes and is most dense at -1.7 °C (29 °F), in contrast to freshwater ice at 0 °C (32 °F).

(2) A freshwater lake freezes in two stages defined by the water temperature. Cooler water at the surface generates a circulation pattern by sinking to the bottom, exposing warmer water, which successively cools. When the lake reaches a uniform 4 °C (39 °F), that is, the lake becomes isothermal, the lake is termed to have "turned over." As the surface water cools further, it becomes less dense than the water below it until it freezes. At this point, an ice sheet grows laterally (primary ice). In turbulent water, the primary ice cover will consist of a congealed frazil sheet and ball ice. When formed in rivers, upon reaching the outlet, severe ice jams may form which can completely fill the outlet cross section. The ice cover thickens (secondary ice) with continuing freezing temperatures, which may be at a rate of 1 in. per day (Wortley 1984). While the primary ice's axis of symmetry, called the c-axis or optic axis, is oriented perpendicular to the free surface, the secondary ice's c-axis is oriented horizontally. The formation of snow ice on the surface, which is randomly oriented, insulates the underlying ice, resulting in a reduction in growth rate of the secondary ice. Ice thicknesses in the Great Lakes generally are about 0.6 m (2 ft) to 0.9 m (3 ft). However, along the shore and near coastal structures, ice can build up considerably thicker due to ridge formation and spray. Ice ridges

or hummocks 3 to 5 times higher than the flat ice thickness are common and are not only confined to along the shore. Ice ridges ranging from 3 m (10 ft) to 4.5 m (15 ft) above the normal ice surface and extending 18 m (60 ft) below have been observed on Lake Erie. The time that ice clears at spring breakup is dependent upon heat gain from the atmosphere, local snow and ice conditions, and wind and water currents (Wortley 1984).

(3) Shoreline recession is not only caused by wave action, but also by downslope movement of material due to gravity (mass wasting). Exposure of permafrost lenses to seawater along the Arctic Alaskan coasts results in melting of these lenses. The resultant loss in strength may cause catastrophic failure of the bluff above it (U.S. Army Corps of Engineers 1994). In other areas, shore ice may protect the bluff from wave action. However, during the spring thaw, the saturated bluff will experience reduced cohesive strength, making it more vulnerable to mass wasting. This can be exacerbated by the presence of springs emerging along the bluff face, especially if the bluffs have been undercut by wave action.

(4) In addition to recognizing the effect of ice on shore processes and the functionality of a proposed project, calculation of ice loads may be required. The effect of ice on coastal projects is summarized in Chapter VI-3-5, with guidance on calculating ice loads in Chapter VI-6-6.b.

V-2-14. Foundation/Geotechnical Requirements

a. Every proposed coastal structure, nourishment project, or dredging operation requires knowledge of the underlying sea, lake, or river bottom materials. A geotechnical site investigation is required to assess the nature and extent of all sediments and their respective properties. The level of detail of the investigation is predicated on the study phase: reconnaissance, feasibility or detailed design, and the scope of the project. For example, only surface sediment data may be required for a beach fill, whereas a major coastal structure may require additional information on subsurface conditions. These investigations will entail researching available information from previous studies/projects in the area and obtaining new data.

b. The investigations seek to identify the elevation, thickness, and the physical, hydraulic, and mechanical properties of the soil, depth to bedrock and its properties, and groundwater level. Knowledge of the general soil group (clay, sand, etc.) allows one to assess the general characteristics of the soil. However, each soil group includes materials with a great variety of properties, and without a proper assessment, serious consequences can result (structural failure, inability to dredge the channel, etc.). Chapter VI-3-1 and Eckert and Callender (1987) present discussions on foundation/geotechnical requirements. Terzaghi and Peck (1967) also discuss the minimum requirements for adequate soil description and present a table of data required for soil identification.

V-2-15. Availability of Materials (Sand/Stone Resources)

The specification of materials for a proposed project requires the identification of the type, location, quantity, and quality of material available. Sand is the primary choice for beach nourishment projects, although gravel and cobble may be considered in certain situations. Rock is a popular construction material for coastal structures because of the range of sizes, durability, and availability.

a. Sand.

(1) Beach nourishment projects rely on the introduction of additional sand to the littoral zone to reduce a supply imbalance. Beach sand is generally a natural material preferably derived from a borrow area close to the project area. Location of a suitable borrow area requires geotechnical investigations of sediment size, type, and quantity in addition to environmental, hazard, and regulatory restrictions. Additional processing of sand (e.g., from an offshore site, the dredge may be fitted with additional screens) may be

necessary to obtain the desired product. Since sand may not be available in unlimited amounts, other alternatives may need to be considered. Manufactured sand (rock crushed to suitable gradation) was used at Maumee Bay State Park, OH, and crushed and tumbled recycled glass was deposited at Moonlight Beach, Encinitas, CA, for an emergency repair (Finkl 1996). At Fisher Island, FL, oolithic aragonite sand imported from the Bahamas was placed due to the local scarcity and environmental sensitivity of upland and offshore sand sources, the developer's interest in creating a unique and attractive beachfront, and the relatively modest size of the beach fill required (Bodge 1992). The political and engineering issues of placing this sand on other Florida beaches is discussed in Higgins (1995) and Beachler (1995), respectively.

(2) The identification of undesirable materials in the beach sand also may be required. For example, calcareous materials in the source materials have been found to react with available water sources (precipitation, groundwater, etc.) to precipitate fine-grained carbonate cement in pore spaces of the previously unconsolidated sand (Stransky and Greene 1989). This results in undesirable cementation of the beach nourishment material. This action leads to the formation of steep beach scarps, which are susceptible to undercutting and collapse, and inhibit the access of beachgoers to the shore.

b. Stone.

(1) Coastal structures may use a large quantity of stone of various sizes. The location, quantity, cost, suitability, and quality of the stone are important aspects, which must be investigated. A firm or agency that regularly requires large quantities of stone should maintain records on quarries within its geographic area of business. The change from using cut rectangular stone to rubble-mound shot stone for the armor layer in coastal structures in the past decades has resulted in savings in time and cost. However, the importance of stone quality has only been recently recognized. Appropriate quarry inspections and quality control by an experienced geologist or inspector are essential.

(2) Stone should be durable, sound, and free from detrimental cracks (both natural and quarry-induced), seams, and other defects that tend to increase deterioration from natural causes or which cause breakage during handling and placing (EM 1110-2-2302). The stone should also be resistant to localized weathering and disintegration from environmental effects. Inspection records of potential stone suppliers are important to help ensure these conditions are met and to determine the location, sizes, and types of stone available. Table V-2-3 lists data needed to perform a quarry inspection.

(3) During annual inspection of an existing project, the presence of stone cracking should be observed, as this will affect the maintenance schedule and structural integrity. Noting characteristics, location, and number of cracks will assist in assessing whether the stone will continue to deteriorate and at what rate. Cracks are generally classified as multiple penetrating/throughgoing (MP/T) cracks and mirror image cracks (MIC). MP/T cracks are commonly blast-induced fractures and characteristically form radial fractures, which run diagonal to the shot face. They are highly destructive to the stone's integrity and longevity. These sharp penetrating cracks are often initially minute and will not enlarge until exposed to the elements. Elimination/reduction of this type of fracturing is accomplished by proper shot design at the quarry. Mirror image cracks occur when a fracture splits the stone in half and the halves split repeatedly. These cracks generally do not form until the stone has been placed in the project. MRC are generally jagged and the result of the weathering of geologic beds and/or stress relief. Reasons for MIC (Marcus 1996) are:

Table V-2-3
Quarry Inspection Checklist

Item	Comment
SOURCE INVESTIGATION	
General	Purpose of inspection, date of inspection, personnel attending.
Location	Source name, address, contacts, geographic coordinates, descriptive directions of source location.
Production/Transportation	Materials produced, complete description of lift/face development, plant equipment used for production operations, transportation modes, operating season, additional materials, sources interested in producing, summary assessment.
Geology	Stratigraphy, lithology, structure, groundwater, summary assessment. Photographs are extremely useful in documenting the geology.
Blasting Operations	Blast design (description, blast design factors, blast design relationships, analysis), blasting effects (description, fragmentation, development of radial fracturing, transverse fracturing, cratering, back break and throw), summary assessment.
Material Sampling	Number, size, location within quarry samples where taken, photographs of samples.
Summary Assessment	Summary assessment of source, quarry personnel, and quality control.
LABORATORY INVESTIGATIONS / TESTING	
General	Purpose of testing (quality, durability).
Testing Program	Petrographic examination, abrasion resistance, accelerated weathering tests (wet-dry, freeze-thaw), resistance to salt crystallization.
Testing by Others	Report/evaluate laboratory testing by others.
Summary Assessment	From laboratory testing, make assessment of suitability of material for the use intended.
SERVICE RECORD INVESTIGATIONS	
General	This investigation documents the condition of stone used on other projects. Note changes in personnel and operations which may affect evaluation of service records.
Case Histories	Project name, location, description, material types, material sources (quarry , lift, etc.), exposure conditions, dates of placement, evaluations.
Summary Assessment	Assessment of how well the stone is holding up and if deteriorating, the cause should be determined.
SOURCE EVALUATION	
General	Indicate whether quarry is now a listed source for particular material.
Source Summary Assessment	List areas/lifts within quarry which are suitable for particular products.
Conclusions of Investigating Geologist	List evaluations of the geologist performing past/present investigations.
Review/Determination of Geologist	The investigating geologist makes an overall determination of the quarry, quality control, and suitability of the stone for the intended use.

(a) Differences in thermal expansion behavior of the component crystalline minerals (unavoidable).

(b) Freeze-thaw expansion and contraction of interstitial pore water (avoidable by stone curing and eliminating winter quarrying in northern locations).

(c) Wet-dry expansion and contraction of interstitial clays and clay mineral (mostly avoidable).

(d) Stress relief (slow-term stress release).

(4) The reader is directed to Marcus (1996), EM 1110-2-2302, and Construction Industry Research and Information Association (1991). Figures V-5-12 and V-2-13 are photographs of the progressive deterioration (after 3 to 4 years and after a maximum of 5 years, respectively) of 80- to 178-kN (9- to 20-ton) armor stone (dolomite) in the lacustrine environment (Lake Erie).

Figure V-2-12. Cracked dolomitic limestone - Cleveland East breakwater, Ohio, 1989 (stone is dolomitic limestone)

V-2-16. Accessibility

a. Access to the project area is required before, during, and after construction. The total project area encompasses not only the geographic limit of the actual project footprint but also extends a certain distance away due to impacts to the littoral zone. Access requirements before, during, and after construction may be very different. Prior to construction, temporary rights of entry may only be required to survey the site. Complete lands, easements, and rights of way will be required during construction. After project completion, rights of entry may only be necessary for project monitoring and inspection, but similar requirements obtained during construction may be needed for project maintenance.

Figure V-2-13. Cracked stone - - Cleveland East breakwater, Ohio, 1990. Note continuing degradation compared to 1989 (stone is dolomitic limestone)

b. Access to the site may be by land, water, or both, and may be over public or privately owned land. Individual topographic and hydrographic conditions will dictate whether the project may be constructed by water-based and/or land-based equipment. The designer will need to assess the anticipated means of construction and acquire the necessary real estate for access. Locations with difficult access can significantly increase the cost of a project. In these instances, a change in the project design or scope may be warranted.

c. The access should be designed to allow the safe and efficient movement of equipment, materials, and personnel. Access and haul roads should be of sufficient width and grade to safely accommodate large construction vehicles. Grades should be as flat as practical with the maximum allowable grade of 10 percent (EM 385-1-1). A traffic control plan must be developed. All marine work must be accomplished with certified and inspected plant and equipment. Mooring lines and cables must be clearly marked and the vessels must follow all navigation rules applicable to the waters on which the vessels will be operated. Plans to remove and secure plant and evacuate personnel to safe haven during hurricanes, storms, or floods must be considered. Safety and health requirements concerning activities and operations are discussed in EM 385-1-1.

d. Easement requirements may be temporary or permanent. Easements at a project site generally consist of temporary and permanent road easements, temporary work area easements, and permanent easements. A road easement grants possession of the land for location, construction, operation, maintenance, alteration and replacement of a road and appurtenances; together with the right to trim, cut, fell and remove therefrom all trees, underbrush, obstructions and other vegetation, structures, or obstacles within the limits of the right-of-way. A temporary work area easement grants the possession of the land as a work area which includes the right to move, store, and remove equipment and supplies, erect and remove temporary structures on the land and to perform any other work necessary and incident to the construction of the project. It may also include the right to trim, cut, fell, and remove all trees, underbrush, obstructions and other

vegetation, structures, or obstacles within the limits of the right-of-way. A permanent easement is a perpetual and assignable right and easement to construct, maintain, repair, operate, patrol, and replace the project, including all appurtenances. In addition to providing the rights of entry and access to the site, it will be necessary to provide and maintain adequate utilities and install and maintain necessary connections. All necessary arrangements with local Government officials or owners must be made for use of public and private roads to the site. Recognition that other construction projects may be occurring simultaneously is essential to minimize interference and work disruptions.

e. In granting access to the site, certain restrictions and requirements will need to be identified to control environmental pollution and damage. An environmental protection plan must be created which identifies methods and procedures for environmental protection, necessary permits for waste disposal, plan of restoration upon project completion, environmental monitoring plans, traffic control plan, surface and groundwater protection methods, list of fish and wildlife which require special attention, and spill response plan. The protection of environmental resources may encompass a wide range of activities, such as:

(1) Protection of land resources and landscape.

(2) Reduction of exposure on unprotected erodible soils.

(3) Temporary protection of disturbed areas.

(4) Erosion and sedimentation control devices.

(5) Control of ground vibration.

(6) Disposal of waste materials and removal of debris.

(7) Preservation of historical, archaeological, and cultural resources.

(8) Protection of water resources.

(9) Protection of fish and wildlife resources.

(10) Protection of air resources.

(11) Protection from sound intrusions.

f. The above list summarizes of types of protection to be considered prior to granting access to the site for the construction of a project. The list is not all-inclusive and needs to be tailored to the particular project site. Certain restrictions may apply only during certain times of the year, certain days, or certain times of day.

V-2-17. Monitoring

a. Collecting data (monitoring) of coastal projects will assist in proper design of a project, and improve design procedures, construction methods, operations, and maintenance. Comparison with historic information will aid in understanding processes and changes at the site of interest. Monitoring may be classified by its purpose; operational or research monitoring (Weggel 1995). *Operational monitoring* is done to obtain data for the design, operation, and maintenance of a project. *Research monitoring* is performed to assess the performance of a project in comparison with its predicted performance or to assist in broadening the understanding of physical processes.

b. In general, there are three types of monitoring: physical processes, biological, and economic (Weggel 1995). Physical process monitoring consists of gathering data on the physical mechanisms, forces, and littoral zone responses that are characteristic of the project. Biological monitoring entails accumulating data on living organisms that may be affected by the project. Economic monitoring involves collecting information on the monetary impact of the project.

c. Data collection needs to be accomplished before, during, and after construction. Data collected prior to project construction establishes the baseline data. Data may need to be updated during the design phase. Some data such as hydrographic surveys need to be updated during the plans and specifications phase in order to have the most current information available prior to bidding the project. Information may be required such as check surveys or environmental monitoring of threatened or endangered species during project construction. Post-construction monitoring may be operational or research-oriented.

d. The success of a monitoring program depends upon creation of an extensive and implementable plan. In developing the plan, the processes and data which most affect the project should be identified. The relative importance of each element will have to be assigned with only the most pertinent selected based upon cost limitations. To be effective, monitoring should occur when changes are likely to happen and at sufficient intervals to properly assess changes. Timing of the monitoring should account for seasonal changes in order to allow differentiation from a project-induced change. Monitoring frequency also should be variable, with more data being gathered immediately after the project is in place. As project effects diminish, frequency can be reduced. It is important to recognize that the most effective monitoring plan is one that is fluid; that is, the type, amount, and frequency of data are adjusted as collected data are analyzed. Data that were important initially may be superseded by other information needs which are more critical because it is impossible to anticipate all project effects. A partial list of measurable physical properties is presented in Table V-2-4. For further information on project monitoring, the reader is directed to Weggel (1995), Morang, Larson, and Gorman (1997a, 1997b), Larson, Morang, and Gorman (1997), Gorman, Morang, and Larson (1998), and EM 1110-2-1810.

V-2-18. Data Needs and Sources

a. The intent of this chapter has been to introduce the many factors that a coastal manager or engineer should consider, measure, or collect at the beginning of a new coastal project. At the initiation of a project, it is imperative that one fully understand the problem. While this may seem obvious, one cannot assume that the request for a solution to a coastal "problem" is valid or accurately stated. Those soliciting a solution may not perceive the problem objectively due to political/personal motivations, may have an inaccurate understanding of physical processes, or may have inadvertently been the cause of the problem. It should be considered mandatory to meet with those involved and to visit the site in order to gain an appreciation of the scope of the problem and to observe the scale and relationships of the various physical/geologic features.

b. Having gained an understanding of the problem, necessary data should be listed. Table V-2-5 presents a list of data needs and sources. The problem to be confronted may entail not only balancing existing data and the need to gather more with available monetary resources, but also what to do when the project needs to be built with minimal data. The latter situation will require a more imaginative approach to assess the basic governing processes of the region. Narrative and verbal sources of information will be very helpful. These may include newspaper reports, diaries, local historians, fishermen, marina operators, harbor masters, and local residents. Long-time residents who are especially familiar with the area may give a description of

Note: Shaded block indicates property to be monitored. Nonshaded block indicates property usually not monitored except in unusual circumstances.

historical positions of the shore, past structures which have since deteriorated, and major storms. It is imperative that the gathered information be cross-checked with other sources to assess its validity, recognizing that proclamations with numerical statements made without actual measurements should be treated with skepticism. For example, statements such as, "The waves were 12 m (40 ft) high" or "I always had a beach at least 61 m (200 ft) wide in front of my house" should be treated with suspicion. The statement needs to be substantiated or modified by further questioning and through consideration of when the event occurred. While visual wave height measurements are generally difficult to make due to the lack of other physical objects offshore, the resulting runup may give a clue. A verbal account of a large storm(s) will narrow the time frame to search through old newspapers. The type, quantity and time of year various fish are caught will give clues to the aquatic diversity. Old town maps and property deeds will be indications of the historic shoreline/bluff position. Diaries of deceased lighthouse keepers and ship captains may give accounts of the conditions (direction and duration) and date of storms.

c. In addition to verbal and written narrations, a geologic interpretation of the present condition will assist in assessing the past or future trends. Abandoned beach lines, sea stacks, and old shore structures/foundations will suggest the position of past shorelines. Old piers and jetties may indicate the alongshore direction of the migration of an inlet. Stratigraphic information may suggest a change in depositional/erosional patterns. For instance, peat and organic deposits may indicate the presence of a barrier island in the past. The size, amount, and distribution of shoals can give clues to inlet processes. Sedimentological trends such as a change in size of offshore material may explain the presence of headlands or variations in erosion rates. The presence of a fillet at a man-made or natural protruding structure/feature will indicate the littoral transport direction and mean incident wave direction. The shape of the shoreline between headlands also will give an indication of the average incident wave direction.

Table V-2-5
Data Needs and Sources

Data Needed	Best Source(s)	Alternate Sources
Site map/real estate (Needed to locate structures, land features, utilities, roads and property boundaries.)	Recent survey	Town maps USGS quad maps Atlases Local utility companies Digitize aerial photographs Sketch of site with proposed structures located by existing features
Site topography & bathymetry (Land and underwater contours needed to transform waves to site, determine dredge and beach fill quantities, structure lengths.)	Recent USACE high-density acoustic surveys, land surveys, or SHOALS hydrographic LIDAR surveys	NOAA charts USGS quad maps Contractor surveys Emery method Visual estimation of elevations and slopes
Directional wave statistics (height, period & direction) (Needed for estimation of incident wave for structure design, time series for sediment transport evaluation, shoreline response and beach fill design, channel design (vessel effects))	Directional wave gauge deployed near site	Deepwater wave gauge with waves refracted to coast WIS hindcast Wave hindcast using wind statistics Wave hindcast using design wind
Water level • **Tidal** • **Storm setup** (Needed for incident wave computations, flood evaluations, structure toe depths)	NOAA water level gauge near site	Interpolation between gauges to site Peak stage gauge Highwater marks Numerical models
Currents • **Tidal** • **Longshore** (Needed for sediment transport evaluations, dredge disposal fate, scour potential)	Directional current meter	Nondirectional current meter Measurements using drogues/floats Seabed drifters Numerical models
Sediment characteristics • **Littoral zone (a)** • **Subsurface (b)** (Needed for sediment transport analysis, beach fill evaluation, structure foundation design)	Extensive surface samples (a) Extensive boring program (b)	Geophysical subsurface investigations (a&b) Subsurface probe to refusal (b) Regional geologic maps (b) Visual comparison of littoral sediments using sediment card (a) Interpolation between known information (a&b)
Historic shoreline positions (Needed for evaluations of natural shoreline change, effects of human activity, erosion rates, regulatory setbacks)	USACE project maps Shoreline studies from universities and state studies	Digitize from aerial photographs Historic NOAA charts Extrapolate from topographic surveys Historic town property maps and deeds Estimate from ruined structures and verbal/written accounts
Sediment budget (Needed for determination of natural sediment movement; existing and potential effects of human activity: beach fill amounts, channel dredging estimates, bypassing quantities around structures)	Direct measurement using sediment traps in conjunction with estimation from quantity of trapped material at protruding features and sediment supply from bluff & shore erosion	Numerical estimates using longshore drift equations and period of record wave hindcast Budgets in engineering reports, published literature

(Continued)

Table V-2-5 (Concluded)

Data Needed	Best Source(s)	Alternate Sources
Environmental data (Needed for evaluation of natural and existing environment, and the potential effects of human activity on flora, fauna, and water quality)	Habitat evaluation procedures	Benthic resource assessment techniques U.S. Fish and Wildlife Service, USACE and State agency reports University studies National & local environmental agencies (Audubon Soc., Sierra Club, Nature Conservancy, etc.) Sportsman's Clubs
Historic bathymetry (Needed for evaluation of shoal growth, project effect on shore, and inlet migration)	USACE condition surveys NOAA charts in digital form from National Geophysical Data Center	Historic U.S. Coast and Geodetic Survey charts Contractor surveys
Sand/stone resources • **Availability (a)** • **Quality (b)** (Needed for confirmation of size, location, and quantity of sand or stone material for project as available product can dictate design. Use of inferior quality product will result in service life reduction and possibly failure)	USACE inventories of quarries/sand deposits (a) Service records (b)	State inventories of quarries/sand deposits (a) Geotechnical search for sand deposits (a) Laboratory testing (b)

Chapter V-3
Shore Protection Projects

V-3-1. Introduction

The main purpose of this chapter is to summarize alternatives and their functional design for shore protection. Coastal defense and stabilization works are used to retain or rebuild natural systems (cliffs, dunes, wetlands, and beaches) or to protect man's artifacts (buildings, infrastructure, etc.) landward of the shoreline. A secondary purpose is to review the many constraints that will influence the final design.

a. Major concerns for shore protection

(1) Storm damage reduction. Coastal storms generally cause damage by two mechanisms.

(a) Coastal floodings. On the Atlantic Ocean and Gulf of Mexico coasts, tropical storms (hurricanes) produce elevated water levels, (storm surge) that inundate and damage coastal property. Extra tropical storms (northeasters) along the eastern seaboard and other coasts also create high water and flood damage. Damage from coastal flooding is arguably greater than that due to high winds on the world's coasts.

- Following the devastating flood in 1953, the Dutch people began the Delta Project to raise the dikes and construct barriers (dams) across the estuarine openings to the North Sea. The last component was the Oosterschelde (Eastern Scheldt) storm surge barrier as displayed in an aerial view in Figure V-3-1a and a photograph of the movable gates in Figure V-3-1b. It is one of the largest coastal engineering projects ever completed in the world and a major engineering achievement.

- Inland flooding also disrupts traffic, business, medical services, and normal life to produce secondary, economic and social impacts.

(b) Wave damage. Elevated water levels also bring higher wave energy inland to damage upland development. Damage is a nonlinear function of wave height. On the West Coast, the elevated ocean surface of El Nino events coupled with high storm waves causes damage to marinas, piers, and coastal infrastructure.

(2) Coastal erosion mitigation. The second major concern is coastal erosion. Storms create short-term erosional events. Natural recovery after the storm and seasonal fluctuations may not be in balance to produce long-term erosion. Shore protection projects moderate the long-term average erosion rate of shoreline change from natural or manmade causes. Reduced erosion means a wider sediment buffer zone between the land and the sea. And consequently, erosion mitigation translates into storm damage reduction from flooding and wave attack. How natural shorelines remain stable and mitigate upland damage is explicitly reviewed in Part V-3-3-a. Use of the terms flood control and erosion control are discouraged. Complete control of coastal flooding and erosion is a myth that gives a false sense of security to the client, the general public, and the media. Man cannot control nature. There is always the chance for a more powerful storm than the level of shore protection provided within the design constraints. A reduction in potential levels of flooding and erosion, i.e., mitigation means storm damage reduction benefits and the need for a risk-based, design philosophy, as discussed herein.

a. Aerial view

b. Moveable gates

Figure V-3-1. Oosterschelde storm surge barrier (courtesy Rijkswaterstaat, The Netherlands)

(3) Ecosystem restoration. A new area of concern is the restoration of lost environmental resources such as wetlands, reefs, nesting areas, etc. In 1990, the U.S. Army Corps of Engineers was directed to also consider ecosystem restoration where a Federal project has contributed to ecosystem degradation. For this chapter, Corps civil works project objectives and special design constraints (economic, environmental, institutional, etc.) have been omitted. They have all been brought together in Part V-7. Where appropriate, differences between the Corps' design approach and a general design approach are discussed here.

b. Alternatives for shore protection.

(1) Overview. Figure V-3-2 (adapted from Gilbert and Vellinga 1990) schematically displays five alternative ways to mitigate the damage of coastal storms, namely, accommodation, protection, beach nourishment, retreat and of course, the do-nothing alternative. Civilization's artifacts at the coast are here represented by the lighthouse at a fixed reference line. Storm surge and storm erosion reduce the distance between the reference line and the sea. Sea level rise and historic, coastal erosion also reduce the distance, but at slower time scales. Beach nourishment accomplishes the same objective as the retreat option (i.e., increase the distance to the sea).

(a) Pope (1997) has a similar classification system summarized in Table V-3-1.

Table V-3-1 Classes of Management and Engineering Response for Shore Protection (Pope 1997)

Type	Common Phrase
1) Armoring	Draw the line
2) Moderation	Slow down the erosion rate
3) Restoration	Fill up the beach
4) Abstention	Do nothing
5) Adaptation	Live with it

(b) The protection category in Figure V-3-2 is divided into armoring (seawalls, bulkheads, etc.) for flooding and moderation (groins, breakwaters, etc.) for erosion mitigation and shoreline stabilization. Beach nourishment or restoration is sometimes called the soft alternative to the armored or hard alternative for shore protection. Figure V-3-3 displays the shift from hard to soft, beach nourishment projects over the past 50 years by the Corps of Engineers (from Hillyer 1996).

(c) For design, consider the following six types of alternatives, namely: armoring, beach stabilization (moderation) structures, beach nourishment, adaptation and retreat, combinations (and new technologies) and the with-no-project (abstention) alternative. Table V-3-2 summarizes these alternatives for coastal hazard mitigation including the sections where full discussions are presented.

(2) Armoring. Seawalls, bulkheads, and protective revetments for cliffs and dikes are the traditional types of armored shorelines. The cost of armoring is justified when flooding and wave damage in low areas threaten substantial human investment. On historic, eroding coasts, it must be expected that erosion will continue to diminish the width of the buffer strip between armored shoreline and the sea. If a recreational beach is present, periodic beach nourishment must be anticipated. Part V-3-2 gives functional design details

Table V-3-2
Alternatives for Coastal Hazard Mitigation

Approach	**Changes to the Natural, Physical System**							
Class	**Armoring Structures**			**Shoreline Stabilization Structures and Facilities**				
Type	**Seawall**	**Bulkhead**	**Dike/Revetment**	**Breakwaters**	**Groins**	**Sills**	**Vegetation**	**Groundwater Drainage**
Geometry (configurations) or location	• Vertical • Curved • Gravity	• Crib • Stepped/Terraced • Cantilevered • Tie-Backed	• Sloped	• Headland • Detached • Single • System • Submerged (reef-type)	• Normal • Angled • Single • System (field) • Notched • Permeable • Adjustable • Shaped (T or L)	• Shoreline • Submerged • Perched beach • Intertidal		• Beachdrain • Bluff dewatering • Interior drainage
Materials of construction	• Concrete • Rock	• Sheet-pile - steel - timber -concrete - aluminum	• Earth • Rock revetment • Geotextiles (bags) • Gabions	• Rock • Precast concrete units • Sheet-pile types - steel - concrete - timber - etc. • Geotextiles bags			• wetland • Submerged Aquatic Vegetation • Mangrove	• System of pipes and pumps with sumps

and summarizes knowledge on the interaction of armored shorelines and adjacent beaches. See also Engineer Manual 1110-2-1614, "Design of Coastal Revetments, Seawalls, and Bulkheads."

(3) Shoreline stabilization. Headland and nearshore breakwaters, groins, sills and reefs, and wetlands all moderate the coastal sediment transport processes to reduce the local erosion rate. These structures should be considered where chronic erosion is a problem due to the diminished sediment supply. They are often combined with beach nourishment to reduce downdrift impacts. Their purpose is to slow the loss of placed sand, not to trap sand from the littoral system and create more problems elsewhere. In many locations, their improper functional design, or construction without adding extra material, has produced adverse environmental impacts by starving the supply of sand to downdrift beaches. Their proper design is one of the great challenges of coastal engineering, and functional design aspects are found in Part V-3-3.

(4) Beach nourishment. Loose sediment material can be placed on the subaerial beach, as underwater mounds, across the subaqueous profile, or as dunes to rebuild the dunes. The soft alternative solution for shore protection is now the common alternative selected for a variety of reasons (constraints). Because of its importance, a separate chapter, Part V-4 contains all the details for design.

(5) Adaptation and retreat. Elevating structures, flood proofing, zoning restrictions, storm warning and evacuation planning are some of the types of coastal adaptation methods. Further details are in Part V-3-4-b. Retreat is permanent evacuation or abandonment of coastal infrastructure, and for communities subject to high erosion rates and flooding damages, this is always a possible alternative. Total costs and constraints of this alternative must include the environmental impact on the new site to where "retreat" takes place. In contrast to the engineering, decision-making process to determine the best alternative considering all the design constraints for each site, some advocate retreat as the only solution. Further discussion is in section Part V-3-4-c.

(6) Combinations and new technologies. In many locations, elevated structures combined with some type of armoring or shoreline stabilization structure together with beach nourishment are employed for shore protection. Nontraditional technologies (e.g., beach drains, geotextile bags, artificial breakwater structures, wetlands, etc.) are also being investigated in field experiments. Part V-3-5 gives more details.

(7) Do nothing. Finally, the option to allow continued erosion and storm damage with the expected, annual costs for this choice should be determined. The without project condition provides the basis for measuring the effectiveness to reduce the expected damages of each proposed alternative. Further details for estimating damage costs are in Part V-3-1-c. Part V-3-6 presents more general information on this option. See also Part VI-2-1 for more details regarding various subtypes of the armoring, shoreline stabilization, and beach nourishment alternatives. Each alternative must be considered under a wide variety of design constraints.

c. Design constraints.

One good definition of engineering is "design under constraint." Engineering is creating and designing what can be, but it is constrained by our understanding of nature, by economics (costs), by concerns of environmental impact, by institutional, social, legal issues and possibly by aesthetics. Listed are the five design constraint categories which are discussed further in the following paragraphs.

Design Constraints
Scientific and Engineering Understanding of Nature
Economics
Environmental
Institutional, Political (Social), Legal
Aesthetics

We also limit the discussion here to the general practice of coastal engineering. Part V-8 is completely devoted to special, U.S. Federal government planning requirements and design constraints.

(1) Scientific and engineering understanding of nature. The coastal setting is dynamic and influenced by land, water, and air interactions and processes. It is a regime of extremes, surprises, and constant motion as the coast responds to changing conditions.

(a) The *Coastal Engineering Manual* (CEM) demonstrates continued improvement in understanding and ability to analytically and numerically model nature. For example, Part III-3 discusses analytical methods to estimate sandy beach shoreline recession rates during storm events that will be useful later in this chapter. Part III of the CEM also introduces many new, dynamic, numerical models that simulate coastal hydrodynamics and sediment transport processes.

(b) CP Module. In V-1, the idea of a Coastal Processes Module, (CP Module) was defined as a repository of physical data and analysis tools relevant to the coastal problem. Wind, waves, currents, water levels, bathymetry, geomorphology, stratigraphy, sediment characteristics, sediment transport processes, etc. and the analysis tools (mainly numerical models) make up the CP Module that is employed many times in the design process (see Figure V-1-1, 2 and 3). However, a fully dynamic, three-dimensional, numerical model of water levels, waves and sediment transport to simulate bathymetric and shoreline change is still under development. It remains a long way from routine application for the functional design of coastal structures. An example would be the simulation of natural, sediment movement behind and through nearshore breakwaters for both normal conditions and storm events. The inability to accurately predict the short-and long-term impacts of coastal structures on the nearshore physical environment remains a design constraint in coastal engineering. Part of the difficulty is the stochastic variability of the natural environment.

(c) Empirical Simulation Technique (EST) methodology. Numerical models are deterministic tools that produce one solution for each set of boundary conditions. The EST procedure is the numerical, computer simulation of multiple, life-cycle sequences of systems such as storm events and their corresponding environmental impacts (Scheffner et al. 1997; 1999). Multiple life-cycle simulations are then used to compute frequency-of-occurrence relationships, mean value frequencies and standard error estimates of deviation about the mean. Using the EST procedure for a specific project generates risk-based frequency information that relates the effectiveness and cost of the project to the level of protection provided.

- A user's guide for application of the EST with examples is found in Scheffner et al. (1999). One example describes calculations of the frequency-of-occurrence relationship for storm-induced, horizontal recession of beaches and dunes in Brenard County, Florida. Previous references to the EST procedure are found in Part II-5 and II-8. See also Part V-1 for discussion.

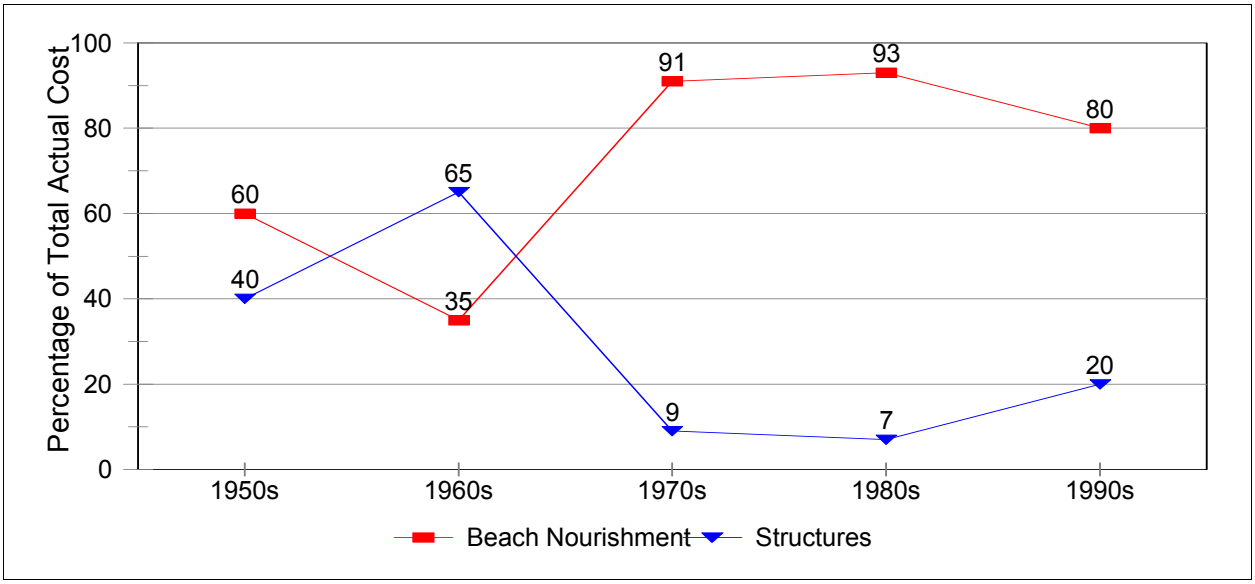

Figure V-3-3. Shift from hard (armored walls, groins, etc.) to soft (beach nourishment) alternatives by the Corps of Engineers (from Hillyer 1996)

- The Corps has specified the EST methodology as a requirement for the risk-based analysis in all shore protection studies (ER 1105-2-101; Thompson et al. 1996). The probabilistic design (functional, structural) of coastal structures remains a constraint, but recent advances such as the EST methodology are helping to produce designs that provide a realistic level of storm protection.

(2) Economics. A key constraint for each shore protection alternative is life-cycle cost. In general, the level of storm protection and, hence, costs (high, medium, low) can only be justified when the corresponding value of property and infrastructure to be protected (benefits) are comparable (high, medium, low). Costs are not subjected to any other constraints. Benefits, however, can be restricted and limited to only those that are perceived to benefit the funding authority. For example, see Part V-8 for the restriction on allowable benefits for Federal government-sponsored projects designed by the Corps.

(a) Cost. It is important to have a clear definition of all terms when discussing costs. Moreover, nothing lasts forever. Advocates for permanent, low cost, or retreat solutions for shore protection fail to understand the following and how they are applied in the professional practice of coastal engineering design economics.

- Costs: The monetary value required for a project. Without additional qualifying words, the word alone is confusing and subject to misinterpretation.

- Initial costs: The total expense for all initial construction and design costs of a project. The year of construction should be noted so that inflationary cost aspects can be estimated in the future. Distinction should be made between estimates and actual contract costs.

- Maintenance costs: The estimated annual expenses required to maintain both the functional and structural integrity of the alternatives which are altered by storm damage and natural processes. Both deterministic estimates and risk-based calculation methods can be employed. (see Part VI-7 for an example of the probabilistic method for rubble-mound breakwaters)

- Alteration/removal costs: The estimated expenses required to alter the design or completely remove the structure if there are significant, downdrift impacts. Evidence from postproject monitoring and decision criteria mechanisms are required for implementation. This cost has been ignored for most projects and could be included in the category of maintenance costs.

- Total, life-cycle cost The combined initial, maintenance and alteration/removal costs required over the design life of the project. Annual maintenance costs are usually converted to their present worth so that they can be directly combined with the initial construction costs. The present worth (value) is determined by multiplying the annual maintenance expense by the present worth factor, PWF. The PWF is a function of the design life and the interest (discount) rate. (See any standard engineering economics text).

- Design life: An estimate of the number of years of useful life of the structure/ alternative. Usually 25 to 50 years is employed for well-designed projects. Design life selection includes structural life of materials (structural integrity), functional life (usefulness), technical life (technologically up-to-date), and aesthetics. Design life is employed for the economic analysis of the present worth of annual maintenance cost for the total, life-cycle cost comparison of all alternatives. It does not mean the length of time the project will last in the field.

- Interest rate: The second variable required to calculate the present worth of the annual maintenance costs. Often, the rate employed is related to the current, bank loan rate for construction projects. It can also be set by government policy as discussed in Part V-8 for the Federal government.

- Damage: When energy levels in storms exceed the design levels, both structural damage and some loss in functional performance may occur. Repair is possible. Damage is an expected aspect of risk-based coastal design.

- Failure: When storms below the design level cause loss of structural integrity and/or functional performance. The design has failed and a redesign is needed before repair or reconstruction. Use of the word “failure” for loss of structural integrity or performance should be avoided until it can be proven that a design failure took place under specified storm conditions.

- Balanced design: The most economical balance between the initial construction costs and maintenance (damage repair) costs so that the total cost is a minimum. Initial costs increase as the level of protection for more powerful (but rarer) storms increases, but maintenance costs decrease because damage is less frequent. The classical U-shaped, total cost curves result. (See Part VI-7 for an example with rubble-mound breakwater design)

(b) Benefits. Storm damage reduction and coastal erosion mitigation are the two major benefits of shore protection. These two along with ecosystems restoration are the only benefits allowed by the Federal government for Corps projects as discussed further in Part V-8.

- Many other benefits exist. As seen in Figure V-3-3, since the 1960s, beach nourishment has been the selected alternative for shore protection. Substantial recreation and tourism benefits have resulted for local, state, and Federal governments. Waterfront property is generally of greater value and generates higher property taxes. Innumerable secondary (ripple effect) benefits result from the coastal, beach-related travel and tourism industry. The economic value of beaches has been well documented (Houston 1995a; 1995b).

- A good example is Miami Beach, Florida, which was renourished in 1979 by a joint Corps of Engineers - City/County government project costing $52 million. The capitalized annual cost is about $4 million and the project has lasted more than 20 years without the need to renourish the beach. Attendance at the beach increased from 8 million in 1978 to 21 million in 1983 (Houston 1995a). More than 2 million foreign visitors spend over $2 billion annually at Miami Beach (Cobb 1992). The Miami Beach experience is roughly $700 return in foreign exchange for every $1 invested in beach nourishment (Houston 1995a; 1995b; 1996).

- Beach nourishment can also enhance the natural environment. Widened beaches reduce the potential for new, tidal inlet formation during storms at narrow reaches of barrier islands. The economic losses to the protected bay environment (property, recreation, farming, fishing, infrastructure, etc.) can be estimated and added to the storm damage and other benefits for the impacted barrier island. In general, however, environmental benefits of the enhanced, flora and fauna habitat are difficult to quantify monetarily.

- All benefits are site specific. Here, we briefly outline the methodology commonly employed to determine storm damage reduction benefits. A key factor, as illustrated in Figure V-3-2 is distance between the reference baseline and the sea. Steps in the methodology are:

  - Make a structure inventory (residential, commercial, public). Employ aerial, orthodigital mapping and Geographic Information System (GIS) technology where possible and adapt new technologies.

  - Obtain software to calculate the depreciated replacement cost of the structures and content value.

  - Obtain the water level, storm frequency-of-occurrence data for the site, and accompanying wave and shoreline erosion data. The EST methodology previously discussed should be employed, whenever possible.

  - Obtain and run storm damage calculation models. Long-term erosion is included to estimated damages under changing future conditions. The key variables are water level and position of each structure in relation to the shoreline. Some models only treat property structure damage and others land and infrastructure (roads, etc.) damage.

  - Apply the models for both the without project conditions and for the alternatives and subalternatives design considered for shore protection.

- The result is the average, annual damages prevented (benefits) of each alternative. Differences for each alternative to prevent or reduce storm damage are quantified by this approach. Complete details can be found in Part V-8 where names and references for some of the software and models presently employed by the Corps are presented. In general, the state of art for these damage calculation models is less well advanced than for other areas of coastal engineering design.

(c) Benefit/cost ratios. A useful indicator of economic performance of each alternative is the benefit to cost ratio (BCR). As previously noted, the total, life-cycle costs do not depend on the other constraints, therefore remain constant. However, the benefits included in the ratio can be limited by the funding authority. Consequently, the BCR calculated can be significantly different depending upon whether all the potential benefits or only limited benefits are considered. Because the Federal government limits the benefits allowable to only storm damage reduction benefits, the total or true BCR is always greater than that specified for Corps projects. In effect, two BCR's exist.

- Federal government, $(BCR)_F$

$$(BCR)_F = \frac{\text{Storm damage reduction benefits}}{\text{Total, life-cycle cost}} \quad \text{(V-3-1)}$$

- Total, true $(BCR)_T$

$$(BCR)_T = \frac{\text{Total benefits}}{\text{Total, life-cycle cost}} \quad \text{(V-3-2)}$$

- Further details regarding the $(BCR)_F$ for Federal-sponsored projects and other methods to measure economic performance are discussed in Part V-8. The total $(BCR)_T$ is never calculated for Corps projects. Consequently, the local sponsors, general public, and media may not understand nor appreciate the true value of shore protection projects to their community. These institutional, political (social), and legal constraints are discussed further in the following paragraphs.

(d) Sea level rise. A detailed summary of present day knowledge of mean sea level change of the world's oceans is given in Part IV-1-6. Over the last 100 years, average, relative sea level rise has been 30 cm (3 mm/year) on the East Coast and 11 cm (1.1 mm/year) along the West Coast (excluding Alaska). The Gulf of Mexico coast is highly variable ranging from 100 cm (10 mm/year) in the Mississippi Delta plain to 20 cm (2 mm/year) along Florida's west coast (National Research Council 1987). Substantial local variability exists. The question remains as to whether these average rates will increase (substantially), stay constant, or decrease in the future. Three things remain clear, however. The existing rates of mean sea level rise at specific sites have not been a severe economic constraint for the shore protection alternatives selected. At many locations, anthropogenic effects (e.g., jettied tidal inlets) causing downdrift, beach erosion are clearly much larger than those occurring due to sea level rise. And finally, long-term, relative changes in sea level can be incorporated into storm surge analysis and the economic design of coastal structures.

(3) Environmental. A third major constraint of shore protection works is their impact on the environment. The Eastern Scheldt, storm-surge barrier shown in Figure V-3-1 was the focus of much discussion in the early 1970s. Environmental scientists favored raising the dikes around the periphery to maintain the saltwater ecology of the tidal estuary. Agricultural and water boards favored a solid dam across the mouth that would create an inland, freshwater lake. A compromise was reached: a storm-surge barrier with movable gates which stay open under normal conditions but are closed at very high storm-surge events. The final design, construction methods and equipment required much research and challenged the ingenuity and technical process of Dutch coastal engineers. In the final analysis, the environmental constraint, to maintain the saltwater ecology, dictated the final design. The additional engineering and construction cost proved to not be the deciding factor.

(a) Types of environmental concerns. As in the preceding example, modification of upland habitat such as land use, resting areas for turtles and shore birds, wetlands, flora and fauna beneficial to the ecosystem, threatened and endangered species, etc. can take place. The aquatic habitat can also be important, for example, water quality, aquatic species, benthic organisms, hazardous, toxic and radiological sediment in

borrow areas, increased turbidity during dredging operations and wave climate alterations by sand volume removal in borrow sites, etc.

- These potentially negative impacts must first be identified. Detailed surveys and sampling investigations are conducted to catalog the species and habitats in the project area under existing conditions. Use should be made of previous studies and summary information. The U.S. Fish and Wildlife Service (F&WS) prepares a planning aid report for large Corps projects that detail existing fish and wildlife resources and their habitats. This report also identifies threatened and endangered species and critical fish and wildlife habitats. The National Marine Fisheries Services (NMFS), state and local resource agencies, and local universities may also provide valuable information.

- The offshore, sand borrow site is the greatest environmental concern for beach nourishment projects. New, benthic sampling and collection efforts are often needed to catalog existing species and habitat. Of concern are species capable of rapid recolonization, commercially important species, or protected species. These surveys provide data on abundance and diversity together with a complete list of all species present. This knowledge can be critical in borrow site selection and hence overall cost of the project.

- In most cases, an Environmental Assessment (EA) report is sufficient to demonstrate the minor environmental impact of shore protection projects. Rarely is a full, Environmental Impact Statement (EIS) needed which is time consuming and can be expensive. Corps project needs for an EIS are discussed in Part V-8.

(b) Impact on natural sediment transport system. The negative, downdrift impact on the local and regional sediment budget can be a key environmental constraint. These concerns are addressed in detail in Part V-3 for armored (Part V-3-2) and shoreline stabilization (Part V-3-3) structures and in Part V-5 for jetties at navigation inlets. A beach nourishment project has many positive, environmental impacts by bringing new material to sand starved beaches and expanding the beach habitat. Studies in turtle nesting areas have proven that renourished beaches increase the number of turtle nests (Broadwell 1991; Nelson et al. 1987).

(c) Mitigation. Procedures, or measures which avoid, minimize and/or compensate for negative impacts are defined as mitigation. Threatened and endangered species such as the piping plover, least tern, sea turtles, and whales required special consideration during the planning and construction stages of shore protection projects. Avoidance of negative impacts is achieved by scheduling construction activities at times when the species do not normally inhabit the project area. Piping plovers and least terns are most vulnerable during the nesting/fledging period from early spring to late summer. Disturbances on the beach cause the nest to be abandoned before the eggs hatch.

- Avoidance for sea turtles and whales is not practical for the southern section of the Atlantic coast because these species inhabit the area for most of the year. Minimization of negative impacts is achieved in various ways including monitoring to document contact; using deflectors on the dragarms and collection boxes on hopper dredges; and conducting turtle relocation projects. These techniques are approved by the National Marine Fisheries Service.

- Mitigation by compensation is employed when resource loss is unavoidable. The most common example is new wetlands construction to compensate for the wetlands area lost due to project construction. Some states require more new area constructed than lost and permit wetland banks that are used to pay for planned, future wetlands loss. New and rebuilt dunes are replanted with grasses to compensate for any plants lost during construction. Mitigation by compensation methods are normally carried out and completed during project construction.

- Ecosystem restoration projects result from habitat lost due to a previous activity such as construction of jetties at a tidal inlet and the long-term, downdrift erosion of the beach. Restoration and protection of unique species habitat could also be the objective. Normally, beach nourishment projects can be designed to meet these project objectives. Methods to quantify these environmental benefits are discussed in Part V-8 as applied by the Corps.

(4) Institutional, political, legal. A fourth area that has a formidable influence on the design process are the institutional, political (social), and legal requirements for all projects.

(a) Institutional (policies and guidelines). The Federal objective of water and related land resources project planning is to contribute to the national economic development (NED) consistent with protecting the nation's environment. Applicable executive orders and other Federal government policies and guidelines as planning requirements are discussed fully in Part V-8. The Corps is responsible for shore protection designs of the Federal government. The Corps District Office engineers with the possible aid of the Coastal Hydraulics Laboratory (CHL), Engineer Research and Development Center (ERDC), do most of the design work. Some design work is performed by the private, civil engineering consulting firms. No general guidelines exist as to when and how the private sector, coastal engineering community participates in the design process for the Federal government.

- Other Federal agencies are responsible for some aspects and alternatives for shore protection. A National Flood Insurance Program (NFIP) was established in 1968 to help reduce the Federal share of costs in connection with flood losses. The NFIP is operated by the Federal Insurance Administration, a division of the Federal Emergency Management Administration (FEMA). An essential component for implementing the NFIP is the Flood Insurance Rate Map (FIRM) which delineates special flood hazard areas and insurance risk zones. These maps are prepared by FEMA's mitigation division. Places subject to flooding at the annual, one percent exceedance probability level are designated as special flood hazard areas. The associated recurrence interval is the so-called, 100-year flood. Use of the 100-year flood designation is discouraged. Many people believe that a 100-year flood happens only once every 100 years. Some areas have experienced flooding at this probability level in consecutive years. The FEMA flood hazard zone maps include special V-zones for both flooding and significant wave energy to cause structural damage. Construction standards (where applicable) and flood insurance rates are usually higher for structures located in V-zones.

- Zoning laws and improved building standards are then implemented by coastal communities based on the FIRM and designated hazard-prone areas. One common standard is the requirement that all, first-floor living quarters of new construction be set at least one foot above the mapped elevation of the one percent chance flood.

- Since 1982, all NFIP policies are actuarial, i.e., the flood insurance policy's annual rates fully reflect the buildings risk of flooding. No taxpayer subsides are required. Presently, about 23 percent of structures vulnerable to flooding damages are covered by the NFIP. And, only 3 percent of these NFIP policies are in coastal communities. These coastal communities generate more premium income that they have received in loss claims (Houston 1999).

•Beaches serving as flood protection works are eligible for disaster relief from FEMA provided the relief is assigned public beach facility status. To qualify, it must have a period renourishment program for long-term maintenance. The local government project sponsor must restore the beach to its normal design shape (template) and pay for the cost of replacing sand eroded prior to the storm. Since natural beach rebuilding begins after the storm, it is not clear what time frame is employed to define the storm erosion volume.

- Several states have established construction setback lines to reduce damage in areas subject to coastal erosion and shoreline retreat. The setback line position is often calculated as some multiple of the annual erosion rate or a specified distance from a contour location in a particular year. In Florida, the line location is based on many factors, namely long-term erosional trends, short-term storm effects, rare water levels at the one percent chance, annual exceedance level, wave uprush, dune line position, wind forces and existing development. In Delaware, 1979 aerial photography has been employed and the restriction line set 30.48 m (100 ft) landward of specified contour elevations, dune toes, or edge of the existing boardwalk structure. These development restrictions affect the without-project calculation of storm damage benefits discussed in Part V-3-1. If homes and structures are not able to be repaired or replaced after a storm by FEMA or state policies, than this will change the without-project estimate of benefits. See also Part III-5-13 for a discussion of setback lines for cohesive shorelines.

(b) Political (social well-being). Specific national policies and laws change as administrations and public interests change. A diverse and broad range of coastal system users with varying economic, social, and environmental expectations and goals exist. Although there have been shifts in the national policy for shore protection by the Administrative Branch of the Federal government, the legislative branch controls the authorization and funding of all Corps projects. Congress has continued to approve and fund the beach nourishment alternative. Shore protection in the U.S. remains political, fragmented, and controversial for a variety of reasons that are further elaborated in Part V-8. National plans for beach management and shore protection do not exist.

- Each project must consider many social aspects.
  - Local, regional and state plans for the coastal zones
  - Public health, safety, and social well-being, including possible loss of life
  - Community cohesion
  - Availability of public facilities and services
  - Potential adverse effects on property values and the tax base
  - Displacement of people, business, and livelihood
  - Disruption of normal and anticipated community and regional growth
  - Sufficient parking and public transport
  - Sufficient dune crossovers

- Public access and safety during construction
- Access for people with disabilities
- Interruption of recreation

- Cultural resources must also be considered.

- Coastal project construction has the potential to severely impact important cultural resources. Project activities such as offshore sand borrowing can damage or destroy important historical sites related to the region's maritime history. Shipwrecks, native American Indian, and prehistoric sites are typically of interest. Investigations by archaeologists to identify cultural resources in the project area provide data necessary to evaluate site significance and potential project impact. Close coordination with the state Historic Preservation Office is necessary for compliance with the National Historic Preservation Act of 1966.

- The politics surrounding shoreline erosion and measures for mitigation provide a wealth of fascinating reading material. For example, the Westhampton groin field on the south shore of Long Island, New York (U.S. Army Engineer District, New York, 1958: Heikoff 1976; Kassner and Black 1983; Nersesian, Kraus, Carson 1992; Spencer and Terchunian 1997; Terchunian 1988) is a classic example of a political decision that significantly altered the original design. The groin field was built in two stages, with 11 units constructed in 1964/65 and four more in 1970/71. It was a Corps project authorized by Congress in 1960. The project area extended from Fire Island Inlet east to Montauk Point and called for beach fill and groins as needed starting at the west end since the natural, net drift of sand was from east to west. A winter storm in 1962 breached the weakened barrier island at Westhampton. Local interests including the Suffolk County government lobbied for and eventually convinced the Corps to construct the groins in reverse sequence, from east to west. In addition, the groins were not filled with sand when constructed and construction was stopped in the middle of the project for political reasons. The result was a massive sand trap along Westhampton that starved the downdrift (westerly) beaches. The interruption of natural sand transport by Shinnecock and Moriches Inlet and the Westhampton Groin Field has accelerated erosion on Fire Island at the west end of the system (Kana 1999). A lawsuit by Fire Island property owners has resulted against the Corps (see Spencer and Terchunian 1997 for more details and reference). The legal constraint has long been a factor in coastal, shore protection design.

(c) Legal (laws). Congress, through passage of the biannual Water Resources Development Acts (WRDA), authorizes studies and funds construction of Corps projects. Sections of this law also include special investigations and establish cost-sharing formulas between the Federal government, state and local interests. For example, in the 1998 WRDA, the cost-sharing law was changed to 50 percent Federal and 50 percent from local/state interest.[1] As a result, some states have passed laws and statues to provide an annual source of funding for the increased cost of participation in Federally-authorized projects.

- The Coastal Barrier Resources Act (CBRA) was passed in 1982 to minimize loss of life, damage to fish, wildlife and natural resources, and wasteful expenditures of Federal revenues on Atlantic Ocean and Gulf of Mexico barrier beaches. The goal is to restrict all Federal government expenditures and assistance that aid development on the coastal barriers. For example, the CBRA relies on the National Flood Insurance Program to discourage building by prohibiting sale of Federal flood insurance in areas covered by the act. The CBRA does permit Federal funding for shoreline

[1] Previously, the formula was 65 percent Federal, 35 percent state/local.

stabilization by nonstructural projects that mimic, enhance, or restore natural stabilization systems, i.e., beach nourishment projects. Federal expenditures are also allowed for the study, management, protection, and enhancement of fish and wildlife resources and habitats.

- The CBRA is one of many Federal laws designed primarily to protect environmental and cultural resources. A partial list includes the following:
  - Archeological Resources Protection Act
  - Clean Air Act
  - Clean Water Act
  - Coastal Barrier Resources Act
  - Coastal Zone Management Act
  - Disabilities Act
  - Endangered Species Act
  - Estuary Protection Act
  - Federal Water Project Recreation Act
  - Fish and Wildlife Coordination Act
  - Land and Water Conservation Act
  - Marine Protection, Research Sanctuaries Act
  - National Historic Preservation Act
  - National Environmental Policy Act
  - Rivers and Harbors Act
  - Watershed Protection and Flood Prevention Act
  - Wild and Scenic River Act
- All shore protection projects must apply for and receive a permit from the USACE prior to construction. This permit is pursuant to Section 10 of Rivers and Harbors Act (1899) and Section 404 of the Clean Water Act (1977). The permit process considers and evaluates many factors, including effects on conservation, economics, aesthetics, general environmental concern, wetlands, cultural values, fish and wildlife resources, flood hazards, flood plain usage, land use, navigation, shore erosion and accretion, recreation, water supply and conservation, water quality, energy needs, safety, food and fiber production, mineral needs, and welfare of people and society. Some states have a Joint Permit Application for local boards, state agencies and the Corps of Engineers permit. This method saves considerable expense and time in that only one permit

application is required to meet the needs of all three levels of government review of the proposed project.

- Some states (North Carolina, Maine) have passed laws banning the use of armored structures (seawalls, bulkheads, revetments) and shore protection on their ocean coasts. South Carolina only bans armored structures and other coastal states are considering similar laws. Florida and California have adopted sand mitigation policies and procedures to permit seawall construction but require the annual placement of sand to compensate for that trapped behind the structure. Further details on seawall and beach interactions are summarized in Part V-3-2.

- Laws for property boundaries at the land-water interface are complex and vary from state to state. A 26-article series entitled "The Law of the Sea in a Clamshell" explaining the applicability and diversity of laws pertaining to the shore has been published by the American Shore and Beach Preservation Association in the magazine *Shore and Beach* (Graber 1980). Clear and legally defendable knowledge of property ownership must be an early step in the design process for coastal protection works.

(5) Aesthetics. A final and especially challenging area in design pertains to the sense of beauty and accepted notions of good taste. Many people feel that natural shorelines (e.g., wide, sandy beaches, rocky cliffs, or vegetated marshes and trees, etc.) are more aesthetically pleasing than ones artificially manipulated for shore protection. An uninterrupted, uncluttered, and natural view of the sea is desirable for most people. Therefore, when possible, an aesthetically balanced and consistent appearance, replicating natural systems is preferred.

(a) The "do nothing" alternative may result in a destructive wake of debris from flooding and wave damage that is visually disturbing for days or weeks following a storm. Some alternatives (e.g., geotextile bags filled with sand) will not survive medium level storm events and leave a debris-strewn beach.

(b) Aesthetics played a major role in selection of the final design for the new, hurricane protection, seawall/boardwalk at Virginia Beach, Virginia. The initial design by the Corps was a massive, curved, concrete seawall patterned after the one in Galveston, Texas. The City of Virginia Beach is a popular tourist, recreation beach and the promenade (boardwalk) features a key aspect of the design. The city rejected this initial design for aesthetic and tourist-economy reasons. First floor hotel guests and restaurant patrons would not be able to see the ocean on the south end. Their view was blocked by the crest elevation of the proposed seawall. The revised design lowered the seawall elevation, modified the structural design, added interior stormwater drainage to accommodate additional overtopping, and widened the nourished beach in front to mitigate storm energy. An artist's perspective and aerial photo are found in Part V-3-2a (Figure V-3-6). The constraints that dictated the final design were aesthetics and the need to accommodate the beach-driven, tourist industry.

(c) Engineering is not applied science. Our limited understanding of nature is one constraint, but it is far from the only one, seldom the hardest one, and almost never the limiting constraint for coastal engineering design.

V-3-2. Coastal Armoring Structures

a. Types.

(1) Seawalls and dikes. The primary purpose of a seawall (and dike) is to prevent inland flooding from major storm events accompanied by large, powerful waves. The key functional element in design is the crest elevation to minimize the overtopping from storm surge and wave runup. A seawall is typically a massive, concrete structure with its weight providing stability against sliding forces and overturning moments. Dikes are typically earth structures (dams) that keep elevated water levels from flooding interior lowlands.

- Various types of seawalls and dikes are depicted in Figure V-3-4. When vertical, they are labeled nonenergy absorbing, whereas if with a sloping surface or rubble mound, they absorb some energy (Pilarczyk 1990). The front face may also be curved or stepped to deflect wave runup. Typical damage modes for seawalls include: toe scour leading to undermining; overtopping and flanking; rotational slide along a slip-surface below and shoreward of the seawall; and corrosion of any steel reinforcement. Vrijling (1990) discusses 14 damage/failure mechanisms for dikes including "stability of the protective revetment." Part VI presents details for functional design.

- Construction of the massive, concrete seawall to protect Galveston, Texas, against overflows from the sea began in 1902, in the aftermath of the major hurricane of September 1900. Over 6,000 (16 percent) of the citizens lost their lives. An original construction photo (top) and chronology of seawall and embankment (dike) cross-section development (bottom) are shown in Figure V-3-5 (from Davis 1961). Major features are the wood piles, a sheet-pile cut-off wall, riprap toe protection, and the curved face to deflect wave runup. Modification and extension occurred in 1909, 1915, 1926, and the last extension to the west completed in 1963. In the almost 100 years of existence, many lives and millions of dollars of property damage have been saved by this project (Davis 1961).

- The City of Virginia Beach has opted for a low-crest elevation, sheet-pile, concrete cap seawall that also serves as a new boardwalk. Figure V-3-6 displays an artist's perspective (top) with cross section and an aerial photo (bottom) of a recently (1998) completed section. Construction of the newly designed, interior drainage system with pumping stations for an ocean outfall and a widened sandy beach will complete the project in 2002.

- Part VI-2 also discusses many other typical cross sections and layouts of seawalls and sea dikes.

(2) Bulkheads. These are vertical retaining walls to hold or prevent soil from sliding seaward. Their main purpose is to reduce land erosion and loss to the sea, not to mitigate coastal flooding and wave damage. For eroding bluffs and cliffs, they increase stability by protecting the toe from undercutting. Bulkheads are either cantilevered or anchored sheet piles or gravity structures such as rock-filled timber cribs and gabions. Cantilever bulkheads derive their support from ground penetration; therefore, the effective embedment length must be sufficient to prevent overturning. Toe scour results in a loss of embedment length and could threaten the stability of such structures. Anchored bulkheads are similar to cantilevered bulkheads except they gain additional support from anchors embedded on the landward side or from structural piles placed at a batter on the seaward side. For anchored bulkheads, corrosion protection at the connectors is particularly important to prevent failures. Gravity structures eliminate the expense of pile driving and can often be used where subsurface conditions support their weight or bedrock is too close to the surface to allow pile driving. They require strong foundation soils to adequately support their weight, and they normally do not sufficiently penetrate the soil to develop reliable passive resisting forces on the offshore side. Therefore, they depend primarily on shearing resistance along the base of the structure to support the applied loads. Gravity bulkheads also cannot prevent rotational slides in materials where the failure surface passes beneath the structure. Typical bulkheads are shown in Figure V-3-7.

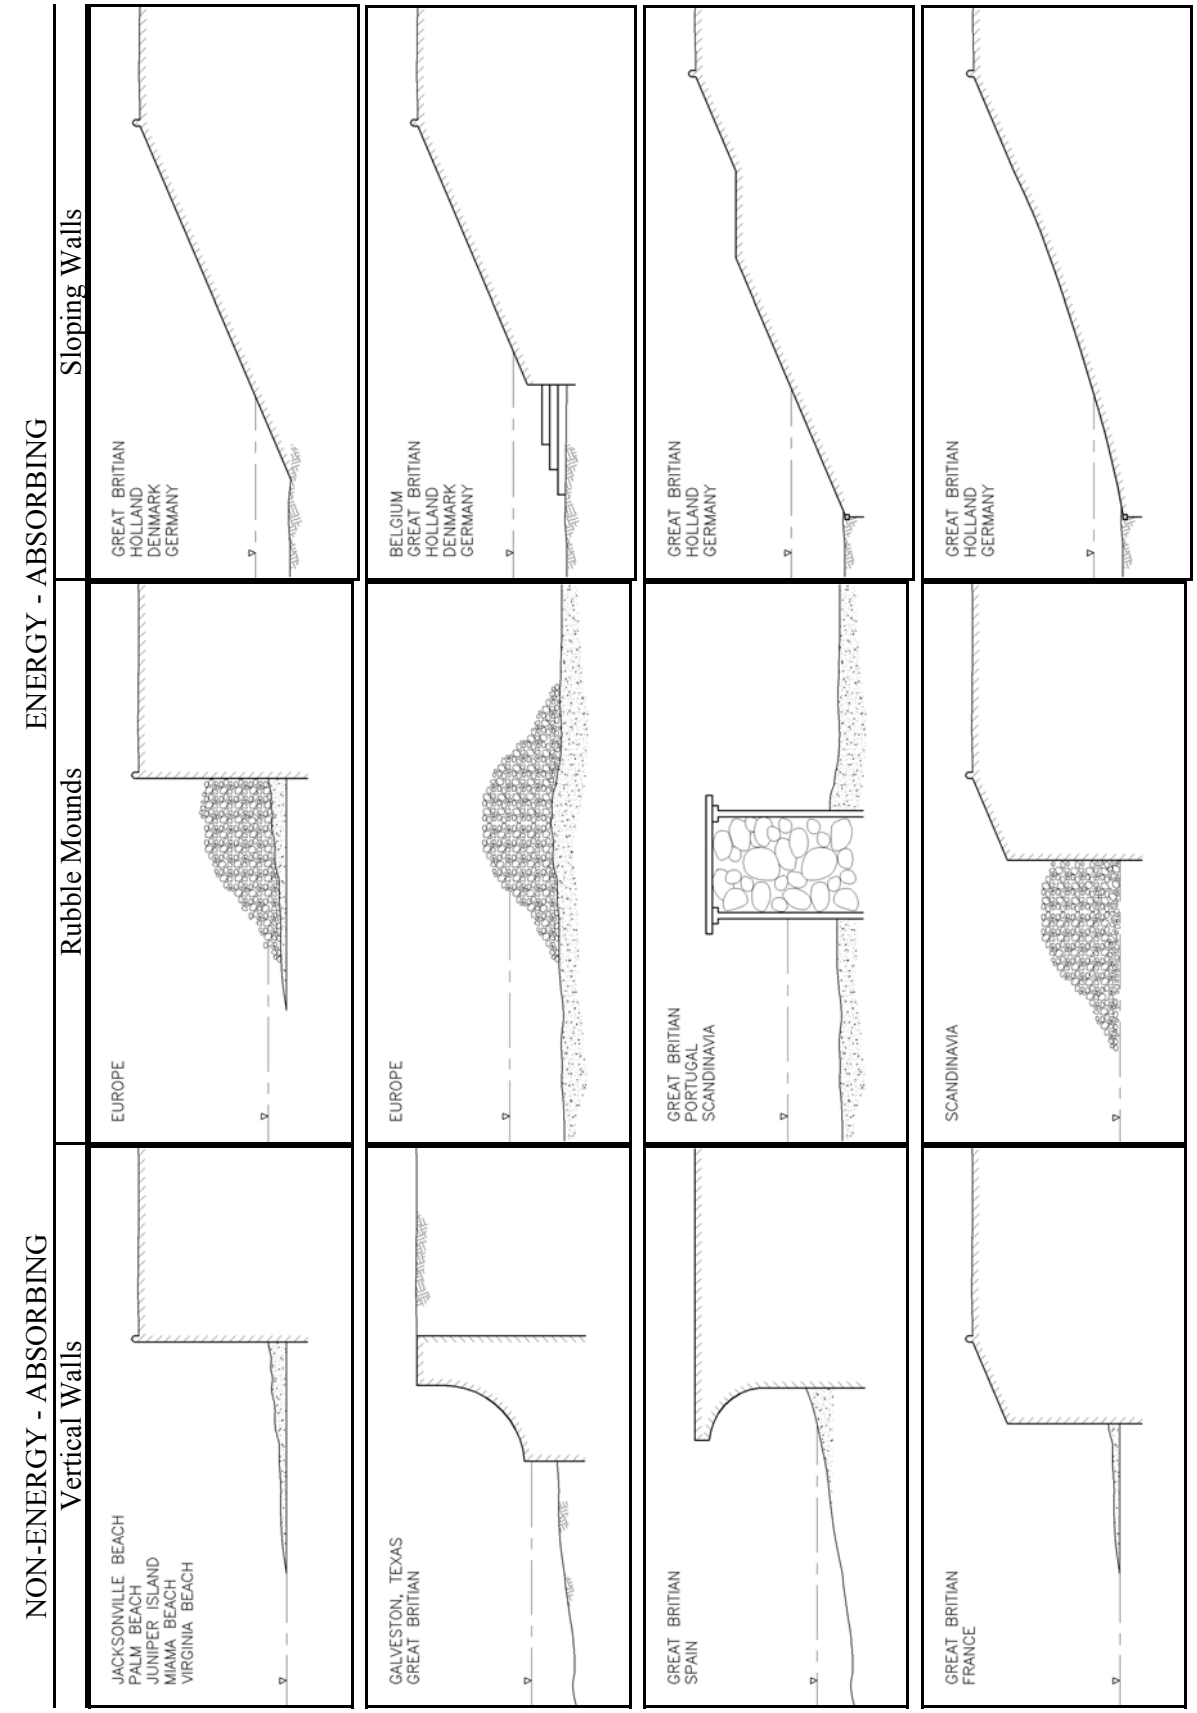

Figure V-3-4. Different types of seawalls and dikes (from Pilarczyk 1990)

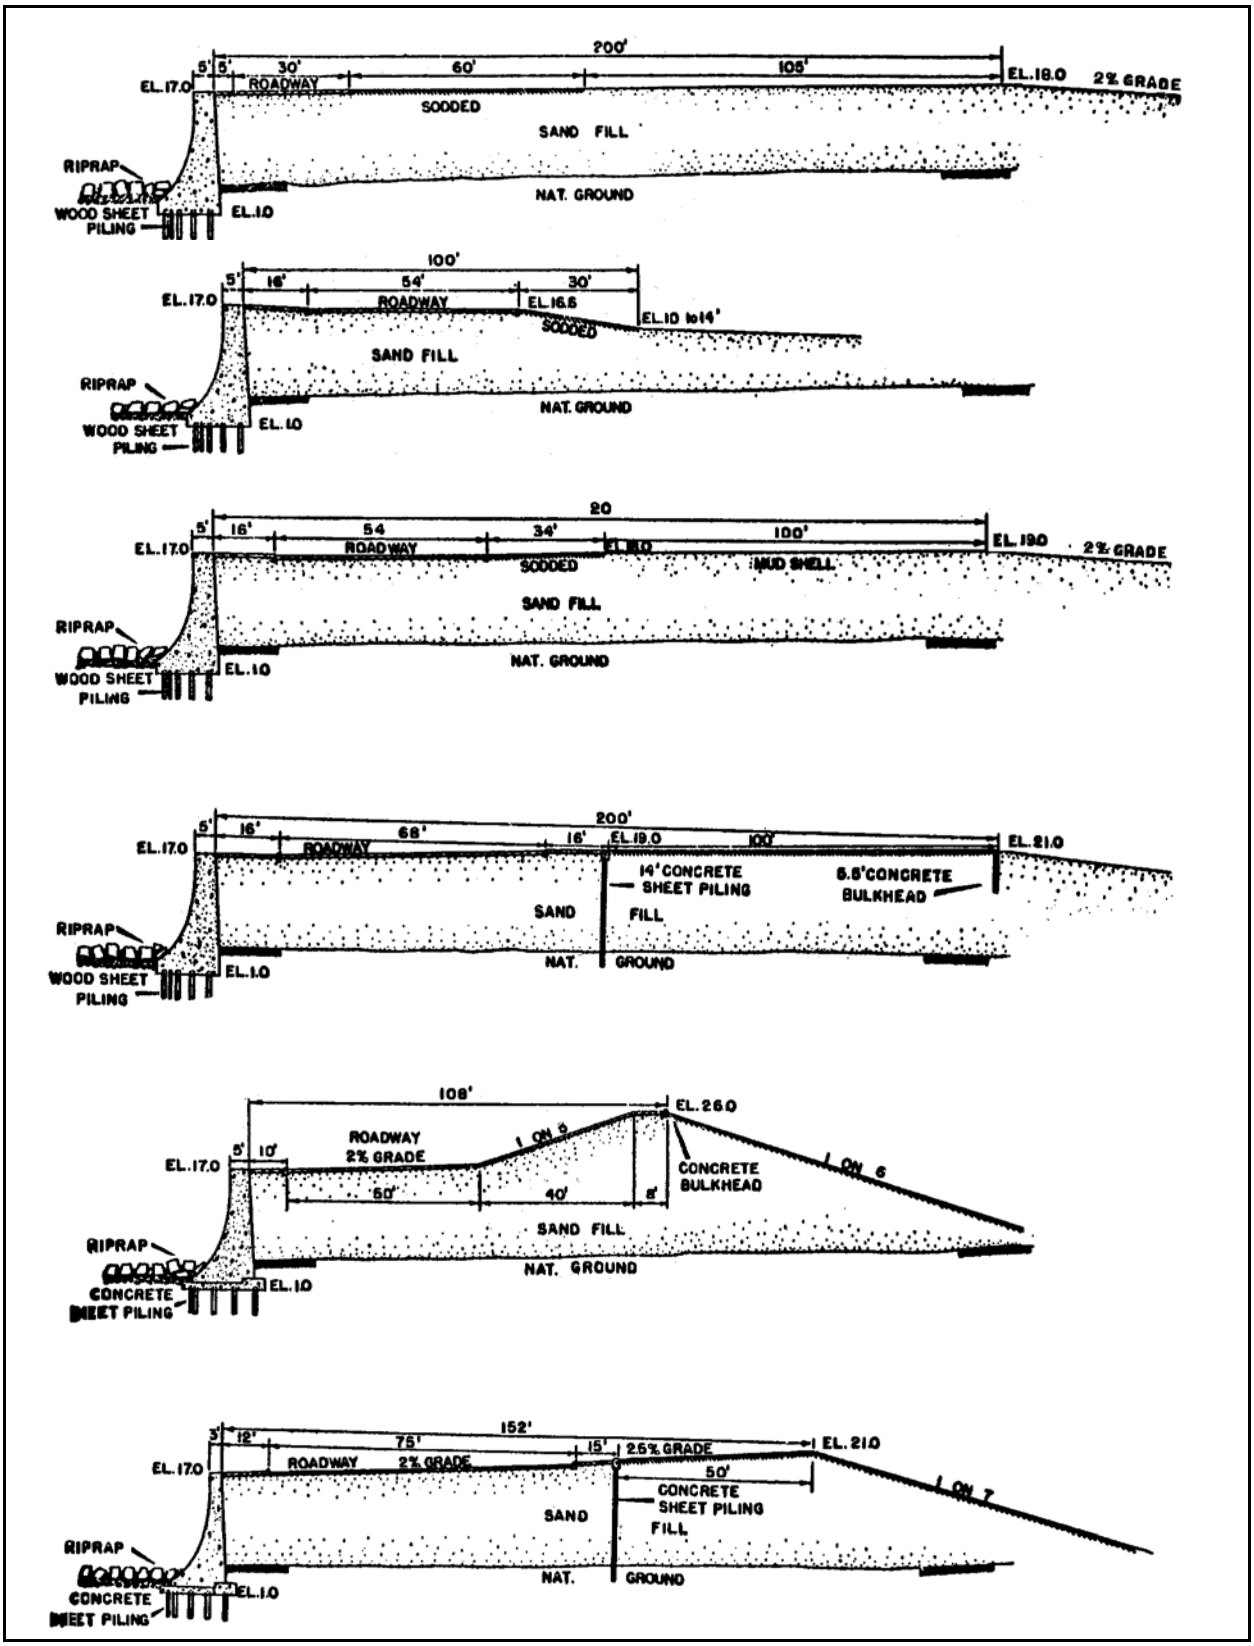
a. Photograph of original construction (from USAED, Galveston)

Figure V-3-5. Galveston, Texas, seawall (Continued)

(a) The primary purpose of bulkheads is to hold land or fill in place and prevent shore side losses. A secondary purpose is to protect the land from wave attack. The strength of a bulkhead to protect against wave attack is provided almost solely by the fill, and if this material is lost, the bulkhead has no practical mechanism to adequately protect against waves. Therefore, two critical elements of a good bulkhead design that prevent or limit loss of backfill are: return walls at the alongshore ends of the structure to prevent high water from washing material away from behind the structure; and geotextiles to allow water but not fines to flow through the structure. Drainage of water through, behind, or laterally away from the structure is important to relieve pore pressure from excessive rainfall or overtopping. Drainage can be provided by drilling weep holes in the structure face to allow water to seep out.

(b) Steel and timber sheetpiling are the most commonly used bulkhead material. Steel sheet piles are individual sheets which can be interlocked and driven into hard, dense soils. The interlocking nature of individual steel sheet piles helps to limit erosion losses of backfill through the bulkhead. However, good design practice also includes installation of a geotextile or gravel filter between the bulkhead and the backfill to further prevent sediment losses. Filters are particularly important for timber bulkheads because they lack an interlocking mechanism, though overlapping timber sheets in a two-to-three layer technique can often limit the pathways for sediment to travel. An often encountered difficulty in installing geotextiles is depth of placement. For sheet piles that are driven, placing the geotextiles the full depth of the structure is practically impossible through the structure below the depth of the filter cloth. The loss of the backfill at a timber bulkhead from water (rain and/or wave overtopping) seeping and carrying sand through the bulkhead below the depth of the filter or below the depth of the timber piles is a common damage mechanism.



b. Chronology of development (from Weigel 1991)

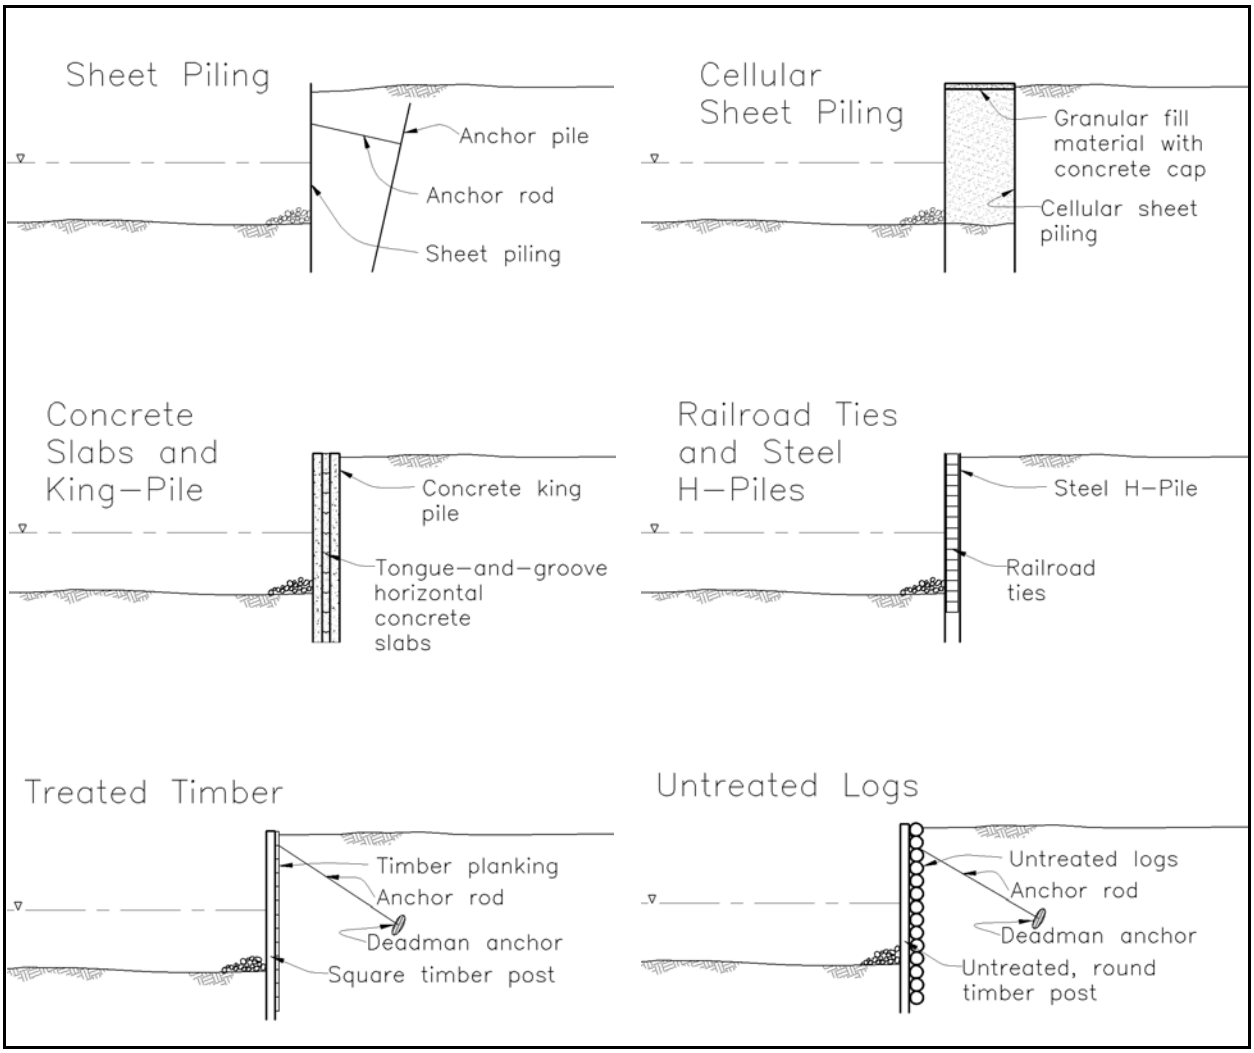

Figure V-3-7. Typical bulkhead types

(3) Revetments. Revetments are a cover or facing of erosion resistant material placed directly on an existing slope, embankment or dike to protect the area from waves and strong currents. Three major features are a stable armor layer, a filter cloth or underlayer, and toe protection. The filter and underlayer support the armor, yet allow for passage of water through the structure. Toe protection prevents undercutting and provides support for all the layer materials previously mentioned. If the toe fails, the entire revetment can unravel.

(a) Figure V-3-8 summarizes a wide range of designs and materials employed for a revetment. Armoring may be either flexible (normal) or rigid. Riprap and quarrystone designs can tolerate some movement and shifting or settling of their underlying foundation, yet remain functional. Rigid, concrete or asphalt slabs-on-grade are generally unable to accommodate any settling.

(b) Typical failure modes for revetment include:

- Armor layer damage and interior exposure.
- Overtopping and loss of foundation material.

- Toe failure and unraveling.
- Excess groundwater pressure and piping failure through the armor layer.
- Rotational sliding along the slip-circle surface
- Flanking of the end sections.

(c) Armor layer stability is discussed in detail in Part VI-5-3-a; toe stability and protection in VI-5-3-d, and filter layer design in VI-5-3-b. Shore protection by revetments can be for all levels of wave energy. For low wave energy environments in bays and rivers, relatively inexpensive and readily available stone sizes makes revetments a common choice for erosion protection by individual property owners. Vegetation and marsh grasses seaward of the revetment also diminish some wave energy to protect the revetment.

(4) Combinations and other types. Protective revetments on dikes are an example of combination coastal armoring structures. Earthen dikes, with stone revetments have been constructed to protect Texas City, Texas, and along the Lake Erie shoreline by the USACE. Due to the nature of the earthen structure, design and specifications should be evaluated by geotechnical engineers (see EM 1110-2-1913, "Design and Construction of Levees"). In the Netherlands, the sea side is heavily armored to protect the dike against the North Sea. On the land side, grazing sheep are used to continually compact the earth.

(a) As previously discussed, a storm surge barrier (see Figure V-3-1) across the opening to the sea provides alternative means of armoring for shore protection. The most notable hurricane barrier in the United States is located at New Bedford Harbor, Massachusetts. The tide (or flood) gate remains open for navigation, then closes to prevent flooding of inland areas during storms.

(b) When insufficient space or earthen dike materials are available, rigid, vertical flood walls may be constructed. Design guidance is available in EM 1110-2-2502, "Retaining and Flood Walls." Crossing the wall requires flood gates that roll, swing, or slide to close the opening EM 1110-2-2705, "Structural Design of Closure Structures for Local Flood Protection Projects." Special, interior drainage facilities may also be needed including pumping stations (EM 1110-2-3102, "General Principles of Pumping Station Design and Layout."). Grade raising, i.e., increasing ground elevation by filling with stable material is also possible. The entire city of Galveston, Texas, was elevated about 4 m to match the seawall crest elevation. (see Figure V-3-5). Sandy material was dredged from nearby Galveston Bay and pumped hydraulically to fill the island. Wiegel (1991) presents a complete history of the Galveston, Texas seawall.

b. Functional design.

(1) The functional design of coastal armoring structures involves calculations of wave runup, wave overtopping, wave transmission, and reflection. These technical factors together with economic, environmental, political (social), and aesthetic constraints all combine to determine the crest elevation of the structure.

(2) Wave runup and overtopping depend on many factors. Part VI-5-2 presents all the details. Empirically determined coefficients, formulas, tables, etc. have mainly come from laboratory scale experiments with irregular waves in large wave tanks. Independent variables include wave characteristics, water depths, slopes, roughness, degree of permeability or impermeable, wave angle, berm or continuous slope, freeboard, etc. Tables VI-6-18, 19, and 20 in Part VI-6 present partial safety factors for runup on rock-armored slopes, hollowed cubes, and dolosse armor units, respectfully.

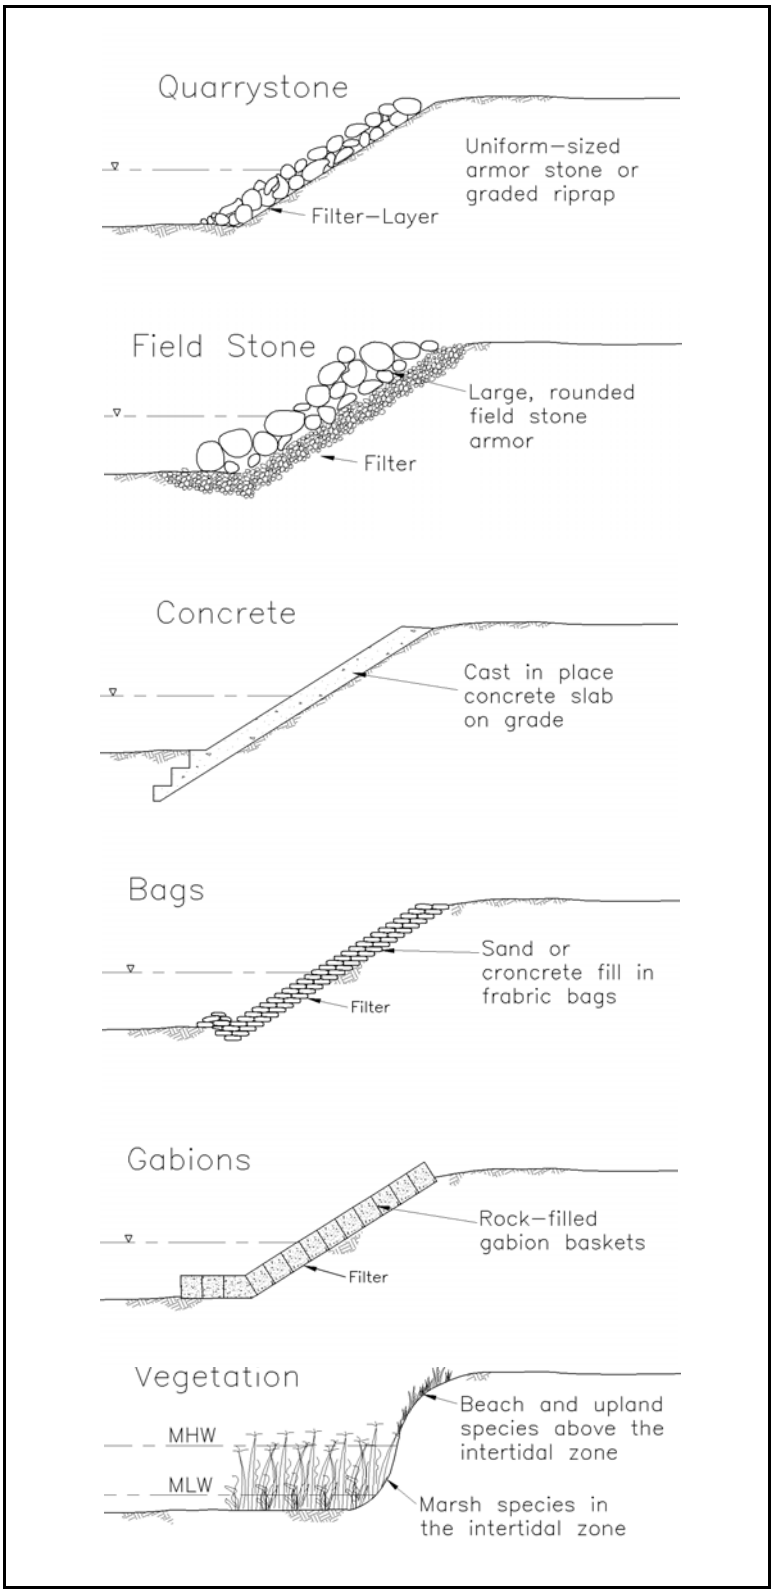

Figure V-3-8. Summary of revetment alternatives (continued)

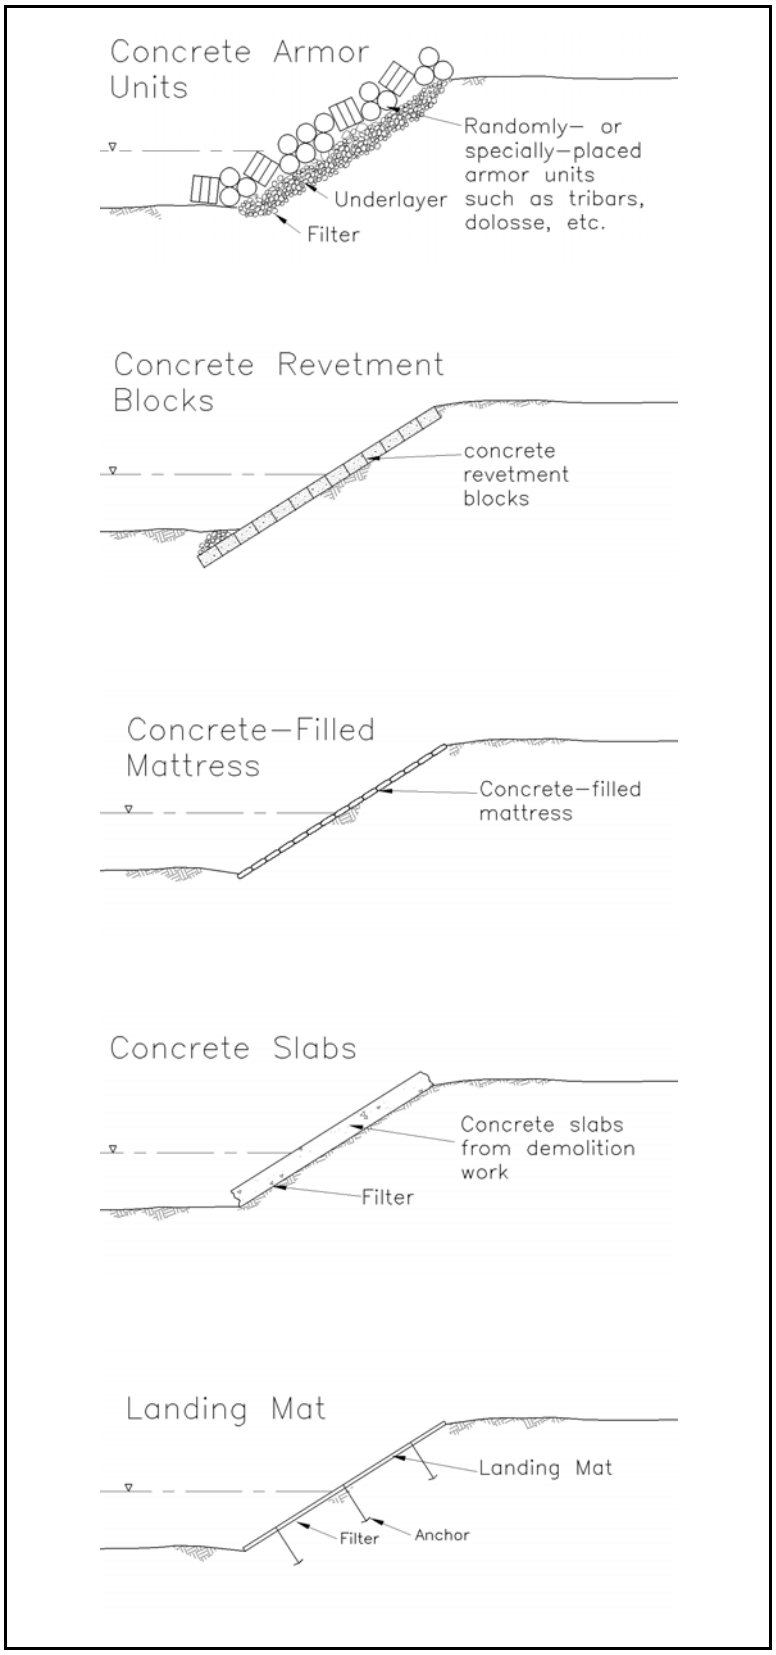

Figure V-3-8. (Concluded)

(3) Wave reflection and transmission through and over sloping structures and beneath vertical wave screens is also found in Part VI-5-2.

c. Interaction with adjacent beaches.

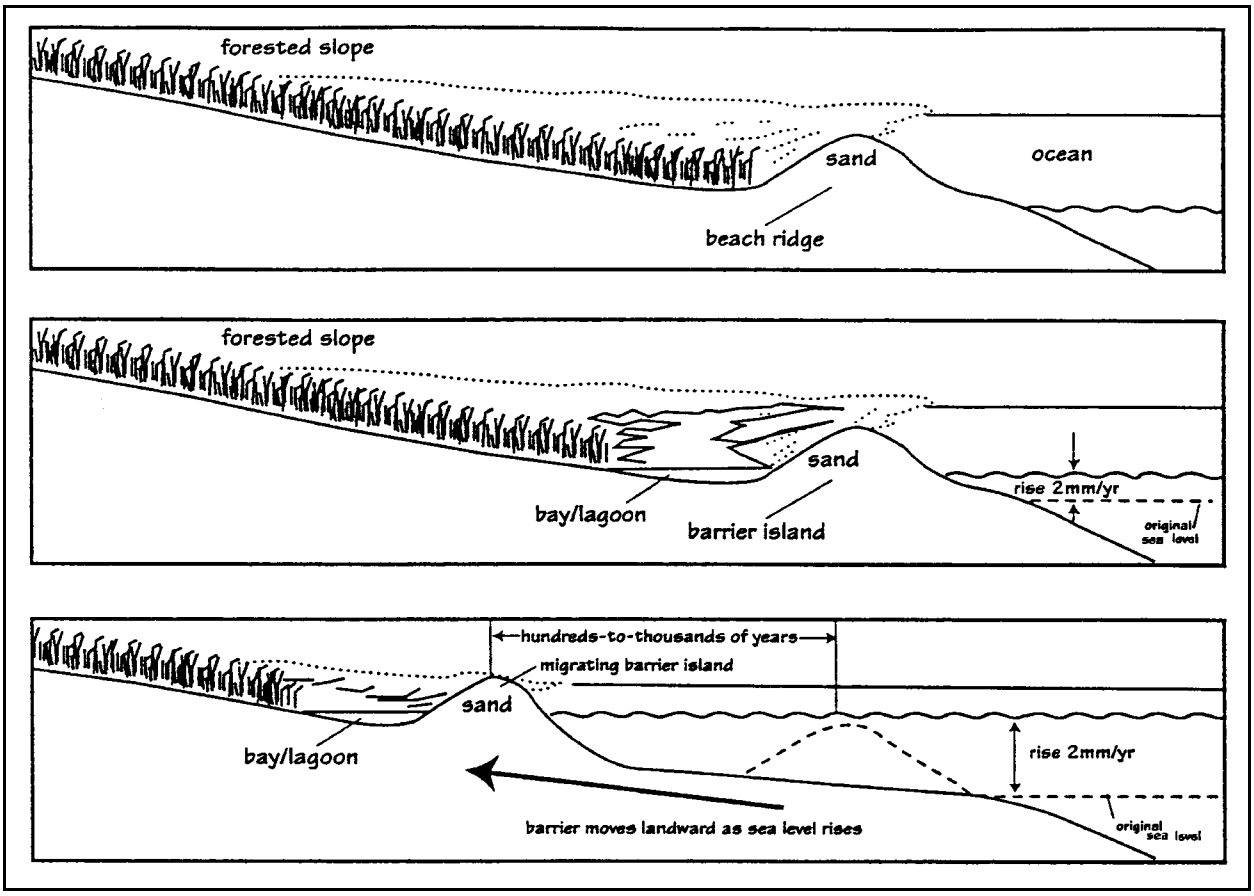
There is a common perception that "… seawalls increase erosion and destroy the beach." The limited available evidence is examined in this section. The term seawall herein means any type of coastal armoring that hardens the shoreline to a fixed position, hence, also applies to bulkheads and revetments.

(1) Background. Concern with how seawalls interact with adjacent beaches can be traced to events in the 1960s and coastal geology studies on the origins and movements of barrier islands (Hoyt 1967). Barrier islands are one of the 11 types of land/water interfaces on earth (Shepard 1976). Barrier beach systems make up about 35 percent of the United States coast stretching from Maine to Texas. They protect the bays and estuaries that lie behind them from direct wave attack, but are dynamic systems with sand volumes that depend on changing ocean conditions, sand supplies, and control boundaries that define the volume.

(a) As depicted schematically in Figure V-3-9a (adapted from Dolan and Lins 1987), barrier islands are commonly perceived to migrate landward with constant volume as sea level rise continues. Storm surge with high waves produce sand overwash into the back bay. The barrier is said to roll over itself, shoreline movement is termed recession, and no volume change means no coastal erosion. Some scientific evidence disputes the rollover model. Leatherman (1988) used shoreline position data to show that tidal inlet formation processes dominate and move far greater sediment quantities over the long term. The migration model also requires the moving sand volume to overlay continuous, basal peat layer from the muds and plants in the lagoon. Stratigraphic evidence contradicts this important aspect along the East Coast of the United States (Oertel et al. 1992). Using the Bruun (1962) rule, a 1-2 mm/year rise in sea level translates to about 0.05-0.2m/year shoreline retreat rate. These are relatively small changes in shoreline position and herein labeled as those at geologic time scales. See Part IV-2-9 for a full discussion of marine depositional coasts and barriers.

(b) When man enters the picture by constructing a road on the shore, he establishes a fixed reference line. The shoreline position relative to the road decreases in time as depicted in Figure V-3-9b. Once development has been permitted, continued erosion may threaten man's artifacts (roads, buildings, bridges, etc.) and some type of shore protection may be undertaken such as seawall construction. These structures are not intended to protect the beach, but areas landward from the beach. Armoring provides a nonmoving reference point on the beach to make the existing, historic erosion more noticeable. Few argue that the road alone is "…destroying the beach", but this same logic is applied by some when a revetment or seawall is present on an eroding shoreline and the dry beach width is reduced each year in front of the hardened shoreline (Pilkey and Wright 1988). Eventually, the ocean will reach the seawall (and road) and the dry beach will be gone.

(c) As also depicted in Figure V-3-9b, a seawall traps sediment behind the structure, reduces overwash and fixes the shoreline position. Continued erosional stress over time acts to deepen the water depth at the structure that is of concern for structural design. The trapped sediment formerly in the dune, bluff or cliff) is removed from that available to contribute to subaqueous bar building during storms. This trapped material is also prevented from contributing to the longshore sediment transport processes along the coast and may alter the sediment budget. The volume trapped relative to that naturally active in the cross-shore profile will be discussed further in the following paragraphs.



a. Barrier island migration at geologic time scales

Figure V-3-9. Time scales for shoreline movements (Continued)

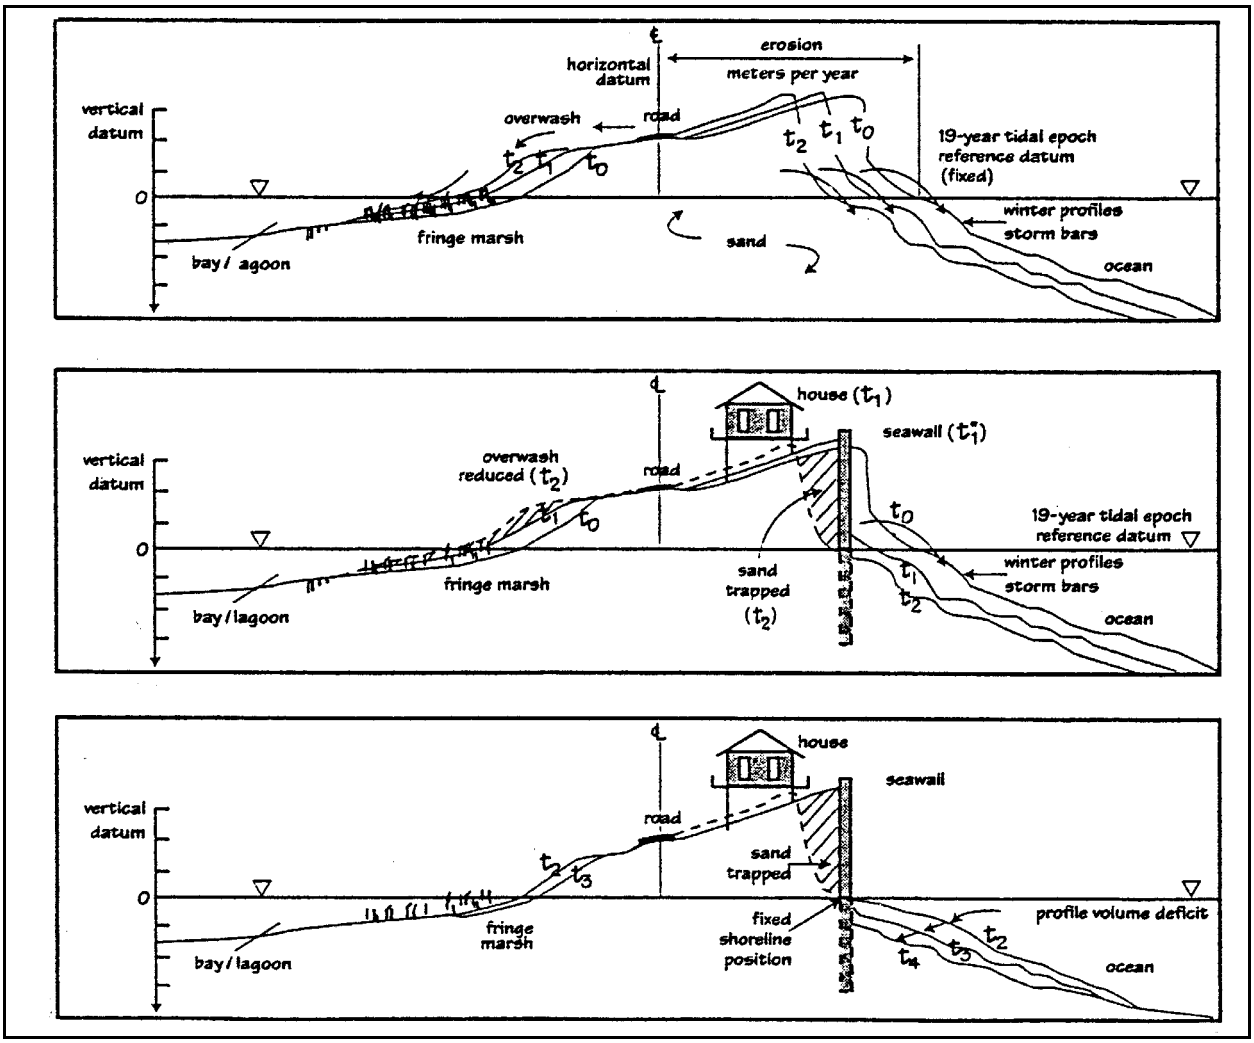
(d) Natural erosion processes (wave-induced, sediment imbalances) plus anthropogenic induced erosion produce larger erosion rates than sea level rise (Komar et al. 1991). These are herein labeled as those at engineering time scales. The degree to which coastal armoring affects the adjacent beach has been the focus of some research effort.

(2) Literature review.

(a) Common concerns. Dean (1987) critically examined nine commonly expressed concerns about seawalls and adjacent beaches as summarized in Table V-3-3. Use was made of conservation of sediment mass, laboratory and field data, and the theory of sediment transport. Conclusions from this analysis were (numbers coincide with Table V-3-4) as follows:

Concerns Probably False (or Unknown)

- profile steepening (6)
- delayed beach recovery after storms (5)
- increased longshore transport (8)



b. Coastal erosion at engineering time scales

Figure V-3-9. (Concluded)

- sand transport far offshore (9)
- increase in long-term, average erosion rate (3)

Concerns Probably True

- frontal effects (toe, scour, depth increase) (1)
- end-wall effects (flanking) (1)
- blockage of littoral drift when projecting into surf zone (groin effect) (4)
- beach width fronting armor likely to diminish (2)

Table V-3-3
Assessment of Commonly Expressed Concerns Related to Coastal Armoring (Dean 1987)

No.	Concern		Assessment
1	Coastal armoring placed in an area of existing erosional stress causes increased erosional stress on the beaches adjacent to the armoring.	True	By preventing the upland from eroding, the beaches adjacent to the armoring share a greater portion of the same total erosional stress.
2	Coastal armoring placed in an area of existing erosional stress will cause the beaches fronting the armoring to diminish.	True	Coastal armoring is designed to protect the upland, but does not prevent erosion of the beach profile waterward of the armoring. Thus, an eroding beach will continue to erode. If the armoring had not been placed, the width of the beach would have remained approximately the same, but with increasing time, would have been located progressively landward (see 2b).
2a	Beaches on eroding coastlines will diminish in front of fixed dune positions.	True	An eroding beach continues to erode relative to a fixed dune position. The width of the beach must diminish if the shoreline is eroding (Figure 1).
2b	Natural beaches on retreating barriers maintain the same beach width.	True	Relative to a retreating duneline, a shoreline eroding at the same rate results in a stable beach width.
3	Coastal armoring causes an acceleration of beach erosion seaward of the armoring.	Probably False	No known data or physical arguments support this concern.
4	An isolated coastal armoring can accelerate downdrift erosion.	True	If an isolated structure is armored on an eroding beach, the structure will eventually protude into the active beach zone and will act to some degree as a groin, interrupting longshore sediment transport and thereby causing downdrift erosion.
5	Coastal armoring results in a greatly delayed poststorm recovery.	Probably False	No known data or physical arguments support this concern.
6	Coastal armoring causes the beach profile to steepen dramatically.	Probably False	No known data or physical arguments support this concern.
6a	Coastal armoring destroys foreshore bar and trough features.	Probably False	No known data or physical arguments support this concern.
7	Coastal armoring placed well-back from a stable beach is detrimental to the beach and serves no useful purpose.	False	In order to have any substantial effects to the beaches, the armoring must be acted upon by the waves and beaches. Moreover, armoring set well-back from the normally active shore zone can provide “insurance” for upland structures against severe storms.
8	Seawalls increase the longshore sediment transport.	Unknown	No known data exists, physical arguments can support or discredit this concern. Needs research.
9	Seawalls cause sand transport a far distance offshore.	Probably False	No known data or physical arguments support this concern.
10	Other		

Kraus (1988) reviewed over 100 references (laboratory, field, theory, and conceptual studies) to make a thorough examination of the literature. This review and seven companion papers are presented in Kraus and Pilkey (eds. 1988). An updated literature review is found in Kraus and McDougal (1996) who examined 40 additional papers. In general, these extensive literature reviews agreed with Dean (1987) regarding which concerns were probably false and which many are true. The interested reader should consult these references for all the details.

(b) Definitions. The natural, background shoreline erosion rate, P_N and the rate *after* human activities P_A can define a coastal erosion ratio, R_P

$$R_p(x,t) = \frac{P_A}{P_N} \tag{V-3-3}$$

where the subscript R_p means shoreline position is used to define R. If profile data are available, then actual, coastal erosion volume could be employed to find a volume ratio, R_V as

$$R_v(x,t) = \frac{V_A}{V_N} \tag{V-3-4}$$

- where V_N is the natural erosion (volume loss) rate and V_A is the volume loss rate after construction of roads, seawalls, etc. at a given location. Clearly, if R_v (or R_p) is proven greater than unity under similar climatological conditions, then we may conclude that armoring has increased the natural, historical conditions at the site. The level of impact (if any) on the frontal and laterally adjacent beaches (1 percent, 5 percent, 10 percent, 50 percent, etc.) needs quantification. Pilkey and Wright (1988) use the terms passive and active erosion of the beach to distinguish between the perceived versus real natural and manmade causes, respectively.

- The volume of sediment trapped behind a seawall depends upon its position on the beach, crest elevation and length. Weggel (1988) defined six types of seawalls depending on their location on the beach and water depth at the toe. At one extreme (type 1) the wall is located landward of the limit of storm wave runup to have zero impact. At the other extreme (type 6) walls are located seaward of the normal breaker line. Types 2-5 lie in between and are said to have increasing effects on coastal sediment processes as the type number increases. Storm surges can create all six type conditions during a single storm event. Coastal erosion may also gradually alter the types.

- Dean (1987) postulated that the sediment trapped behind the wall resulted in an excess erosional stress to produce toe scour and excess erosion on unprotected adjacent property.

(c) Frontal impacts. Beach profile change, toe scour during storms and nearshore bar differences have been attributed to seawalls. Conventional wisdom has been that these impacts were due to wave reflection. Kraus and McDougal (1996) studied the field results by Griggs et al. (1997); laboratory work by Barnett and Wang (1998) and Moody and Madsen (1995) and their own research in the SUPERTANK (large scale) seawall tests (McDougal, Kraus, and Ajiwibowo 1996) to conclude that reflection is not a significant factor in profile change or toe scour. In the field, toe scour is more dependent on local, sediment transport gradients and the return of overtopping water (through permeable revetments or beneath walls) than a result of direct, cross-section wave action. Their conclusions also negate the common perception that sloping and permeable

surfaces produce less effects than vertical, impermeable walls. Scour and scour protection is covered in detail in Part VI-5-6.

(d) Impacts on laterally adjacent beach. Perhaps the key environmental concern is how a seawall affects a neighbor beach with no armoring. Does the wall create end-of-wall or flanking effects, i.e., R (x,t) greater than unity? Two studies are often cited to demonstrate flanking effects. Walton and Sensabaugh (1979) provide posthurricane Eloise field observations (14 data points) of additional bluff (contour) recession adjacent to seawalls in Florida. McDougal, Sturtevant, and Komar (1987) and Komar and McDougal (1988) present small scale, equilibrium beach, laboratory measurements (nine data points) for 7-14-cm waves at 1.1-sec periods normal to a median grain-size, sandy beach. The 23 data points are then combined to demonstrate the excess flanking erosion. The extent and length of the excess erosion is related to seawall length and is explained in terms of the seawall denying sand to the littoral system (e.g., Dean 1987).

- However, other mechanisms may be responsible. If the seawall extends seaward, it may act like a groin to cause downdrift impacts. Tait and Griggs (1991) measured an area of lowered beach profile extending 150 m downcoast at Site No. 4 in California. They proved that the upcoast end of the wall produced sand impoundment or a groin effect. Toue and Wang (1990) conducted laboratory experiments with waves attacking walled and nonwalled beaches at angles and concluded that downdrift impacts were a groin effect.

- Plant (1990) and Plant and Griggs (1992) observed rip currents at interior sections and at the ends of armored sections. These rip currents were attributed to wave overtopping, return flows and elevated, beach water tables during storms. McDougal, Sturtevant, and Komar (1987) also observed rip currents in their model tests previously described and from field evidence in Oregon. They concluded that this mechanism may be more responsible for end-of-wall, flanking effects than the sand trapping theory of Dean (1987).

- Griggs et al. (1997) discuss eight full years of field monitoring including the intense winter storm of January 1995. This storm did not produce end scour on the control beach at Site No. 4. They concluded from a comparison of summer and winter beach profiles at beaches with seawalls and on adjacent, control beaches, that no significant long-term effects were revealed.

- Basco et al. (1997) summarize the results of 15 years of profile survey data with 8-9 years taken before seawall construction at Sandbridge, Virginia, on the Atlantic Ocean. The shoreline has been eroding on average 2m/year (Everts, Battley, and Gibson 1983) long before wall construction began. One part of the study used five years of monthly and poststorm profile data at 28 locations (62 percent walled; 38 percent nonwalled) of the 7,670 m study reach. They concluded that the volume erosion rate was not higher in front of seawalls. However, seasonal variability of sand volume was slightly greater in front of the walled locations. Winter waves drag more sand offshore in front of walls, but summer swell waves pile more sand up against walls in beach rebuilding. Walled sections recovered about the same time as nonwalled beaches for both seasonal transitions (winter to summer) and following erosional storm events. These results were for a weighted average of total sand volume (subaerial) in front of the walled section and seaward of a partition for the nonwalled beach sections.

- At individual profile locations adjacent to walls, using the full 15 years of data, R_v values varied considerably. The evidence for any long-term, end-of-wall effects were considered inclusive for Sandbridge beach. There was never evidence of flanking effects after storms on adjacent beaches (Basco et al. 1997). This study continues. In general, Basco et al. (1997) have confirmed all the conclusions of Dean (1987), Kraus (1988) and Kraus and McDougal (1996) except the end-wall, flanking effect.

- Natural beaches coexist in front of the rocky cliffs and naturally-hardened shorelines at many locations throughout the world. A major, comprehensive research effort is needed to quantify the effect of sand trapping on frontal and downdrift beaches.

(3) Active volume in the cross-shore profile. Successive cross-shore surveys of the beach profile to closure depth reveal spatial variations in vertical elevation at each location. In the absence of lateral transport, the eroded sections balance the accreted areas, i.e., sediment volume is conserved. The active sediment volume is defined as one-half of the total volume change between two successive surveys. The 12-year, biweekly nearshore bathymetric data set surveyed at the Corps of Engineers Field Research Facility, Duck, North Carolina, has been analyzed to quantify the total active sand volume, its spatial variation across the profile, and its relation to long-term, fair-weather, and storm periods (Ozger 2000). An empirical relationship between storm wave power and active sand volume has been developed for the Duck site. Prestorm morphology and duration of storm surge are possible factors for the scatter in the power versus active sand volume relationship. The maximum value of active sand volume was $140 m^3/m$ (350 cu yd/ft). Different tidal conditions, wave climate and hard bottoms (or reefs) limit the cross-shore movement of sediment. Determinations of the naturally active, sand volume should be made for other sites. Basco and Ozger (2001) summarize the above results and discuss various applications in coastal engineering. The seawall trap ratio, WTR can be defined as:

$$\text{WTR} = \frac{\text{Wall Trap Volume}}{\text{Active Sediment Volume}} \tag{V-3-5}$$

to quantify the relative impact of the sand volume removed from the system. Dean (1987) failed to consider the WTR. Weggel (1988) qualitatively addresses the importance of the numerator increasing with type number but also did not consider the significance of the denominator. The spatial distribution of the WTR is also important relative to wall location. At locations with seawalls where the WTR is small, annual mitigation may be economic.

(4) Sand rights and mitigation. A few states have adopted sand mitigation polices and procedures to permit seawall construction and maintain a healthy beach. The idea is to annually replace the beach materials trapped behind the structure with a volume calculated by some formula. The methodology in Florida has both on offshore and longshore transport components which require knowledge of the annual erosion rate and net, longshore transport rate, respectively (Terchunain 1988). Sarb and Ewing (1996) present formulas for cliff and bluff erosion impacted by seawall construction in California. These formulas attempt to deterministically estimate the wall trap volume (numerator) but do not consider the active sediment volume (denominator) in Equation V-3-5. The relative volume trapped is unknown. Field research efforts to date have yet to confirm the trapping theory of Dean (1987). The reason may be that the trapped volume is only a small percentage of the total, active sand volume in the profile. The WTR is near zero so that downdrift impacts are minimal and lost in the data scatter. See also Part III-5-13 for discussion of measures to manage human influence on sediment supply. Who owns the sediments on eroding shorelines, the local property owners or downdrift interests, is a legal question facing society. The subject of sand rights (Magoon 2000) is an extremely complicated issue that may require settlement by the nation's courts.

V-3-3. Beach Stabilization Structures

a. Naturally stable shorelines. Part IV-2 classifies coasts and their morphology. Marine depositional coasts with barriers and beaches are one of the most widely distributed geomorphic forms around the world. (Part IV-2-9, 10). They form a flexible buffer zone between land and sea. The subaerial beach has two major zones. The foreshore extends from the low-water line to the limit of wave uprush at high water. At this point, the backshore extends to the normal landward limit of storm wave effects. This landward limit is usually marked by a foredune, cliff, structure, or seaward extent of permanent vegetation. The backshore is only affected during storms when surges and high waves transport backshore sediments. This exposed, subaerial beach definition is accepted by the general public. Some authors include the surf zone and bars out to closure depth, i.e., the subaqueous part of the beach, because both parts, subaerial and subaqueous, exchange sediment. Beaches may stretch for hundreds of kilometers or others, called pocket beaches, are restricted by headlands and are only tens of meters in length. Figure IV-3-31 schematically summarizes factors controlling morphodynamics along a range of coastal environments extending from rocky, to noncohesive sediments to cohesive shorelines.

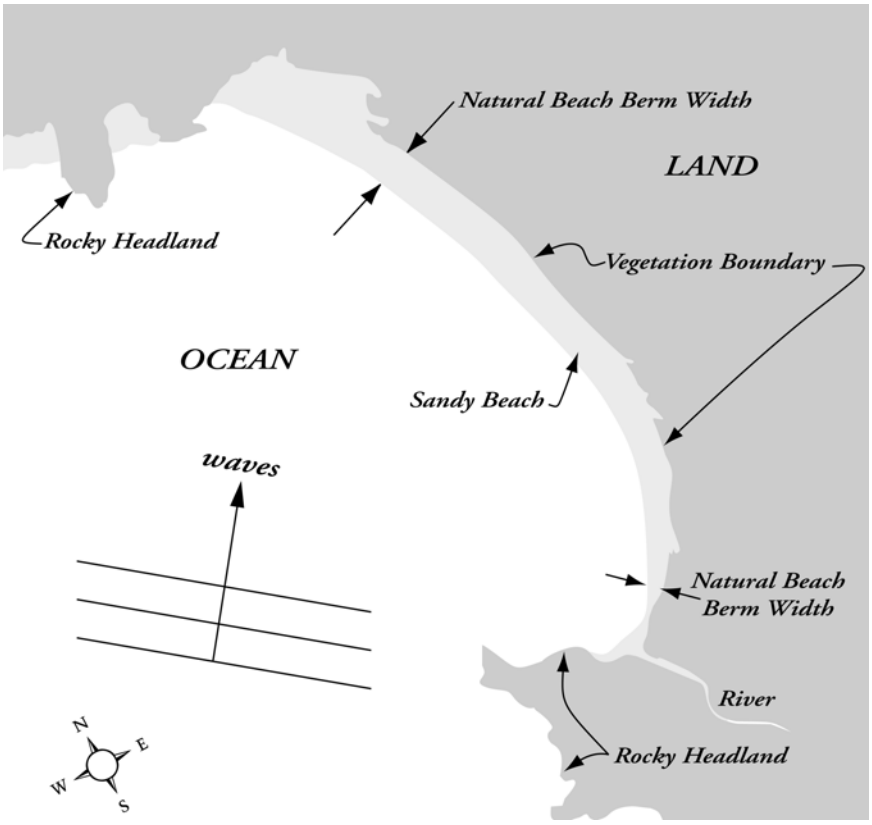
(1) Many beaches are naturally stable. In general, wide beaches are exposed to more severe wave conditions at that location, but the relationship between beach width (or section volume) and storm energy for naturally stable shorelines has yet to be determined. Figure V-3-10a displays a stable, pocket beach on Bruny Island, Tasmania, Australia, where beach width increases along the more exposed section of coast (from Silvester and Hsu 1993). The protected reach behind the headland is much narrower than that receiving a direct attack by large waves during storms. The dark area is vegetation and landward limit of the backshore, subject to normal storm wave effects. If this photo were taken at high tide, a minimum beach width for a stable shoreline could be determined.

(2) This concept of a minimum beach width (or volume) is schematically illustrated in Figure V-3-10b. The volume of sediment present protects the uplands (foredune, cliff, structure, or vegetation) from damage under normal or average storm conditions. The landward boundary of the backshore is a reference baseline for shore protection. On eroding beaches, the backshore may be missing, and the high-water uprush may impinge directly on cliffs or structures. Both natural and anthropogenic agents may cause the erosion. But a minimum, beach width is still necessary for natural shore protection at the eroding site.

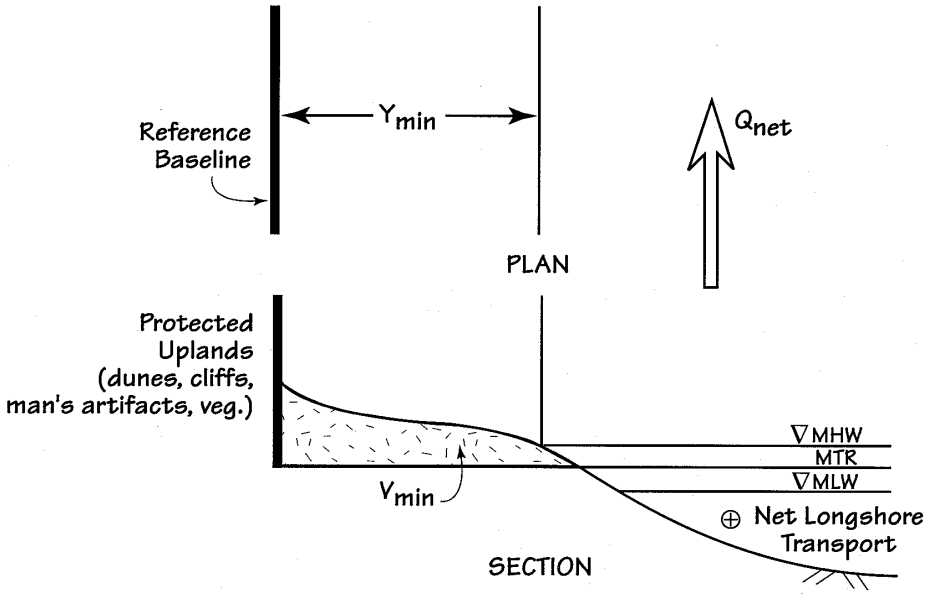
b. Minimum dry beach width. Professor Richard Silvester in an article on the stabilization of sedimentary coastlines (Silvester 1960) wrote:

> "…to allow for storm-cycles and the short-term reversals of drift, a sufficient width of beach should be allowed as working capital on which the sea can operate. Once the coast has been stabilized, by preventing the net movement of sediment, no long-term erosion need be anticipated and the 'active' beach width can be minimized." (p. 469)

(1) As illustrated in Figure V-3-11a,b, for both naturally open beaches and pocket beaches between headlands, the minimum, dry beach width, Y_{min} is defined as the horizontal distance between the mean highwater (mhw) shoreline and the landward boundary or base (reference) line. The mhw shoreline is employed because it is the common, land/water boundary shoreline on maps; it is more readily identified from aerial photos; and it is a more conservative, minimum width (and volume) for shore protection. It is the minimum, dry beach width required to protect the foredune, cliff, structure, or vegetation behind the baseline from normal storm conditions. The beach does the work, and it's resilience and recovery are critical for long-term shore protection.



a. Aerial view (schematic from photograph) of Cloudy Bay, Bruny Island, Tasmania, Australia, showing greater natural beach berm width along the more exposed section of coast (adapted from cover photograph and Figure 3-21 in Silvester and Hsu (1993))



b. Schematic of minimum dry beach width, Y_{min}

Figure V-3-10. Naturally stable shorelines with beach width dependent on stormwave energy (from Silvester and Hsu 1993)

(2) Normal storm wave conditions are expected once every two years or maybe every year. More intense, less frequent storms will reach the foredune, cliffs, structure or vegetation line. Beach stabilization structures can provide upland protection beyond the baseline for these rarer storm events. At a minimum, these structures should be designed to provide the minimum, dry beach width for shore protection.

(3) Figure V-3-11c,d,e depict the three most common beach erosion mitigation structures, namely headland breakwaters, nearshore breakwaters, and a groin field. And, each schematic displays the minimum, dry beach width, Y_{min} that is required for design. In each case, it is located in the gap area with greatest wave energy. The EST methodology discussed in V-3-1-c can be applied to determine the probability distribution of dry beach widths including the minimum for normal storm conditions. Functional design of these structures based on empirical knowledge is presented in the next sections. Two key factors are the minimum dry beach width (or volume) and the natural, sediment transport processes at the site. Explicit acknowledgment of Y_{min} as design criteria is often missing in coastal engineering design.

c. Headland breakwaters.

(1) Background and definitions. Natural sandy beaches between rocky headlands have been called a variety of names in the literature, related to the curved shape of the bay found at many coasts around the world. Silvester and Hsu (1993) summarize the literature. See also Part III-2-3-i. for a list of references. Because of their geometry, they have been called spiral beaches, crenulate-shaped bays, log-spiral and parabolic-shaped shorelines, headland bay beaches and pocket beaches. Half-Moon Bay in California is a good example as first discussed by Krumbein (1944) and shown as Figure 4.3 in Silvester and Hsu (1993). Many researchers have studied the dynamic processes of this geomorphic feature, but Silvester (1960) was the first to examine their static equilibrium and propose the creation of artificial headland breakwaters as a shore protection structure. Figure V-3-12 presents a sketch of an artificial headland system and beach planform (from EM 1110-2-1617, "Coastal Groins and Nearshore Breakwaters."). Normal wave conditions with a predominant swell direction produce a maximum indentation between two fixed points (breakwater structures) and a fully equilibrated, planform shape. Thus man can mimic nature by building the headland breakwaters and letting nature sculpture the beach with a limiting indentation and shoreline that is stable.

(2) Physical processes. Waves from one persistent, dominant direction, β, diffract around the upcoast headland and refract into the bay. Waves will break at angles to the shoreline causing sediment transport and shoreline shape adjustment (nonequilibrium shape) until a full equilibrium shape is reached. At this stage, waves break simultaneously around the entire periphery, no longshore currents and no littoral drifts occur within the embayment. The tangent section, adjacent to the downdrift headland is exactly parallel to the normal wave crest direction from offshore. Such a bay is said to be in static equilibrium (i.e., it is stable until there is a shift in the dominant wave direction). Minimal amounts of additional sediments enter or leave past the headland boundaries. Bidirectional, dominant, wave impact (swells and storms) and sediment bypassing the headlands are two reasons for littoral drift to continue around the bay. These bays are said to be in dynamic equilibrium and can be predicted within certain tolerances. Only the static equilibrium shapes can be related to wave input. The ability to calculate the static equilibrium shape and maximum indentation are needed for the functional design of headland breakwaters.

(3) Functional design. Early investigators employed a log-spiral curve to fit the planform shape (Yasso 1964; Silvester 1970). In practice it is difficult to apply because the center of the log-spiral does not match the point at which diffraction begins to take place.

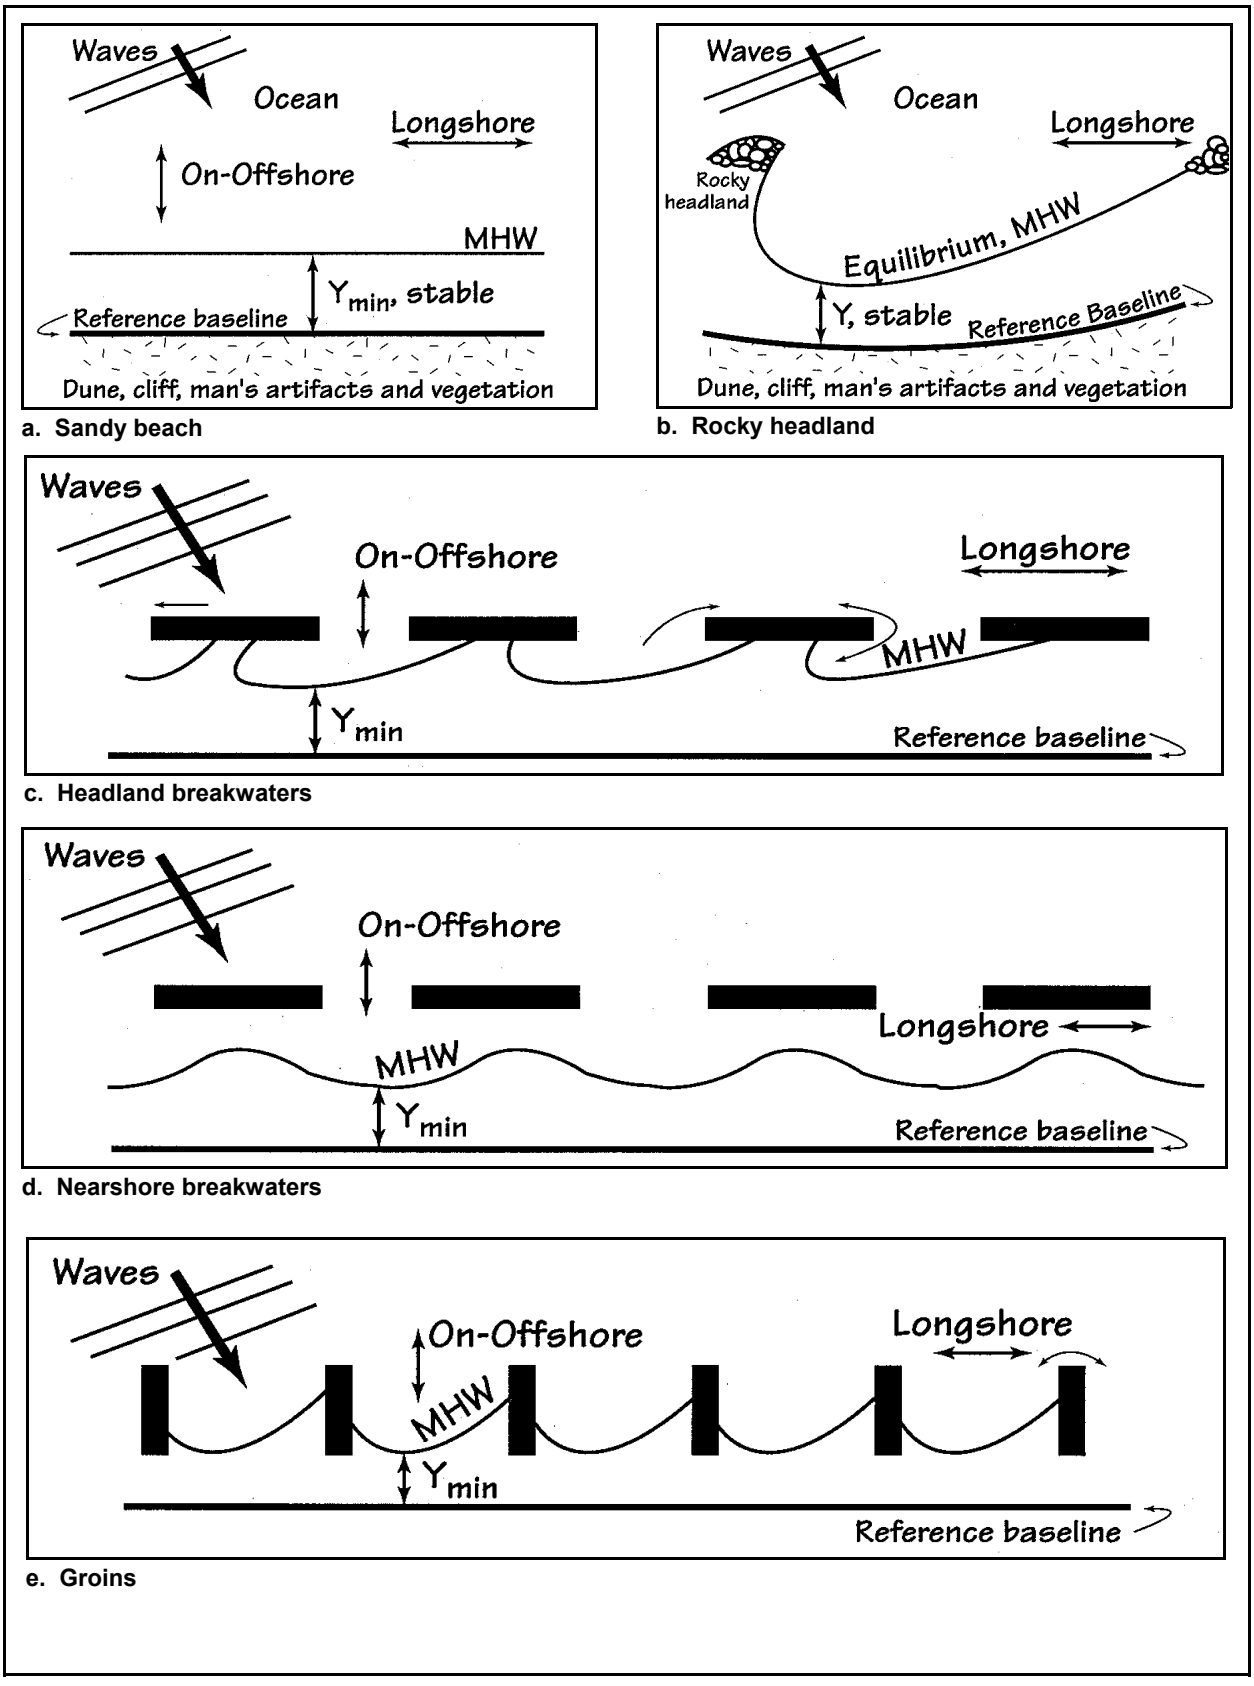


Figure V-3-11. Natural and artificial stable shorelines with minimum dry beach width, Y_{min}

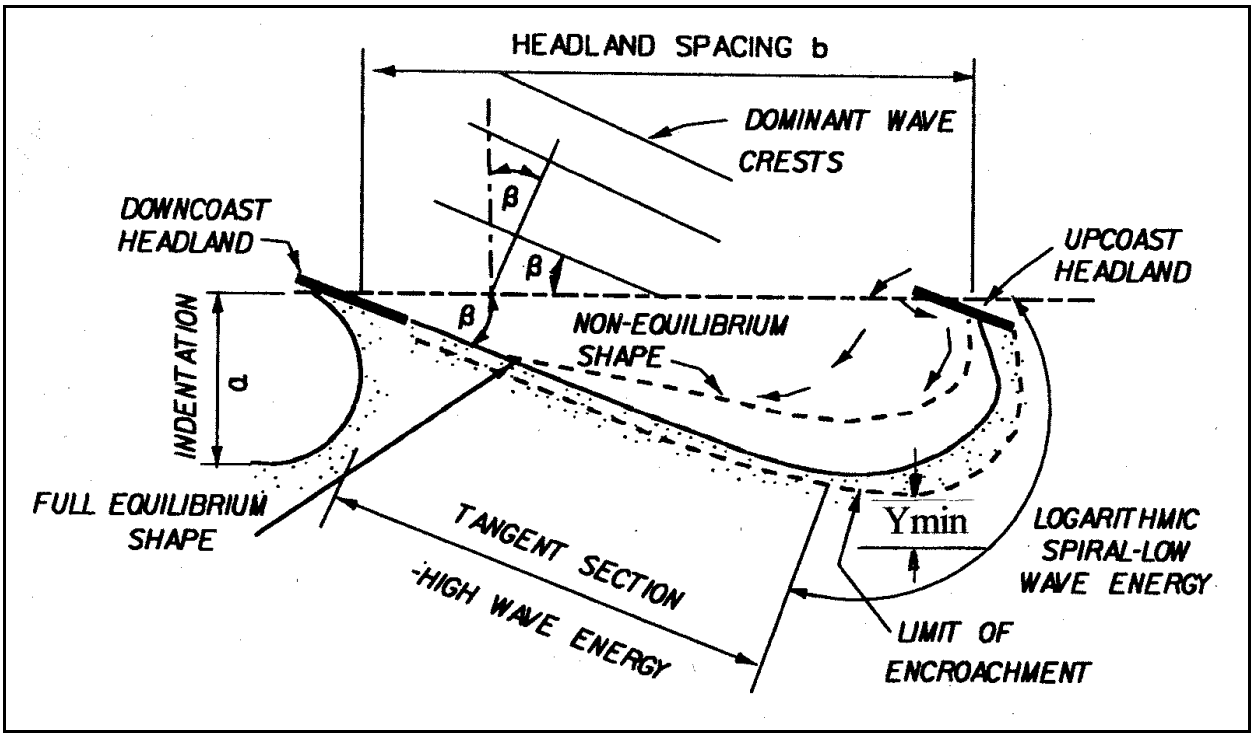

Figure V-3-12. Definition sketch of artificial headland system and beach planform (from EM 1110-2-1617)

(a) Parabolic bay shape. A new empirical approach that uses shoreline data from bays in static equilibrium and physical models has been developed by Hsu, Silvester, and Xia (1987, 1989). It is called a parabolic model because the data has been used to fit a second order polynomial. Figure V-3-13 presents a definition sketch of the four key geometric variables, R, R_o, β and θ, that form the parabolic model. The model center now exactly matches the initial diffraction point. Part III-2-3-i presents complete details including definitions of R, R_o, β and θ; the parabolic model equation (2-24); the three coefficients C_o,C_1, C_2 related to wave angle β in Figure III-2-27 and limitations of the data. An Example Problem III-2-8 is also presented to illustrate an application of the model which assumes one predominant wave direction exists at the site of interest. Many more examples and discussion is found in Silverster and Hsu 1993.

(b) Minimum width for storm protection. As illustrated in Figure V-3-12, storm waves may be from a different direction to cut back the beach and form a new limit of encroachment planform shape. A more detailed definition sketch in perspective and cross section is presented in Figure V-3-14 (adopted from Hardaway, Thomas, and Li 1991). Two nearshore breakwaters together with beach nourishment form the headland breakwater design for shore protection. The following terms are defined:

L_s Length of breakwater structure

L_g Gap distance between adjacent breakwaters

d_s Depth (average) at breakwater below mean water level

e Erosion of shoreline (mhw) from design storm

Y_o Distance of breakwater from original shoreline

Y_g Maximum indentation under normal wave conditions

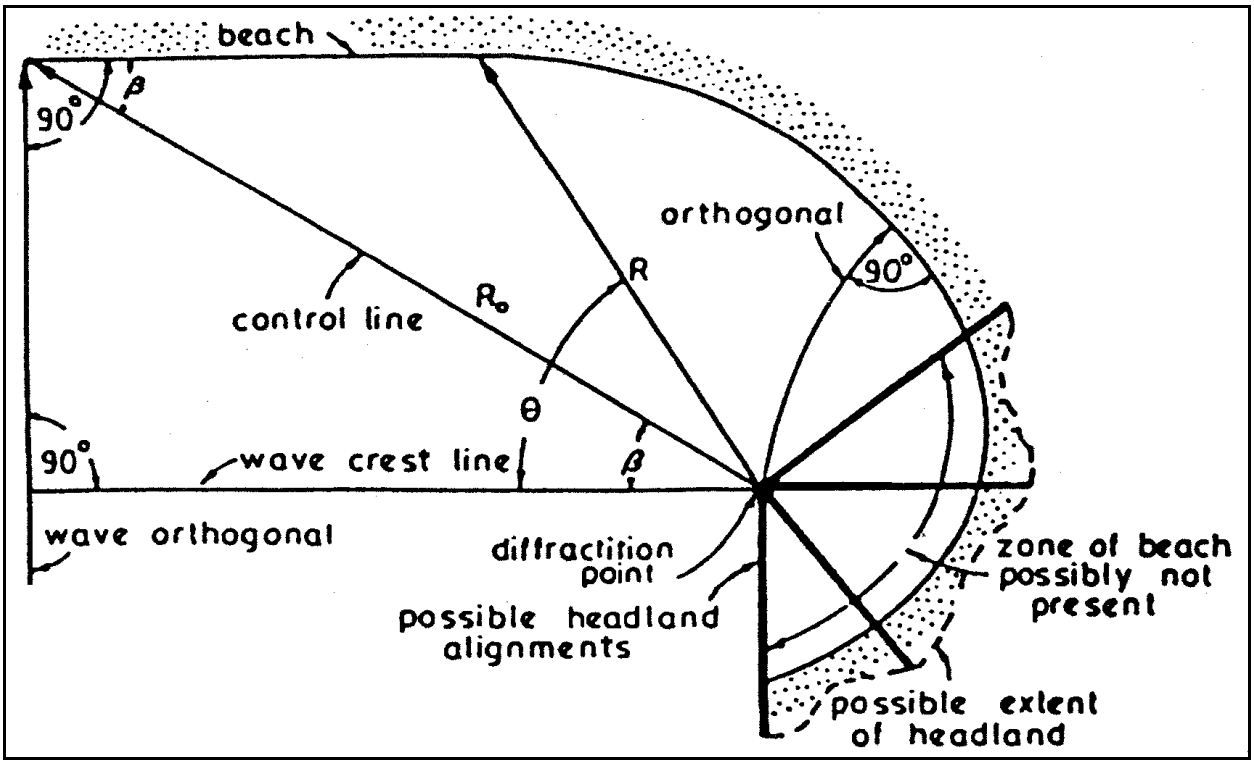

Figure V-3-13. Definition sketch of parabolic model for planform shape

Y Distance of breakwater from nourished shoreline

Y_{min} Minimum distance from base (reference) line to mhw shoreline after design storm event

B Minimum beach width at mhw after nourishment

W Width of design beach nourishment

Z_s Backshore elevation at baseline

F_B Breakwater freeboard, mhw to crest

Q_{net} Net longshore sediment transport rate

Q_{gross} Gross longshore sediment transport rate

$Q_{offshore}$ Offshore sediment transport rate for design storm

The planform shape and maximum indentation, Y_g can be estimated by the parabolic shape model previously discussed above. A hyperbolic tangent shape was developed by Moreno and Kraus (1999), which may be more convenient to apply than the parabolic shape.

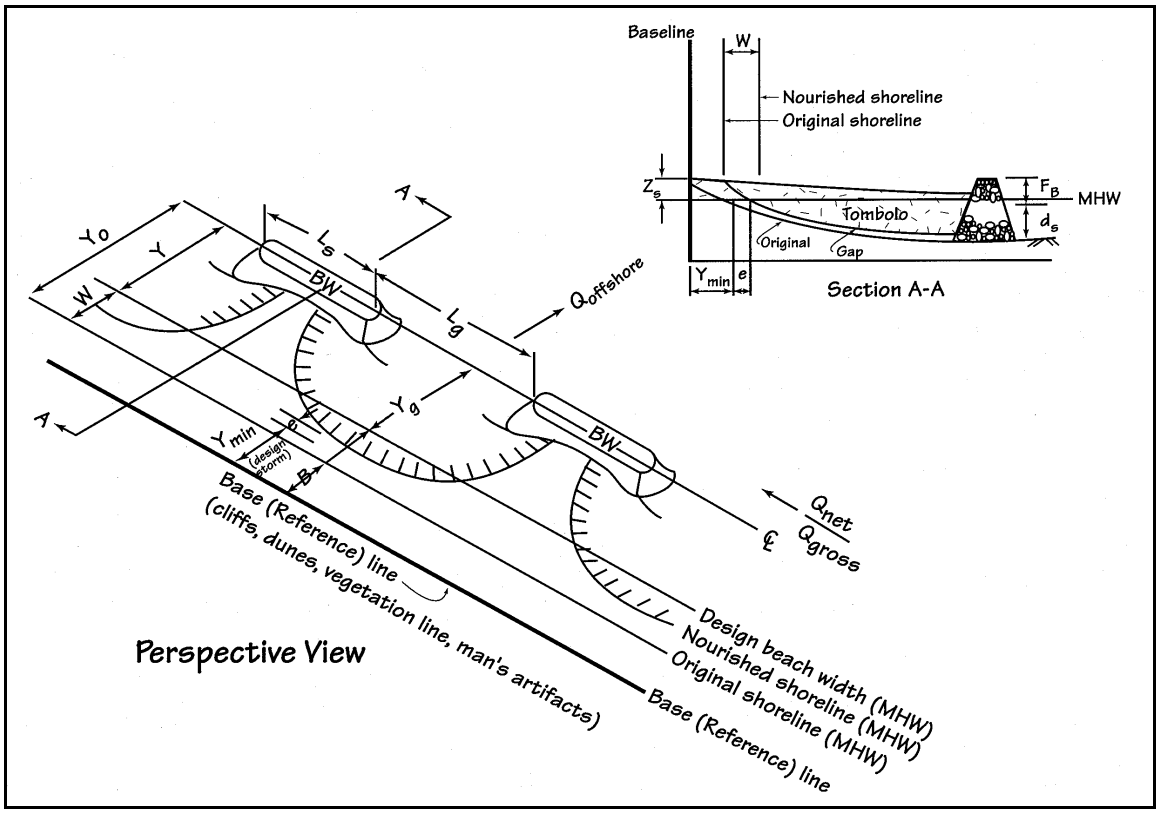

Figure V-3-14. Definition sketch, headland breakwaters

(4) Applications on Chesapeake Bay. Headland breakwater systems have been built along the shoreline of the Chesapeake Bay for shore protection and to maintain recreational beaches. Since 1985, 60 breakwaters at 19 sites have been designed, constructed, monitored and analyzed to learn about their functional performance (Hardaway, Thomas, and Li 1991; Hardaway, Gunn, and Reynolds 1995; Hardaway and Gunn 1991, 1995, 1998, 1999). The design method employs a three-step procedure that accounts for bimodal annual wave climates (annual and storm wave direction) a numerical wave transformation model for near-shore wave refraction and shoaling, and the beach planform shape model for static equilibrium (Silverster and Hsu 1993). System design also includes upland runoff, bank geology, shoreline morphology, sedimentation, and aesthetics. Potential impacts to adjacent shorelines must also be considered and minimized.

Figure V-3-15a displays before and after photos for the Van Dyke project on the James River. The dark area along the shore is vegetation after the new bank was graded to provide sand for beach nourishment as part of the construction. Figure V-3-15b displays 12 nearshore breakwaters at the Luter project site (James River) one year after construction. Note the use of Y-shaped breakwaters to refine the shape of the planform beach. Moving the breakwater ends further offshore changes the diffraction point to provide the desired planform beach shape. Short breakwaters at both ends pin the downdrift beach. Experience since 1991 indicates that on the Chesapeake Bay, the ratio of Y_g/L_g is about 1.7 for stable, equilibrium-shaped beaches. As illustrated in Figure V-3-16, at the Murphy project site (Potomac River) the present shore is still eroding and will require several years to reach the predicted embayment shoreline shape. Hardaway, Thomas, and Li 1991 present minimum design parameters for medium wave energy shorelines (average fetch 1-5 nautical

a. Van Dyke Project

b. Luter Project

miles) that include guidelines for distance B (Figure V-3-14) related to storm surge and wave conditions. Much more research is needed to relate Y_{min} to design storm conditions for the functional design of headland breakwater systems. The next section discusses analytical methods to estimate Y_{min} during storm conditions.

d. Nearshore breakwaters.

(1) Background and definitions. Nearshore breakwaters are detached, generally shore-parallel structures that reduce the amount of wave energy reaching a protected area. They are similar to natural bars, reefs or nearshore islands that dissipate wave energy. The reduction in wave energy slows the littoral drift, produces sediment deposition and a shoreline bulge or salient feature in the sheltered area behind the breakwater. Some longshore sediment transport may continue along the coast behind the nearshore breakwater.

(a) Figure V-3-17 displays a salient behind a single breakwater and a multiple breakwater system with both salient and a tombolo when the shoreline is attached to the breakwater. The tombolo may occur naturally or be forced during construction to produce a headland breakwater as discussed in the previous section. The tombolo blocks normal, longshore sediment transport behind the structure. Daily tidal variations may expose a tombolo at low tide while only a salient feature is visible at high tide as occurs at the Winthrop Beach, Massachusetts, nearshore breakwaters constructed in 1935 (Dally and Pope 1986). Figure V-3-18 displays the single 610 m long, rubble-mound breakwater at Santa Monica, California, and salient feature (circa 1967). Periodic dredging is needed to prevent tombolo formation. The multiple, nearshore breakwater system at Presque Isle, Pennsylvania, is shown in Figure V-3-19 (Fall 1992). Fifty-five breakwaters were built in 1989-1992 to protect 8.3 km (13.8 miles) of Lake Erie shoreline (Mohr 1994).

(b) In general, the primary objectives of a nearshore breakwater system are to:

- Increase the fill life (longevity) of a beach-fill project.
- Provide protection to upland areas from storm damage.
- Provide a wide beach for recreation.
- Create or stabilize wetland areas.

(c) In addition, adverse effects on downdrift beaches should be minimized by consideration of the impact on longshore sediment transport.

(d) Numerous variations of breakwater types exist. Here, the focus is on detached, offshore breakwaters not connected to shore by any type of sand-holding structure. They may be low-crested to permit increased wave transmission and lower construction costs. They also may be reef-type breakwaters constructed of homogeneous stone size as opposed to the traditional, multilayer, cross-section design. Headland breakwaters (natural or constructed tombolos) are discussed (Part V-3-3). Another type of shore-parallel, offshore structure is called the submerged sill or perched beach and is discussed in (Part V-3-3). Additional

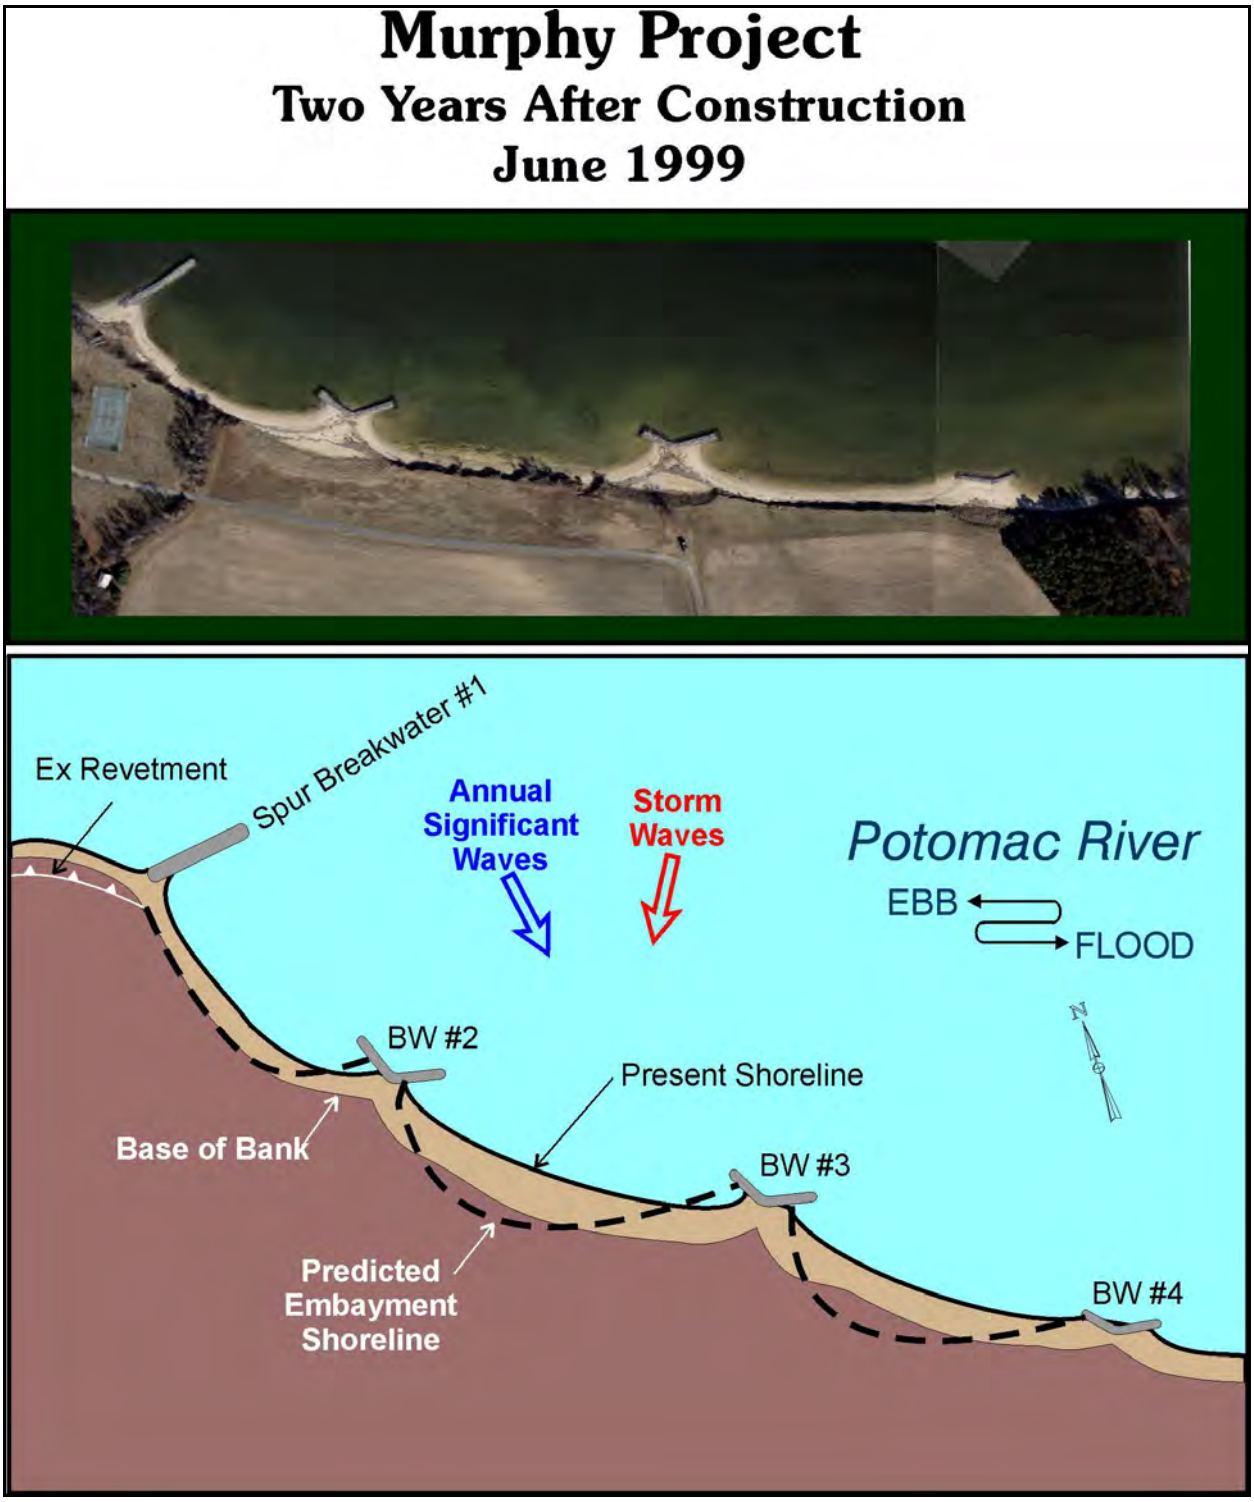

Figure V-3-16. Headland breakwater project on the Chesapeake Bay (from Hardaway and Gunn 1999)

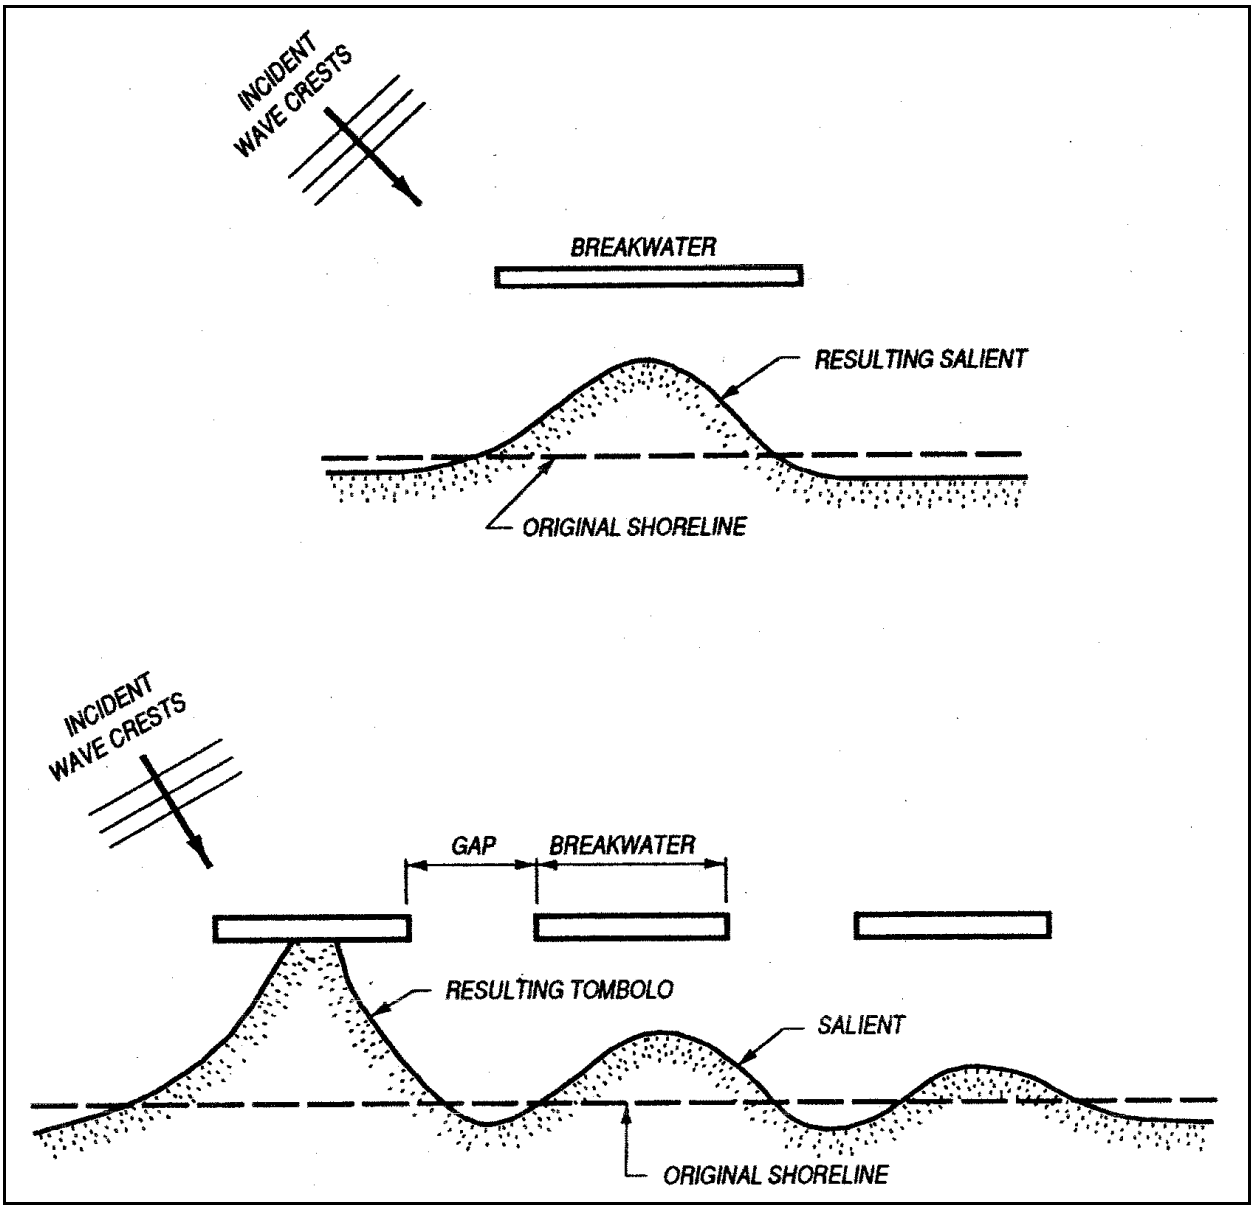

Figure V-3-17. Types of shoreline changes associated with single and multiple breakwater (from EM 1110-2-1617)

information and references on other breakwater classifications can be found in Lesnik (1979), Fulford (1985), Dally and Pope (1986), EM 1110-2-1617 and Chasten et al. (1993).

(2) Physical processes.

(a) Normal morphological responses. Waves breaking at an angle to the shore produce time-averaged, longshore (littoral) currents and longshore sediment transport. Consider the left breakwater in Figure V-3-20 with wave energy in the plus direction. Physical processes at macro-level scales in the vicinity of the breakwater for normal wave and water level conditions are as follows. The breakwater shelters the coast immediately behind the structure and adjacent areas (diffraction) from the incoming waves. Breaking wave heights are smaller in the sheltered areas. The exposed, gap areas have larger breaking wave heights. The

a. Salient with eroded downdrift (longshore drift is from bottom to top)

b. Deteriorated breakwater allowing wave transmission

Figure V-3-18. Santa Monica, California, breakwater and salient (circa 1967). Littoral drift from bottom to top (from Chasten et al. 1993)

Figure V-3-19. Breakwater construction and salients; two views of Presque Isle, Pennsylvania (from Mohr 1994)

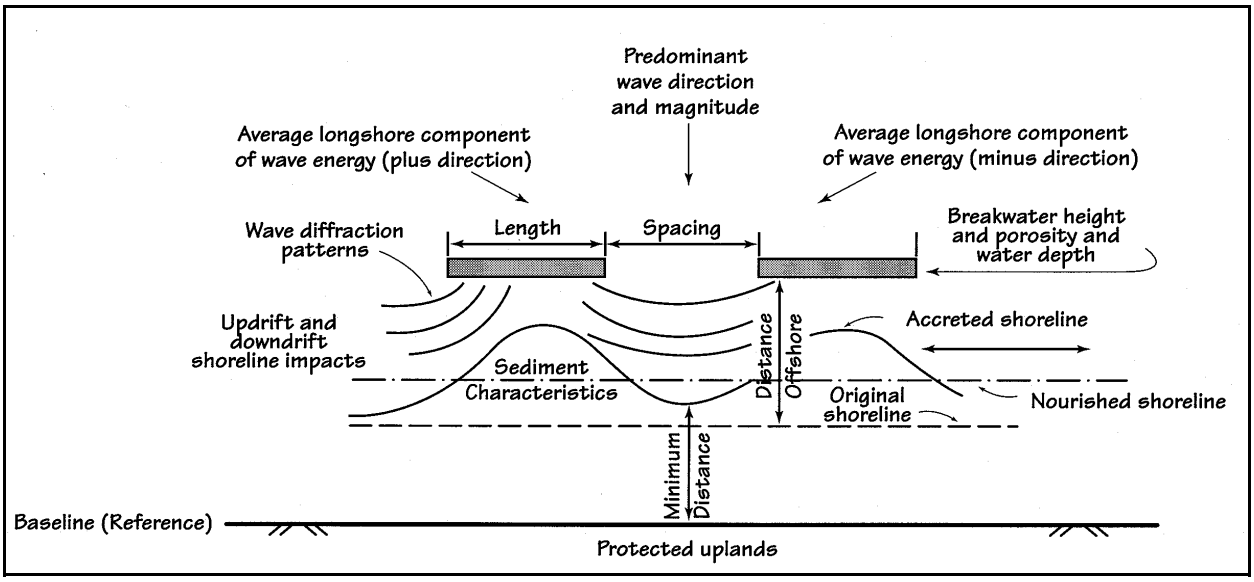

Figure V-3-20. Definition schematic for nearshore breakwaters

wave induced, mean water level change (setup) in the exposed, gap areas is larger than in the sheltered areas. Longshore variability in the wave setup produces gradients in the mean water surface. Water flows from the elevated levels in the gap area towards the lower, sheltered area to accelerate the longshore current flowing towards the sheltered area behind the structure from the left side. These gradients also change the direction of the current which is driven away from the breakwater in the region immediately downdrift of the breakwater (right side). These two current systems (littoral current and setup current) merge behind the structure to give rise to complex circulation patterns. The acceleration of the littoral current updrift causes initial erosion of the beach on the updrift side. The same occurs in the area immediately downdrift. These currents carry the eroded material towards the sheltered area, where it deposits. These mechanisms cause the patterns of deposition behind and erosion on either side that is observed in nature (see Figure V-3-20). The above physical description had been confirmed by a two-dimensional, numerical (horizontal plane) joint processes (waves, currents, sediment transport) morphological modeling system (Zyserman et al. 1998).

(b) Storm processes and response. Protection afforded by the breakwater will limit erosion of the salient during significant storms. The exposed gap area will be eroded with sediment dragged offshore during storms. Breakwater height, length, wave transmission characteristics and distance from shore contribute to its effectiveness to provide a minimum dry beach width, as discussed further in the following paragraphs.

(3) Functional design. Prototype experience for the functional design of nearshore breakwaters in the United States is generally limited to sediment-starved shores with fetch-limited wave climates on the Great Lakes, Chesapeake Bay, and Gulf of Mexico shores (Pope and Dean 1986). Table V-3-4 is a summary of U.S. projects up to 1993 (Chasten et al. 1993). Nearshore breakwaters for shore protection have also been used extensively for shore protection in Japan and Israel (Toyoshima 1982) and in Denmark, Singapore and Spain (Rosati 1990). Detailed summaries of the literature, previous projects, and design guidance are provided in a number of references (Lesnick 1979; Dally and Pope 1986; Pope and Dean 1986; Kraft and Herbich 1989; Pope 1989; Rosati 1990; Rosati and Truitt 1990; EM 1110-2-1617; and Chasten et al. 1993). One key aspect of all these efforts has been to determine under what conditions salients or tombolos will naturally form behind the breakwater.

Table V-3-4
Summary of U.S. Breakwater Projects (from Chasten et al. 1993)

[1] Beach response is coded as follows: 1-permanent tombolos, 2-periodic tombolos, 3-well developed salients, 4-subdued salients, 5-no sinuosity.

(a) Salients or tombolos. A salient is the preferred shoreline response for a detached breakwater system designed for the Corps as stated in EM 1110-2-1617 and in Chasten et al. (1993). This is to allow longshore sediment transport to continue to move through the project area to downdrift beaches. Salients are likely to predominate when the breakwaters are sufficiently far from shore, short relative to incident wavelength, and relatively transmissible (low crested or large gaps with low sediment input). Wave action and longshore currents tend to keep the salient from connecting to the structure.

- Sand will more likely accumulate in the structure lee and form a tombolo when the breakwater is close to shore, is long relative to incident wavelength, and is relatively impermeable (high crest and small gaps and with large sediment input). A tombolo-detached breakwater functions like a tee-shaped groin by blocking longshore transport and promoting sediment movements offshore in rip currents through the gaps. Although some longshore transport can occur seaward of the breakwater, the interruption in the littoral system may starve downdrift beaches of their normal sediment supply, causing erosion. Variable wave energy regimes may produce periodic tombolos to temporarily store and then release sediment to the downdrift region.

- Salient formation provides a recreational swimming environment and limits access for maintenance and to the public. Tombolo formation provides a recreational beach environment and allows direct access to the structure for maintenance, but public access may not be desirable.

- Figure V-3-21 presents a definition sketch for the variables that have been employed to develop empirical relationships for detached, breakwater design by many research efforts listed in Table V-3-5 dating back to the 1960s. For salient or tombolo formation, the key variables are:

Y Distance of breakwater from nourished shoreline

L_s Length of breakwater structure

L_g Gap distance between adjacent breakwater segments

d_s Depth (average) at breakwater structure below mean water level

Three dimensionless ratios, Y/d_s, L_s/L_g and L_s/Y have emerged to separate salient and tombolo response.

- As qualitatively discussed, when the breakwater is long and/or located close to shore, conditions favor tombolo formation. As shown in Table V-3-6, "Conditions for the Formation of Tombolos," many references say $L_s/Y > 1$-2 for tombolo formation (except Gourlay 1981). Dally and Pope (1986) recommend

$$\frac{L_s}{Y} = 1.5 \text{ to } 2 \qquad \text{single breakwater} \tag{V-3-6}$$

$$\frac{L_s}{Y} = 1.5 \qquad L \le L_g \le L_s \text{ segmented breakwater} \tag{V-3-7}$$

where L is the wavelength at the structure.

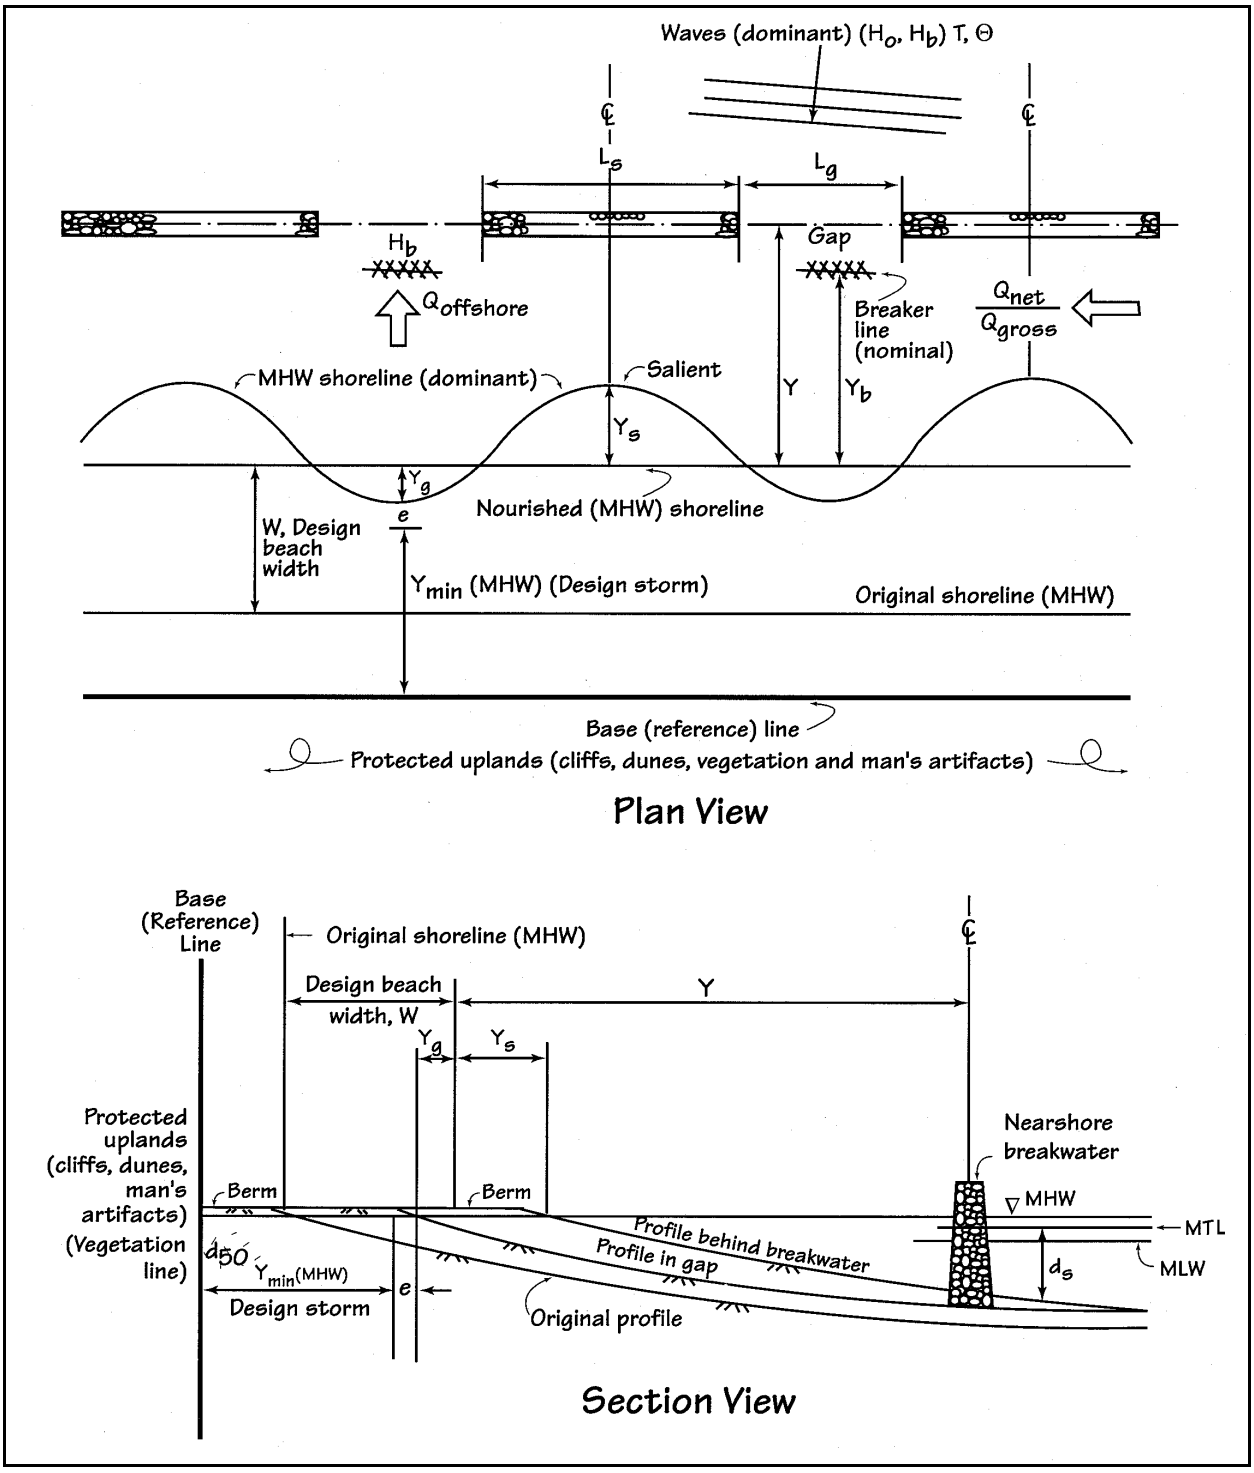

Figure V-3-21. Definitions of key variables for nearshore breakwater

Table V-3-5
Empirical Relationships for Nearshore Breakwater Design

Inman and Frautschy (1966)	Predicts accretion condition; based on beach response at Venice in Santa Monica, CA
Toyoshima (1972, 1974)	Recommends design guidance based on prototype performance of 86 breakwater systems along the Japanese coast
Noble (1978)	Predicts coastal impact of structures in terms of offshore distance and length; based on California prototype breakwaters
Walker, Clark, and Pope (1980)	Discusses method used to design the Lakeview Park, Lorain, OH, segmented system for salient formation; develops the Diffraction Energy Method based on diffraction coefficient isolines for representative waves from predominant directions
Gourlay (1981)	Predicts beach response; based on physical model and field observations
Nir (1982)	Predicts accretion condition; based on performance of 12 Israeli breakwaters
Rosen and Vadja (1982)	Graphically presents relationships to predict equilbrium salient and tombolo size; based on physical model/prototype data
Hallermeier (1983)	Develops relationships for depth limit of sediment transport and prevention of tombolo formation; based on field/laboratory data
Noda (1984)	Evaluates physical parameters controlling development of tombolos/salients; especially due to on-offshore transport; based on laboratory experiments
Shore Protection Manual (1984)	Presents limits of tombolo formation from structure length and distance offshore; based on the pattern of diffracting wave crests in the lee of a breakwater
Dally and Pope (1986)	Recommends limits of structure-distance ratio based on type of shoreline advance desired and length of beach to be protected
Harris and Herbich (1986)	Presents relationship for average quantity of sand deposited in lee and gap areas; based on laboratory tests
Japanese Ministry of Construction (1986); Rosati and Truitt (1990)	Develops step-by-step iterative procedure, providing specific guidelines towards final design; tends to result in tombolo formation; based on Japanese breakwaters
Pope and Dean (1986)	Presents bounds of beach response based on prototype performance; response given as a function of segment length-to-gap ratio and effective distance offshore-to-depth at structure ratio; provides beach response index classification
Seiji, Uda, and Tanaka (1987)	Predicts gap erosion; based on performance of 1,500 Japanese breakwaters
Sonu and Warwar (1987)	Presents relationship for tombolo growth at the Santa Monica, CA breakwater
Suh and Dalrymple (1987)	Gives relationship for salient length given structure length and surf zone location; based on lab tests and prototype data
Berenguer and Enriquez (1988)	Presents various relationships for pocket beaches including gap erosion and maximum stable surface area (i.e., beach fill); based on projects along the Spanish coast
Ahrens and Cox (1990)	Uses Pope and Dean (1986) to develop a relationship for expected morphological response as function of segment-to-gap ratio

(from Chasten et al. 1993)

- Conversely, short breakwaters at greater distance from shore favor salient formation. The "Conditions for the Formation of Salients" in Table V-3-6 presents a wide range of conditions with generally, $L_s/Y < 1$. Dally and Pope (1986) recommend for salient formation

$$\frac{L_s}{Y} = 0.5 \text{ to } 0.67 \tag{V-3-8}$$

for both single and segmented breakwaters. However, for very long distances, to insure that tombolos do not form, the recommended ratio for a segmented system (Dally and Pope 1986) is

$$\frac{L_s}{Y} = 0.125 \text{ (long systems)} \tag{V-3-9}$$

- Permeable structure systems (partly submerged, large gaps) also allow sufficient wave energy to minimize the chance for tombolo formation: As shown in Table V-3-6, "Conditions for Minimal Shoreline Response," the references cited generally recommend $L_s/Y < (0.125 – 0.33)$ to produce a minimal shoreline response. Ahrens and Cox (1990) defined a beach response index, I_s

$$I_s = \exp (1.72 - 0.41\ L_s/Y) \tag{V-3-10}$$

where the five types of beach response (Pope and Dean 1986) give I_s value as:

Permanent tombolo formation, $I_s=1$

Periodic tombolos, $I_s=2$

Well-developed salients, $I_s=3$

Subdued salients, $I_s=4$

No sinuosity, $I_s=5$

- These results are preliminary and require verification.

- The ratio L_s/L_g is also important for salient or tombolo formation. Large gaps will let more wave energy reach the shore to promote salient formation. And, this will coincide with smaller L_s/L_g ratios. A dimensionless plot of U.S. segmented, nearshore breakwater projects by Pope and Dean (1986) using L_s/L_g is shown in Figure V-3-22 and verifies this trend. The vertical axis is Y/d_s and is the distance offshore relative to the local, mean water depth at the breakwater. The water depth is important for it is related to the nominal, surf zone width at breaking Y_b. The dimensionless ratio Y/Y_b is a measure of breaker location relative to the width of the surf zone. For a given L_s/L_g, larger Y/d_s values (or Y/Y_b) mean the breakwater is located further offshore (beyond the normal surf zone width) to foster salient formation. Obviously, breakwaters located far offshore will have less effection the shoreline.

Table V-3-6
Conditions for Shoreline Response Behind Nearshore Breakwaters (from Chasten et al. 1993)

Condition	Comments	Reference
Conditions for the Formation of Tombolos		
$L_s/Y > 2.0$		*Shore Protection Manual* (1984)
$L_s/Y > 2.0$	Double tombolo	Gourlay (1981)
$L_s/Y > 0.67$ to 1.0	Tombolo (shallow water)	Gourlay (1981)
$L_s/Y > 2.5$	Periodic tombolo	Ahrens and Cox (1990)
$L_s/Y > 1.5$ to 2.0	Tombolo	Dally and Pope (1986)
$L_s/Y > 1.5$	Tombolo (multiple breakwaters)	Dally and Pope (1986)
$L_s/Y > 1.0$	Tombolo (single breakwaters)	Suh and Dalrymple (1987)
$L_s/Y > 2\ b/L_s$	Tombolo (multiple breakwaters)	Suh and Dalrymple (1987)
Conditions for the Formation of Salients		
$L_s/Y < 1.0$	No tombolo	*Shore Protection Manual* (1984)
$L_s/Y < 0.4$ to 0.5	Salient	Gourlay (1981)
$L_s/Y = 0.5$ to 0.67	Salient	Dally and Pope (1986)
$L_s/Y < 1.0$	No tombolo (single breakwater)	Suh and Dalrymple (1987)
$L_s/Y < 2\ b/L_s$	No tombolo (multiple breakwater)	Suh and Dalrymple (1987)
$L_s/Y < 1.5$	Well-developed salient	Ahrens and Cox (1990)
$L_s/Y < 0.8$ to 1.5	Subdued salient	Ahrens and Cox (1990)
Conditions for Minimal Shoreline Response		
$L_s/Y \leq 0.17$ to 0.33	No response	Inman and Frautschy (1966)
$L_s/Y \leq 0.27$	No sinuosity	Ahrens and Cox (1990)
$L_s/Y \leq 0.5$	No deposition	Nir (1982)
$L_s/Y \leq 0.125$	Uniform protection	Dally and Pope (1986)
$L_s/Y \leq 0.17$	Minimal impact	Noble (1978)

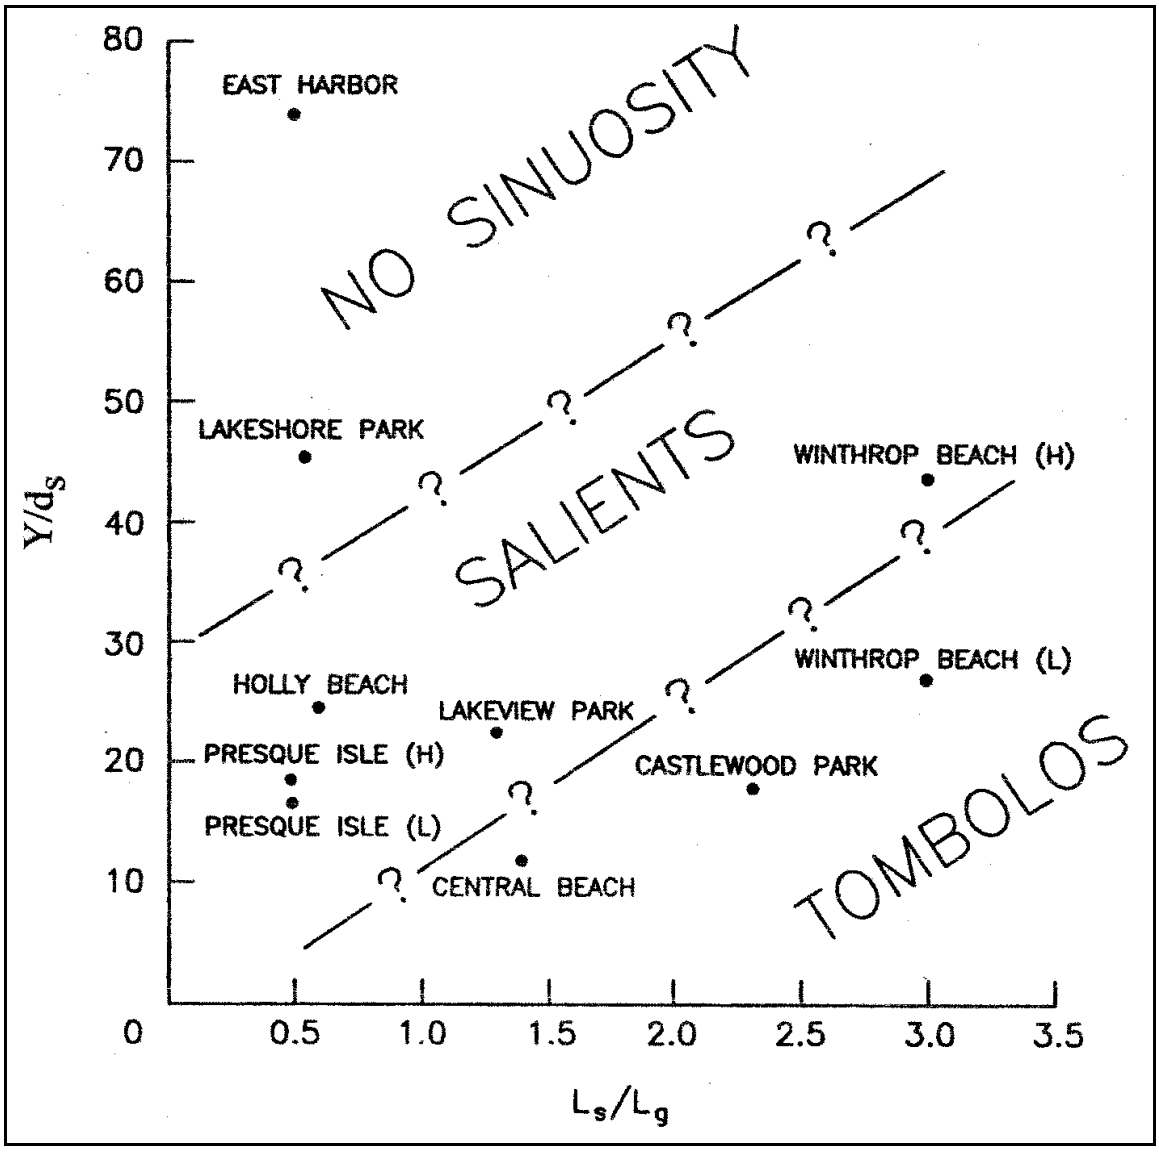

Figure V-3-22. Dimensionless plot of nearshore breakwater projects For Y/d_s versus L_s/L_g (from Pope and Dean 1986)

- Zyserman et al. (1998) used the Y/Y_b ratio in their numerical model, process-oriented studies of nearshore breakwaters. The distance Y_b was taken as Y_{80}, meaning the distance from shore where 80 percent of the undisturbed littoral transport takes place and, hence, a measure of the width of the surf zone. Their research using a numerical model confirmed the empirical formulas of Dally and Pope (1986) for tombolo and salient formation previously summarized.

(b) Planform configuration. Some research has provided insight into other variables that quantify the planform shape of the shoreline as shown in Figure V-3-21. The length of the salient, Y_s increased as the L_s/Y ratio increased, as expected. Suh and Dalrymple (1987) developed an exponential expression involving $L_g Y L_s^2$, where L_g is the gap length for prediction of Y_s, by combining movable-bed laboratory results and prototype data. Rosati (1990) evaluated the relation and found it over-predicted Y_s for the majority of

prototype data. Seiji, Uda, and Tanaka (1987) gave conditions on the L_g/Y ratio for no, possible, and certain erosion, Y_g opposite the gap. The magnitude of Y_g was not determined, but gap erosion occurred for L_g/Y greater than 0.8. Hallermeier (1981) gave an equation for the water depth to locate nearshore breakwaters when tombolo formation was to be avoided. The relation requires knowledge of wave height and period statistics at the 12 hr per year exceedance level. Rosati (1990) also evaluated Hallermeier's relation with the limited, available field data. The correlation was said to be good for seven of the nine data points tested. These relationships to quantify $Y_{s,}$ Y_g and d_s can be found in Chasten et al. (1993).

- Walker, Clark, and Pope (1981) discuss a procedure to apply diffraction analysis to determine the approximate shoreline configuration behind a breakwater. Their studies indicate that if the isolines of the $K' = 0.3$ diffraction coefficients are constructed from each end of the breakwater for a range of incident wave directions (monochromatic waves) and they intersect seaward of the postproject shoreline, a tombolo will not form. This corresponds to $L_g/Y \geq 2$, where Y is after placement of the beach fill, as part of the project shown in Figure V-3-21. Waves coming around each end of the breakwater meet each other before the undiffracted, incident wave (outside the breakwater's shadow) reach the shoreline. The postproject shoreline is estimated as a smoothed crest pattern for all diffracted crests and a balance in the sediment volume.

- The Japanese Ministry of Construction presented a step-by-step interactive procedure for nearshore breakwater design (Japanese Ministry of Construction 1986). Rosati (1990) and Rosati and Truitt (1990) found that 60 percent of the designs produced tombolos and therefore the JMC method was more suitable for headland breakwater design. All are for nonpermeable, high-crested, nearshore breakwaters.

(c) Other design factors. The crest elevation and crest width, permeability, slope of front face, and type of construction are additional design factors that influence functional performance. No general guidelines presently exist.

- Generally, low crests allow more energy to penetrate into the lee of the breakwater to prevent tombolo formation or remove a tombolo by storm waves. Wide crests on low breakwaters can promote breaking to diminish wave energy penetration and encourage tombolo formation. Permeable structures can allow significant amounts of energy to propagate through them to prevent tombolo formation. Types of construction including nontraditional, patented devices are discussed in Part V-3-5.

- Waves in the lee of the breakwater are determined by three processes: diffraction around the ends, wave transmission by overtopping and wave transmission through the structure. For diffraction around single and multiple breakwaters with gaps, see Part II-7-2 for irregular waves and the *Shore Protection Manual* (1984) for many cases with monochromatic waves. Wave transmission due to overtopping and through the structure by permeability is discussed in Part VI-5-2. Wave reflection is covered in Part VI-5-2. The Automated Coastal Engineering Systems (ACES) (Leenknecht, Szuawalski, and Sherlock 1992) provides an application to determine wave transmission coefficients and transmitted wave heights for permeable breakwaters with crest elevation at or above the still-water level.

- Breakwater impact on littoral currents and creation of wave setup gradients to produce setup currents was previously discussed. If the crest elevation is low enough to permit wave overtopping, the mass carried over the structure causes a net seaward return flow of water through the gaps. Seelig and Walton (1980) present a method for estimating the strength of the seaward flowing currents. The effect of the combined littoral and setup currents on the longshore sediment transport to produce salient features with adjacent erosional areas was also previously discussed (physical processes).

- The primary function of nearshore breakwaters is to reduce the offshore sand transport during storms. Hence, these structures help retain sand on nourished beaches for longer intervals. However, overtopping can result in a net seaward flow of water and sand through the gaps between breakwater segments during storm events. The breakwater can also reduce the onshore sediment movement during normal, swell wave conditions that naturally rebuild the beach. The structure blocks the return of sediment to the beach. Following breakwater construction, a new equilibrium between onshore and offshore transport will be established.

(d) Minimum dry beach width, Y_{min}. Figure V-3-21 schematically displays the mhw shoreline for normal wave conditions. During storms, some gap erosion, *e* will occur to impact the minimum, dry beach width, Y_{min} required for shore protection.

- A conservative estimate of the gap erosion, *e*, can be made using analytical models for the dynamic response of natural beach profiles to storm effects (e.g., Kobayashi 1987; Kriebel and Dean 1993). Part III-3-3 gives a general description of these methods and also example applications of the Kriebel and Dean (1993) analytical model. The theory is for open coastal beaches so that wave diffraction in the gap area and wave overtopping to increase the return flows through the gap region are not considered, but tend to offset each other. See Example Problem V-3-1.

- Dynamic, numerical, cross-shore sediment transport models (e.g., SBEACH, Larson and Kraus 1989) could also be applied in the gap area to estimate the erosion potential, e (see Part III-3-3). These two-dimensional (vertical) models also do not consider wave diffraction and return flows in the gap area. These results would be a worst case scenario and the actual erosion can be expected to be significantly less. A general, three-dimensional, wave, current, and sediment transport model is clearly needed in this area.

- Hughes (1994) presents a complete discussion of scaling laws as applied to predicting cross-shore sediment transport in physical, hydraulic models.

(4) Nontraditional designs. Most nearshore breakwaters built in the United States and foreign countries for shore protection have been rubble-mound type structures. Availability of materials and construction equipment have made construction costs relatively inexpensive.

- Several patented, nontraditional devices have been tested in the United States. These have been precast concrete units or sand-filled geotextile tubes and bags. If constructed to the same dimensions as rubble-mound structures, they may produce similar functional performance. Their success (or failure) has been a function of structural stability of the units during storm conditions and their durability over an economic life. Their functional success (or failure) has also been dependent on maintaining the design crest elevation for wave energy reduction. Proper attention to foundation design to minimize settlement must be given for precast, concrete units.

- Some nontraditional designs reduce the bottom footprint to minimize impacts on benthic organisms. And, the costs for removal and/or adjustments to reduce downdrift impacts on adjacent shorelines can be significantly less than for traditional, rubble-mound designs. The need to reduce impact on the environment is increasing the necessity for further research and comprehensive field testing programs for nontraditional designs. (See Part V-3-5 for further details.)

EXAMPLE PROBLEM V-3-1

FIND: Functional design of a nearshore breakwater system coupled with beach nourishment for shore protection, but maintain recreational beach.

GIVEN: A sandy beach shoreline, 685 m in length with historic erosion rate of 0.6-0.9 m/year that threatens a 2.4-7.3-m bank, with road and sewer line parallel to the shoreline along the top of the bank. For an annual probability of exceedance of 2 percent (50-year recurrence interval design storm) the storm surge level is 1.83 m (mlw) and corresponding wave characteristics are H_s=2.2 m, T_p=9.7 sec at the -9.0 m (mwl) depth contour. The design, still water, storm depth is 3.05 m at this location and includes a 0.3 m, astronomical tide. Net sediment transport (sand, d_{50} = 0.6 mm) is 3,750 to 7,500 m^3/year to the north. The existing beach berm is at +0.76 m (mlw) elevation.

Solution:

1. To maintain the longshore transport rate, the desired planform is subdued to well-developed salients. From a table of possible L_s and Y values, the ratio 0.75 is selected giving a breakwater length, L_s=30m and the offshore distance, Y=40 m. This gives the beach response index, I_s=4.1, hence, subdued salients are expected.

2. For shore protection, waves entering the breakwater gaps and diffracting behind the structures will reach the shoreline. Sufficient beach width (Y_{min}) and berm height (Z_s) are required to dissipate this wave energy prior to reaching the toe of the banks. Analysis of nearshore, wave diffraction diagrams indicate that the 50-year design wave height of 2.2 m will be reduced to about 0.9 m at a distance of about 14 m from the bank toe when the breakwater gap is about 30 m. This gap width, L_g=30 m is considered a practical minimum width for this project. For shallow-water wave breaking, (γ_b=0.78, II-4-3), this wave will break in about 1.16 m depth of water. For a design storm surge of 1.83 m (mlw) and existing beach berm elevation of 0.76 m (mlw), these waves will break directly on the bank toe and cause significant erosion. The existing beach width and height are not sufficient to dissipate the storm wave energy at the 50-year frequency level. Two options exist. One is to further decrease the wave energy propagating through the gaps by using smaller gap widths, and resulting longer lengths of breakwater segments. The second option is to add beach fill to the shoreline area and this option is selected to provide the desired protection for the bank area.

3. A beach-fill plan was considered that would increase the beach width to 10 m from the toe of the bank and raise the berm elevation to + 1.8 m (mlw) at a 1:8 construction slope. Wave heights are now reduced to less than 30 cm near the bank toe for the 50-year storm event. The beach fill would be expected to evolve (see Part V-4) to a stable planform with salients behind each breakwater and embayments opposite each gap. The mhw shoreline would recede about 4.5-6 m opposite the gaps as estimated from analysis of diffraction patterns. The beach shape would also evolve to a more natural and milder slope to match those in the area (1:10 to 1:15).

(Continued)

EXAMPLE PROBLEM V-3-1 (Concluded)

4. Protection of the bank toe depends on the performance of the beach berm during storm events. A worst case scenario can be evaluated first by considering the adjusted beach slope and shoreline area with storm wave conditions prior to reduction by the nearshore breakwaters. Using the analytical model of Kriebel and Dean (1993) or a numerical, storm erosion model (e.g., SBEACH, Larson and Kraus 1989) gives the results (for the worst-case, 50-year storm event scenario) that the storm berm would remain with a width of 1.5-3 m. The actual erosion would be expected to be significantly less due to reduction in the storm wave energy as a result of wave diffraction through the gaps. The gap width, L_g=30 m was selected for design.

5. Wave energy is also transmitted over the top of nearshore breakwaters during elevated water level, storm surge events. A wave transmission model (see Part VI-5-2) capable of predicting wave energy over and through submerged, reef-type breakwaters was used for analysis with crest heights of + 1.2 m, +1.5 m and 1.8 m above mlw datum. During the 50-year design storm, wave heights immediately behind the breakwaters are reduced about 60 percent, 54 percent, and 46 percent, respectively for these three breakwater crest elevations. These transmitted waves then propagate shoreward and are further dissipated by the beach salients. With the proposed beach fill in place, a breakwater crest elevation of +1.2 m (mlw) is selected to limit the transmitted, design wave height to about 1.2 m. This is the same, diffracted, design wave height opposite the gaps and is dissipated by the storm berm.

Note: Further details of this example problem are found in Appendix A of Chasten et al. 1993 and was developed by Mr. Ed Fulford of Andrews Miller and Assoc., Inc., Cambridge, Maryland. It is taken from a real project on the Chesapeake Bay for the community of Bay Ridge near Annapolis, Maryland. Construction was completed in July 1991 and postconstruction monitoring commenced soon after and at a November 1991 survey. As of 2000, the project has performed as expected with subdued salients forming behind each breakwater resulting in the overall stability of the shoreline. Numerous, significant storms occurred and the project prevented erosion of the bank area to protect the roadway and sewer pipeline. The project has been well-received by the residents of the community as a result of the stability of the shoreline and the enhancement of the recreational beach area.

e. Groins.

(1) Background and definitions. Groins are the oldest and most common shore-connected, beach stabilization structure. They are probably the most misused and improperly designed of all coastal structures. They are usually perpendicular or nearly at right angles to the shoreline and relatively short when compared to navigation jetties at tidal inlets. As illustrated schematically in Figure V-3-23, for single and multiple groins (groin field) the shoreline adjusts to the presence of the obstruction in longshore sediment transport. Over the course of some time interval, accretion causes a positive increase in beach width updrift of the groin. Conservation of sand mass therefore produces erosion and a decrease in beach width on the downdrift side of the groin. The planform pattern of shoreline adjustment over 1 year is a good indicator of the direction of the annual net longshore transport of sediment at that location.

(a) Groins are constructed to maintain a minimum, dry beach width for storm damage reduction (Figure V-3-11) or to control the amount of sand moving alongshore. Previously stated purposes such as trapping littoral drift are discouraged for this implies removal of sand from the system. Modern coastal

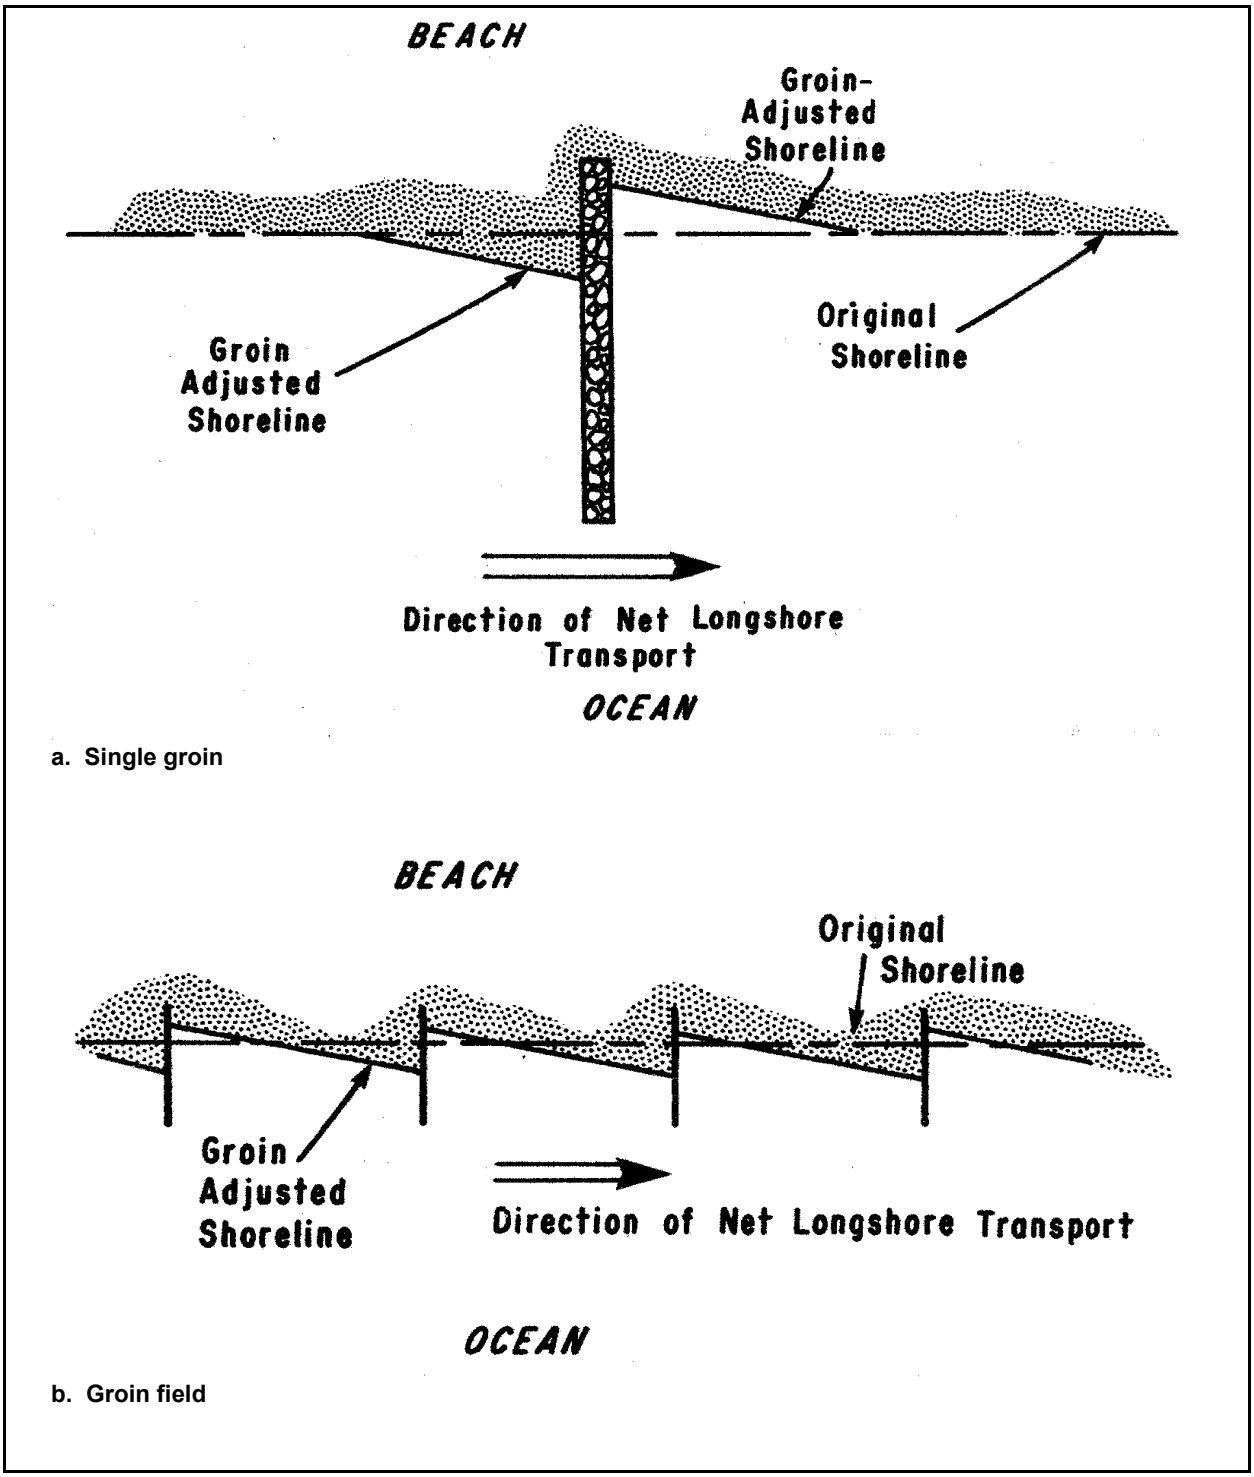

Figure V-3-23. General shoreline adjustment for direction of net longshore transport

engineering practice is to combine beach nourishment with groin construction to permit sand to immediately begin to bypass the groin field. At the end of the sediment cell, terminal groins may be used to anchor the beach and limit the movement of sand into a navigational channel or onto an ebb-tidal shoal at tidal inlets.

(b) Figure V-3-24 shows a photo, profile and cross section of a rubble-mound groin at Westhampton Beach, New York. Sheet-pile construction with timber (Figure V-3-25) timber-steel (Figure V-3-26) prestressed-concrete (Figure V-3-27) or cellular-steel (filled) sheets (Figure V-3-28) have also been constructed in the United States.

(c) Kraus, Hanson, and Blomgren 1994 cite the following situations when the groin field alternative for shore protection and sand management should be considered.

- At divergent, nodal points for littoral drift.
- In the diffraction, shadow some of a harbor breakwater, or jetty.
- On the downdrift side of a harbor breakwater or jetty.
- At the updrift side of an inlet entrance where intruding sand is to be managed
- To reduce the loss of beach fill, but provide material to downdrift beaches in a controlled manner.
- Along the banks at inlets, where tidal currents alongshore are strong.
- Along an entire littoral cell (spit, barrier island, submarine canyon) where sand is lost without return in an engineering time frame.

(d) Groins may not function well and should not be considered under the following conditions (Kraus, Hanson, and Blomgren 1994):

- Where a large tidal range permits too much bypassing at low tide and overpassing at high tide.
- Where cross-shore sediment transport is dominant
- When constructed too long or impermeable, causing sand to be jetted seaward
- When strong rip currents are created to cause potentially dangerous swimming conditions

(e) Coastal zone management policy in many countries and the United States presently discourages the use of groins for shore protection. Many examples of poorly designed and improperly sited groins caused by lack of understanding of their functional design, or failure to implement the correct construction sequence, or failure to fill up the groin compartments with sand during construction, or improper cross-sectional shape are responsible for these restrictions. However, when properly designed, constructed and combined with beach nourishment, groins can function effectively under certain conditions, particularly for increasing the fill life (longevity) of renourished beaches.

(f) Groins are now being reevaluated as sand-retention structures (Kraus, Hanson, and Blomgren 1994; Kraus and Bocamazo 2000) by now asking the question “how much sand can be allowed to pass,” while still maintaining a minimum width of beach at the groin for some level of shore protection.

(2) Literature review. Although groins have been around a long time and many references exist, most only provide a few rules of thumb. No systematic methods for functional design under a wide range of structural shapes, waves, and sediment transport conditions presently exist. Reviews for the functional design of groins can be found in Bruun (1952); Bakker (1968); Balsillie and Berg (1972); Balsillie and Bruno (1972); Nayak (1976) (unpublished); Tomlinson (1980); Fleming (1990); and EM 1110-2-1617. All these reviews restate the same beliefs but fail to reference the sources that verify the concepts and conclusions from theory, model studies (laboratory or numerical), or field experiments. As stated by Kraus, Hanson, and Blomgren (1994)

> "…the literature (on groins) may appear to assign validity to certain concepts and conclusions by weight of repetition (but) not by independent confirmation." (p. 1329).

(a) Laboratory investigations suffered from severe scale distortions in sediment transport to cast serious doubt and questions on their results.

(b) A fresh approach is needed that begins with a summary of over 20 parameters that govern beach response to groins as listed in Table V-3-7 (from Kraus, Hanson, and Blomgren 1994). They are grouped into three main categories (structure, beach, and hydrodynamic conditions), but the large number of variables make analysis difficult. Missing from this table is the minimum, design beach width for shore protection. Groin geometry and possible sediment size for the beach fill can be controlled in the design.

Table V-3-7
Main Parameters Governing Beach Response and Bypassing at Groins (from Kraus, Hanson, and Blomgren 1994)

Groin(s)	Beach and Sediment	Waves, Wind, and a Tide
Length	Depth at tip of groin	Wave height and variability
Elevation	Depth of closure	Wave period and variability
Porosity	Sediment availability	Wave angle and variability
Configuration (straight, T, L, etc.)	Median grain size and variability	Tidal range
Orientation to the shoreline	Sediment density	Wind speed and variability
Spacing between groins	--	Wind direction and variability
Tapering	--	Wind duration and variability

Note: Two integrated parameters governing groin functioning are the ratio of net to gross longshore sand transport, and the presence, location, and number of longshore bars.

(c) From the previously listed review papers, other references and their own experience, Kraus, Hanson, and Blomgren 1994 listed 13 functional properties attributed to groins and present a critical evaluation of each as shown in Table V-3-8. The first five are well accepted properties that have led to the general rule of the thumb to make the groin spacing to length ratio about two to four. However, this rule omits any consideration of the cross-sectional shape of the groin. The length controls water depth at the end and, hence, the amount of sediment by-passing around the tip. But the cross-sectional elevation in the swash zone controls over-passing, the length and elevation on the beach berm control shore-passing, and the structural materials control through-passing as takes place in rubble-mound and permeable groins. Tidal range, predominant wave characteristics (height, period, direction), net and gross longshore sediment transport and grain size are key hydrodynamic and sediment parameters. All these factors together produce the optimum spacing and planform configuration of the shoreline within each compartment for average climate conditions.

Table V-3-8
Functional Properties Attributed to Groins and their Critical Evaluation (from Kraus, Hanson, and Blomgren 1994)

Property	Comment
1. Wave angle and wave height are leading parameters (longshore transport).	Accepted. For fixed groin length, these parameters determine bypassing and the net and gross longshore transport rates.
2. Groin length is a leading parameter for single groins. (Length controls depth at tip of groin.)	Accepted, with groin length defined relative to surfzone width.
3. Groin length to spacing ratio is a leading parameter for groin fields.	Accepted. See previous item.
4. Groins should be permeable.	Accepted. Permeable groins allow water and sand to move alongshore, and reduce rip current formation and cell circulation.
5. Groins function best on beaches with a pre-dominant longshore transport direction.	Accepted. Groins act as rectifiers of transport. As the ratio of gross to net transport increases, the retention functioning decreases.
6. The updrift shoreline at a groin seldom reaches the seaward end of the groin. (This observation was not found in the literature review and appears to be original to the present paper.)	Accepted. Because of sand bypassing, groin permeability, and reversals in transport, the updrift shoreline cannot reach the end of a groin by longshore transport processes alone. On-shore transport is required for the shoreline to reach a groin tip, for a groin to be buried, or for a groin compartment to fill naturally.
7. Groin fields should be filled (and/or feeder beaches emplaced on the downdrift side).	Accepted. Filling promotes bypassing and mitigates downdrift erosion.
8. Groin fields should be tapered if located adjacent to an unprotected beach.	Accepted. Tapering decreases the impoundment and acts as a transition from regions of erosion to regions of stability.
9. Groin fields should be built from the downdrift to updrift direction.	Accepted, but with the caution that the construction schedule should be coordinated with expected changes in seasonal drift direction.
10. Groins cause impoundment to the farthest point of the updrift beach and erosion to the farthest point of the downdrift beach.	Accepted. Filling a groin field does not guarantee 100% sand bypassing. Sand will be impounded along the entire updrift reach, causing erosion downdrift of the groin(s).
11. Groins erode the offshore profile.	Questionable and doubtful. No clear physical mechanism has been proposed.
12. Groins erode the beach by rip current jetting of sand far offshore.	Questionable. Short groins cannot jet material far offshore, and permeable groins reduce the rip current effect. However, long impermeable jetties might produce large rips and jet material beyond the average surfzone width.
13. For beaches with a large predominant wave direction, groins should be oriented perpendicular to the breaking wave crests.	Tentatively accepted. Oblique orientation may reduce rip current generation.

(d) Kraus, Hanson, and Blomgren 1994 also discovered that the updrift shoreline rarely reached the seaward end of the groin (Table V-3-8, No. 6). On-shore sediment transport processes appear to be necessary for a groin to be filled naturally so that the shoreline reaches the tip, or the tip is buried. Longshore sand transport direction reversals, sand bypassing under water at the end, and groin permeability all normally keep the updrift shoreline well landward of the end of the groin.

(e) Properties No. 7, 8, and 9 in Table V-3-8 have long been accepted standard conditions for groin field design and construction. Even so, as noted in No. 10, filling a groin field does not guarantee that 100 percent of the original longshore transport will continue as sand bypassing. The entire, filled, groin field system will impound sand updrift to cause some erosion downdrift of the system.

(f) Properties No. 11 and 12 are often stated reasons by opponents of groins but are questionable because they cannot be supported by physical mechanisms nor principles of conservation of sand. No. 13 will be considered under innovations discussed in the following paragraphs.

(g) A critical review of the literature also shows that little, if any, previous discussion exists on how to judge success (or failure) of a groin design. As discussed further, success should be judged on two factors: to maintain a minimum, dry beach width for specified storm conditions for protection beyond a reference baseline; and to bypass an average, annual amount of sediment to minimize downdrift impacts.

(3) Physical processes.

(a) Normal morphological response. How do groins work? Waves breaking alongshore at an angle create a time-averaged, longshore current and longshore sediment transport. The cross-shore distribution of longshore sediment transport is discussed in Part III-2 (see Equation III-2-23 and Example Problem III-2-7). A key variable is the surf zone width for the theory cited (Bodge and Dean 1987) which assumes sediment mobilized in proportion to the local rate of wave energy dissipation and transported alongshore by the local, wave-induced current. The groin simply blocks a part of this normal transport of sand alongshore and causes it to accumulate in a fillet on the groin's updrift side (the side from which the sediment is coming). This accumulation reorients the shoreline and reduces the angle between the shoreline and the prevailing incident wave direction. The reorientation reduces the local rate of longshore sand transport to produce accumulation and/or redistribution of sand updrift of the groin. The amount of sand transported past the groin is greatly reduced (or eliminated) to significantly impact the downdrift area. The ratio of groin length to some statistical measure of surf zone width (or water depth at the groin tip) is a key factor in sand bypassing, as discussed further in the following paragraphs. Wave diffraction causes reduced wave energy in the lee of the groin relative to the midcompartment, mean water-level setup gradients, and setup induced currents behind the groin. These contribute to complex, current circulation patterns that move sediment alongshore and offshore along the leeside of the groin (Dean 1978). The strength of these internal current patterns depends on groin planform geometry, but also on groin cross-sectional elevation and permeability across the surf zone. Waves diffract around the groin tip, propagate over the submerged section and reflect off the body of the groin. These interactions vary with water depth changes during the tidal cycle. Consequently, sediment can also move over the top of submerged groins (over-passing), through the permeable, groin structure (through-passing) and behind the end of the structure (shore-passing). Impermeable, high crested groins created internal and external current patterns that are far different than permeable, submerged structures. Fleming (1990) discusses the results of physical model studies with current and sediment movements for both high and low groin cross sections. Complex flow patterns were produced, and it was stated that strong local currents may cause a net loss of sediment from the compartment by offshore movement during storm events.

(b) Storm response. Groins offer little or no reduction in wave energy to shore-normal waves during storms. Consequently, cross-shore sediment transport processes as discussed in Part III-3-3 for natural beaches are similar for groin field compartments. And, for near normal wave incidence, the groin system can

create strong local current and rip currents which add to the offshore movement of beach material during storms.

(4) Functional design.

(a) Insight from numerical models.

- Some numerical models of shoreline change include groin field effects (e.g., GENESIS, Hanson and Kraus 1989, see Part III-2-4 for details) Boundary conditions for groins in these models give insight into how they must function (Gravens and Kraus 1989). They are as follows:

  - As the groin length increases, its impact on the shoreline regarding time evolution and equilibrium planform must increase.

  - Increasing groin permeability should decrease the impact of the structure on the shoreline. Different groin permeabilities must produce different equilibrium planforms.

  - A permeability of 100 percent should give longshore transport rates and shoreline evolution identical to that modeled with no structures.

- Groin bypassing around the seaward end is calculated at each time step in the GENESIS model. Key variables are the water depth at the tip and the breaking wave height. In GENESIS, the depth of active longshore sediment transport is taken at 1.6 times the significant breaking wave height (from Hallermeier 1981). Groin length relative to surf zone width could also be employed to calculate the bypassing factor.

- A permeability factor representing groin elevation, groin porosity and tidal range must also be estimated in the model. These three variables represent over-passing, through-passing and shore-passing respectively as sketched in Figure V-3-29. The permeability factor is assigned and must approach unity to satisfy the third criterion previously described.

- A third key factor is the ratio of net transport rate, Q_n to the gross rate, Q_g (Bodge 1992). When the Q_n/ Q_g ratio is zero, a perfectly balanced transport (no net) exists to produce symmetrical fillets on both sides of a single groin. The opposite extreme is $Q_n/Q_g=1$ meaning unidirectional transport. A single fillet on one side results.

- These key factors controlling groin functioning are summarized in Table V-3-9 (Kraus and Bocamazo 2000) with symbols shown in Figure V-3-29.

- These three process factors incorporate many of the 20 or more fundamental variables. The geometry ratio of spacing, X_g to length Y_g is also the controlling factor for groin systems, as found in the literature. Note from Figure V-3-29 that Y_g represents a mean groin length measured from the average, nourished beach shoreline. Using Y_{gu} (updrift) gives a larger ratio or using Y_{gd} (downdrift) produces a smaller ratio that may account for some variability. The *Shore Protection Manual* (1984) says $X_g/ Y_g=2$-3 for the proper functioning of shore-normal groins.

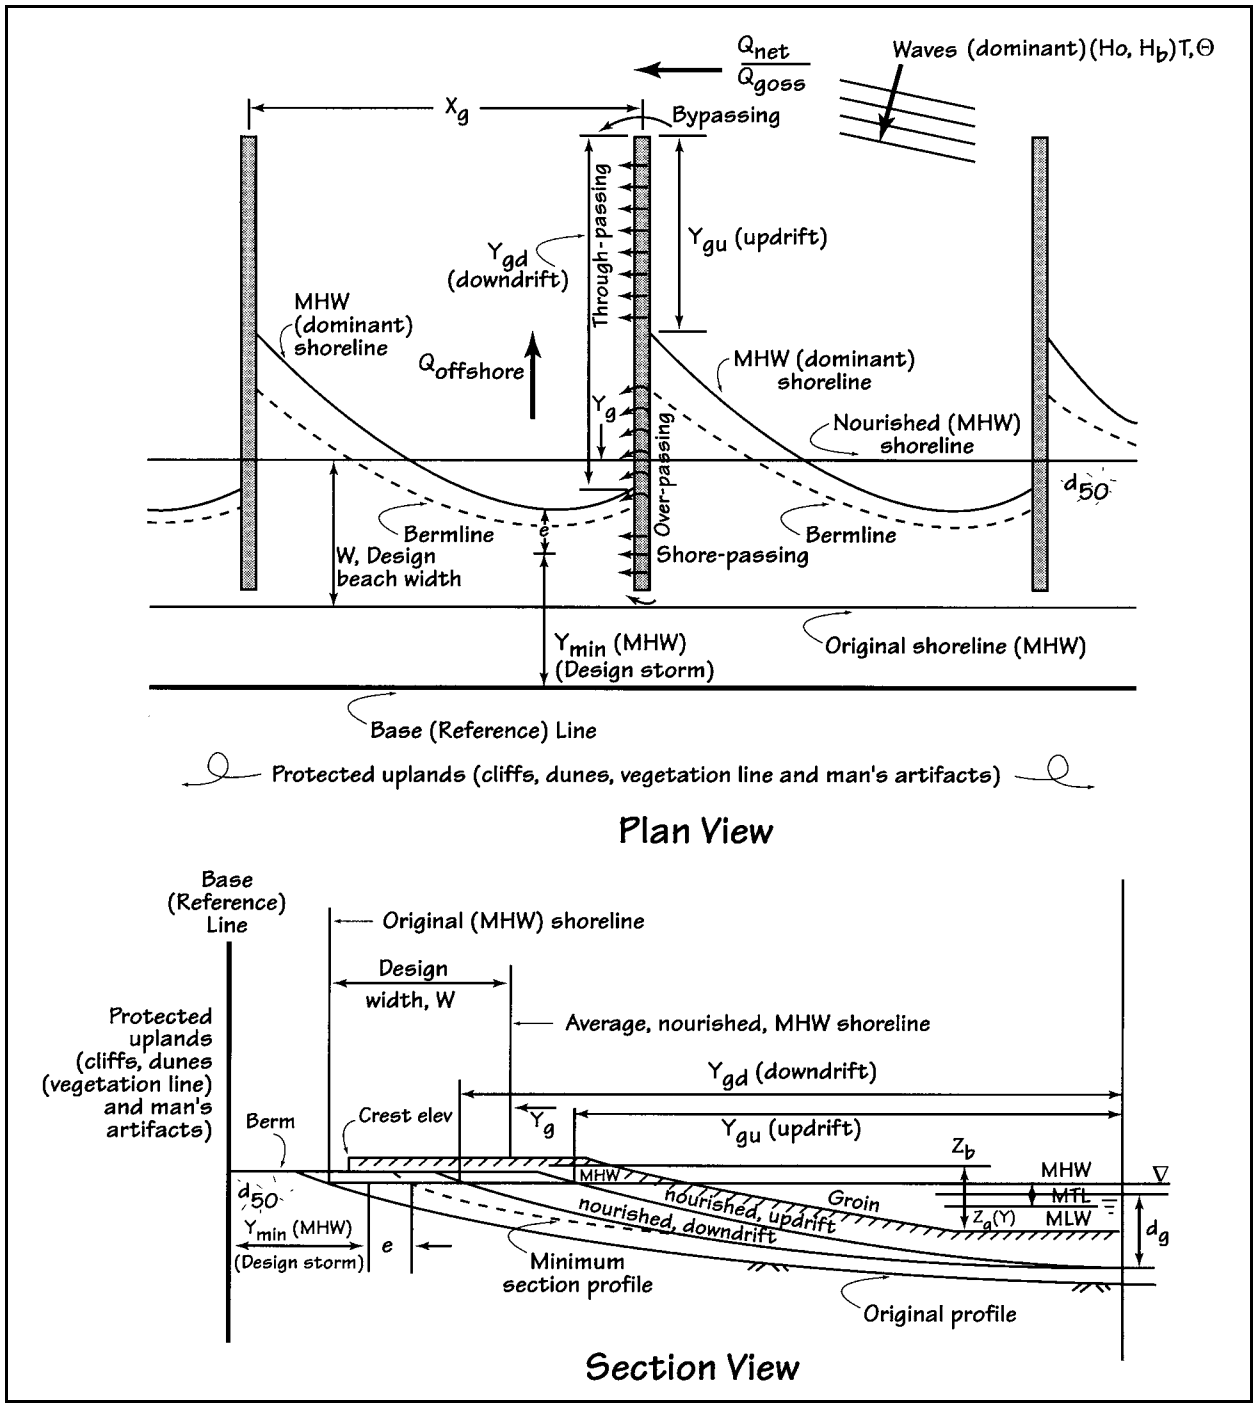

Figure V-3-29. Definition sketch of key variables in the functioning of groins

Table V-3-9
Process-Based Factors Controlling Groins

	Process	Parameter	Description
1	Bypassing	D_g/H_b	depth at groin tip/breaking wave height
2	Permeability		
	• Over-passing	$Z_g(y)$	groin elevation across profile, tidal range
	• Through-passing	P(y)	grain permeability across shore
	• Shore-passing	Z_b/R	berm elevation/runup elevation
3	Longshore Transport	Q_n/Q_g	net rate/gross rate

- Kraus, Hanson, and Blomgren (1994) exercised the GENESIS model for a single groin and studied the bypassing formulation. Rapid filling was followed by a gradual buildup over time that meant an increased amount of material must bypass the groin as the shoreline grows out towards the tip. Filling to capacity was only possible for $Q_n/Q_g=1$ for the unidirectional case. As $Q_g>Q_n$, growth of the shoreline seaward decreased. These tests mean groins seldom fill to capacity by longshore transport processes alone. Cross-shore sediment transport processes must be added to understand how beach elevation and width can build beyond that capable of representation on one-line, shoreline change models. Simulations with multiple-groins and the Westhampton Beach, New York, groin field are also discussed in this paper. An aerial view looking east of the Westhampton Beach, New York, groin field with beach nourishment in 1998 is shown in Figure V-3-30.

- Realistic distributions of longshore current and sediment transport across the surf zone, beach profile shapes with bars and troughs, and other sediment transport mechanisms (wind, tide) are further complicating factors that have yet to be addressed in numerical models.

(b) Groin profile. A typical groin profile with inshore (berm) section, sloping middle section, and horizontal seaward section is shown in Figure V-3-31. In general the landward end is set at the elevation of the natural, existing beach berm, the sloping section is set at the slope of the beach face in the swash zone and the outer, seaward section at a lower elevation such as mean low water (mlw) or lower. The landward and sloping sections function as a beach template for sand to accumulate on the updrift side. The groin profile is shaped to approximately match the postproject beach profile, after nourishment is complete. The seaward end (depth) and seaward elevation are set to the planned bypassing and overpassing in the surf zone. A lower seaward section permits longshore currents to carry sediment over the structure and reduces wave reflections from the groin. A significant amount of sand is transported on the beach face in the swash zone (Weggel and Vitale 1985) and therefore overpassing also takes place in the sloped section when the groin has been filled in this area. Prevention of flanking is the main concern to locate the shoreward end. As seen in Figure V-3-29, calculations of the storm erosion distance, e, together with maximum shoreline recession are needed to establish this position. Seaward limit of the shore section is set relative to the desire, nourished beach width, W, or even further seaward to help retain the nourished beach. Seaward limit of the outer section is the groin length, Y_g, and depends on the amount of longshore sediment transport to be bypassed, as discussed.

(c) Permeability. In general, sheet-pile groins of all types are impermeable whereas rubble-mound groins permit some material to wash through the structure. Some rubble-mound design contain impermeable cores and/or are treated with sealant materials to ensure sand tightness (see EM 1110-2-1617). There are no quantitative guidelines for determining the permeability of sand for a given groin geometry of the rubble-mound type. Some patented, precast concrete groin systems are permeable, as will be discussed later.

Figure V-3-30. Westhampton Beach, New York, groin field and renourished beach, 1998 (courtesy USAED, New York)

(d) Terminal groins. Groins on the updrift side of inlets can benefit nearby beach nourishment projects by controlling (or gating) the amount entering (lost) to the inlet. These terminal structures also benefit navigation projects by reducing the sediment rates within the inlet. They normally are impermeable and high and long to prevent sand from being carried through, over, or around them. Eventually, they will fill and sand bypassing around the end will be maintained. It should be noted that terminal groins are short compared with the length of navigation jetties constructed to reduce wave heights for ships entering the inlet. Consequently, the scale of interruption of normal, longshore sediment transport processes for ebb-and flood- tidal shoals are far different for navigation jetties. Terminal groins fill quickly and do not have major impacts on ebb-tidal shoals and normal, inlet, sand-passing processes. A successful terminal groin is that located on the southern bank of Oregon Inlet, North Carolina. Design and monitoring details are found in Overton et al. (1992); Dennis and Miller (1993); Miller, Dennis, and Wutkowski (1996); and Joyner,

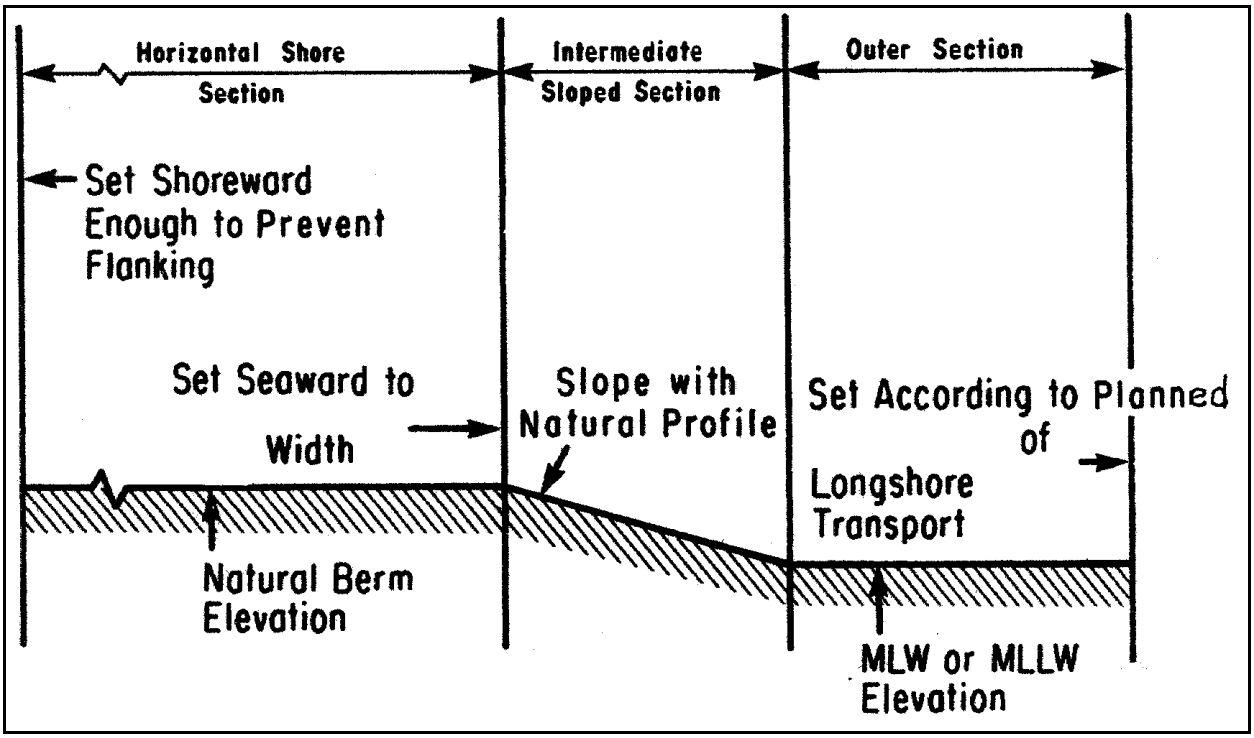

Figure V-3-31. Typical groin profile with sloping section

Overton, and Fisher (1998). See also Dean (1993; 1996) for detailed analysis of terminal structures at the ends of littoral systems.

(e) Groins system transitions. A transition reach is required from a groin field to the adjacent, natural beach. Groin lengths are gradually shortened to allow more bypassing. Generally, groin lengths are decreased along a line converging to the shoreline from the last full-length groin, making an angle of about 6 deg with the natural shoreline as depicted in Figure V-3-32 (Bruun 1952). The spacing is also reduced to maintain the same X_g/Y_g ratio (2-3) used in the design.

(f) Order of construction. The sequence in which a groin field is constructed is a practical design consideration and may not be straightforward. To minimize downdrift impacts, beach nourishment and groin construction should be concurrent. Construction of the first groin should be at the downdrift end of the project, preferably the terminal groin adjacent to an inlet. Net drift will combine with the artificial beach nourishment to fill and stabilize the first compartment. The second groin is then constructed and the process repeated. Gradually working updrift, the groin field construction is completed. This process together with tapering the ends will help to minimize the impact to adjacent, downdrift beaches. This method may increase costs, but it also may result in a more practical guide to spacing of the groins than originally designed.

(5) Nontraditional configurations. Most groins are straight structures, perpendicular to the shoreline. Figure V-3-33 illustrates other possible planform shapes. T-shaped groins are similar to nearshore breakwaters when the tee end is above the mean water level. Inclined groins may reduce rip currents along the updrift side when inclined in the direction of net sediment transport. All shapes shown have been constructed and provide some degree of shoreline stabilization. Sectional variations are also possible as listed in Table V-3-10.

Table V-3-10
Types of Groins-Section Views

Concepts	Comments
Flat (Horizontal)	old
Sloped	common
Notched	(swash zone, new)
Concrete-pile (permeable)	(innovative, patented)
Adjustable	(elevation, length)
Rectifying	(transport-direction sensitive)
Tuned	(elevation, T-head)
Temporary	(geotextiles, sand)
Spur	

(a) Notched groins have recently undergone laboratory and field testing by the USACE (Kraus 2000). Trial notched groins have been implemented by the U.S. Army Engineer District, New York, and the U.S. Army Engineer District, Philadelphia, along the south shore of New Jersey. The purpose of notching is to bypass beach fill and littoral sediment so that the fillet and erosive response of the shoreline are smoothed out, i.e., to straighten the shoreline adjacent to the groin. The goal is shoreline readjustment to approach a smooth, continuous shoreline through a groin field. The efficiency of notching was defined as the amount of sediment that passes the groin system, but that remains on the subaerial beach. Tentative conclusions based on both the laboratory and field experiments are: notches in the swash zone are most efficient; notches in the surf zone are less efficient and can have strong longshore currents, and be hazardous to swimmers; surf zone notches may move sediment further from shore; notching a groin in the swash zone may not be successful depending on how and at what rate sediment typically moves alongshore on the subject beach.

(b) Spur groins are short, stub groins constructed at right angles to navigation jetties and the end groins of groin fields to redirect currents and sediment transports. Sorensen (1990) describes a spur jetty constructed as an emergency measure on the leeward side of two curved jetties to prevent a breach at the landward end. Anderson, Hardaway, and Gunn (1983) document eleven locations in the Chesapeake Bay where short, shore parallel groins are attached to the terminal groin near the beach. Over 12 years of beach response at one site reveals that the spur groins cause diffraction and refraction effects to prevent the detachment of the terminal groin at its landward end.

(c) Another way to smooth the shoreline is to make the groin more permeable as illustrated in Figure V-3-34. A patented, concrete pile, permeable groin field has existed on Cayman Kai, Caribbean Sea, for over 10 years and has survived many hurricanes (from Kraus and Bocamazo 2000). Environmental restrictions against hardened shorelines in North Carolina has resulted in a groin field constructed from geotextile materials filled with sand on Bald Head Island, North Carolina (Denison 1998). In theory, these structures will provide sand for shore protection if they are damaged or fail in major storm events. Other revisited or fresh concepts for groin designs listed in Table V-3-9 have only been proposed conceptually and have yet to be field tested. These new and innovative approaches to groin design benefit from experience and modern understanding of coastal sediment processes.

(6) Basic rules for functional design of groins. Ten modern rules for groins design can be summarized as follows:

- Rule 1 If cross-shore sediment transport processes are dominant, consider nearshore breakwater systems first.

- Rule 2 Conservation of mass for transport of sediment alongshore and cross-shore means groins neither create nor destroy sediment.

- Rule 3 To avoid erosion of adjacent beaches, always include a beach fill in the design

- Rule 4 Agree on the minimum, dry beach width, $Y_{min.}$ for upland protection during storm events as a measured to judge success.

a. Aerial photo

b. Cross-section model

Figure V-3-34. Patented concrete pile permeable groins Cayman Kai, Caribbean Sea (surviving for 10 years, including hurricanes). Innovation is groin design to enhance sediment through-passing and smooth the shoreline variation in the groin field (from Kraus and Bocamazo 2000)

- Rule 5 Begin with X_g/Y_g=2-3 where X_g is the longshore spacing and Y_g is the effective length of the groin from its seaward tip to the design shoreline for beach fill at time of construction.

- Rule 6 Use a modern, numerical simulation model (e.g., GENESIS) to estimate shoreline change around single groins and groin fields.

- Rule 7 Use a cross-shore, sediment transport model (e.g., SBEACH) to estimate the minimum, dry beach width, Y_{min} during storm events.

- Rule 8 Bypassing, structure permeability and the balance between net and gross longshore transport rates are the three key factors in the functional design. Use the model simulation to iterate a final design to meet the Y_{min} criterion.

- Rule 9 Consider tapered ends, alternate planforms and cross sections to minimize impacts on adjacent beaches.

- Rule 10 Establish a field monitoring effort to determine if the project is successful and adjacent beach impacts.

- Rule 11 Establish a "trigger" mechanism for decisions to provide modification (or removal) if adjacent beach impacts are found nonacceptable.

f. Reefs, sills and wetlands.

(1) Background and definitions. Additional types of shore protection alternatives for both high and low wave energy coasts function by reducing the wave energy striking the shoreline. Reefs are platforms of biotic organisms built up to a strict elevation in relation to low tide. Natural reefs require high wave energy to survive. Wetlands are coastal salt or freshwater marshes that are low-lying meadows of herbaceous plants subject to periodic, water level inundations. Wetlands are fragile and only survive in low wave energy environments. See IV-2-11 and IV-2-12 for further details on wetland and reef-type coastlines, respectively. The word "sill" has evolved to take on two separate identities in coastal engineering. Both meanings imply wave attenuation in the lee of the structure. A submerged, continuous, nearshore dike to hold sand moving offshore from a nourished beach is one definition and also labeled a perched beach. Free-standing, low-profile, continuous shoreline structures to permit establishment of a marsh fringe in the lee of the structure are also called sills.

(2) Reefs.

(a) Natural types. Coral reefs are massive calcareous rock structures that slowly grow upward by secretions from simple animals living on the rock surface. They exist throughout the Florida Keys, on both Florida coasts, the Hawaiian Islands, and the U.S. Island territories and serve significantly lower the mean wave energy striking the adjacent shore. Fringing reefs border a coast, barrier reefs lie offshore enclosing a lagoon, and atolls encircle a lagoon. Under favorable growth conditions, coral reefs build upward to form wide, broad platforms that are exposed at low tide. Thus they cause waves to break and to continue breaking across the reef.

- Oyster reefs can exist in much colder, brackish water conditions of lagoons, bays and estuaries. They are found along both coasts and in the Gulf of Mexico. They are wave-resistant structures that can biologically adapt to rising sea levels. Their maximum elevation is related to the minimum time of inundation in the middle range of the intertidal zone.

- A third type of natural reef is produced by colonies of tube worms called a worm reef. The east coast of Florida has some of this type.

- With respect to natural shore protection, reefs are a biological wave damper that can accommodate rising sea levels as long as they are alive. Protection of reefs is essential.

(b) Wave attenuation. Wave transformation processes across broad, flat coral reefs include shoaling, refraction, reflection, and energy dissipation by both bottom friction and wave breaking. Wave energy is also transferred to both higher and lower frequencies in the wave spectrum as the spectral shape flattens (Hardy and Young 1991). Wave setup variations along reefs can occur due to gradients in wave breaking characteristics to produce longshore currents. For engineering purposes, depth-limited wave breaking is the dominant transformation process. A methodology to estimate random wave energy transformation across reefs is presented in USACE (1993). It is based on the breaking wave model of Dally, Dean, and Dalrymple (1985) extended to random waves following Kraus and Larson (1991). Comparison of the numerical model results with field experiments of rms, wave height attenuation on the Great Barrier Reef in Australia (Young 1989) showed good agreement with the measurements. The breaker model without bottom friction is available in the PC-based computer program NMLONG (Kraus and Larson 1991; USACE 1993).

(c) Artificial reefs. The functional design of artificial reef systems for shore protection; increasing the fill life of renourished beaches, and to enhance recreational surfing is a relatively new area of coastal engineering. No general design rules exist. Numerical and physical models have recently been employed for site specific designs in California and Australia of artificial reefs for surfing. These models aid in both wave breaker-type design (Pattiaratchi and Bancroft 2000) and to insure that the structure will not create downdrift erosion. (Turner et al. 2000).

(3) Sills.

(a) Perched beach. A beach or fillet of sand retained above the otherwise normal profile level by a submerged dike (sill) has only been used twice in the United States (National Research Council 1995). Ferrante, Franco, and Boer (1992) describe a successful, 3,000-m-long perched beach project on the coast at Lido di Ostica about 35 km from Rome, Italy, on the Tyrrhenian Sea. The rubble-mound sill was located about 150 m from shore with crest -1.5 below msl datum in -5.0 water depth. An additional 1.000-m stretch with sill closer to shore in shallower water performed better to hold a wider beach. A feasibility study of the perched beach concept in the Netherlands was reported by Ruig and Roelse (1992). Model studies and calculations of life-cycle costs demonstrated that this alternative was roughly as expensive as repeated beach nourishments with no sill construction over a 30-40-year period. Construction at the site selected, Cadzand, Tien Honderd Polder, Zeeland, The Netherlands, has yet to be implemented.

(b) Wetlands protection. In low wave-energy environments, natural, wide, fringe marshes can provide sufficient erosion protection for upland areas, as discussed later. However, for many reasons, the fringe marsh itself may be eroding and require protection, enhancement and/or to be re-established. Sills are typically low, small, continuous rock structures placed at mean low water with some sand fill in the lee to provide a substrate for marsh growth (Hardaway and Byrne 1999). Figure V-3-35b displays a curved, stone sill connecting headland breakwaters with sand fill and marsh planting on the Choptank River, Chesapeake Bay (from Hardaway and Byrne 1999). After 5 years, the sill is practically invisible as shown in Figure V-3-35c. Sills can thus be used in higher wave energy regimes to establish intertidal marsh grasses that aid in the shore protection. Periodic marsh replanting and maintenance may be required under higher wave energy conditions. Advantages and disadvantages of a wide variety of erosion mitigation structures and materials to protect wetlands can be found in the Wetlands Engineering Handbook (Olin et al. 2000).

(4) Wetlands. The final alternative in this section on shoreline stabilization structures are fringe marshes or wetlands. Part IV-2-11 considers their values, distribution classification sediment characteristics, and causes for loss of wetlands in the coastal zone. However, little is known about their importance for shoreline erosion mitigation.

(a) Tidal creeks with fetch exposures less than 0.5 nautical miles and low wave-energy environments can naturally sustain a sufficiently wide marsh fringe. Also, they generally have little or no problem with upland bank erosion because the established marsh fringe absorbs most of the wave energy before it can impact the upland area (Hardaway and Byrne 1999). On the Chesapeake Bay, Hardaway and Anderson (1980) found that low, upland banks erode almost twice as fast as marsh shorelines with similar fetch exposures and nearshore depths.

(b) Some recent field and laboratory research has focused on wave attenuation by wetland vegetation (Kobayashi, Raichle, and Asano 1993; Wallace and Cox 1997; Tschirky, Turke, and Hall 2000). Wave heights are typically reduced by 50 percent and the peak spectral period also drops as the spectrum becomes more broad banded with higher frequency components. No significant design guidance on allowable wave heights or currents for wetlands presently exists. The Wetlands Engineering Handbook (Olin, Fischenich, and Palermo 2000) provides a wealth of valuable information for the restoration and creation of wetlands.

V-3-4. Nonstructural Alternatives

a. Introduction.

Nonstructural alternatives are management strategies for coastal hazard mitigation that are not armoring (Part V-3-2) nor beach stabilization structures (Part V-3-3), nor beach nourishment (Part V-4). Society has developed ways to adapt by setting requirements for the elevation of buildings, providing insurance and planning for continual erosion with setback limits for new construction. The final nonstructural alternative is to retreat by relocation, abandonment, or demolition.

- Three Federal government agencies (the USACE, Federal Emergency Management Administration (FEMA), National Oceanographic and Atmospheric Administration (NOAA)) with different missions, planning methods, and requirements for benefits determination employ or promote the use of nonstructural methods. This section briefly summarizes the role of each and presents some examples of the retreat alternative. Full details of the Federal government's planning requirements and design constraints for all three agencies involved are presented in Part V-8.

- Coastal hazard mitigation is addressed in a piecemeal manner by multiple agencies within states, at the county, city and community level, and by businesses and individuals operating and living at the water front. Property ownership (Federal, state, municipal, community, and individual) and the value of scarce waterfront property strongly motivates all parties to protect their valuable investments. Part V-8 presents details of how each Federal agency (CORPS, FEMA, and NOAA) interacts with each level of responsible group, but details of approaches by these parties are beyond the scope of this chapter.

b. Adaptation.

(1) Zoning and building codes. Any structural or nonstructural change in the design, construction or alteration of a building to reduce damage caused by flooding and flood related factors (storm surges, waves, and erosion) is considered a flood proofing alternative by FEMA. The mechanism to require change in old construction practices is the National Flood Insurance Program (NFIP) administered by FEMA using Flood

b. Stone sill connecting breakwaters with sand fill and marsh implantation on Choptank River, Talbot County, MD

c. Breakwater and sill project after 5 years

Figure V-3-35. Sills and breakwaters (from Hardaway and Bryne 1999)

Insurance Rate Maps (FIRM's) prepared by FEMA. A storm surge elevation at the one percent exceedance level (100-year recurrence interval) plus waves is employed to determine risk and insurance rates for individual properties located on the flood maps. Insurance rates are much lower for structures elevated above the 100-year flood level and is a requirement for all new construction in the coastal, high-hazard zone (including waves). In effect, these regulations become floodplain zoning laws applicable to individual property owners and have resulted in a reduction in Federal government expenditures for insurance claims and disaster assistance benefits (National Research Council 1990).

(2) Setback limits. A second way to adapt is to limit construction close to the shoreline. The NOAA has identified land-use planning and construction siting as the most effective means to reduce coastal storm hazards, particularly on eroding coasts. Here, the mechanism to require change in old construction practices is the Coastal Zone Management Act (CZMA) of 1972. Through the CZMA, the NOAA provides funds to individual states to help solve their own coastal hazard problems. As a result, many states have developed coastal construction setback lines and zones that include historic erosion rates at each site. The methods, definitions, widths, etc., vary from state to state as summarized in Part V-8. A key element is the historic, average erosion rate at each site. Presently, FEMA does not include delineation of erosion zones and erosion hazards on its flood maps. Methods to incorporate both coastal erosion (National Research Council 1990) and beach nourishment (National Research Council 1995) in the national, flood insurance program have been proposed but have yet to be formally adopted. Clearly, coastal erosion increases the risk and beach nourishment reduces the risk of coastal flood and wave damage.

c. Retreat.

Retreat is the final adaptation option. Relocation here also considers abandonment and demolition. To some, retreat is the only option. But practically, all constraints (economic, environmental, social, legal, etc.) must be evaluated for this alternative as well as for all others as previously discussed. This approach may be employed by the Corps as the Federal government agency designated by Congress to protect the nation's shores from the chronic effects of erosion and coastal flooding. Two examples illustrate the USACE's approach and focus on why the retreat alternative was selected.

(1) Cape Shoalwater, Washington. The northern shoreline of the inlet to Willapa Bay, Washington, has been receding at an average rate of 30 to 40 m/year for over 100 years (Terich and Levenseller 1986). Erosion of this area (Cape Shoalwater) has been faster and has lasted longer than any other site on the U.S. Pacific Ocean coast (Komar 1998). Natural, northern migration and progressive deepening of the channel inlet are the two main factors responsible for erosion of the cape. A few homes have been lost, a lighthouse destroyed, the main road moved inland and a historic, pioneer cemetery relocated in this rural area.

(a) In the 1960s and 1970s, the USACE studied the construction of a jetty to stabilize the inlet location and reduce the erosion of the cape. They concluded that a structural solution was not economically feasible to the Federal government. The USACE recommended that if Federal government funds were available at this site, they should be used to purchase land threatened by future erosion. However, no Federal project for relocation could be justified based on the relative benefits and costs to the Federal government.

(b) The rural area (low benefits) and extremely high erosion rate (high costs) were responsible for this outcome, as may have been expected. At other sites, this result is not as obvious.

(2) Baytown, Texas. The northern, upper end of Galveston Bay on the Gulf of Mexico includes Burnett, Crystal, and Scott Bays and low-lying areas that are part of Baytown, Texas, about 24 km east of Houston. Flooding occurs routinely from minor storms and is compounded by subsidence of the ground surface. Withdrawal of oil and gas and groundwater for the metropolitan area of Houston produced 2.5 m (9 ft) of subsidence between 1915 and 1975 (U.S. Army Engineer District, Galveston, 1975).

(a) Both structural (earth levee, concrete floodwall) and nonstructural (permanent relocation and evacuation) alternatives were studied in the early 1970s by the USACE to mitigate the flooding problem. The feasibility study report to Congress (U.S. Army Engineer District, Galveston, 1975) recommended the retreat alternative. Congress authorized this project under the Water Resources Development Act (WRDA 1978).

(b) The final project report (U.S. Army Engineer District, Galveston, 1979) called for the Federal government to purchase approximately 303.51 ha (750 acres), 448 homes and relocate 1,550 people within the 50-year floodplain. Total project costs were $32.131 million (1979 dollars) with the local sponsors' share to be 20 percent or $7.826 million. Annual project benefits were estimated to be $3.530 million and included:

- Reductions for insurable flood damages.
- Reductions for utility service costs.
- Reductions of temporary, emergency evacuation, public health and public relief costs.
- Value of land under new uses.

(c) Other benefits (constant anxiety from flood hazards, depressed property values, health hazards, inconvenience of repetitive, temporary evacuations, and damages to real property and personal possessions) cannot be included as net gain benefits to the national economy. Total, annual costs were $2.678 million giving a benefit to cost (B/C) ratio of 1.3 to the Federal government for the retreat alternative. In contrast, the structural alternative, B/C ratios were 0.1 - 0.3 (USAED, Galveston, 1979).

(d) In 1978, the environment assessment report to the EPA was approved. Plans called for converting the land into a natural area, with possible development of nature areas, bird sanctuaries, green belts, wildlife areas, nature walks, and other uses consistent with the high flood potential. Besides the local sponsor (City of Baytown) paying 20 percent of the final cost, they were also responsible for management of the vacated area.

(e) Unfortunately, the project floundered on local disagreement over the value of the land to be purchased and was never funded. Estimates of project costs rose from $16.980 million in 1975 to $39.131 million in 1979 (less than 5 years). People in the community who did not live in the floodplain were being asked to help buy out those who did. The community was divided over what the property was worth. Some believed their neighbors would be paid far too much for relocation. In July 1979, a bond election was held to provide the local funding for the project and it failed by a 60/40 percent margin (Pendergrass and Pendergrass 1990).

(f) In 1980, Congress was ready to authorize funding, but the local, 20 percent cost share could not be provided. The local residents decided to stay and the Corps placed the project in its inactive category. In the final analysis, the Corps' requirement for cost sharing ($7,589 per residence in 1975 and rising to $17,469 per residence in 1979) prevented an economically viable and environmentally sound project from being implemented. Because the B/C ratio was 1.3, the annual benefits to the Federal government exceeded the 20 percent, local cost share amount. In other words, the Federal government could have paid for the entire project and still realized net economic benefits to the Federal government. This result also does not consider NFIP payments then and over the last 20 years. Partial protection by the NFIP also contributed to the local residents' decisions to stay.

(g) In summary, a nonstructural solution for part of the community of Baytown, Texas, proved difficult to implement because the entire community would not share in the local cost requirement. In contrast, a flood dike and revetment to protect the Texas City – La Marque area on the lower Galveston bay has been

constructed. Here, the perception that all the affected community was "protected" made the local sponsor share obtainable (Pendergrass & Pendergrass 1990).

(3) Special cases.

(a) Brighton Beach Hotel, Coney Island, New York. Komar (1998) shows etchings of the 1888 relocation of a large, beachfront hotel on Coney Island, New York. Twenty-four railway tracks were laid to span the entire hotel width, and the wooden pile-supported hotel was lifted onto freight cars on each track. Six locomotives pulled the hotel inland 150 m. No details on costs were provided for this private project which required property ownership and grading of the inland site. Its economic viability also depended on the availability of railway equipment in that era over 100 years ago. Full details are in Scientific American (1888).

(b) Cape Hatteras Lighthouse, North Carolina. Very recently, relocation of the Cape Hatteras Lighthouse has been completed by the National Park Service (NPS), U.S. Department of Commerce (see, e.g., Civil Engineering 1999). The lighthouse is on the east coast of Hatteras Island about 4.02 km (2.5 miles) north of the tip of Cape Hatteras and 64.37 km (40 miles) south of the Oregon Inlet (Figure I-2-6). It is located within Cape Hatteras National Seashore Park, administered by the NPS. The original lighthouse built at this site in 1803 was replaced in 1870 by the present structure, which is the tallest (61 m) and perhaps best-known brick lighthouse in the United States. When built in 1870, it was approximately 490 m from the shoreline. By 1935, this distance diminished to about 30 m due to landward migration of this cape feature. The mhw, average recession rate between 1852 - 1980 (128 years) has been 5.9 m/year and 3.9 m/year for the 1870 - 1980 (110 years) period (Everts, Battley, and Gibson 1983). In 1996, partly due to a wide variety of piecemeal, temporary and emergency measures (see Table V-3-11), the lighthouse stood about 50 - 90 m from the Atlantic Ocean (U.S. Army Engineer District, Wilmington, 1996) depending on the season and tidal conditions. The existing, steel, sheet-pile groin field was actually designed and constructed by the Navy to protect its installation to the north in 1970. The lighthouse, a national historic landmark, remained in operation, and the NPS decided in 1980 that a long-term solution of the erosion problem was needed.

- A 1982 conference of experts from many disciplines (engineering, geology, economy, and historic preservation) together with a 1985 study by the Wilmington District convinced the NPS to employ a structural solution. A seawall/revetment structure was selected. Also a factor in this decision was scientific and engineering opinion that the lighthouse could not be moved without suffering serious structural damage. Congress approved $5.3 million and construction was to begin during the summer of 1986.

- A Move the Lighthouse Committee Report (private) convinced the NPS to seek the advice of the National Academy of Sciences. Their final report (National Research Council 1988) recommended the retreat alternative and in December 1989, the NPS reversed its decision and announced its approval of the relocation alternative. The next 10 years were filled with further controversy and debate due to lack of congressional funding for the relocation; public sentiment in North Carolina against the move (Save the Lighthouse Committee, private), and other ad hoc committee reports with updated studies. During the period, other structural engineers and large-scale relocation experts became convinced that the lighthouse could be moved without damage.

Table V-3-11
Cape Hatteras, North Carolina, Shore Protection History

Year	Action Taken
1930s	Civilian Conservation Corps builds sand dune system along Hatteras Island
1966	Beach Nourishment – 239,000 m^3 (312,000 cu yd) of sand placed along Buxton Motel area north of lighthouse
1967	Sandbags placed along 340 m of shoreline to protect former Navy Facility north of lighthouse
1970	Navy constructs three concrete & steel groins
1971	Beach Nourishment – 150,000 m^3 (200,000 cu yd) of sand placed along Buxton Motel area north of lighthouse
1973	Beach Nourishment – 960,000 m^3 (1,250,000 cu yd) of sand placed along Buxton Motel area north of lighthouse
1974	Repairs made to northern & southern Navy groins
1980	Emergency Repairs – 50 m landward extension of south groin
1981	Riprap and sandbags placed beyond landward extension of south groin
1982	Additional 50 m landward extension of south groin. Seven hundred sandbags placed around the base of the lighthouse
1983	Riprap scour apron placed along landward end of south groin
1992	Additional sandbags placed around base of lighthouse
1994	Additional sandbags placed around base of lighthouse
1995	Rehabilitation of landward end of south groin with 56 m of steel sheetpiling

- Also contributing to the controversy was a NPS committee study in 1992 to make recommendations for *interim* measures, as required, to ensure that the lighthouse remain protected, until the retreat solution could be implemented. An intermediate measure (15 - 25-year design life) was selected to add a fourth groin south of the existing groin field. The NPS employed the Wilmington District to make this design (USAED, Wilmington, 1996). Opponents to the move cited the costs for the fourth groin alternative ($3.5 million) in the USACE study when objecting to the retreat alternative costs (estimated as $12 million). A complete economic analysis using a 100-year design life to determine life-cycle costs of a groin field with terminal groin versus the retreat alternative has never been made by the USACE.

- The National Academy of Sciences study and report (National Research Council 1988) reveals the following NPS policies that dictated the choice of the retreat alternative.

  - Historic preservation is more important than a do nothing or “let nature take its course” policy.

  - The NPS does not have to follow a benefit/cost analysis procedure with benefits exceeding costs regarding the choice of alternative for shore protection.

  - The NPS policy for coastal shorelines is to not interfere with natural, coastal processes. This policy eliminated all structural options as discussed in Chapter 5 of the NRC 1988 report and made their analysis superficial and irrelevant. The retreat option was the only alternative given consideration.

- The NPS strategy was to use the Cape Hatteras Lighthouse relocations as an example and model of "enlightenment" (page numbers refer to NRC 1988)

  - "an exemplary response ... to the generic problem of shoreline erosion" (p. 72)
    "attract much media attention ... to educate a large national audience on the nature of coastal barriers" (p. 72)
    "use national parks as models of wise management of natural and cultural resources" (p. 71)
    "act as a signal to the country of the problems confronting the coast" (p. 39) and
    "illuminate approaches to solving the problems of living with a rising sea" (p. 39).

- The Cape Hatteras Lighthouse was moved successfully inland about 488 m (1,600 ft) from the mhw shoreline in 1999. Recognizing the engineering and construction skills required to complete the move safely, the project received the Outstanding Civil Engineering Achievement Award from the American Society of Civil Engineers in 2000.

- In the final analysis, the NPS policy against any structural interference with natural, coastal processes was the deciding factor. The decision to relocate was taken in 1989 at a time when the possible, accelerated rise in sea level was also of major concern.

(4) Impact of sea level rise. A detailed summary of present-day knowledge of sea level rise rates is presented in Part IV-1-6. Substantial variability exists when including local subsidence as previously discussed for Baytown, Texas. A National Academy of Sciences report on engineering implications (National Research Council 1987) concluded that whether to defend or to retreat depended on several factors, but mainly the future sea level rise rate and the cost of retreat which varies by site. The NRC recommended that all options should be kept open to enable the most appropriate response to be selected. Retreat is most appropriate in areas of low development. Given that a proper choice exists for each location, selecting an incorrect response alternative could be unduly expensive (National Research Council 1987).

V-3-5. Combinations and New Technologies

Pope (1997) lists the following common types of coastal erosion and flooding problems:

- Long-term, chronic land loss associated with the erosion of cohesive sediments, reduced supply of sandy sediments, and/or subsidence.

- Localized erosion impacts caused by a navigation project jetties or other coastal construction works.

- Lands and facilities impacted by storm-induced erosion.

- Flooding by a storm surge with associated wave attack damages.

- Loss of environmental resources (i.e., wetlands, oyster reefs, nesting areas, etc.).

- Need for more land.

In many cases, combinations of these problems exist that require a combination of structural measures together with nonstructural alternatives to be implemented within a comprehensive, coastal region, management plan for hazard reduction.

a. Combinations.

(1) Structural combinations.

(a) Beach stabilization structures and beach nourishment. Groins and detached breakwaters combined with beach fills are discussed in Part V-3-3e. The combination mitigates downdrift impacts and/or increases the fill life of the renourished beach. Together, their life-cycle costs and environmental impact may be less than if selectively implemented. Construction of the beach stabilization structures without fill is likely to damage adjacent beaches.

(b) Seawalls, revetments, and beach nourishment. The original design of the new seawall for hurricane protection at Virginia Beach was to be a curved, concrete-type structure as at Galveston, Texas (Figure V-3-5). To accommodate a lowered seawall crest for aesthetic reasons (see Part V-3-1-c-(5)and Figure V-3-6) a wide beach nourishment project was added to the design to reduce flooding and wave damage (USAED, Norfolk, 1994). Together with improved interior drainage and pumping equipment, this combined design provides the same hurricane flooding and wave damage protection as the original seawall design.

(c) Beach nourishment and rebuilt dune with buried seawall/revetment. The soft alternative (beach and dune with buried rock seawall/revetment) was determined to be both environmental and economically advantageous when compared against an armored revetment for storm protection against the 1 percent change storm event at Dam Neck, Virginia, on the Atlantic Ocean (Basco 1998). The final design cross section is shown in Figure V-3-36a and includes a buried rock seawall/revetment beneath the dune. In the event of a major storm causing severe dune erosion, the buried seawall will prevent storm damage if a second major storm occurs in the same season. Figure V-3-36b shows a photograph of dune construction with the buried, rock seawall (Basco 2000a). A similar approach was incorporated at Ocean City, Maryland, where a steel, sheet-pile bulkhead was incorporated as a buried backup feature in the design.

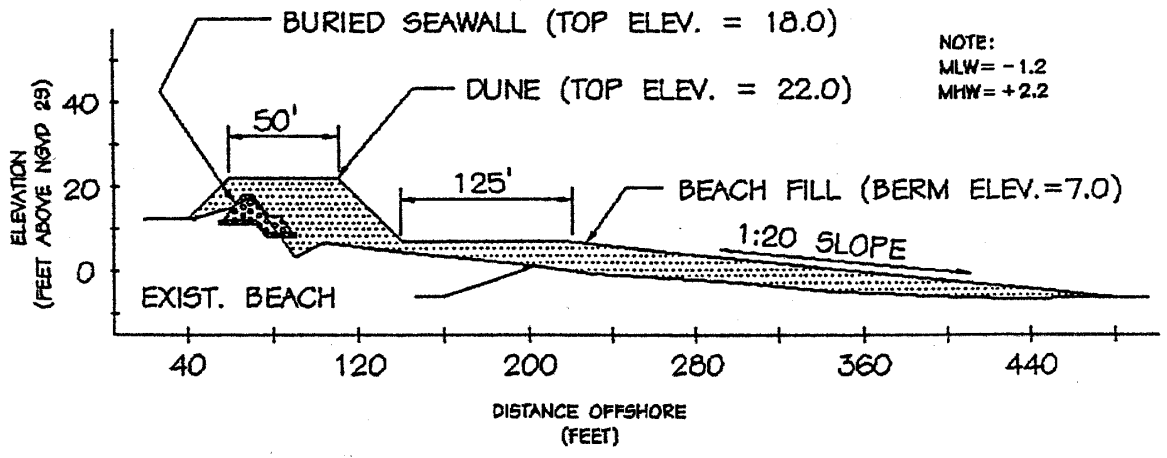
(2) Nonstructural and structural combinations.

At many locations, elevated structures combined with some type of armoring or shoreline stabilization together with beach nourishment are employed in combination for coastal hazard mitigation. Presently, 32 of 35 coastal states and territories have some type of setback requirements for new construction and existing structures found uninhabitable after a storm (Heinz Center 2000). These nonstructural, adaptive measures and structural alternatives are often combined to address the wide range of coastal problems previously cited. An example is the barrier island of Grand Isle, Louisiana, where beach nourishment, rebuilt dunes, a groin field and nearshore breakwaters are used for a community where the first floor of most residences are constructed above the 1 percent chance flood level (with waves) and the public lands on the rapidly eroding east end are restricted from any development (Pope 1997).

b. New technologies.

(1) Introduction.

Many nontraditional ways to armor, stabilize, or restore the beach including the use of patented, precast concrete units, geotextile-filled bags, and beach dewatering systems have been tried in the field. Their success depends on their stability during storm events and durability over the economic, design life. Their initial cost and cost for removal if environmental impacts warrant can be less than traditional methods, at some sites. These new technologies often involve nontraditional materials or shapes but are employed in a traditional manner, e.g., nearshore breakwaters. See Pope (1997) for more details.



a. Cross section

b. Photo during construction, Dam Neck, Virginia (from Basco 2000)

Figure V-3-36. Rebuilt dune with buried seawall (Basco 2000a)

(2) Precast, concrete units. Patented, modular, precast concrete units that can be interconnected to form one or more, nearshore breakwaters have been tested in Florida, Georgia, and New Jersey.

(a) In late 1989, two nearshore breakwater sections were installed at Sea Isle City, New Jersey, on the Atlantic Ocean. Each unit is 1.7 m long, 4.9 m wide and 2.1 m high and placed on a geotextile fabric. Each unit weighs about 12 metric tonnes and has 1.1 - 1.2 m freeboard at mean sea level (tidal range of 1.2 m). The two breakwaters were about 50 m in length with a 34-m gap and placed 37 m offshore (msl) in about 0.9-m water depth. This position was determined by the developer of the unit called the “Beachsaver” system

(Breakwaters International, Inc., Flemington, New Jersey). Independent monitoring over 18 months revealed significant structure settlement with the maximum over 1.2 m and average about 0.6 m (Sorensen & Weggel 1992). Most settlement occurred the first two months after installation. A large scour hole was found landward of one section and the sand trapping volume in two salients was only about 300 m^3, before settlement (Sorensen & Weggel 1992).

(b) The Town of Palm Beach, Florida, in the early 1990s, experimented with another design labeled the "Prefabricated Erosion Protection" or P.E.P. reef system by its developer, American Coastal Engineering, Inc., West Palm Beach, Florida. Each unit is 3.7 m long, 4.6 m wide, 1.8 m high and is placed on a cloth filter fabric. Each unit weights about 22 metric tonnes with crest elevation below msl to act as a thin-crested, submerged, reef-type breakwater. One long breakwater/reef system, 1,270 m in length, placed 76 m offshore (msl) in 2.9 m National Geodetic Vertical Datum (NGVD) water depth consisting of 330 interlocking units was constructed. The submergence was 1.1 m at msl. Monitoring by the University of Florida's, Department of Coastal and Oceanographical Engineering included nearshore profiles and wave gauges landward and seaward of the structure (Dean and Chen 1996). About 17 percent of the units settled 0.8 m with the remainder settling 0.5 m. Wave transmission coefficients ranged from 0.65 for normal conditions (tide range 1.0 m) to 0.85 for storm conditions. A detailed analysis of the leeward project area revealed that wave overtopping, wave setup, pounding, excess longshore currents and sediment transport (both directions) resulted in an increased erosion trend relative to that present before construction (Dean and Chen 1996; Martin and Smith 1997). The conclusion, that the reef breakwater provided little benefit, resulted in its removal. The units have since been salvaged and used to construct a groin field with beach nourishment at the site (Erickson 1998).

(c) These negative results at West Palm Beach, Florida, resulted in a staggered and gapped, planform configuration being the modified plan for the next P.E.P. reef installation at Vero Beach, Florida, in the late 1990s. Monitoring is being conducted by the USACE (Stauble and Smith 1999) with the latest results reported by Wooduff and Dean (2000). Analysis of nearshore profiles over 25 months (August 1996 - June 1999) when compared with historic volume change (1972 - 1986) revealed that erosion has increased landward of the reef. And, background erosion decreased north but remained the same south in control areas outside the reef area (Stauble and Smith 1999).

(d) The Beachsaver breakwater unit and P.E.P. reef unit shapes are similar, namely triangular with flatter slope on the seaward side than on the landward end. The have been called pyramid-shaped. Both have a thin crest width. In contrast, a vertical, cylindrical shape (circular, concrete pipe) combined with a concrete base forms the Hollow Core Reef System (HCR) as patented by Hollow Core Reef Enterprises, Inc., Newport News, Virginia. Each unit is typically 3.6 m long at its base and 1.7 m wide, but the height varies (pipe length) and is specifically designed for intertidal regions with 1-3-m tidal range. Since 1996, a 116-m-long, nearshore breakwater consisting of 46 units, 2.6 m in height has been installed at Sea Island, Georgia, on the Atlantic Ocean (tide range 1.8 - 2.7 m). Each unit weighs about 22 metric tonnes. Freeboard above msl is unknown. The foundation is timber cross-members to form a subbase and initial settlement was measured at less than 0.5 m. The units have been stable since construction and remain in place after several hurricanes along the south Georgia coast.

(e) In summary, crest width, planform configuration, siting and foundation design appear to be the weakest aspect as revealed by field monitoring of precast, concrete, modules for breakwaters and submerged reefs.

(3) Geotextile filled bags.

(a) Geotextile materials or filter fabrics have a long history for foundation mats beneath rubble-mound structures (See Part VI-5-3); and, they have been used as silt curtains to contain dredged materials in the water column. They have also been formed into bags and long, sausage-shaped cylinders (called Longard Tubes) and filled with sand. They have been deployed as revetments for dune protection, as nearshore breakwaters, and as groins. In the 1980s and 1990s, there has been significant improvement in the quality and durability of geotextile fabrics, making them suitable for a variety of coastal applications.

(b) The design life of a geotextile filled bag depends on many factors. It is generally less than properly designed rock structures serving the same function. However, if found to cause negative impacts to adjacent shorelines, the bags can be cut open and removed with the filled sand remaining on the beach. It is for this reason that a soft groin field was permitted by the North Carolina Coastal Resource Commission (CRC) together with a beach nourishment project for South Beach on the western end of Bald Head Island, North Carolina (Denison 1998). The North Carolina CRC prohibits hardened structures on its ocean coast. Fourteen 2.75-m diameter and 100-m-long geotextile bags filled with sand were constructed to grade out to - 1.2 to - 1.5-m (mlw) depths at 120-m spacing to form the groin field. The beach was also prefilled with 496,960.7 cu m (650,000 cu yd) of sand to + 1.8 m (NGVD) berm elevation and 25 - 30-m berm width over 3.65 km. Two hurricanes in 1996 removed about 76,455.49 cu m (100,000 cu yd) from the beach, but caused no damage to the groin tubes (Denison 1998). The long-term survivability of this system has yet to be determined.

(4) Beach drains.

(a) Beach face dewatering by lowering the groundwater table along the coastline began in Denmark in the early 1980s, by accident. After installation of a filtered, seawater system for a seaside aquarium, it was discovered that the sandy beach width increased where the beach parallel, longitudinal pipe intake was buried beneath the surface (Lenz 1994). Patents were obtained by the Danish Geotechnical Institute (DGI) in many countries including the United States where the system is called Stabeach by the licensee, Coastal Stabilization, Inc., Rockaway, NJ.

(b) Lowering the groundwater table is accomplished by draining water from buried, almost horizontal, filter pipes running parallel to the coastline. The pipes are connected to a collector sump and pumping station further inland. Gravity drains the groundwater beneath the beach and through the pipes to the sump and then the water is pumped from the sump. The sand-filtered seawater can be returned to the sea or used for other purposes.

(c) Lenz (1994) describes laboratory experiments (no reference) and field tests at Stuart, Florida, and Englewood Beach, Florida. The patent belongs to Hans Vesterby, DGI, Denmark. Vesterby (1994) reviews the theory and design elements and describes field tests at three sites on the west coast of Denmark in the North Sea.

(d) Long-term, independent field monitoring is needed to learn more about the functional performance of dewatering systems. The system by itself does not produce new sand, so that its greatest contribution may be in increasing the fill life of renourished beaches.

(5) Innovative technology demonstration program.

(a) Many other ideas and devices have been deployed and/or proposed including beach cones (Davis and Law 1994); ultra-low profile, geotextiles injected with concrete (Janis and Holmberg 1994) and fishnets, stabilizers and artificial seaweed (Stephen 1994) for erosion mitigation. Most do not satisfactorily address

nor answer the questions listed by Pope (1997). Alternative technologies for beach preservation was the theme for the 7th National Beach Technology Conference (Tait 1994, ed.).

(b) Section 227 of the Water Resources Development Act of 1996 authorized a National Shoreline Erosion Control Development and Demonstration (NSECDD) program. Emphasis is on "... the development and demonstration of innovative technologies" to advance the state of the art in coastal shoreline protection. Funding the 6-year effort began in fiscal year 2000. A minimum of seven projects on the Atlantic, Pacific, Gulf of Mexico, and the Great Lakes is mandated by this legislation. Pope (1997) discusses many issues surrounding the application of nontraditional and innovative technologies. The ability to perform their promised function, survive for a predictable life, impact on the environment, and total costs (initial and long-term maintenance) must be carefully examined. Pope (1997) then raises many questions that should be addressed, when considering innovative, alternative, shore protection approaches including:

- Is it heavy enough, particularly considering storm waves?
- Will it be properly anchored so that it doesn't fall apart?
- If the structure does fail, could the loose components become an environmental or public safety hazard?
- Will the installation be tolerant of erosion or scour effects around its base?
- Will the material from which it is being constructed last?
- What are the design criteria in terms of events for longevity?
- How will it perform and will it do what we want it to do?
- If it does perform as promised, could there be adverse impacts to adjacent areas?
- How much will constructing the nontraditional or innovative system cost compared to more traditional methods?
- What will it cost to maintain and can it be repaired when damaged?
- What is its effective (functional and economic) life?
- What will it cost to remove the system, if necessary?

(c) All of these questions and more will be addressed for the nontraditional and innovative technologies deployed in the National Demonstration Program. The search for new and innovative approaches has primarily been driven by the shift from hard to soft alternatives for shore protection (Figure V-3-3) and the need to reduce long-term costs of beach nourishment projects by increasing the time interval between renourishment events. As an example, precast, concrete modules, serving as nearshore breakwaters could replace conventional, rubble-mound breakwaters at some locations, and serve the same function of increasing the fill life of the renourished beach. If properly sited (see Part V-3-3) and set on a proper foundation, these units are attractive to permitting agencies because they have a smaller footprint on the bottom and can be adjusted or removed easily, if downdrift impacts are detected, by monitoring. Nontraditional and innovative technologies are subject to all the same design constraints previously discussed (Part V-3-1) plus the extra need to overcome previous shortcomings and prove that they work. The National Demonstration Program will greatly aid in this effort.

V-3-6. Do-Nothing

a. Introduction.

One final alternative that must always be evaluated is the do-nothing or no-project case. The risk of flooding and wave damage continues or increases if historic erosion is also present at the site. When this response is appropriate, what happens to the area, and what government programs are available to help are briefly discussed in the following paragraphs. Further details of the Federal government's response are found in Part V-8.

b. Appropriate response.

Whenever all structural and nonstructural alternatives considered are too costly, then no economically viable solution exists. If the life-cycle costs for protection or relocation exceed the value of the investment, then do-nothing is the appropriate response. This standard for economic feasibility is adopted automatically in Federal project studies of the Corps. If the benefit to cost ratio exceeds unity but social and environmental constraints govern, then the no-action alternative plan can become the Federally recommended plan. When the natural, coastal sediment transport processes (erosion and accretion) are the most important aspect (character, attractiveness, aesthetics, etc.) of the system, then do-nothing may also be the appropriate response. Many examples exist of highly dynamic barrier island systems that are best left alone. An example is the National Park Service policy. The exception for Cape Hatteras was the historic importance of the lighthouse as previously discussed. Individuals may also explicitly decide to take no action (flood proofing or retreat). The homeowner is willing to take the risk when the potential rental income from the property is high. If the house is eventually damaged or destroyed, it would still be covered by the NFIP, if a policy is in effect for the residence. The problem is when this no-action policy is taken, no NFIP policy exists, flooding damage takes place, and the Federal government declares the damaged region eligible for emergency financial assistance.

c. After the flood.

What happens when the do nothing alternative is selected by economics policy decisions? It is clear that the flood and wave damage potential remains, and the risk increases where erosion exists. It is almost certain that the area impacted will decline economically. Social and economic stresses will continue. Examples include: social stresses from apprehension and helplessness; economic stresses of depressed property values; personal property losses continue; cost and inconvenience of restoration after repetitive flooding continues; reduced recreational opportunities for citizens; reduced tourism benefits; reduced employment opportunities for tourism; property values decrease and related property taxes diminish. The no-action alternative may perpetuate a more costly Federal commitment than would be realized otherwise, because other Federal assistance programs exist (see Part V-8 for further details).

d. Government programs available.

When the no action plan remains, the Federal government relies on three methods to mitigate coastal damages and the possibility of loss of human life. As previously discussed (Part V-3-4), the NFIP provides compensation for flooding and wave damages, but it does not protect property from flooding. The NFIP also only encourages adaptation measures; but they are not mandatory, except for new construction where local authorities have adopted flood zoning ordinances. The Federal government also participates in measures for emergency, evacuation route planning. As discussed in Part V-8, because many coastal communities lack sufficient bridge and highway capacities, emergency evacuation is not a dependable means of hazard mitigation. The third program is Emergency Assistance from FEMA when the President declares the region eligible for this financial package after a major, coastal storm event.

e. National coastal hazard mitigation plan.

The need for a national plan of shore protection and coastal hazard mitigation is addressed in Part V-8.

V-3-8. Definition of Symbols

γ_b	Breaker depth index (Equation II-4-3) [dimensionless]
B	Minimum beach width at mhw after nourishment [length]
d_{50}	Size of the 50th percentile of the sediment sample [length]
d_S	Average depth at breakwater below mean water level [length]
e	Erosion of shoreline (mhw) from design storm [length]
F_B	Breakwater freeboard, mhw to crest [length]
I_S	Beach response factor (Equation V-3-10) [dimensionless]
L_g	Gap distance between adjacent breakwaters [length]
L_S	Length of breakwater structure [length]
P_A	Erosion rate after human activities [length^3/time]
P_N	Natural background erosion rate [length^3/time]
Q_{gross}	Gross longshore sediment transport rate [length^3/time]
Q_{net}	Net longshore sediment transport rate [length^3/time]
$Q_{offshore}$	Offshore sediment transport rate for design storm [length^3/time]
R_p	Coastal erosion ratio [dimensionless]
R_v	Coastal erosion volume ratio [dimensionless]
V_A	Volume loss rate after construction of roads, seawalls, etc. [length^3/time]
V_N	Natural erosion volume loss rate [length^3/time]
W	Width of design beach nourishment [length]
WTR	Seawall trap ratio [dimensionless]
X_g	Longshore groin spacing [length]
Y	Distance of breakwater from nourished shoreline [length]
Y_g	Maximum indentation under normal wave conditions [length]
Y_g	Effective groin length measured from its seaward tip to the design shoreline for beach fill at the time of construction [length]
Y_{min}	Minimum dry beach width [length]
Y_{min}	Minimum distance from base (reference) line to mhw shoreline after design storm event [length]
Y_o	Distance of breakwater from original shoreline [length]
Z_S	Backshore elevation at baseline [length]

Chapter V-4
Beach Fill Design

V-4-1. Engineering Aspects of Beach-Fill Design

a. Project objectives.

(1) The primary function of a Federal beach nourishment project is to provide improved protection to upland structures and infrastructure from the effects of storms. Figure V-4-1 shows how storms damage upland property. The top panel shows the beach under normal wave and water level conditions. The letters mhw and mlw denote the mean high and low water lines, respectively, which represent the normal range of tidally-induced water level fluctuations. The elevation of the natural beach berm is above the normal high tide elevation. Under nonstorm conditions, breaking waves are confined to the seaward face of the berm. The berm and dune act as a protective buffer between upland structures and the water and waves. Sites with little or no sand buffer are candidates for shore protection projects. The middle panel shows the beach during a storm. The water level is elevated above the normal range. This exposes higher beach elevations to the action of breaking waves, which erode the berm and transport the sand offshore and along the beach. Sand moved offshore during the storm continues to aid in dissipating wave energy; it often forms a shore-parallel bar system. In this panel, a scarp forms on the seaward face of the dune, but the dune remains relatively intact and protects the structures behind it. Had there been no dune, or a much narrower berm, the structure may have been damaged as shown in the bottom panel. The lower panel shows a more severe condition, in which even higher water levels and wave action have completely eroded the dune. Some of the dune material is transported offshore. Some is transported onshore and deposited as a result of wave runup and overwash processes. The exposed structure is subject to damage by undermining, flooding, and by waves breaking directly on it.

(2) A beach nourishment project typically involves constructing a wider beach and/or more substantial dune to reduce storm damage relative to the level of damage that would have resulted without the project. The level of storm protection provided by a nourishment project is not an absolute measure due to the uncertainties in the frequency of high intensity storms. There is always some chance, or risk, that a storm will cause property damage even with the project in place. The level of protection, reduced in the aftermath of a major storm, will remain compromised if proper poststorm maintenance is not performed. The level of protection will also be compromised if scheduled periodic renourishment, which is usually a key element of the design, is not performed when needed.

(3) The wider beach created through construction of a nourishment project also provides recreational benefits. Enhanced recreational opportunity can also be a project objective.

b. Project features. Beach nourishment projects typically involve construction of one or several of the following features: berm, dune, feeder beach, nearshore berm, dune stabilization (i.e., sand fences or vegetation), or structural stabilization (i.e., groins). There are also several aspects of a beach nourishment project that specifically address the future integrity of the dune/berm. These include: periodic renourishment, advance nourishment, and emergency maintenance. These project features are discussed in more detail in the following paragraphs.

(1) Beach berm.

(a) The beach berm is the primary feature of most beach nourishment projects. Most beaches have a natural berm or berms. The lowest berm closest to the water is formed by the uprush of wave action during the ordinary range of water-level fluctuations. Sometimes, several berms will be noticeable at slightly higher

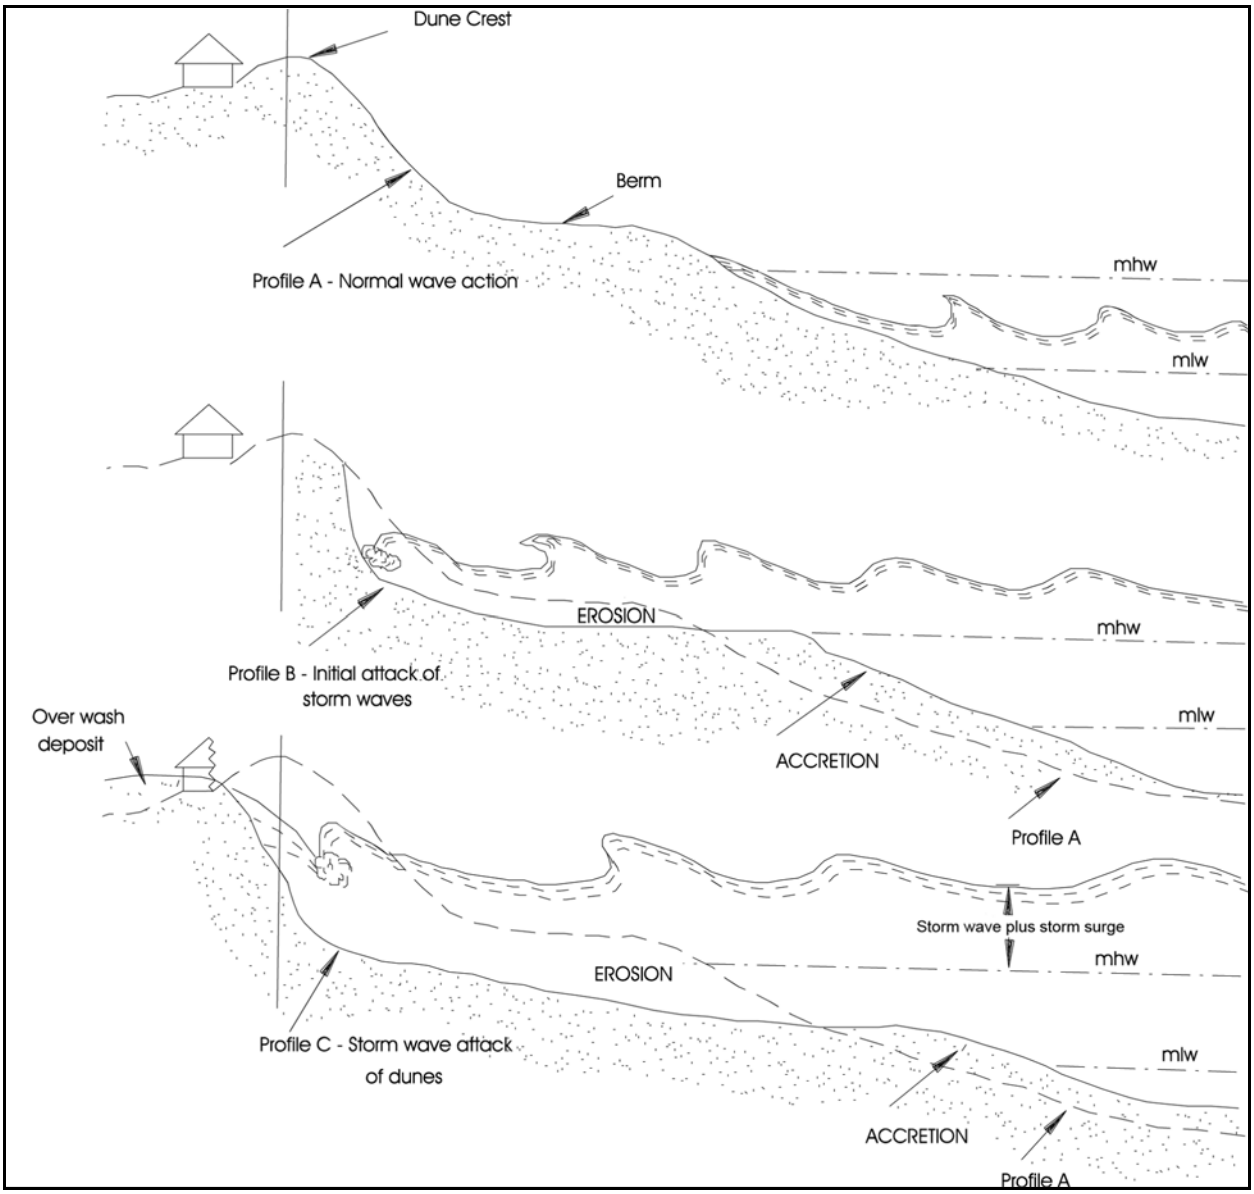

Figure V-4-1. Schematic diagram of storm wave attack on a beach, dune, and upland structures

elevations on the beach. These were formed during previous storms and are either remnant scarps left behind as a result of erosion of the lower berm or as a result of deposits left from wave uprush during higher-than-normal water levels associated with storms. Beaches that are in a severely eroded condition might have little or no berm at high tide.

(b) A nourishment project usually involves widening the beach (i.e., translating it seaward) to create a wider sand buffer for dissipating storm wave energy. The amount of additional width is determined based on the desired level of storm protection, the persistent long-term erosional trends that characterize the project area, and the target renourishment interval. The design berm width is determined through an iterative process that evaluates economic benefits as a function of width. The elevation of the constructed berm is usually set at the same elevation as the natural berm, or slightly higher. If the berm is constructed at an elevation lower than the natural berm crest, a ridge will form along the seaward edge of the fill. Wave uprush during higher water will overtop the ridge, causing temporary undesirable ponding on the beach until the berm elevation

increases naturally. If the berm is constructed to an elevation that is much higher than the natural berm crest, an undesirable persistent scarp may form along the shoreline.

(c) For practical and economic reasons, during the construction of the beach berm, the total fill volume required to advance the berm to the desired width is placed on the visible portion of the beach. This construction method, sometimes referred to as the "over-building" method, enables the economic use of standard earth-moving equipment for the distribution of the fill and minimizes relocation of the discharge point. The method also enables effective verification that the sectional fill volume (design fill volume per unit length of shoreline) has been placed on the beach by the contractor using standard land-based survey techniques. The result of this construction technique is a beach berm that is initially considerably wider than the target design width. Postconstruction berm widths are often two to three times wider than the target design width. Design specifications required a 30-m (100-ft) design berm width in the northern New Jersey beach nourishment project while postconstruction surveys indicated constructed berm widths of 60 to 90 m (200 to 300 ft) and along some survey lines berm widths approaching 120 m (400 ft) were measured. While recognized by project designers, lay persons are often unaware that the initial overbuilt berm is a temporary condition. Consequently, they incorrectly judge the project as a failure when the beach berm adjusts dramatically landward immediately after construction, especially during the first storm season. For this reason, it is important that public outreach programs include easy-to-understand information concerning the expected remolding of the fill material after initial construction. Figure V-4-2 provides a schematic illustration of the preproject beach profile, the post-construction over-built beach berm, and the expected design berm after cross-shore equilibration.

(2) Dune.

(a) Sand dunes are an important protective feature. Naturally occurring dune ridges along the coast prevent storm tides, wave runup, and overtopping from directly damaging oceanfront structures and flooding interior areas. Dune features of beach nourishment projects are intended to function in the same way. A beach nourishment project may involve either reinforcing an existing natural dune by adding elevation and/or cross-sectional area, or constructing a dune where none existed beforehand. Dunes also provide a small reservoir of sand for nourishing the beach during severe storms. However, after the storm, maintenance is required to rebuild the dune because natural dune rebuilding occurs at a much slower rate than natural berm rebuilding.

(b) During hurricanes and very severe northeasters, substantial sections of dune can disappear. This is caused by offshore transport of dune material into the surf zone and by beach and dune sediments being swept landward by wave uprush and overtopping. In the case of overtopped barrier islands, flooding from ocean-side storm surges and waves and/or return flow of water from flooded bays can erode enough sand to cut shallow channels, or breaches, through the island. Occasionally, the channels will evolve into new inlets. Areas most prone to breaching are those where the barrier island is narrow and the dunes are lowest or nonexistent. The crest elevations of natural dunes often varies considerably, and nature tends to erode the low spots first. Dunes and berms built as part of a nourishment project can reduce the potential for barrier island breaching because a relatively uniform dune elevation eliminates the low spots where breaches are most likely to form.

(c) Dune growth can be promoted and the dune structure can be made more resistant to erosion if suitable vegetation can be grown on the dunes for an adequate length of time to establish an extensive root system. It generally takes 2 to 5 years for beach grass to establish a healthy root system, and up to 10 years before the maximum resistance to erosion and breaching is obtained. An active grass fertilization and

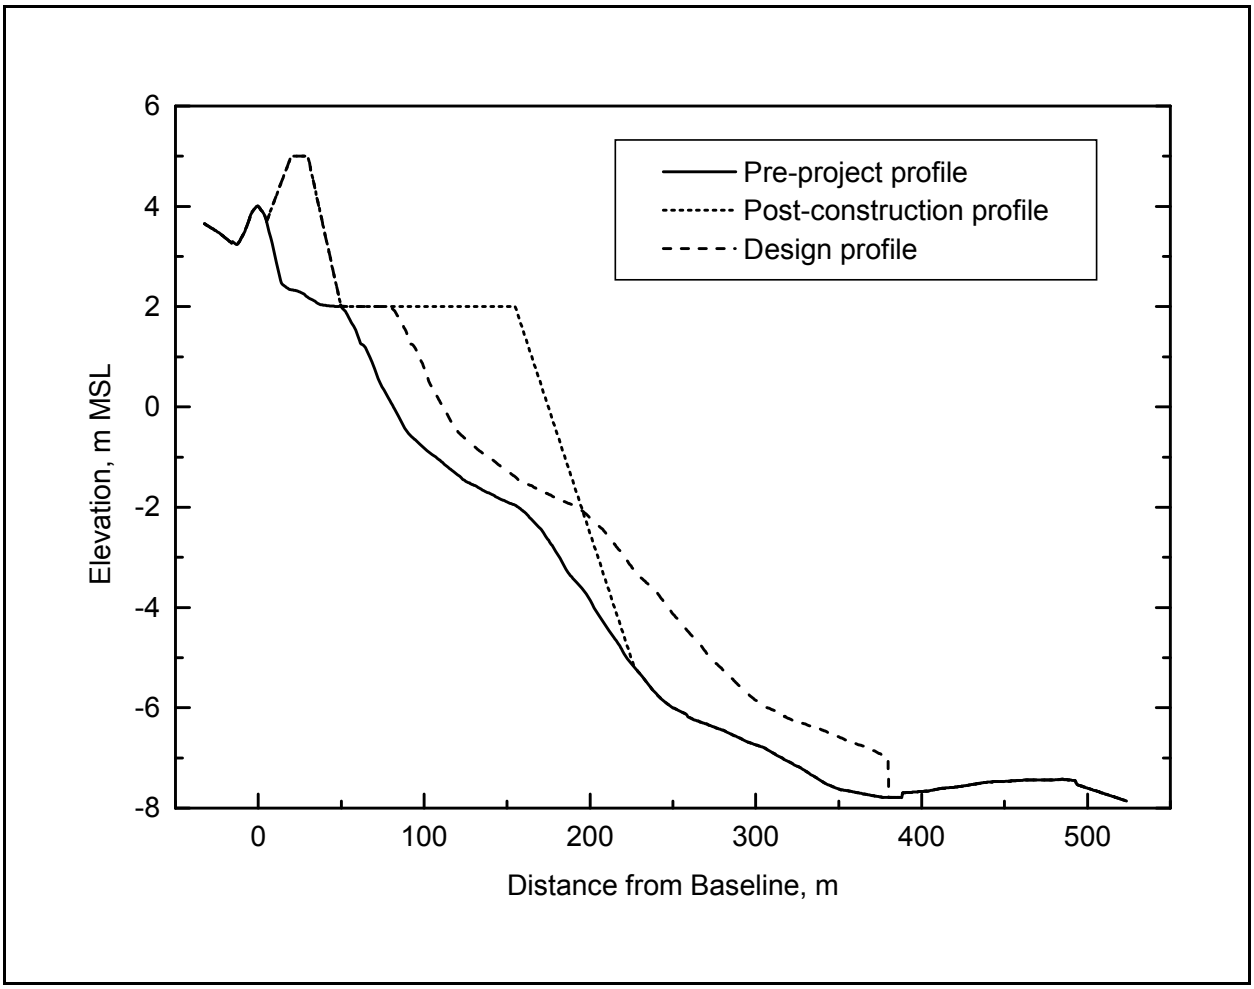

Figure V-4-2. Schematic illustration of pre-project, post-construction and design profile

maintenance program can greatly enhance the survival and effectiveness of beach grass. Part V-4-1-i provides more detailed information on dune stabilization.

(d) Preliminary estimates of dune height, width, and side slope for a beach nourishment project can be made based on characteristics of natural dunes in the vicinity of the project. To be most effective, the crest height of the dune should be above the limit of wave runup for the types of storms for which protection is sought, and the beach berm in front of the dune must be of sufficient width to withstand the erosion associated with these types of storms. If the berm in front of the dune is too narrow, the dune can quickly erode, even for relatively frequent storms, and the benefits of the higher dune elevations will be lost. The design dune height and width (along with the width of the berm) are usually selected based on results of an iterative process in which the benefits are compared with the cost of each configuration. Part V-4-1-f provides more detail on the dune/berm design process. Sometimes other factors such as real estate acquisition issues or aesthetics are factored into the selection of dune crest elevation and width.

(3) Nearshore berm. Beach-fill projects are usually constructed via direct placement of sand on the beach. Sometimes, in an effort to reduce cost, or because of limits in available dredge equipment, or in response to concerns with direct placement of fill material on the beach, material is placed offshore in an underwater berm (i.e., bar). Nearshore berm creation is intended to simulate storm bar formation by creating an artificial shore-parallel bar to dissipate storm wave energy before impacting the beach. If the berm is

placed shallower than the depth of closure (see Part III-3-3-b), it is expected that with time, the material will move onshore, eventually becoming part of the beach berm and beach face system. The material placed in the nearshore berm, however, does not provide direct shore protection to the upland, and prototype experience with the practice has met with mixed results and uncertain net benefit.

(4) Feeder beach. Beach-fill projects usually involve placement of a berm along a finite length of shoreline. Sometimes, beach nourishment projects include the creation of a feeder beach, in which fill material is introduced at the updrift end of the area intended to receive the fill. Then, longshore transport distributes the fill to the rest of the project area. Feeder beaches work best in areas that serve as a source of littoral material for downdrift beaches, in areas that are presently experiencing a deficit in the supply of littoral material and have unusually high loss rates, and in areas where the net longshore transport direction is predictable and the net transport rate is "strong" (i.e., longshore sand transport in one direction greatly exceeds the transport in the other direction). Candidate sites for feeder beaches include areas immediately downdrift from inlets or other manmade structures that form a littoral barrier or in areas that have been identified as erosional "hot spots." As the feeder material spreads under the influence of waves, the orientation of the feeder beach shoreline approaches that of the adjacent beach, resulting in longshore transport out of the feeder area equal to the transport along the adjacent area. Eventually, the shoreline orientation in the feeder beach area will return to its original configuration. Protection provided by feeder beaches will not have the same degree of alongshore uniformity as that provided by placing fill in a prescribed manner throughout the project area.

(5) Structures in conjunction with beach nourishment. Structures can enhance the performance of a beach nourishment project. Figure V-4-3 shows several such examples. When the project is relatively short in length, or significantly affected by an inlet, it may be desirable to limit alongshore losses through the use of a terminal structure or structures (Figures V-4-3a and V-4-3b show examples). Another use of structures is to place them in the interior of the nourishment project, with the intent of increasing project longevity (Figure V-4-3c) by reducing the longshore sand transport rate and minimizing end losses. Structures can also be used locally within a project to maintain the desired level of protection. For example, structures may be used to compartmentalize and stabilize a beach in anticipation of, or in response to, an area of unusually high volume losses (i.e., presence of a hotspot). Whenever structures are used, their potential updrift and downdrift impacts should be assessed. It is important to note that structures do not create sand, they only control its movement. If structures are built without adding beach fill, then sand may accumulate at one location at the expense of erosion at another area. As a general rule, compartments between structures, and the beach immediately updrift and/or downdrift of the structures, should be filled with sand to minimize adverse effects on adjacent beaches. Potential adverse effects of a groin field can be minimized by tapering the lengths of groins at the end of the groin field (see Figure V-4-3c), and adding sand on the downdrift side of the project. Part V-4-1-i provides additional information about the functional design of structures used in conjunction with beach fill projects. Part VI presents information on the structural design aspects of coastal structures.

c. Define regional setting and site history. To maximize a beach nourishment project's effectiveness, it is important to understand the project's physical setting. The term "setting" encompasses local- and regional-scale coastal processes, the geology, and infrastructure that characterize the site and surrounding area. Part V-3 provides a general discussion of site characterization for all coastal projects. The following sections focus on those aspects that are most pertinent to engineering design of beach nourishment projects. A beach fill project can be a significant perturbation to the coastal system, and project performance is directly related to its interaction with its surroundings. The following are a few questions regarding project setting that should be answered at the beginning of the design process: In what type of littoral system, or littoral cell, will the project be constructed?

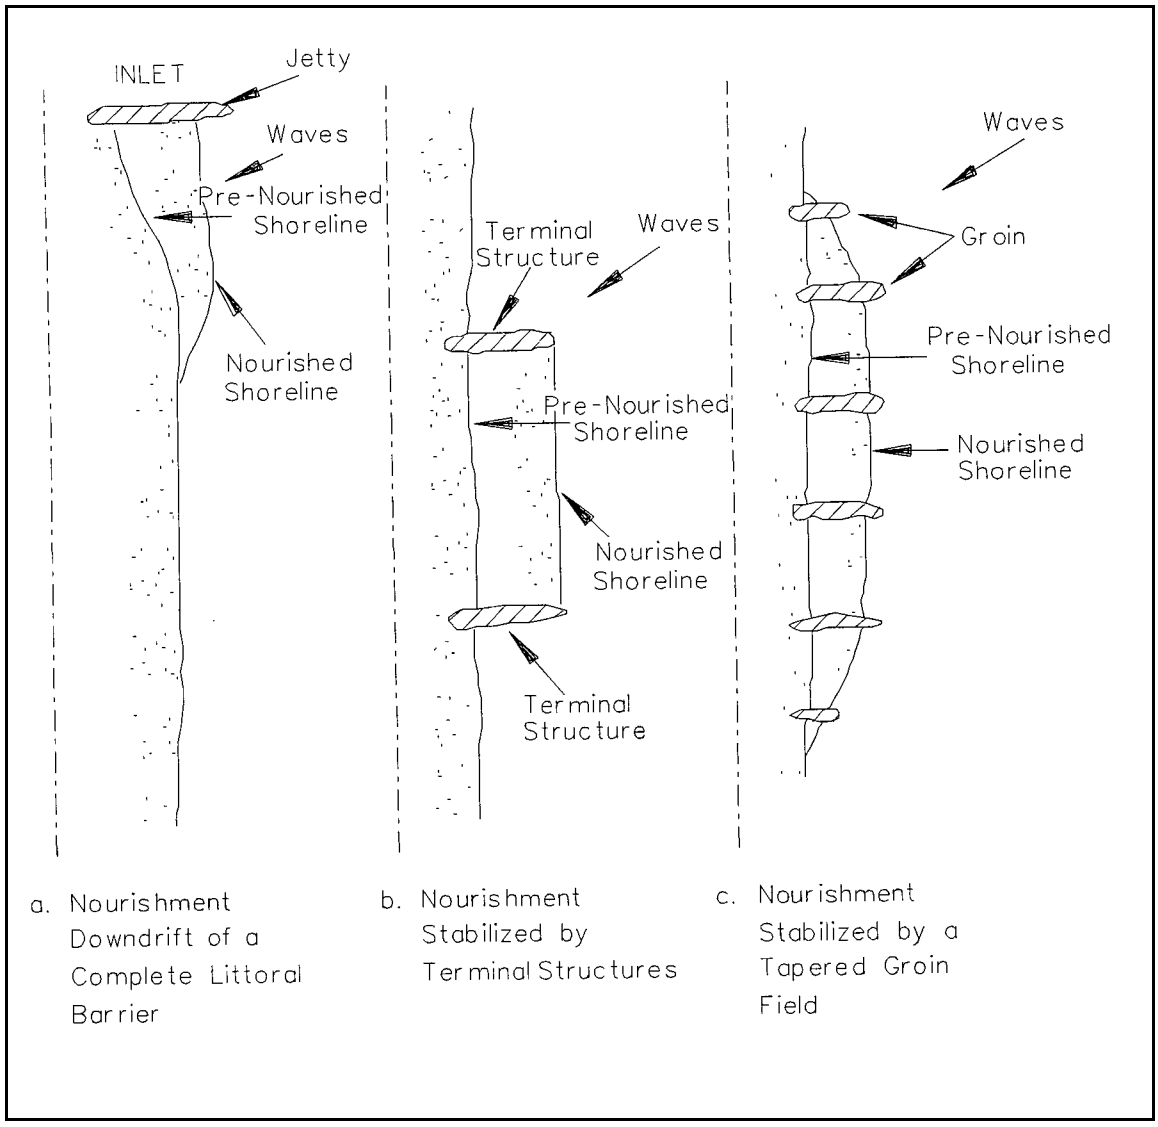

Figure V-4-3. Use of groin structures to enhance beach nourishment projects

What is the extent of the littoral cell, and where within the cell will the project reside? What are the important coastal processes that characterize the littoral cell and the project site? The answers to these questions will influence how a project is designed, how it performs, and what if any impacts it may have on adjacent beaches.

(1) Site location within littoral cell. The location of the project within a littoral cell has great influence on all aspects of a beach nourishment project, from understanding the underlying coastal processes at work, to determining the design concept that might be most effective, to the choice of methods and tools used in the design process. For example, will the project be constructed well within the interior of a littoral cell, miles from the inlets that serve as boundaries of the cell, or will it be built immediately downdrift of an inlet stabilization structure, or along the throat of an unstructured inlet? Sand transport by tidal currents, wave refraction over complex bathymetry, and wave-current interaction may not be important design issues in the former case whereas these processes may be critical in designing an effective project in the latter. In the former case, the project may experience beach recovery following a storm, where much of the sand moved offshore into a storm bar, migrates back onto the shore face with little net loss of sand. In the latter case, sand

moved offshore can be swept into tidal channels, carried away by currents into the inlet's shoals, and not return to the beach face. This will result in a significant permanent loss of sand. Different design concepts may be utilized in each of these two cases. In the former case, beach fill alone may meet the design requirements. In the latter, structures such as T-groins, may be needed to improve beach-fill retention. Different design methods may be utilized in each case. The former case may lend itself to simple analytical design tools, whereas the latter case may require more sophisticated physical or numerical modeling to aid in the design.

(2) Pathways of sediment movement.

(a) Because beach nourishment projects involve placing additional sand into the littoral system, project design is greatly aided by knowing how sand presently moves within the project domain and the littoral cell that is the setting for the project. Specifically, the following pieces of information are valuable: knowledge of the quantities of sand that presently enter and leave the littoral cell, where the sand enters and leaves, and what quantity moves through the project site. The more information known about the movement of sand the better, although this "picture" can be difficult to develop, especially for project sites with sparse data. Estimates of these quantities are often developed through formulation of a sand budget for the littoral cell and project domain. Parts IV and VI discuss development of a sediment budget. The following are types of questions regarding pathways and quantities of sand movement that might be important to the design of the project. If a project is to be constructed within a littoral cell flanked by inlets, are the inlets bypassing sand into the cell? If so, how much is bypassed? Are structures present that might be blocking (partially or completely) the flux of sand into the site from adjacent beaches? Is the project site located on a convex stretch of the barrier island that may be undergoing persistent erosion, or is the site in an area that experiences intermittent periods of erosion and accretion? Is the project to be located in a pocket beach flanked by headlands, and are those headlands blocking longshore sand transport? Are there sources of sand within the littoral cell, such as a river or lagoon, that might periodically discharge sediments to the beach system, or bluffs behind the beach that might serve as a sediment source? Are there sinks within the littoral cell, such as offshore canyons, impoundment fillets updrift of coastal structures, or loss of sand into an adjacent inlet and its shoal system? The closer to inlets, the greater the chance that tidal currents will have an important role in defining sediment pathways. It is important to gain an understanding of the littoral processes at work in the region, including the magnitude and direction of longshore sand transport (net and gross transport rates), sand sources and sinks, and the effects of existing coastal structures on the movement of sand. Parts III-2 and III-3 address the subject of longshore and cross-shore sediment transport processes, respectively, in greater detail.

(b) Historical and current charts, maps, and aerial photographs provide valuable information about the regional setting for a project. They can be valuable data sets for characterizing littoral processes at a project site, and aid in developing a sand budget. A persistent signature of impoundment at coastal structures over several years provides evidence of predominant wave direction and net longshore sand transport direction. Formation and evolution of spits, or migration paths of submerged relic ebb tidal shoals, can provide the same information. Noticeable changes in shoreline orientation and curvature, or persistent changes in bathymetric contour orientation may indicate gradients in longshore sand transport rates or a change in net transport direction. Shoreline positions that are accurately digitized from properly rectified aerial photos and/or charts provide information for identifying current and past erosional and accretional areas, and for calculating shoreline change rates. Calculated change rates can be used to estimate changes in sand volumes along different portions of the beach. Nautical charts and bathymetric surveys show the presence of canyons and proximity of the canyons to the shore, tidal channels, shoals, other morphologic features, and changes in these features through time. Controlled bathymetric surveys (relative to common horizontal and vertical datums) can be analyzed to determine volume changes for use in formulating a sand budget.

(3) Beach topography.

(a) The shape of the beach, above and below water, sheds light on the coastal processes that are at work at the project site. Beach shape also is an important factor in determining the quantity of beach nourishment material needed. The existing beach profile shape seaward of the natural berm crest can be a good indicator of the expected postnourishment beach shape, provided the sand to be placed has similar grain size characteristics as the native beach and there are no coastal structures or other features that are controlling the shape of the beach. One situation where the present profile shape may not be a good indicator of the postconstruction shape would be a beach that is heavily seawalled or reveted, with little to no dry beach in front of the structure at high tide. In this instance, the present beach shape might be unnatural (overly steep) due to the loss of a sand supply at the shoreline (i.e., the beach profile is very much starved of sand). Proximity to a tidal channel or a coastal structure may also produce an "unnatural" beach profile shape, compared to the shape that might exist for the same sediment characteristics but located away from the inlet or coastal structure. Also, if the material to be placed has grain size characteristics that are much different than the native beach, then the present beach profile shape may not be a good indicator of the shape following nourishment. Use of sand finer than the native sand will produce a beach with gentler slopes; use of coarser material will result in a beach with steeper slopes.

(b) Dunes are also an important aspect of project setting. Dune elevation, continuity of the dune "line," position of the dunes relative to the shoreline, and volume of sand in the dune above the natural berm crest elevation are important factors in determining the existing level of protection to property and infrastructure. Well-established vegetated dunes are usually a sign of a healthy beach system. A scarped dune, evidence of regular overwash, or no dune at all indicate an area vulnerable to storm damage. Beach profile surveys, or fully 3-D bathymetric and topographic surveys acquired by lidar systems such as systems such as SHOALS, can effectively characterize the beach/dune system as well as submerged morphologic features. Analysis of well-controlled beach profiles (relative to consistent horizontal and vertical datums) can provide volume change information for use in developing a sand budget, selecting design profiles for the nourishment project, and estimating the required amount of nourishment material.

(4) Sediment characteristics.

(a) Information about the grain size characteristics of the native beach material can shed light on the coastal processes at work. Systematic variations in median grain diameter along the beach, or evidence of natural tracers in the sand, may suggest the direction of net longshore transport. Grain size characteristics are a critical design parameter. Most often, sand with grain size characteristics similar to those of the native beach is sought as beach-fill. This is done to maximize compatibility with the existing beach system. Indirectly, selecting compatible material also maximizes the accuracy of predictions of future project performance, which is often based on past observations of the native beach response. Occasionally, fills are designed using material with different size properties because of limitations on sand availability and the cost to transport it to the project site. Sometimes the choice of a nourishment material with different characteristics is made to satisfy a particular design objective, such as use of coarser-grained fill material to improve resistance to erosion.

(b) Grain size characteristics are quantified based on a sieve analyses of samples which are collected throughout the project domain. Those samples acquired on the profile between the berm crest (or mean high water line) and a water depth corresponding to the position of the typical storm bar should be used to characterize native beach sand for the purpose of assessing the compatibility of sand from potential borrow sources. Compatibility of borrow and native beach material is primarily based on grain size characteristics, and to a lesser extent on color. Part V-4-1-e discusses sediment characterization and compatibility of fill in more detail.

(5) Wave and water level climate.

(a) The wave and water level conditions at the project site represent the major forces that shape the beach, and determine both the longer-term lateral spreading of material comprising the beach nourishment project and the short-term response of the project to storms. Exposure of the project site to wave energy from various directions determines the predominant longshore sand transport rate and direction. Offshore islands or coastal structures, peninsulas, or adjacent land masses may partially or completely shelter the project site from certain waves. The presence of these features modifies the energy, frequency, and directional characteristics of the incident waves that approach the site from deeper water. The presence of submerged offshore shoals, reef outcroppings, shore-attached shoals, or depressions (in general, any irregular bathymetry), also can have a significant persistent influence on local wave transformation and the longshore sand transport regime created by the incident breaking waves. It is important to assess the degree in which the wave climate varies from one end of the project to the other. Persistent variations in wave conditions of 5 to 10 percent can create significant local differences in project performance.

(b) There are several time scales of importance with regard to wave climate. The design life of a beach nourishment project is usually tens of years. Periodic renourishment is typically done every 3 to 5 years. There is evidence of cyclical patterns in weather (e.g., El Niño) that vary on the order of years, which would tend to produce wave climate patterns having similar multiple-year cycles. Annual changes in weather, and annual variations in the frequency and intensity of storm activity create a longshore sand transport regime that can vary considerably from year to year. Definition of the wave climate at these different time scales helps in assessing long-term beach nourishment project performance, potential variation in performance from one renourishment cycle to the next, and from year to year.

(c) Wave and water level conditions that accompany extratropical and tropical storms are also an important aspect of project setting and project design. The time scale of these events is on the order of days. Since most beach nourishment projects are justified based on storm protection benefits, it is important to quantify the frequency and severity of storms that can impact the project site during its design life. Lower-intensity storms typically erode the beach berm. More severe storms, particularly those with higher water levels, can inundate the berm and focus direct wave attack on dunes and exposed upland property. The most important storm parameter influencing beach and dune erosion is maximum water level, followed by wave energy and storm duration.

(d) Hindcast wave and water level information, or data measured nearby, can be used to characterize the wave and water level climate near the project site at the time scales of importance. Sometimes wave information is available in deep water, and other methods must be used to "transform" the information to the project site (e.g., to transform deepwater wave information past islands or very irregular bathymetry). Part II-2 discusses methods for developing wave climate information, including wave hindcasting. Part II-3 discusses techniques for estimating nearshore waves, including wave transformation methods. Part II-5 discusses methods for estimating water levels due to storms.

(6) Existing structures and infrastructure.

(a) How threatened are commercial and private structures, and infrastructure such as roads and utilities, by storm waves and water levels? Formulation of a beach nourishment project often involves compiling an inventory and description of the location of existing infrastructure and commercial and private properties to assess their vulnerability. The properties are valued to aid in quantifying the benefits that accrue from construction of a beach nourishment project. Are there structures that protrude beyond the predominant shoreline position? If so, it may be difficult and not cost-effective to provide a lasting beach having the design width in front of those structures. Attempting to do so may result in a persistent apparent erosional "hot-spot" in these locations. Aerial photos provide a good source of information for describing the

characteristics of infrastructure and property, and the positions of structures relative to the present shoreline. Historical surveys or charts are useful in determining the degree to which existing infrastructure encroaches upon, or is seaward of, the historical beach location. Ground inspections and photos also can be used to characterize the condition and value of structures.

(b) The presence of existing coastal structures, and their characteristics, are also important parameters. What measures are already in place to provide protection to structures (e.g., seawalls and revetments), and what is the condition and effectiveness of those structures? Structures that alter or block the alongshore movement of sand, such as groins, detached breakwaters, or artificial headlands influence the pathways of sand movement at the site. Crest elevation, composition, and condition of groins, revetments, and seawalls determine the structures' functional effectiveness. The "signature" of impoundment adjacent to groins, or lack thereof, can be an indicator of groin functionality. Aerial and ground photos can be used to characterize the condition and effectiveness of existing coastal structures. Engineering drawings that show the subsurface characteristics of the structures, including any toe protection, in concert with present beach profile surveys, can be used to characterize the vulnerability of revetments and seawalls to damage caused by recession of the beach during storms.

(7) Prior engineering activities.

(a) Usually, areas being considered for a beach nourishment project have experienced problematic erosion for some time. Often, there is a record of previous studies and perhaps a record of past engineering activities at the site. This information can shed light on what may or may not work in the future, and why; and aid in designing a nourishment project. For example, records of past beach-fill activities can provide information about expected fill longevity and net longshore transport rates. Historical records documenting impoundment at groins can provide information about net longshore sand transport rates. Dredging and placement records are vital information in the development of a sand budget. The record of past engineering activities may also help explain a particular beach response that has been observed. Compiling a complete chronology and record of past engineering activities can prove to be a very valuable design aid.

(b) This section briefly highlighted some of the more important aspects of project setting and site characterization and history, and how they relate to design of beach nourishment projects. Subsequent sections provide more detailed information about how these factors enter into the design process.

d. Reach delineation.

(1) In addition to the setting for a beach nourishment project and its design features, an equally important design issue is delineation of sections of coast along which a project is to be constructed. Project economics is often a controlling factor in the process of reach delineation. The values of property and infrastructure assets fronting the beach and benefits gained by providing storm-damage reduction enter in assigning bounds of a project reach or subreaches. Project boundaries may be determined by limits of political jurisdiction such as municipal or state boundaries, or may coincide with physical features such as inlets or headlands. Environmental considerations and local preferences may also influence project boundaries.

(2) From an engineering perspective, reach delineation should be evaluated based on physical processes controlling project response. For example, location and characteristics of project terminal boundaries may be evaluated on the basis of fill retention within project bounds and project impacts on adjacent shorelines. Where reaches terminate along the open coast, fill transitions may be used to reduce the rate of spreading losses from project bounds. Transitions may be placed either within or outside project bounds based on design objectives and/or constraints. A more detailed discussion of beach fill transitions is provided in Part V-4-1-h. In cases where reaches terminate at shore-normal structures (e.g., groins and jetties), effects of interrupting littoral drift on downdrift beaches should be assessed. Whether boundaries occur at structures

or on the open coast, project reaches should be of sufficient length to minimize the effect of end losses on the central portion of the project. Part V-4-1-g discusses design parameters and environmental processes that affect project longevity. Economic analyses may identify several discontinuous subreaches within the project main reach (e.g., where areas of development are separated by areas of undeveloped coast). In such cases, a project may function more effectively by designing a single reach spanning both developed and undeveloped sections to avoid multiple areas of end losses.

(3) Beach-fill projects have often employed a uniform design template, with constant berm width and dune elevation, along the entire project. Under most circumstances, however, improved performance can be achieved by modifying the design template along specific subreaches where longshore nonuniformity exists in the without-project condition. For example, consider an existing condition where a particular shore-fronting structure is positioned closer to the shoreline than adjacent structures. A design calling for a uniform width of beach in front of all structures along the entire project reach will produce a planform perturbation at the protruding structure, and will lead to an ongoing problem of accelerated recession in front of the structure. In this case, a viable alternative may be to design a narrower berm in the area of the protrusion with additional storm damage protection provided by higher dunes or protective structures such as seawalls. Other cases where nonuniform design templates may be appropriate include presence of erosional hot spots, changes in shoreline orientation, or nonuniform placement of shore protection structures along the project reach. In design, a practical goal is to distribute the sand fill volume alongshore so as to yield a more or less uniform shoreline location after initial equilibration of the placed fill. Care must be taken in using a variable design template to avoid compromising project performance. For example, dunes placed in front of a developed subreach to prevent overtopping and flooding may not be functional if lower dunes or no dunes are placed on adjacent subreaches of undeveloped shore. In this case, storms could erode and overtop the adjacent low dunes and flank the high dunes, resulting in flooding of the developed area.

e. Evaluate sediment sources.

(1) Borrow source types. Borrow sources for beach fill can be divided into four general categories: terrestrial, backbarrier, offshore, and navigation channels. Each category has favorable and unfavorable aspects; however, selection of an optimum borrow source depends more on individual site characteristics relative to project requirements than type of source. The single most important borrow material characteristic is the sediment grain size.

(a) Terrestrial sources. Terrestrial sources of beach-fill material can be found in many coastal areas. Ancient fluvial and marine terrace and channel deposits, and certain glacial features such as eskers and outwash plains often contain usable material. Because of their potential economic value, information on sand and gravel deposits is often collected by state geological surveys. With this information, field investigations can focus on a few likely sources, thus eliminating need for more general exploration. In some places, commercial sand and gravel mining operations may provide suitable material for direct purchase. In their absence, it would be necessary to locate a suitable deposit and set up a borrow operation specifically for the project. Use of terrestrial borrow sites usually involves lower costs for mobilization-demobilization operations and plant rental, and less weather-related downtime than the use of a submerged borrow source. However, the production capacity of terrestrial borrow operations is comparatively low, and haul distances may be long. Thus, costs per unit volume of placed material may exceed those from alternate submerged sites. In general, terrestrial borrow sources are most advantageous for projects where exploration and mobilization-demobilization costs, relative to the cost of fill, are a large part of overall expense of the operation. Unfavorable aspects of terrestrial borrow sources are typically related to adverse secondary impacts caused by mining and overland transport. Compared to hydraulic placement, mechanical (dump truck) placement of fill additionally results in practical limits in fill volume, and fill placement is mostly limited to the dry and intertidal beach. Consequently, more rapid equilibration and recession of the placed fill is experienced.

(b) Backbarrier sources. Sediment deposits in the backbarrier marsh, tidal creek, bay, estuary, and lagoon environments behind barrier islands and spits have been used in the past for beach fill. They are an attractive source because they are protected from ocean waves and are often close enough to the project beach to allow direct transfer of the material by pipeline. This eliminates the need for separate transport and transfer operations. However, most backbarrier sediments are too fine-grained to use as beach fill. In addition, many backbarrier areas are highly important elements in the coastal ecosystem and are sensitive to disturbance and alteration by dredging. Material in backbarrier sediments coarse enough for beach fill is generally confined to overwash deposits and flood tidal shoals associated with active or relic inlets. Overwash deposits occur on the landward margin of the barrier where storm waves have carried beach and dune sediments across the island or spit. Flood tidal shoals occur inshore of tidal inlets and consist of sediment transported by tidal currents flowing in and out of the inlet. These sediments are usually derived from littoral drift from adjacent beaches. Overwash deposits and relict flood tidal shoals may be ecologically important because they may provide suitable substrate for marsh growth. In addition, on retreating barriers, they may comprise a reserve of sand that will be recycled into the active beach deposits as retreat progresses. Flood tidal shoals at an active inlet may be suitable for borrow sites because the material removed is likely to be replaced by ongoing inlet processes. However, dredging material from active flood tidal shoals can adversely alter both the hydraulic conditions in the inlet and wave action on adjacent shores. A study of the hydraulic effects should be made prior to dredging flood-tidal shoals.

(c) Harbors, navigation channels, and waterways. Creation of harbors, navigation channels, and waterways, and deepening or maintenance dredging of existing navigation projects often requires the excavation and disposal of large volumes of sediment. In some cases, where the dredged sediment is of suitable quality, it can be used as fill on nearby beaches rather than placing it in offshore, upland, or contained disposal sites. Operations of this type are economically attractive because dual benefits are realized at considerably less cost than if both operations were carried out separately.

- Maintenance dredging of projects in low energy environments such as estuaries or protected bays is least likely to produce suitable beach-fill material. In such areas, the dredged material often consists of clay, silt, and very fine sand. However, when dredging new harbors, channels or waterways, or deepening existing channels in low energy areas, the dredge may cut into previously undisturbed material of suitable characteristics.

- Dredged material from higher energy areas, such as rivers above tidewater and open coast inlet shoals, is often more acceptable for beach fill. On barrier coasts, inlets trap beach sediment that has been carried to the inlet by littoral drift. Therefore, material dredged from inlets is typically similar to the native material on the project beach. However, sediment compatibility tests should be performed to determine its suitability for use as beach fill.

(d) Offshore sources. Investigations of potential offshore sources of beach-fill material under the Coastal Engineering Research Center's (CERC's), Inner Continental Shelf Sediments Study (ICONS), by the USACE Districts and others (i.e., Bodge and Rosen (1988)), indicate that large deposits of suitable material often occur in offshore deposits. Data from the Atlantic coast show that the most common suitable sources are in ebb tidal shoals off inlets, and in linear and cape-associated shoals on the inner continental shelf, such as those shown in Figure V-4-4. Potential sources on the inner shelf have also been identified in submerged glaciofluvial features, relic stream channels, and featureless sheet-type deposits.

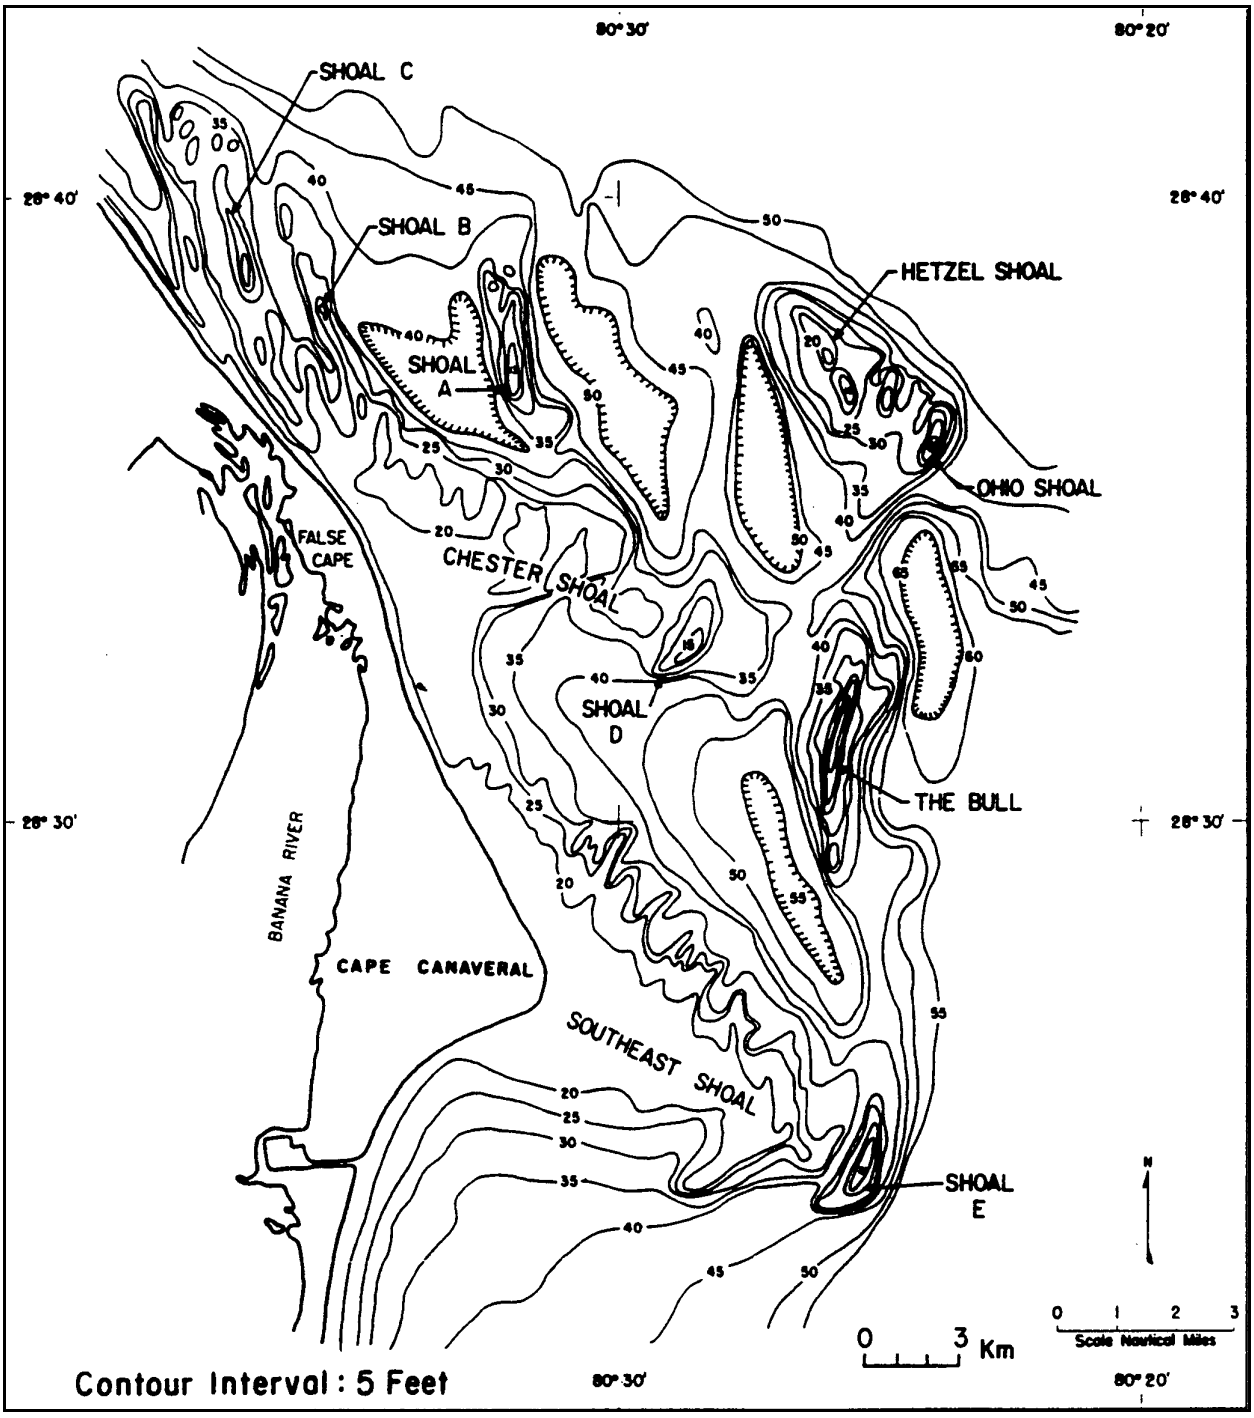

Figure V-4-4. Cape-associated inner continental shelf shoals off Cape Canaveral, Florida (Field and Duane 1974)

- Offshore deposits can be excavated by dredges designed to operate in the open sea. When borrow material is obtained by dredges, it is typically either pumped directly to the beach via pipelines or, in the case of self-propelled hopper dredges with pumpout capability, transported to the shore and pumped onto the beach. Hopper dredges are typically more cost-effective for borrow areas located more than a few kilometers from the project site. These dredges practically require a borrow area

with at least one long dimension that allows the hopper vessel to transit the site; i.e., on the order of at least 1.5 km (5,000 ft). In some cases, the dredged material is taken to a rehandle site and offloaded, then transferred to the beach by hydraulic pipeline or truck haul.

- An alternate placement method is to dump material in a nearshore berm as close as possible to the project beach, in water depths shallower than the depth of closure, where it will possibly be moved ashore by wave action. Experiments in offshore dumping near New River Inlet, NC, in 1.82 to 3.65-m- (6- to 12-ft) depth, resulted in a general onshore and lateral migration of fill material (Schwartz and Musialowski 1980). Placing material in water this shallow requires special equipment such as split hull barges, dredges, or other equipment to cast the material shoreward.

- Offshore borrow sources have several favorable features. Suitable deposits can often be located close to the project area. Offshore deposits, particularly linear and cape-associated shoals usually contain large volumes of sediment with uniform characteristics and little or no silt or clay. Large dredges with high production rates can be used. Environmental effects can be kept at acceptable levels with proper planning.

- An unfavorable aspect of offshore borrow operations is the necessity of operating under open sea conditions. Restrictions on the placement of fill material on beaches during the sea turtle nesting season often requires dredging during the winter, when wave energy is highest. In more protected places, such as backbarrier or otherwise sheltered sources, less seaworthy dredging plant can be used. Dredges capable of working in open sea conditions generally have higher rental and operating costs, although this may be offset by greater production capacity.

- Evaluation of offshore sources should also consider the possible effect of dredging a borrow area on littoral processes along and adjacent to the project area. This analysis should include the use of a numerical wave transformation model and the calculation of longshore sand transport rates and transport rate gradients. Nearshore transformation of a project area's principal incident wave conditions over the pre- and postdredging bathymetry should be simulated. The incipient breaking wave conditions and littoral transport potential alongshore, leeward of the borrow area, should be compared between conditions. The proposed limits or geometry of the borrow area may require alteration to avoid unintended concentrations of wave energy, or alongshore transport gradients, produced by the excavated topography. Additionally, borrow areas near the shoreline or inlet shoals may result in accelerated transport of sediment from the beach to the dredged borrow area. In general, where practicable, borrow areas should be sited in water depths greater than the estimated depth of closure (a rough rule of thumb would be twice as deep).

- In some cases, the original relief maybe restored by natural processes over time. This is more likely to occur in active features such as inlet shoals than in relic features, or on ones that are active only during intense storms. Because the depth of closure is well inshore of offshore relic sand borrow sites, these borrow pits usually fill in with fine-grained material that is not suitable for beach fill.

(e) Environmental factors. In general, environmental effects of borrow operations can be made acceptable by careful site selection, and choice of equipment, technique and scheduling of operations. Restoration of flora and fauna often takes place in a short time after operations (Stauble and Nelson 1984). Alterations in physical features (the pit left behind after excavation) may, in some circumstances, be restored by natural processes.

- One effect of borrow operations is direct mortality of organisms due to the operation itself, and destruction or modification of the natural habitat. Direct mortality of motile fauna, such as fish, is usually not great because they move to other areas during the borrow operation. Sessile flora and fauna cannot vacate the area; mortality of these organisms is therefore higher. However, they usually are replaced by the reproduction of survivors or stocks in unaffected peripheral areas (Nelson 1985; Johnson and Nelson 1985).

- Another consideration is the destruction or modification of the habitat needed for survival of native species. A common alteration is the exposure of a substrate that differs from the natural substrate as a result of excavating overlying material. Many marine benthic, and some pelagic, organisms are adapted to specific substrate conditions. Even though larvae of the native species reach the affected area, they may not survive.

- In comparing borrow sites, it is necessary to consider whether or not natural substrate will be modified by the planned operation. This depends on the thickness of the surficial layer and the depth of excavation needed to produce sufficient fill. In many instances, where the layer of suitable fill material is thin, an increase in the areal extent of the borrow area will allow excavation of sufficient material without altering substrate conditions. While this alternative increases direct mortality, it will preserve favorable conditions for repopulation of native organisms.

- In subaqueous areas, detrimental effects on native organisms, both within and near the borrow site, may occur due to suspending silt and clay size material in the water column as a result of the dredging operation. Deposits containing more than a small amount (generally taken as less than 10 percent by volume) of silt and clay are thus less desirable sources of fill from an environmental standpoint. In addition, the fine fraction will be unstable in the beach environment.

(f) Utilization of bypassing/backpassing material. Consideration should be given to bypassing sand across tidal inlets from accreted areas at updrift jetties and from ebb and flood deltas at inlets. Likewise, back-passing of sand from a terminal downdrift jetty to an updrift beach-fill project should be evaluated as a possible cost-effective sand recycling measure. Different types of sand transfer systems are discussed in Richardson (1977). The effect of these measures on adjacent beaches must be evaluated.

(2) Borrow site exploration. A field exploration program to locate and characterize potential borrow sources is usually necessary for offshore and backbarrier environments. For a detailed discussion of procedures, see Prins (1980) and Meisburger (1990). In terrestrial areas, information on deposits is usually available from state geological surveys. There may be existing commercial sand and gravel mining operations. For existing navigation projects, or planned improvements, information on the dimensions and characteristics of material to be dredged is usually available. Field exploration programs involve four phases: a preliminary office study, general field exploration, detailed survey of the site, and characterization of potential sites. The geographical area covered by these investigations is limited by the distance from the project site that is within an economically feasible range for transportation of fill material. Borrow sources within a few miles of the site should be considered initially. Sources farther away should be considered only if no suitable sources are within this range.

(a) Office study. The first phase of the exploration program is an office study of maps, charts, aerial photographs, and literature sources concerning the survey area (Morang, Mossa, and Larson 1993). A study of these materials provides general information on the geomorphology and geology of the area, and helps to identify features that might contain potential fill material. The office study also involves laying out a plan for the next phase, general field exploration of potential sources. Such a plan would include specification of an exploratory field data collection program and definition of the equipment needed to execute the program.

- The most important equipment used for general field exploration and detailed site surveys are: seismic reflection equipment, vibracore apparatus, navigation positioning system, and vessels. Grab samples of surface sediments and side-scan sonar records are also valuable components of the general exploration phase, and can usually be conducted for a relatively small additional cost. Prins (1980) provides a detailed list of equipment and equipment capabilities recommended for use in general field exploration operations. Seismic reflection equipment should provide the highest resolution possible, consistent with achieving a subbottom penetration of at least 15 m (50 ft). High powered seismic reflection systems used for many deep penetration studies are not suitable because of their relatively poor resolution of closely spaced reflectors. Obtaining sediment cores using vibratory coring equipment is more economical than standard soil boring methods, which require more expensive support equipment. Vibratory coring equipment having 3-, 6-, and 12-m (10-, 20-, and 40-ft) penetration capability is available. A 6-m coring device is necessary; a 12-m capability is desirable. Navigation control should be established using an electronic navigation positioning system having an accuracy of about 3 m (10 ft) at the maximum range anticipated for survey and coring operations. Global Positioning Satellites (GPS) technology provides this type of accurate positioning.

- An important task of an office study is to lay out trackline plots, similar to those shown in Figure V-4-5, that are to be followed by the survey vessel in collecting seismic reflection data during the general reconnaissance phase. A grid pattern as illustrated in Figure V-4-6, having lines approximately (0.8 km (0.5 miles) apart, should be employed for areas that are judged to be the most viable either because they are located near the project site or give promise of containing deposits of usable fill material (Meisburger 1990). Zigzag lines are used to cover areas between grids. The detail of coverage is determined by trackline spacing. More complex or promising areas may call for closer spacing.

- Core sites can be tentatively selected during the office study. However, final locations should be determined based on analysis of the seismic reflection records.

(b) General field exploration. During the general field exploration program, data are collected throughout the survey area to locate and obtain information on potential borrow sources and shallow subbottom stratigraphy. This phase involves collection of a comprehensive set of seismic reflection profiles to identify sediment bodies, and a small number of cores to identify and test potential borrow sources.

- The initial part of the general exploration phase is the collection of echosounder and seismic reflection records along predetermined tracklines. The basic survey procedure is for the survey vessel to proceed along each trackline, collecting data while its position is being monitored by an electronic positioning system with fixes recorded at a minimum of 2-min intervals. Fixes are keyed to the records by means of an event marker and identified by a serial fix number. Because seismic reflection records tend to deteriorate in quality with increasing boat speed, the survey vessel's speed should be slow enough to avoid significant reduction in record quality. In general, a suitable boat speed is likely to be less than 4 or 5 knots. The records should be continuously monitored as they become available. Changes in trackline patterns, if considered desirable, can be made as work progresses.

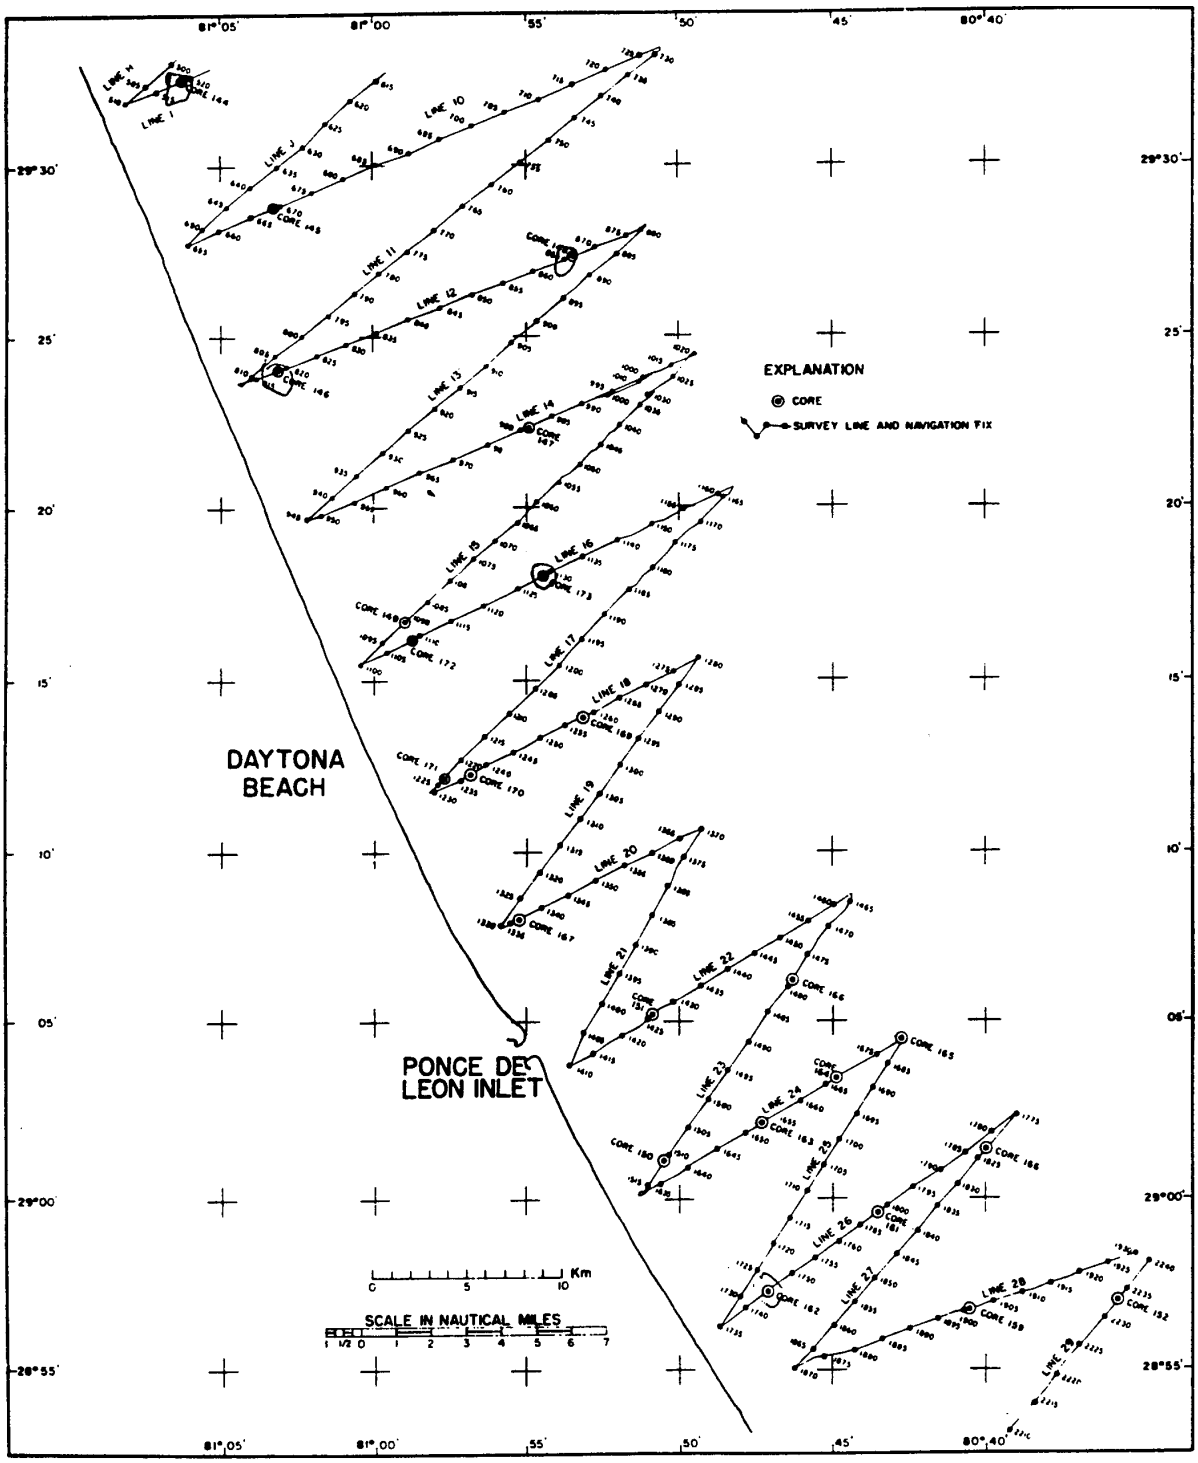

Figure V-4-5. Reconnaissance zigzag line plot from the north Florida coast (from Meisburger and Field 1975)

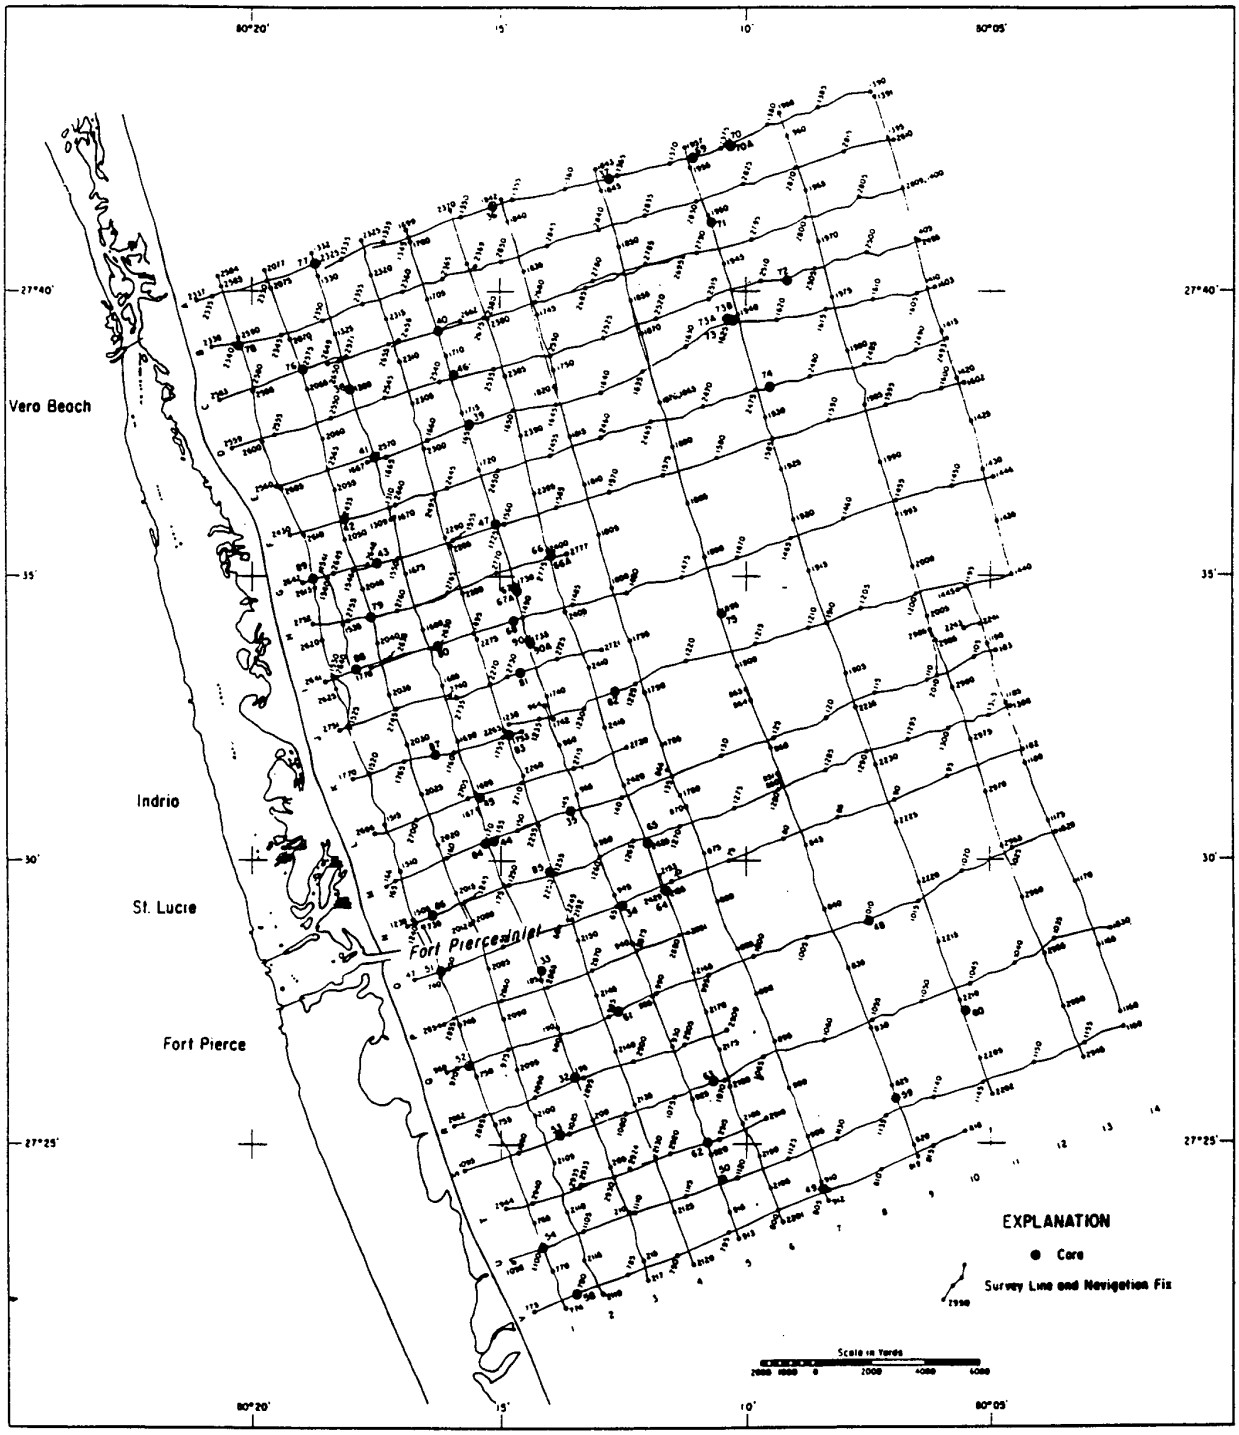

Figure V-4-6. Grid lines covering a detailed survey area off Fort Pierce, Florida (from Meisburger and Duane 1971)

- Sediment core sites are usually selected after the seismic reflection survey, to allow time for preliminary analysis of the records to determine the most prudent and informative core locations.

- Cores should be examined as they are taken. Inspection of cores is often hampered by the presence of silt and by scratching of the acrylic core liners. However, the top and bottom sediments can be directly viewed before the core is capped. As work progresses, changes can be made in core locations.

(c) Detailed site survey. The third phase of borrow site exploration and investigation consists of a detailed investigation of potential sites, which are selected on the basis of data collected during the general exploration survey. If sufficient seismic reflection data were collected at potential sites during the general exploration phase, the detailed site study may only require the collection of additional, more densely-spaced, cores. Since few large sand bodies have uniform size characteristics, it is important to obtain a sufficient number of cores and borings to accurately reflect the variations in size characteristics throughout the deposit. The number of cores and spacing between cores should be determined based on a review of survey and seismic data as well as other geological studies of the area. These values will vary throughout a borrow site, and from one borrow site to another. But in most cases, collection of cores at less than 300-m (1000-ft) nominal spacing is recommended for purposes of ultimately defining the borrow site(s) to be used in construction. It is important to have adequate data for reliably defining the borrow site. Additional seismic reflection data, if needed, should be collected at this time.

- Sometimes the general and detailed field surveys are made in succeeding years so that ample time is available to study results of the seismic reflection survey before coring is undertaken. However, it is possible to complete the operation entirely in one season. This can be done by mobilizing both geophysical and coring equipment early in the most favorable season, and allowing sufficient lag time between the seismic work and the bulk of the coring work for thorough data analyses and selection of core sites.

- Additional data collection is typically required to fully examine the selected borrow area or areas. These additional data include: magnetometer survey to detect cultural resources of historical significance (shipwrecks, etc.) and obstructions to dredging; archaeological-diver survey to investigate magnetic anomalies; sidescan sonar survey to detect obstructions, hard-bottom, or other environmental resources; detailed bathymetric survey suitable for preparation of construction drawings; and benthic or other biologic surveys, if required, to assess the existing biotic resource.

(3) Borrow site characterization. Any beach erosion or shore protection study in which beach fill is considered should include examination of all potential borrow sources and a comparative evaluation of their suitability. The characteristics of potential borrow sources that are most important in evaluating suitability are: location, accessibility, site morphology, stratigraphy, volume of material available, sediment characteristics, geological history, environmental factors, and economic factors.

(a) Location. The distance that the material must be transported and the feasible means of transport have a large influence on project costs and may be decisive in selecting the most suitable source. Location is also important in terms of the surroundings. Use of terrestrial sources located in developed areas may have a direct impact on the population by creating undesirable noise, traffic congestion, and spillage. Offshore sources may involve questions of jurisdiction and be situated in areas where the dredging and transport activities impede or endanger navigation.

(b) Accessibility. In order to be usable, a borrow source must be accessible or made accessible for the equipment needed to excavate and transport the material. Access to terrestrial deposits may involve road construction or improvement of existing routes. Onsite reconnaissance is the best method of determining the adequacy of access and any necessary improvements. A cost estimate of work needed to create accessibility should be prepared and included in the economic analysis.

- In evaluating subaqueous deposits, one of the principal factors is water depth. To be accessible, the deposit must lie in the depth range between the maximum depth to which the dredge can excavate material, and the minimum depth to keep the dredge afloat when laden with fuel and/or sediment. Subaqueous borrow sites should be located sufficiently far offshore and in deeper water so that excavation does not induce adverse shoreline impacts by altering to the incident wave climate.

- Another aspect of accessibility is the presence of incompatible overburden above the usable sediments. The composition, areal extent, and thickness of any overburden should be determined and considered in the economic analysis (i.e., the cost to remove and dispose of it).

(c) Site morphology. Information on borrow site morphology is valuable in defining and evaluating site characteristics. In many cases, the source deposit has surface morphological features that can be used to delineate boundaries and to assist in interpolating between seismic and coring data points. In addition, site morphology may provide indications of the origin and history of the deposit. Subsurface deposits such as filled stream channels are more difficult to delineate because the only sources of data are seismic reflection records, cores, and borings.

- Description of borrow site morphology should contain information on dimensions, relief, configuration, and boundaries, and be illustrated by large-scale maps or charts. Information for compiling the reports can usually be found in hydrographic survey data available from the National Ocean Survey (NOS), National Oceanic and Atmospheric Administration (NOAA), for submerged deposits, and in published U.S. Geological Survey (USGS) topographic maps for terrestrial sources. Fathometer records, which should be made concurrently with the seismic reflection profiles, are valuable for supplementing and updating other sources.

- In cases where the existing information is inadequate, a special detailed bathymetric survey of the site should be made before the main field collection effort is undertaken.

(d) Site stratigraphy. The stratigraphic relationships within and peripheral to the site deposits should be developed from the existing sources and the seismic and coring records to define: limits of the deposit; thickness of usable material; thickness of any overburden; sedimentary structures, and sediment characteristics of each definable bed. The detail and reliability of the stratigraphic analysis depends on the complexity of the deposit, the number of outcrops, number of cores or borings available, and the degree to which stratigraphic features are revealed by seismic reflection profiles.

- In terrestrial areas, outcrops of potentially useful materials may or may not be present. In many cases, such deposits have no topographic expression and must be defined solely on the basis of borings. Seismic refraction surveys in such situations are valuable in defining the areas between data points. Seismic refraction techniques for subsurface exploration are covered in detail in Engineer Manual 1110-1-1802, "Geophysical Exploration for Engineering and Environmental Investigations."

- In submerged areas, site characteristics must be determined by a combination of bathymetric survey, seismic reflection profiling, and sediment coring. It is important, in both seismic reflection and refraction surveys, to collect enough cores or boring samples to identify and correlate the reflectors

with reliable data on sediment properties, and to show significant boundaries that may not have been recorded by the seismic systems.

(e) Volume available. Most beach-fill projects require thousands or millions of cubic meters of suitable fill material. The volume in each potential source must be calculated to determine if a sufficient amount is available to construct and maintain the project for its entire economic life (including initial construction, all subsequent renourishment, and emergency maintenance). In order to do this, it is necessary to delineate the lateral extent and thickness of the deposit. Boundaries may be defined by physical criteria or, in large deposits, arbitrarily set to encompass ample material for the projected fill operation. The thickness of the usable material can be determined from an analysis of site stratigraphy.

- If deposits have a uniform thickness throughout, the available volume can be calculated by multiplying their areas by their thicknesses. Many deposits such as shoals and filled stream channels have more complex shapes, including sloping boundaries and variable thickness. To determine the volume of these deposits, an isopach map of the deposit must be created. An isopach map is a contour map showing the thickness of a deposit between two physical or arbitrary boundaries. Figure V-4-7 shows an isopach map of a borrow area used at Ocean City, Maryland. In this case, the upper boundary of the deposit is defined by the surface of the shoal and can be delineated by bathymetric data. The lower boundary was fixed at a level seismic reflection horizon passing beneath the shoal. Contours, at 1.52-m (5-ft) intervals, were drawn for all the shoal area above the base reflector. Measurements from this type of map can be used to calculate the volume. Commercially available Geographical Information System (GIS) software with Digital Terrain Modeling (DTM) capabilities is now routinely used to generate isopach maps and calculate available sediment volumes.

- Computation of the source's available volume must account for practical limitations of excavation. Particularly for hydraulic dredging (excepting small suction dredge systems), sediment deposits less than about 1-m (3-ft) thickness are impractical to specify. Buffers must be delineated between suitable and nonsuitable sediments, which cannot be included in the source's available volume. These buffers vary with the site and the nature of the sediment strata, but they typically have a minimum thickness of 0.3 m (1 ft) to 0.6 m (2 ft) in subaqueous sources. Buffer areas around sensitive environmental or cultural resources, or around known obstructions, must also be excluded. The size of these radial buffers depends upon the resource or obstruction to be avoided, but a typical radius is 45 to 90 m (150 to 300 ft). Computation of the source's volume must also be limited to those areas or strata in which the sediment is known to be beach-compatible.

(f) Sediment composition. The physical properties of a sediment sample that are most important for determination of suitability for fill on a project beach are composition and grain size distribution. The desirable physical properties of beach-fill material are mechanical strength, resistance to abrasion, and chemical stability.

- In most places, sand-sized sediment is predominantly composed of quartz particles with lesser amounts of other minerals such as feldspar. Quartz has good mechanical strength, resistance to abrasion, and chemical stability. In some deposits, particularly those of marine origin, there is a large and sometimes dominant amount of calcium carbonate that is in most cases of organic origin (biogenic). Calcium carbonate is more susceptible than quartz to breakage, abrasion, and chemical dissolution; but, if it is not highly porous or hollow, it will make serviceable beach fill.

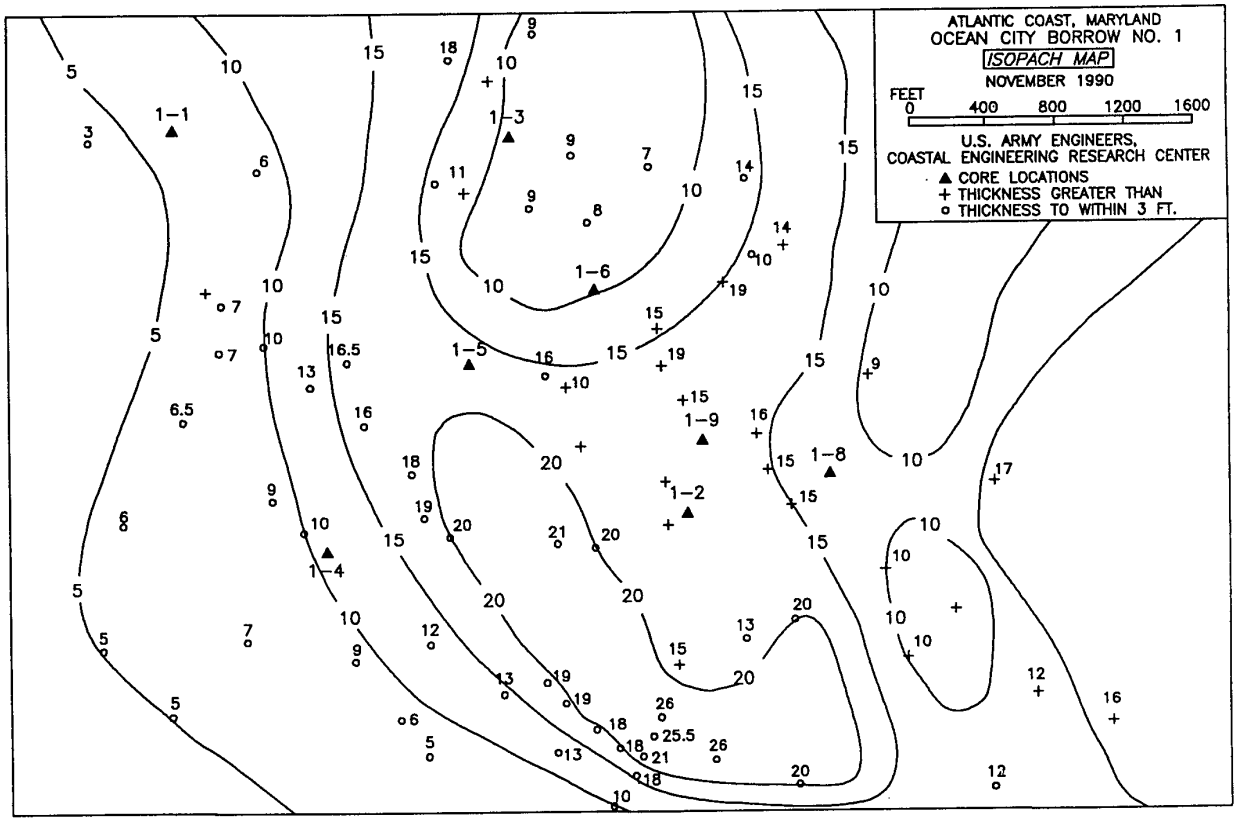

Figure V-4-7. Isopach map of a borrow area used at Ocean City, Maryland

- Sediment composition can be determined by examining representative samples under a binocular microscope. Samples should be prepared by thorough washing to remove fines and clean the surface of the particles. If the material is not well sorted, it should be subdivided into sieve fractions for analysis. A subdivision into the Wentworth classes (see Part III-1) for sand-sized and coarser material is convenient for this purpose. The percentage of carbonate in the material can be estimated by dissolving the carbonate fraction in multiple baths of hydrochloric acid with a subsequent sodium hydroxide wash.

(g) Sediment size characteristics. Generally, suitable material will have grain sizes predominantly in the fine to very coarse sand size range. The presence of very fine sand, silt, and clay in small amounts (generally less that 10 percent) is acceptable, but sources having a substantial amount of fines should be avoided if other more suitable sources are available. When using a borrow area with higher silt or clay content, a large amount of material must be handled to obtain the usable portion, thereby increasing costs. Also, the creation of turbidity during excavation and placement on the beach is environmentally undesirable. However, in the future, as sand resources become more scarce, sand separation may prove to be economically justified depending on the volume of material required and the relative silt and clay content of the borrow site. Borrow material presently discounted because of a comparatively high percentage of fines may become economically viable sand sources in the future.

- One of the main considerations in selecting a borrow source is the similarity between the grain size distributions of the borrow material and the native beach, i.e., the borrow material's compatibility with the native material. To make this comparison, it is necessary to determine, for both native beach and each potential borrow source, a composite grain size distribution representative of overall textural properties. The method used to determine grain size characteristics for both the fill and

borrow sites should be the same. Beach and borrow material should be analyzed with standard sieves as described in Part III-1.

- Native beach composite sediment statistics should be computed based on sieve analyses of samples collected along cross-shore transects through the most active portion of the beach profile (see Part III-1 for information concerning sediment composite statistics). The most active portion is located between the crest of the natural berm (immediately landward of the mean high waterline) and the depth corresponding to the position of the typical storm bar. The composite statistics should be developed for a number of cross-shore transects throughout the project domain. Grain size statistics calculated from such a sampling scheme will account for most of the natural variability on the profile. If cross-shore composites exhibit a wide range of median grain size and sorting values, an alongshore composite should be calculated for the entire project domain to reduce the variability.

- Borrow area composite statistics should be determined using grain size distributions computed for samples taken from several cores within the potential borrow site. For general uniform cores, samples should be collected from the top, middle, and bottom of useable sand within the core. The composite characteristics of the borrow material should be weighted based on the estimated volume of each type of material present in the deposit.

- Figure V-4-8 shows a comparison between the native beach and borrow material used for nourishment at Ocean City, Maryland. The shaded area represents common characteristics between the native beach and fill material.

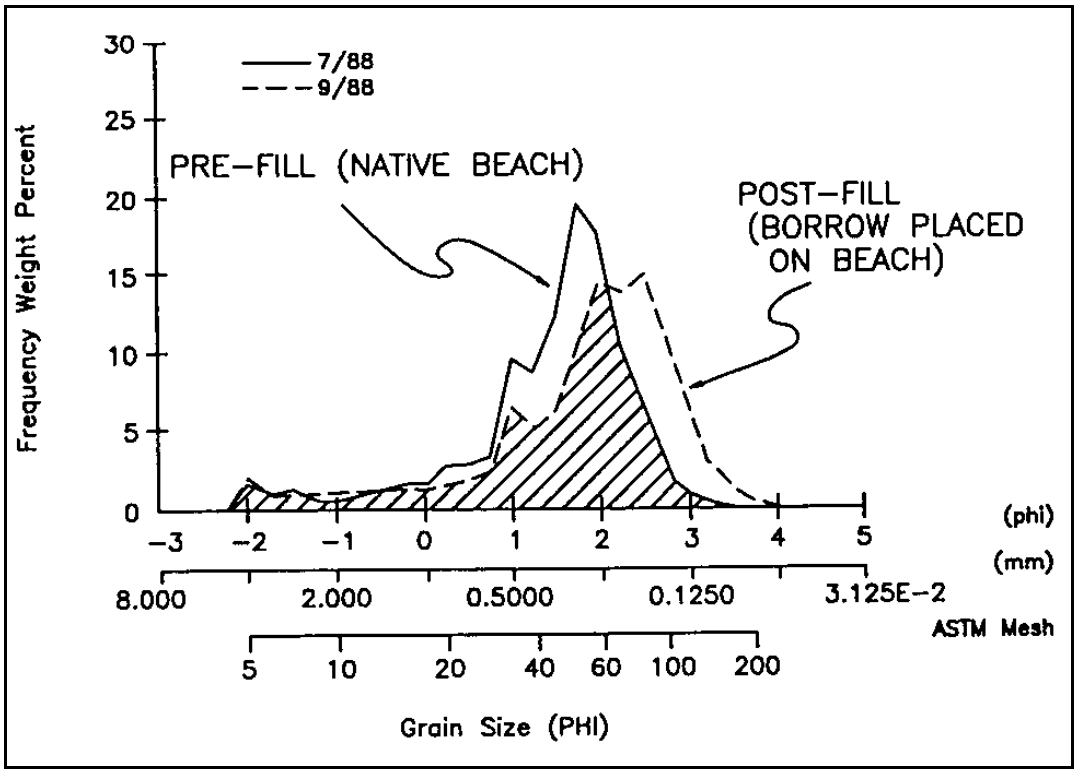

Figure V-4-8. Comparison of composite grain size analysis between the native beach and the borrow material used at Ocean City, Maryland

(h) Sediment suitability. The grain-size distribution of the borrow material will affect the cross-shore shape of the nourished beach profile, the rate at which fill material is eroded from the project, and how the beach will respond to storms. Typically, borrow material will not exactly match the native beach (except perhaps in some bypassing projects). An analysis is required to assess the compatibility of the borrow material with the native beach, from a functional perspective. A comparative analysis of sand suitability is also required to economically evaluate alternative borrow areas for a given project.

- Early research into compatibility of borrow area material by Krumbein (1957), Krumbein and James (1965), James (1974, 1975), and Dean (1974) addressed this issue by various comparative analysis techniques that utilize the sand-size distributions of the natural beach in the fill area and the borrow material in the candidate borrow sites. These approaches develop a factor, or parameter, indicating how much fill material is required in light of the different sediment characteristics between the borrow and native beach materials. They assume that borrow material placed on the beach will undergo sorting as a result of the coastal processes; and given enough time, will approach the native grain-size distribution. The portion of borrow material that does not match the native sediment grain-size distribution is assumed to be lost to the offshore. James (1975) developed this concept into a method to calculate an overfill factor, R_A, and a renourishment factor, R_J. Conceptually, the overfill factor is the volume of borrow material required to produce a stable unit of usable fill material with the same grain size characteristics as the native beach sand. The renourishment factor addresses the higher alongshore transportability of the finer grain sizes in the borrow sands and provides an estimate of renourishment needs. Use of the renourishment factor is no longer recommended in beach-fill design calculations; however, details concerning the renourishment factor and it's calculation may be obtained from the *Shore Protection Manual* (1984).

- Recent research and beach nourishment experiences have questioned the continued use of these grain-size-based factors, R_A and R_J, to estimate beach-fill performance (Dean 2000). Present guidance recommends that design be based on equilibrium beach profile concepts, an assessment of storm-induced erosion, and an assessment of wave-driven longshore transport losses; and that these methods be used to replace or complement the overfill and renourishment factor approaches (National Research Council (NRC) 1995). In practice, these recommended methods treat sediment characteristics using a single grain size parameter, the median grain diameter. They do not consider natural variations in grain size that occur on natural and nourished beaches. However, they have the advantage of incorporating more of the physics of coastal processes into the design, much more so than use of the overfill and renourishment factors. The overfill factor attempts to consider the distribution of grain sizes. Therefore, it does provide an additional piece of information on the amount of borrow material that might be needed to construct a beach nourishment project in more difficult design cases where the grain size characteristics of the borrow material differ significantly from those of the native beach material, especially the case where the borrow sediments are finer than the native sediments. The overfill factor is discussed in more detail in the next section.

- As a general recommendation, a nourishment project should use fill material with a composite median grain diameter equal to that of the native beach material, and with an overfill factor within the range of 1.00 to 1.05. This is the optimal level of sediment compatibility. However, obtaining this level of compatibility is not always possible due to limitations in available borrow sites. Both the overfill factor and equilibrium beach profile concepts indicate that sediment compatibility is sensitive to the native composite median grain diameter. As such, the compatibility range varies depending on the characteristics of the native beach material, with coarse material being less sensitive to small variations between the native and borrow sediments than fine material. As a rule of thumb, for native beach material with a composite median grain diameter exceeding 0.2 mm, borrow material with a composite median diameter within plus or minus 0.02 mm of the native median grain diameter is considered compatible. For native beach material with composite median diameter between 0.15

and 0.2 mm, borrow material can be considered compatible if its composite median diameter is within plus or minus 0.01 mm of the native diameter. For native beach material with a composite median diameter less than 0.15 mm, use of material at least as coarse as the native beach is recommended. Even though material is deemed compatible based on these rules, the designer should factor grain-size differences into estimates of required fill volume through use of equilibrium beach profile methods, or the overfill factor, or both. Methods for computing beach- fill volumes are discussed in Part V-4-1-f. These guidelines are based on composite median diameters established for the entire project and borrow site. Typically, composites for individual profiles, or subsections of the borrow site, will have variations in median diameter which may exceed the compatibility ranges previously discussed.

- Materials that are not compatible according to these guidelines may still be suitable. Borrow material that is coarser than the native material will produce a beach which is at least as stable as a fill comprised of native material. Fills with coarser material provide improved resistance to storm-induced erosion. A lesser volume of coarser fill will be required to create a beach of a given width, compared to the volume of native beach sand that would be needed. If the median diameter of the borrow material exceeds the median diameter of the native material by more than 0.02 mm, a noticeably steeper beach may form. A steeper beach may become a design issue, along with the different texture of the coarser fill. Use of material finer than the native material should be avoided, if possible, but such material still may be suitable. A much greater volume of material will be required to form a beach of a given width, compared to the volume of native sand that would be required. Use of finer sand will produce a beach with flatter slopes, which could be a design issue too. For example, it may be problematic to construct a more gentle beach adjacent to an existing groin or jetty that is intended to block the longshore movement of sand. Sand transport around the structure and into a navigation channel may increase.

(i) Overfill factor. The overfill factor, R_A, is determined by comparing mean sediment diameter and sorting values of the native beach and borrow sediments (in phi,ϕ, units). The phi, ϕ, scale of sediment diameter is defined and discussed in Part III-1, and Equations III-1-1a and III-1-1b enable conversion between sediment grain size diameter in millimeters and the ϕ scale and vice versa. The overfill factor is computed using the following relationships between the borrow and native beach material:

$$\frac{\sigma_{\phi b}}{\sigma_{\phi n}} = \frac{\left[\frac{(\phi_{84}-\phi_{16})}{4} + \frac{(\phi_{95}-\phi_{5})}{6}\right]_b}{\left[\frac{(\phi_{84}-\phi_{16})}{4} + \frac{(\phi_{95}-\phi_{5})}{6}\right]_n} \tag{V-4-3}$$

and

$$\frac{M_{\phi b} - M_{\phi n}}{\sigma_{\phi n}} = \frac{\left[\frac{(\phi_{16}+\phi_{50}+\phi_{84})}{3}\right]_b - \left[\frac{(\phi_{16}+\phi_{50}+\phi_{84})}{3}\right]_n}{\left[\frac{(\phi_{84}-\phi_{16})}{4} + \frac{(\phi_{95}-\phi_{5})}{6}\right]_n} \tag{V-4-4}$$

where:

$\sigma_{\phi b}$ = standard deviation or measure of sorting for borrow material (Equation III-1-3)

$\sigma_{\phi n}$ = standard deviation or measure of sorting for native material (Equation III-1-3)

$M_{\phi n}$ = mean sediment diameter for native material (Equation III-1-2)

$M_{\phi b}$ = mean sediment diameter for borrow material (Equation III-1-2)

- Values obtained using the relationships in Equations V-4-3 and V-4-4 are then plotted on the graph presented in Figure V-4-9. The value of R_A can be obtained by interpolating between the values represented by the isolines. Values of the overfill factor greater than 1.0 indicate that more than one unit of borrow material will be needed to produce one unit of fill material. Example V-4-1 illustrates computation of the overfill factor.

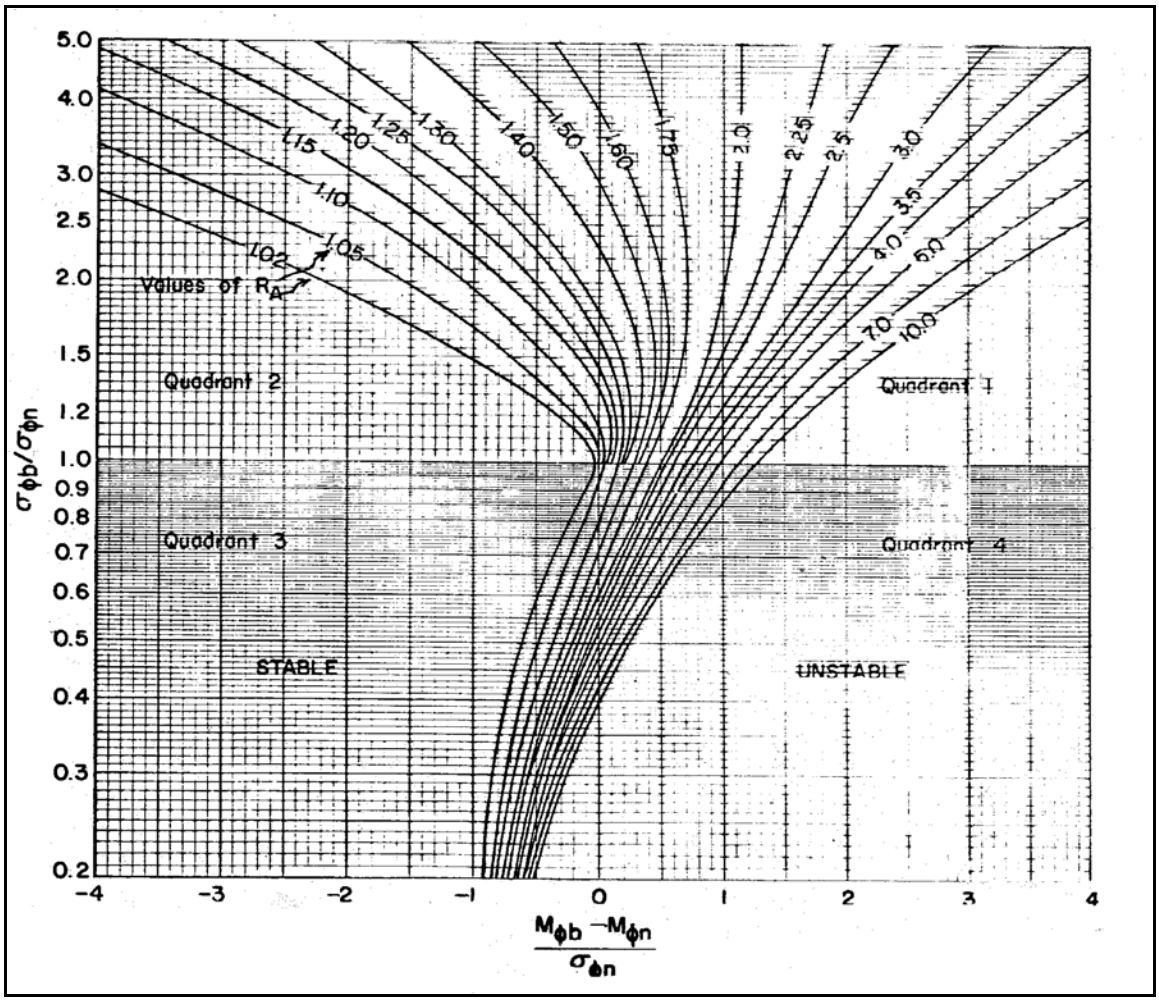

Figure V-4-9. Isolines of the adjusted overfill ratio (R_A) for values of ϕ mean difference and ϕ sorting ratio (*Shore Protection Manual* 1984)

EXAMPLE PROBLEM V-4-1

FIND:

The overfill factor, R_A.

GIVEN:

The native and borrow area phi values are:

native beach: ϕ_{05}=0.95, ϕ_{16}=1.31, ϕ_{50}=1.91, ϕ_{84}=2.66, ϕ_{95}=2.90
borrow area: ϕ_{05}=1.42, ϕ_{16}=1.63, ϕ_{50}=2.49, ϕ_{84}=3.08, ϕ_{95}=3.55

The median grain diameter for native and borrow material is 0.27 and 0.18 mm, respectively.

SOLUTION:

The mean sediment diameter in phi units is given in Part III-1 as

$$M_\phi = (\phi_{16} + \phi_{50} + \phi_{84}) / 3 \qquad \text{(III-1-2)}$$

$M_{\phi n} = (1.31 + 1.91 + 2.66) / 3 = 1.96$
$M_{\phi b} = (1.63 + 2.49 + 3.08) / 3 = 2.40$

The standard deviation in phi units is given in Part III-1 as

$$\sigma_\phi = (\phi_{84} - \phi_{16}) / 4 + (\phi_{95} - \phi_{05}) / 6 \qquad \text{(III-1-3)}$$

$\sigma_{\phi n} = (2.66 - 1.31) / 4 + (2.90 - 0.95) / 6 = 0.66$
$\sigma_{\phi b} = (3.08 - 1.63) / 4 + (3.55 - 1.42) / 6 = 0.72$

The sorting ratio from Equation V-4-3 is

$\sigma_{\phi b} / \sigma_{\phi n} = 0.72 / 0.66 = 1.09$

The phi mean differences ratio from Equation V-4-4 is

$(M_{\phi b} - M_{\phi n}) / \sigma_{\phi n} = (2.40 - 1.96) / 0.66 = 0.67$

Entering Figure V-4-9 with x = 0.67 and y = 1.09 results in an overfill ratio (R_A) equal to 2.5. The finer borrow material may be suitable for use, but it is quite incompatible with the native beach sand. The value of the overfill ratio suggests that 2.5 units of borrow material will be required to create 1.0 unit of stable native beach material.

- The overfill method previously described is the Krumbein-James technique (Krumbein and James 1965). Dean (1974) presents an alternative method for computing the overfill factor, not shown, which generally yields less conservative (lower) estimates of the overfill factor.

f. Beach-fill cross-section design. The design of Federal beach-fill projects is based on the optimization of net annual benefits defined as the difference between average annual costs and average annual benefits. This optimization procedure produces a plan known as the National Economic Development (NED) plan. The NED plan considers the storm damage reduction potential of various beach fill design alternatives and the averaged annual cost. Primary design parameters of each alternative include the physical dimensions of the cross-sectional design profile and the volume of sand required to obtain the design profile. Beach-fill design alternatives typically include combinations of beach berms of varying width and dunes of varying height (see Part V-4-1-b for a description of the characteristics and functions of beach berms and dunes). Design berms are characterized by berm crest elevation and berm width. Dune design dimensions include crest elevation, crest width, and side slopes.

(1) Berm elevation. The elevation of the design berm should generally correspond to the natural berm crest elevation. If the design berm is lower than the natural one, a ridge will form along the crest, which, when overtopped by high water will produce flooding and ponding on the berm. A design berm higher than the natural berm will produce a beach face slope steeper than the natural beach and may result in formation of scarps that interfere with sea turtle nesting and recreational beach use. Many healthy, natural beaches exhibit a gentle downward slope from the toe of the dune to the seaward limit of the berm. Therefore, a gentle berm slope can be specified as an element of the design profile. The berm slope is most appropriately estimated from profiles that represent a nearby, healthy beach. Or the slope can be estimated to fall in the range from 1:100 to 1:150. Adding a gentle slope to the berm also helps prevent overtopping and ponding.

(a) The natural berm elevation can be determined by examining beach profile surveys of existing and historical conditions at the project site. Because beach berms form naturally under low-energy waves, they are typically most well-developed in form at the end of the summer season. Seasonal profile surveys can be used to examine temporal changes in berm shape and to identify well developed berm features from which to estimate the natural berm height. When survey data indicate alongshore variations in the natural berm height, a representative berm height may be determined either by visual inspection of plots showing the alongshore variations or by computing an average profile shape. The Beach Morphology Analysis Package (BMAP) provides automated calculation and visualization tools for performing such analyses. Sommerfeld et al. (1994) provide an overview of the capabilities and a user's guide for operation of the BMAP software.

(b) Figure V-4-10 shows an example of seasonal variation in berm shape measured over two consecutive years at a given profile station. The fall surveys show that the beach berm is widest following the calmer summer waves, whereas the spring surveys show the berm to be in a more eroded condition following winter waves. Based on visual inspection of Figure V-4-10, a natural berm height for this profile can be approximated by the horizontal dotted line, corresponding to an elevation of 3.6 m. Figure V-4-10 shows that it would be difficult to identify the natural berm height based solely on the first spring survey, and illustrates the advantage of using multiple surveys for profile characterization.

(c) Figure V-4-11a shows beach profiles measured during a single fall survey at five different profile stations along the beach. The berm is seen to vary alongshore in height and width. To determine a representative berm height, the beach profiles are horizontally aligned on the seaward face of the dune to superimpose the berm profiles at the base of the dune, as shown in Figure V-4-11b. An average profile is computed by averaging the elevations of the aligned profiles at 1-m increments in distance offshore. Figure V-4-11c shows the average profile, from which a representative berm elevation of 3.5 m is obtained by inspecting the horizontal portion of the profile between the offshore distances of 75 and 100 m.

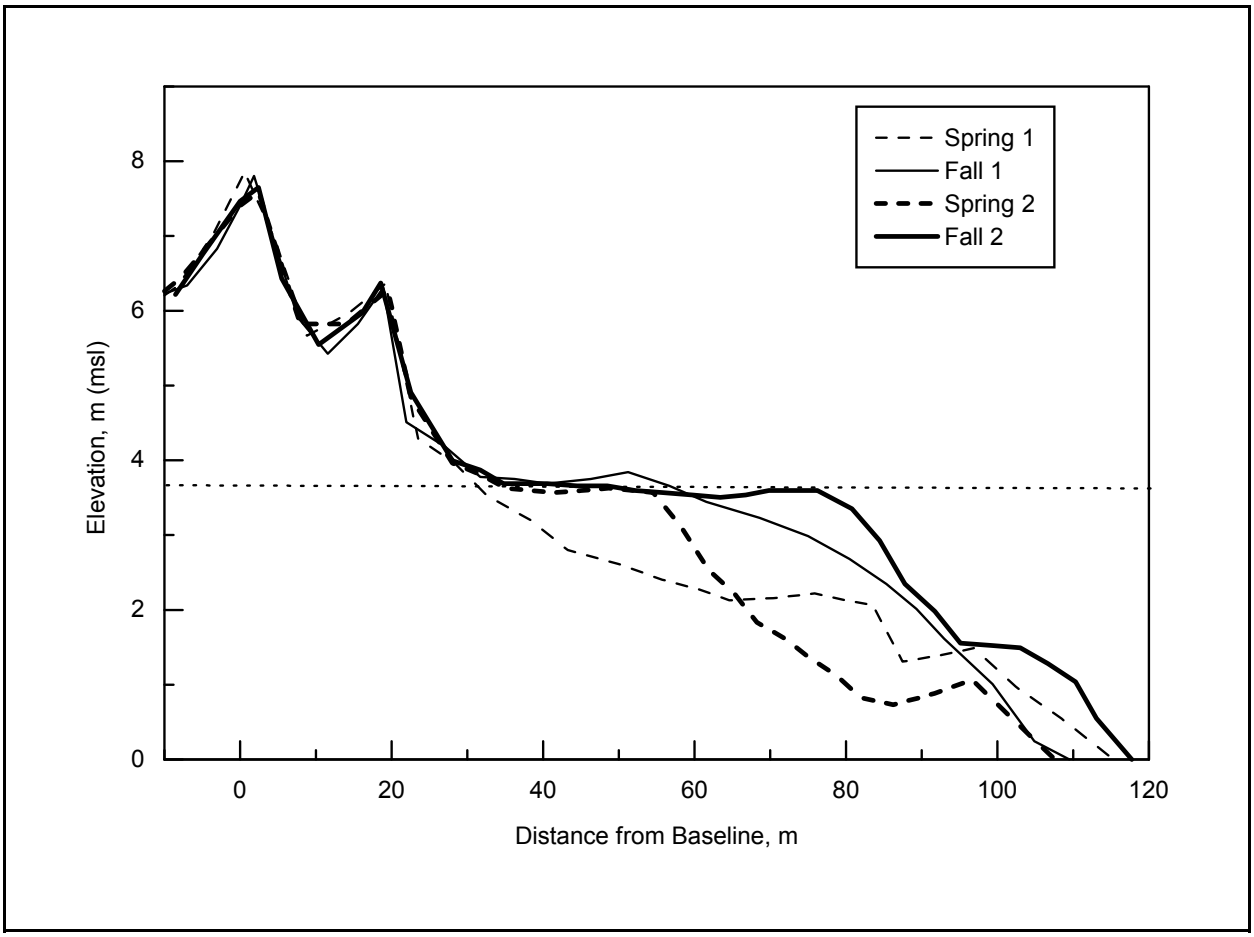

Figure V-4-10. Seasonal variation of a beach berm

(d) In cases where no dry beach exists at the project site, or where the existing beach has a deficit of sand due to substantial reduction or elimination of a critical sediment source, such as in front of a seawall or downdrift of a shore-perpendicular structure, the natural berm elevation should be estimated using profile data from adjacent beaches which are healthier in terms of sand availability but are exposed to similar waves and water levels. Priority should be given to identifying a natural berm elevation using beach measurements from the project site or a similar site. As a last resort, when no suitable beach profile data are available to determine a natural berm height, the limit of wave runup under average (nonstorm) wave and tide conditions at the site can be estimated to establish a design berm height (see Part II-4-4 for calculation of wave runup on beaches).

(2) Berm width.

(a) Selection of the design berm width depends on the purpose of the project and is often constrained by factors such as project economics, environmental issues, or local sponsor preferences. For Federal beach nourishment projects, the berm width is determined through a process of optimization based on storm damage reduction. The design beach width is optimized by computing costs and benefits of various design alternatives and selecting the alternative that maximizes net benefits (USACE 1991). Numerical models of beach profile change such as Storm-Induced BEAch CHange (Larson and Kraus 1989) provide a means of evaluating beach response as a function of berm width. Figure V-4-12 illustrates how berm width influences the landward extent of erosion during a storm. Figure V-4-12a shows four beach profiles with identical dune

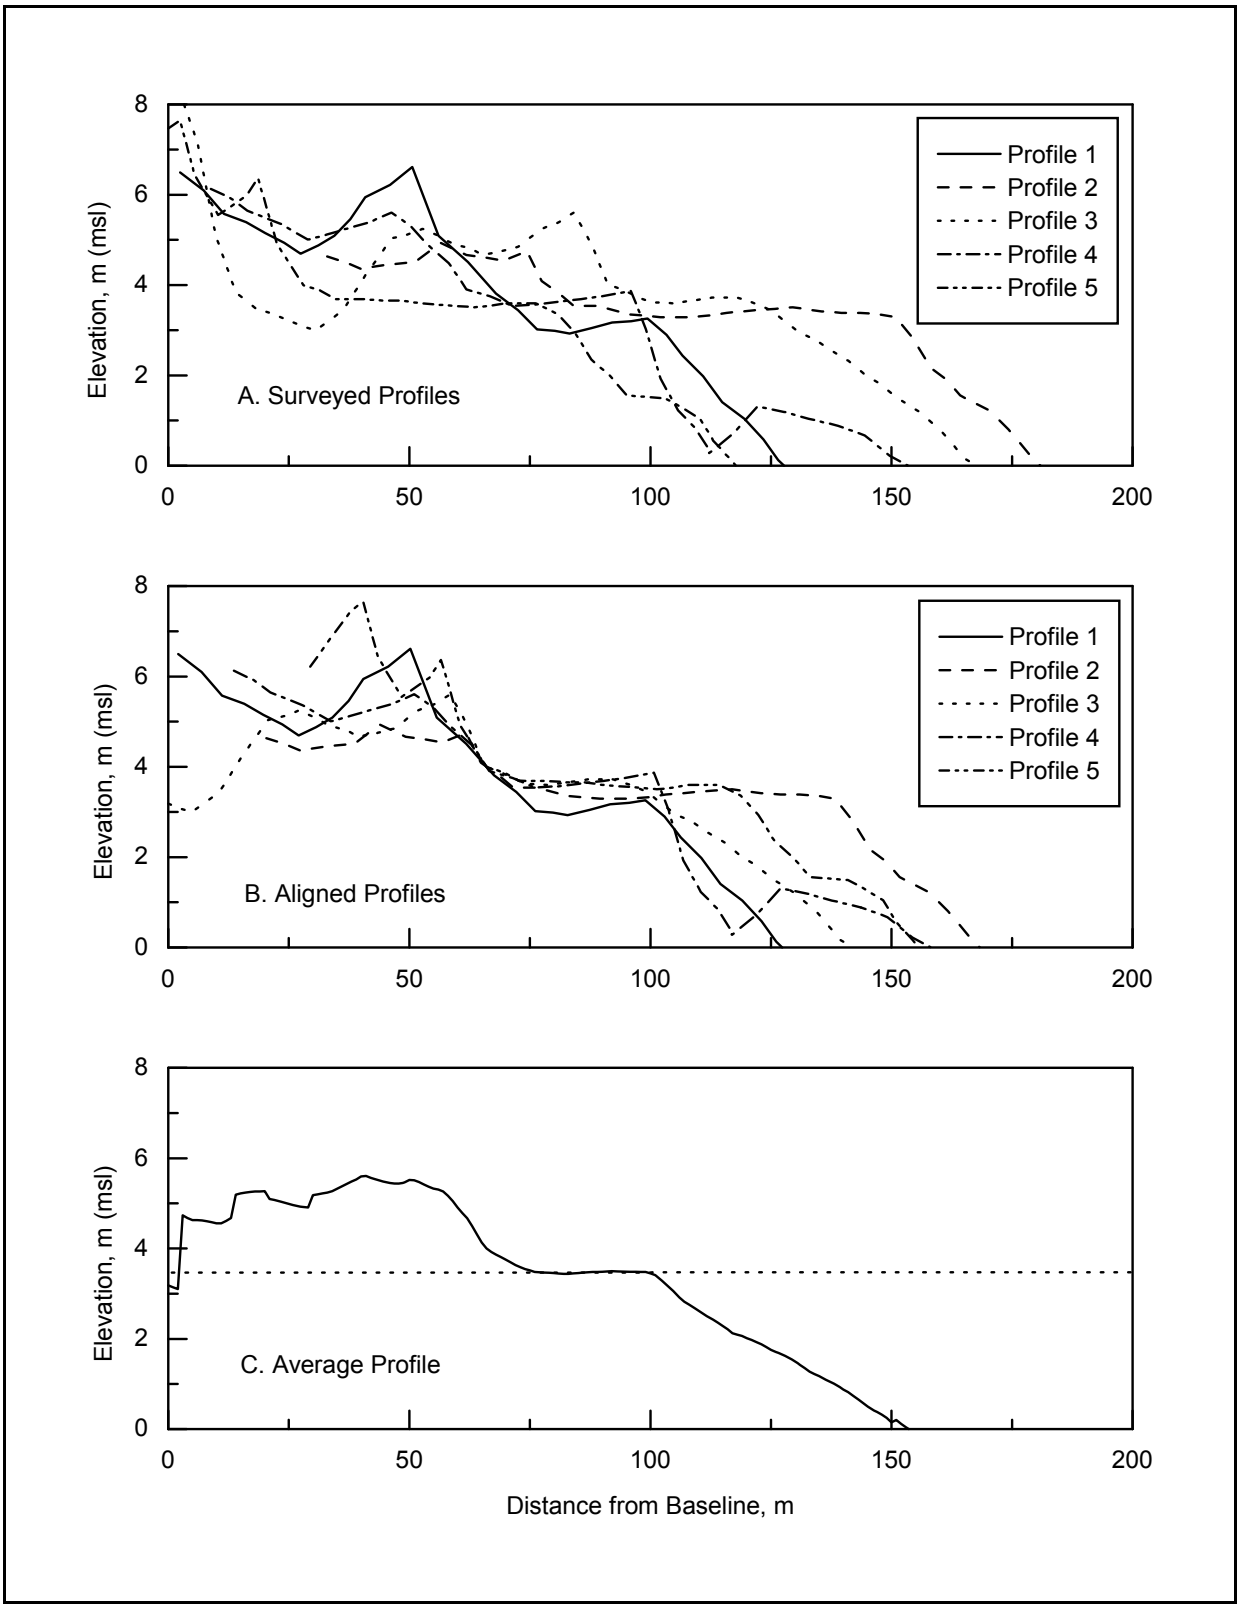

Figure V-4-11. Berm elevation determined from beach profiles measured at various alongshore stations

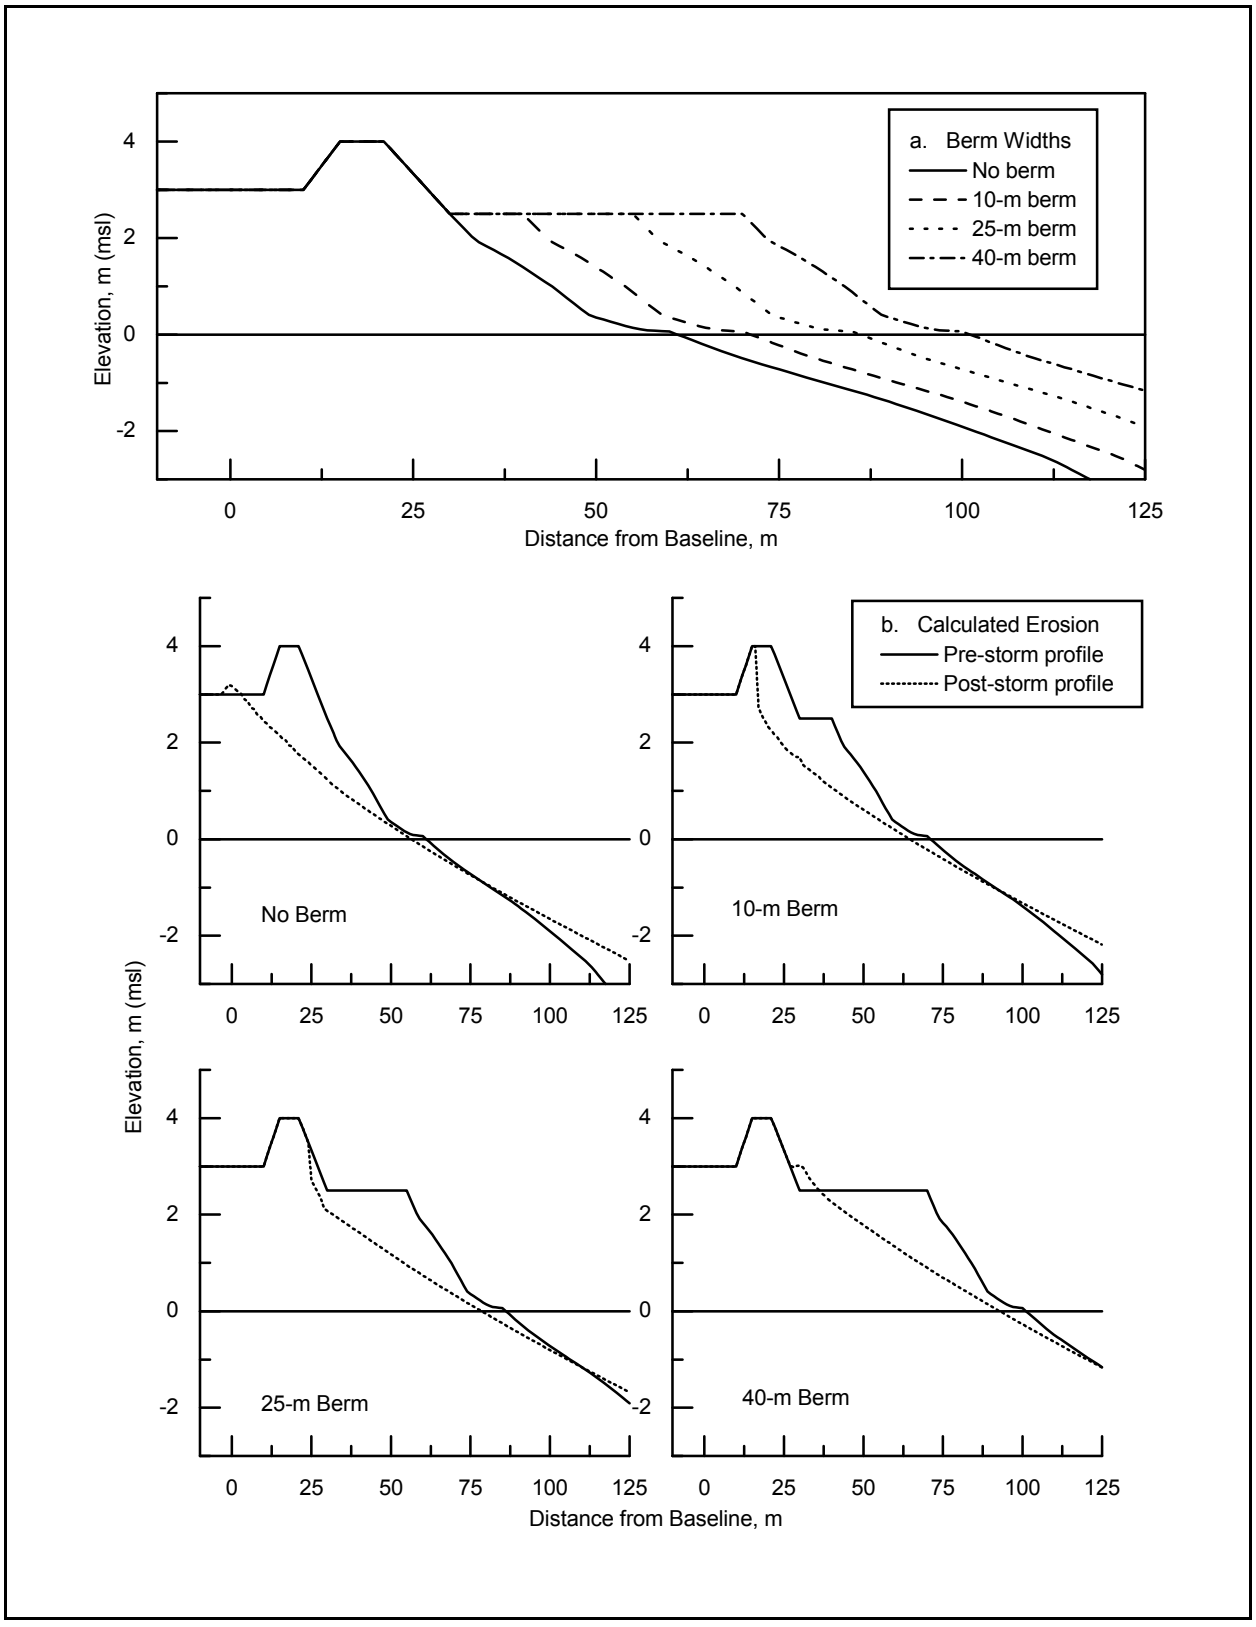

Figure V-4-12. Example of storm-induced beach erosion as a function of berm width

cross sections and varying berm widths. The SBEACH model was used to simulate profile change, and each profile was subjected to a constant wave height of 3 m, wave period of 10 sec, and water level of 1.5 m msl over a duration of 24 hr. Figure V-4-12b shows the calculated results for each profile. The profile with no berm experienced complete erosion and overtopping of the dune. Most of the dune was eroded on the 10-m berm profile, whereas the 25-m berm profile experienced only minor dune erosion. The 40-m berm provided full protection against erosion of the dune and backbeach, and some sand was pushed up against the base of the dune due to overwash across the wide berm. In this example, a shorefront property located immediately landward of the dune would experience varying degrees of damage and/or vulnerability to future storm erosion and flooding as a function of the beach berm width.

(b) Factors other than storm erosion that influence beach width include the rate and variability of long-term shoreline recession, planform spreading losses, and presence of erosional hot spots. These factors typically do not enter in the optimization of the design berm width for storm damage reduction projects, but should be accounted for in optimization of the advanced fill section and renourishment interval as discussed in Part V-4-1-g.

(c) Storm berms may be used in conjunction with a natural berm to provide added protection against damage during storms. Storm berms are constructed at an elevation higher than the natural berm and are set back, landward, from the crest of the natural berm. Storm berms are built to reduce the chance for wave action and erosion from reaching the dune during higher water levels associated with a specified degree of storm intensity (usually, the type of storm that can be expected once every few years). The crest elevation of a storm berm should be set based on the water level and runup elevation associated with the type of storm(s) against which protection is sought. If a storm berm is included in the design, the width of the storm berm can be optimized to maximize net benefits. The seaward extent of the storm berm should also consider the possibility for undesirable, persistent scarp formation.

(3) Dune dimensions.

(a) Dunes protect upland property against wave attack, erosion, and flooding during extreme storm events which overtop or severely erode the beach berm. Design parameters of a dune include the crest elevation, crest width, and side slopes. The design dune crest elevation is typically determined through economic optimization. The dune crest width may also be optimized but is typically fixed at a selected width for all design alternatives. In selecting dune crest width and side slopes, constructibility constraints and angle of repose of the fill material grain size should be considered. A typical dune design may have dimensions on the order of 5-m crest elevation above msl, 10-m dune crest width and one on five side slopes. Planting beach grasses on the constructed dune helps to maintain and build dune volume over time by trapping wind-blown sand.

(b) To illustrate the influence of dune height on storm-induced beach profile change, the no-berm profile shown in Figure V-4-12 was modified to increase the dune elevation from 4 to 4.5 m while maintaining the same crest width and side slopes. The original and modified dune configuration are shown in Figure V-4-13a. The increase in dune height translates to an added volume of 10 cu m/m for this profile. Figure V-4-13b shows profile erosion modeled by SBEACH for the same storm conditions used in the previous berm erosion example. The calculated results in Figure V-4-13b indicate the added dune height prevented dune overtopping and back-beach erosion for these particular wave and water level conditions.

(4) Design profile shape. The shape of the design profile is needed to compute cross-sectional fill volume requirements and as input to storm-induced erosion modeling that is done to optimize berm and dune dimensions. In order to obtain the design dune and berm template on the beach, sufficient sand must be placed to nourish the entire profile out to the depth of closure (see Figure V-4-14 and Part III-3-3-b for details

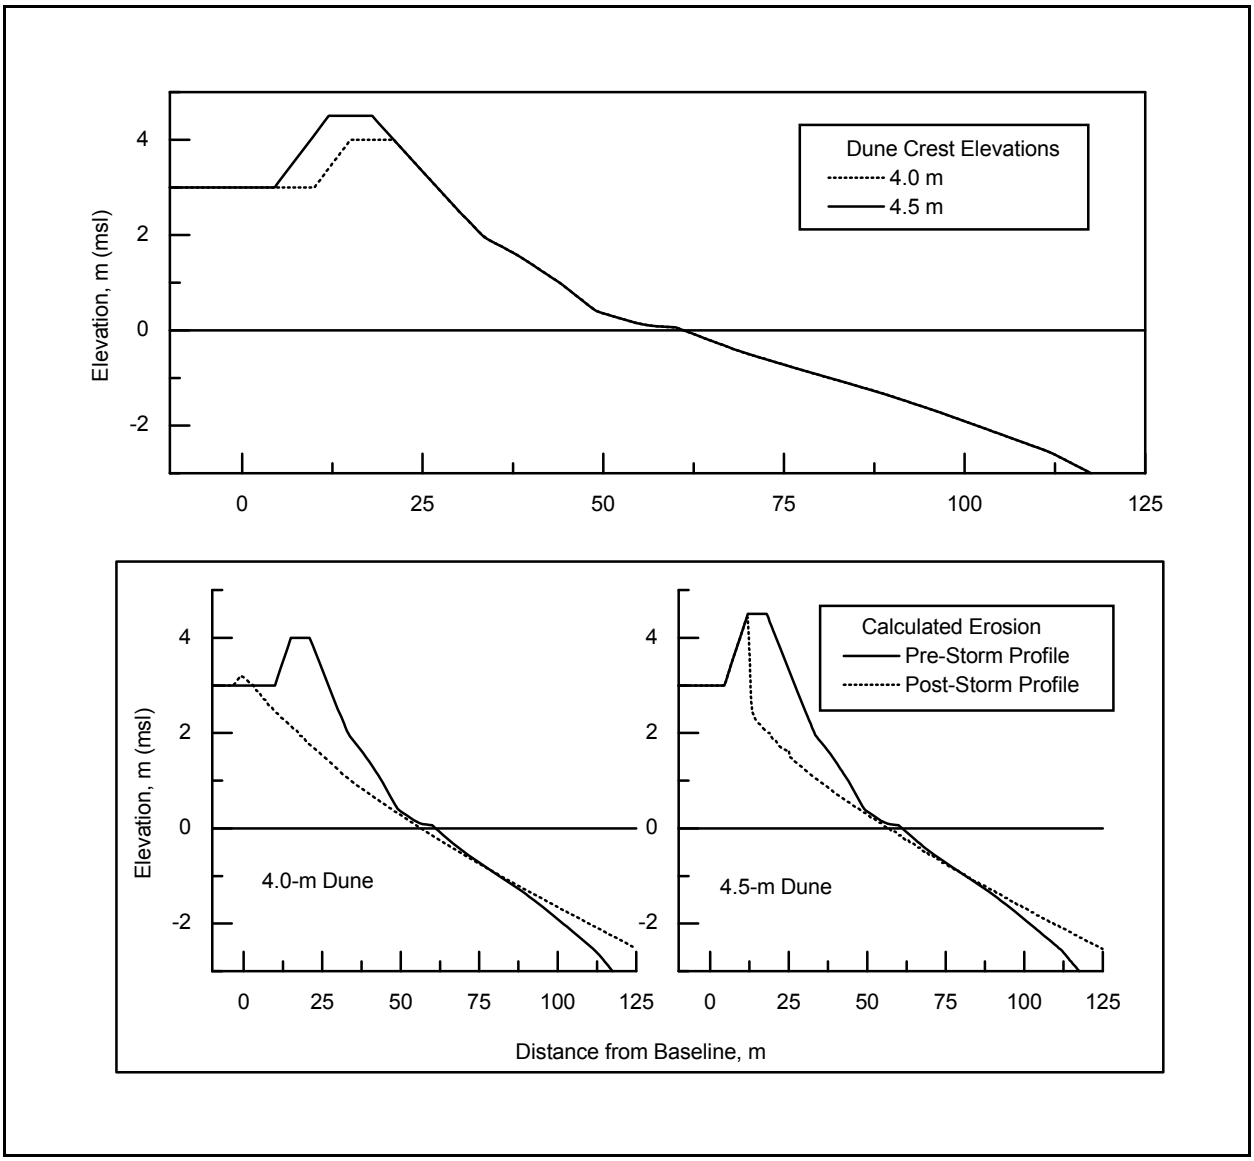

Figure V-4-13. Example of storm-induced beach erosion as a function of dune crest elevation

on depth of closure). Whereas dune and berm dimensions are determined through optimization, the shape of the design profile below the beach berm is a function of the local morphology and grain size of the fill. Local beach morphology often includes a nearshore bar system, which may be absent in erosion-stressed preproject beaches. In such cases, a berm also might be absent from the profile, or may be unnaturally low in elevation; or the preproject profile may reflect an overly steep beach face. A key aspect of defining the design profile shape is to recognize whether or not the preproject beach reflects an unnatural, sediment-starved condition, in which the preproject shape is different from that which will evolve once the fill is placed. For example, a severely eroded beach may lack the commonly observed nearshore bar system, but the bar system will likely form under sediment-rich conditions that follow nourishment. Consequently, the sectional fill volume should include an estimate of bar volume. In these situations, design profile shape can be defined by examining nearby beaches that are healthier in terms of available sediment supply (from the upland beach and from longshore sources). Profile data from adjacent beaches within the project domain, or data from a nearby site that is exposed to similar wave and

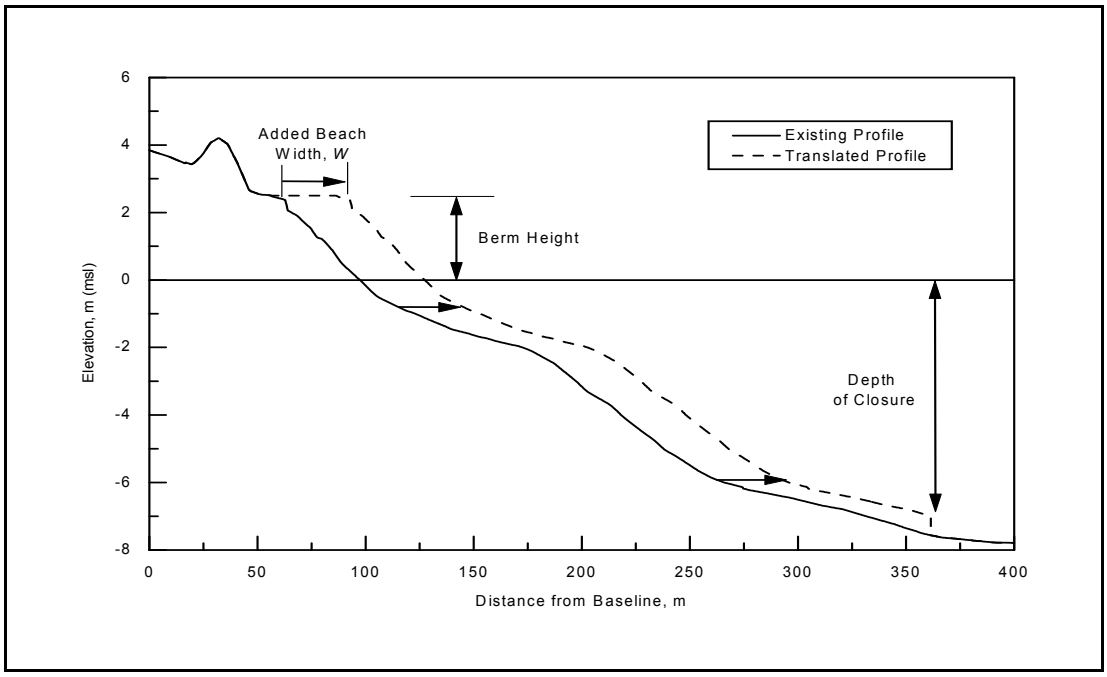

Figure V-4-14. Beach-fill design profile shape determined by profile translation

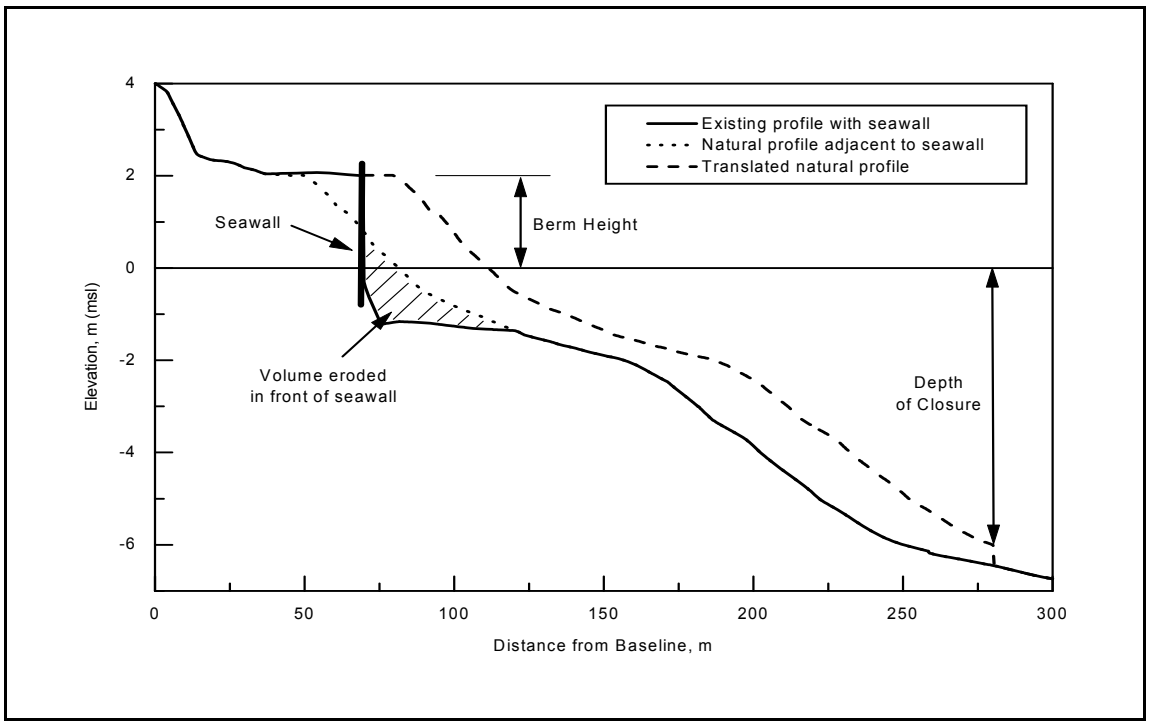

Figure V-4-15. Design profile in front of a seawall

tide conditions and has similar grain size characteristics, can be used to estimate the healthy beach profile shape for reaches where in situ profiles might be misleading. Figure V-4-15 shows an eroded profile in front of an exposed seawall. Translating the existing profile would incorrectly estimate the shape of the nourished beach and would result in an underestimate of the volume required to obtain the design beach width in front of the seawall. In Figure V-4-15, the design profile is determined by translating the natural (healthy) profile shape seaward to obtain the design berm width in front of the seawall. Grain-size differences between the native beach and the fill material also must be considered in defining the design profile shape. If the median grain size of the fill is the same as that of the native beach, the design profile shape should be obtained by translating an average profile shape that represents locally healthy (sediment-rich) beach conditions. For example, given the same composite median grain sizes, the design profile for a beach with 30 m of added berm width is determined by translating the existing profile 30 m seaward between the elevation of the berm crest and the depth of closure, as shown in Figure V-4-14. When applying the profile translation method, the existing beach shape should be determined based on an average of multiple surveys to account for seasonal and/or alongshore variability in profile shape and to avoid including anomalous profile features in the design profile shape.

(a) When fill material is finer or coarser than the native sediment, the design beach profile shape should be estimated based on equilibrium profile concepts (see Part III-3-3-c for details on equilibrium beach profiles). According to equilibrium profile theory, coarser sand will produce a steeper design profile whereas finer sand will produce a profile with a gentler slope as illustrated in Figure V-4-16. Dean (1991) provides additional discussion of equilibrium beach profile concepts and their application. To estimate the design profile shape using equilibrium profile concepts, the average profile shape that represents locally healthy (sediment-rich) beach conditions should first be translated seaward a distance equal to the added berm width (see Figure V-4-14 and Figure V-4-15). To account for the difference in profile shape due to different composite sand sizes, the profile is translated an additional distance as a function of depth between the still-water level and depth of closure, based on differences in the theoretical equilibrium profile shapes as shown in Figure V-4-17. The added distance of translation W_{add} as a function of depth y is given by

$$W_{add}(y) = y^{3/2}\left[\left(\frac{1}{A_F}\right)^{3/2} - \left(\frac{1}{A_N}\right)^{3/2}\right] \tag{V-4-5}$$

where A_N is the A parameter for native sand and A_F is the A parameter for fill sand (see Table III-3-3 for values of the A parameter for different sand sizes). In Equation V-4-5, when the fill material is finer than the native sand, W_{add} is positive, which produces a design profile that is gentler in slope than the native profile. Conversely, for fill that is coarser than the native beach, W_{add} is negative which produces a steeper design profile. If the representative sediment-rich beach profile includes a bar, some smoothing in the bar region may be necessary. The BMAP software provides automated methods for estimating the design profile shape for different native and fill sand sizes based on Equation V-4-5, and for the same sand sizes using the uniform profile translation technique.

(5) Optimization of design profile. Optimization of the design profile involves selecting a range of design alternatives with different dune and berm dimensions, and evaluating the design alternatives together with the existing condition to determine the alternative that provides maximum net economic benefits. Storm-induced beach erosion modeling is the primary engineering analysis performed as part of the optimization process. Model simulations of profile response to a suite of historical or characteristic storms are performed for each alternative to assess erosion, flooding, and wave attack damages to shorefront property and infrastructure.

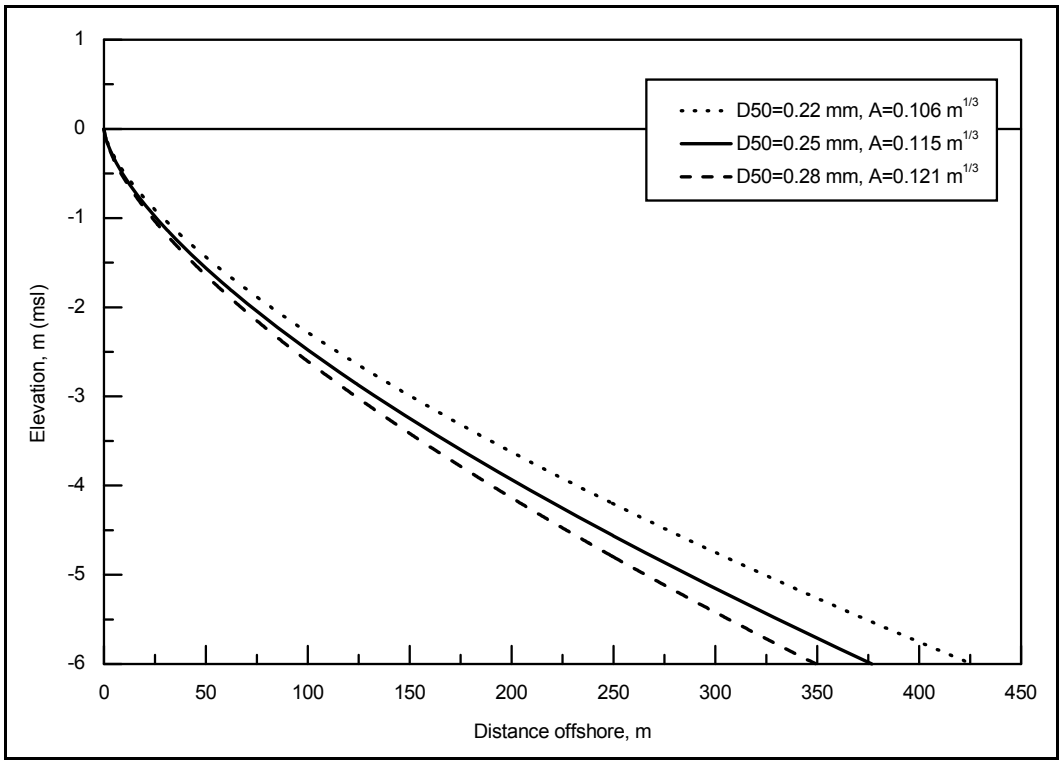

Figure V-4-16. Theoretical equilibrium profile shapes for different sand grain sizes

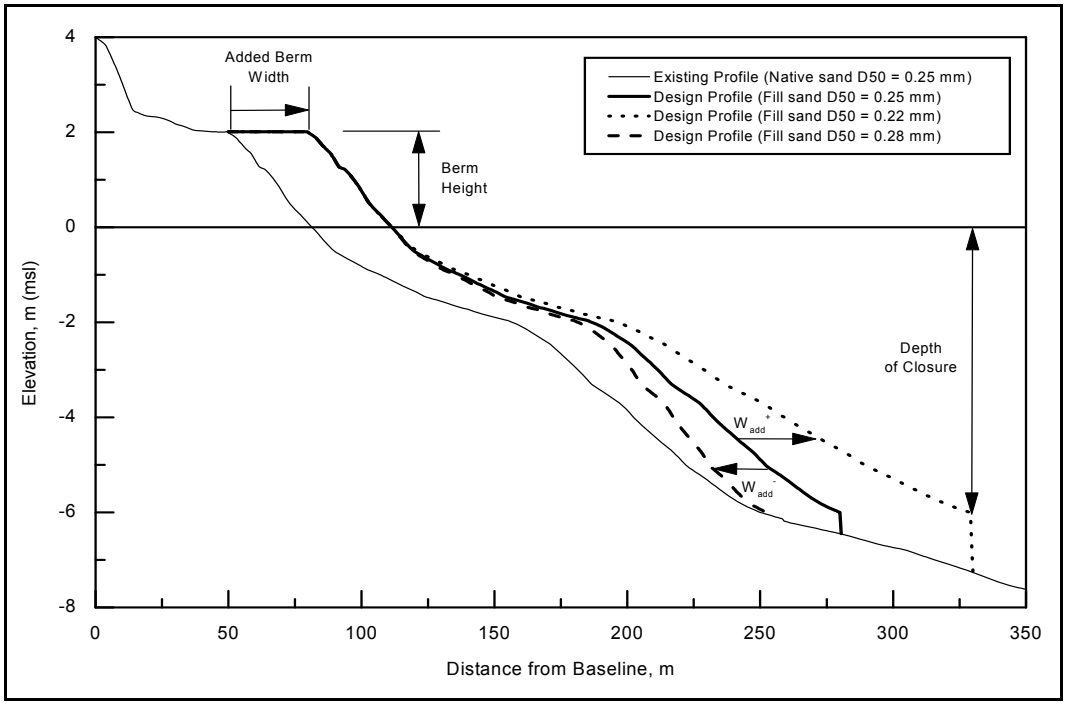

Figure V-4-17. Design profiles for different fill sand sizes

(a) Without-project condition.

- The existing or without-project condition is included in the optimization process to determine baseline damages. Morphologic features of the existing beach, such as dune height, berm width, and offshore profile shape, typically vary along the project study domain. To accurately estimate storm erosion response for the existing condition, a set of representative morphologic reaches should be developed to describe variations in profile shape along the project domain. The BMAP software can be used to define morphologic reaches by analyzing profiles, grouping similar profiles, and calculating an average representative profile for each reach.

- Profile characteristics that should be considered when developing morphologic reaches include dune height and width, berm width, nearshore and offshore profile slopes, sand grain size, presence of seawalls or other structures, and proximity to inlets. As part of the economic analysis to evaluate damages and benefits, the project domain is divided into a series of economic reaches based on value of property and infrastructure (see Part V-4-1-d). Boundaries of economic domains should also be considered in morphologic reach delineation to ensure that storm erosion modeling is consistent with the economic analysis.

(b) Storm selection.

- Evaluation of potential storm damages requires selection of a set of storms representative of future events that may impact the project area. The set of storms should reflect a range of intensities and frequencies of events consistent with the historical record. In developing the storm set, tropical and extratropical events should be treated distinctly because of differences in storm characteristics and frequencies of occurrence.

- One approach to storm selection has been to develop a set of storms characterized by peak surge return period ranging from frequent events (5-year return period or less) to extremely rare events (100-year return period). Peak surges for selected return periods are obtained from available stage-frequency information, and representative storm surge hydrographs are developed using assumed hydrograph shapes and durations. Differences in hydrograph shape between tropical and extratropical storms should be considered; tropical storms typically have much shorter durations. The storm surge hydrographs are combined with corresponding wave height and wave period time histories to fully describe the storms. Using this approach, the frequency of modeled responses are assumed to correspond to return periods of the input storm surges (e.g., a 50-year storm surge produces a 50-year erosion response). This assumption simplifies the analysis but is not strictly accurate because, in addition to peak storm surge, other factors influence the magnitude of erosion (storm duration, hydrograph shape, and wave characteristics). Inconsistencies may arise with this approach related to characterizing the storm based on peak surge alone. For example, a 20-year storm (where frequency is defined solely on maximum surge) may produce more erosion than a 50-year storm, if the 20-year storm has higher waves or a longer duration.

- An alternate and preferred approach is to develop a “training set” of storms by selecting events from historical records and/or hindcasts. A sufficiently long historical period is identified, such as 20 years for extratropical storms or 100 years for tropical storms. All historical events within the period exceeding a selected threshold are included in the training set. For example, all events which have a peak surge exceeding 0.3 m may be considered significant from a storm erosion standpoint and included in the training set. No return periods are assigned to storms in the training set a priori. Each storm is modeled for the existing condition and each project alternative to calculate corresponding erosion responses. Using the training set of storms and modeled responses, life cycle analyses are performed by employing the Empirical Simulation Technique (EST) to generate

frequency-of-occurrence relationships, whereby return periods are associated with storm responses rather than storm input. Scheffner and Borgman (1999) provide detailed guidance in applying the EST to coastal studies. Advantages of this approach are that it involves no arbitrary assignment of recurrence relationships and it utilizes historical rather than representative or hypothetical events to determine frequency-of-occurrence relationships. Part II discusses methods for estimated storm waves and water levels.

- Because water level is a primary factor controlling beach erosion, tide variations should be considered when developing the input storm set. Tide variations can be accounted for by combining storm surges with different tidal phases and ranges. For example, peak storm surges may be aligned with high tide, low tide, midtide preceding high tide, and midtide preceding low tide to generate four different but equally probable events derived from each base storm. Variations in tide ranges (neap, spring, and average) may also be considered in developing a full set of storms.

(c) Storm erosion modeling.

- Upon selection of design alternatives, characterization of the without-project condition, and selection of the storm set, storm-induced beach erosion modeling is performed to calculate parameters required for assessing economic damages based on beach erosion, flooding, and wave attack. The SBEACH model computes relevant storm response parameters such as recession distance, maximum water level and wave height at the shoreline, and wave runup. Required input to the model includes beach profiles describing the design alternatives and without-project condition, time-histories of storm water level, wave height and wave period, median sand grain size, and calibration parameters.
- Detailed examples and guidance for applying the SBEACH model to predict storm erosion are provided in the SBEACH technical report series (Larson and Kraus 1989; Larson, Kraus, and Byrnes 1990; Rosati et al. 1993; Wise, Smith, and Larson 1996; and Larson and Kraus 1998).

(d) Storm damage recurrence relationships and risk analysis. Modeled erosion responses are expressed in terms of frequency of occurrence for input to economic damage models. Typically, tropical and extra-tropical erosion responses are joined to generate a combined frequency curve spanning the recurrence intervals of interest. Risk and uncertainty of storm damage parameters can be addressed by developing mean-value frequency-of-occurrence curves together with confidence bands that indicate the variability or uncertainty associated with the calculated storm responses.

- The EST and supporting analysis tools can be used to calculate mean-value frequency curves and confidence bands. Figure V-4-18 shows an example of frequency-of-occurence relationships generated by the EST technique. The solid line represents the mean or expected value of beach recession as a function of return period, and the dashed lines show the 90 percent confidence band, indicating that 90 percent of variability in beach recession for a given return period falls within these limits.

(6) Cross-sectional fill volume requirements.

(a) A key quantity in beach-fill design is the volume of sand required to produce the desired beach cross-section. The design profile is determined using methods presented in Part V-4-1-f-(4) and results from the optimization process outlined in Part V-4-1-f-(5). The berm width is then increased to reflect the amount of advance nourishment needed to maintain the design profile prior to the first renourishment. The modified design profile shape, which includes advance nourishment, is then estimated

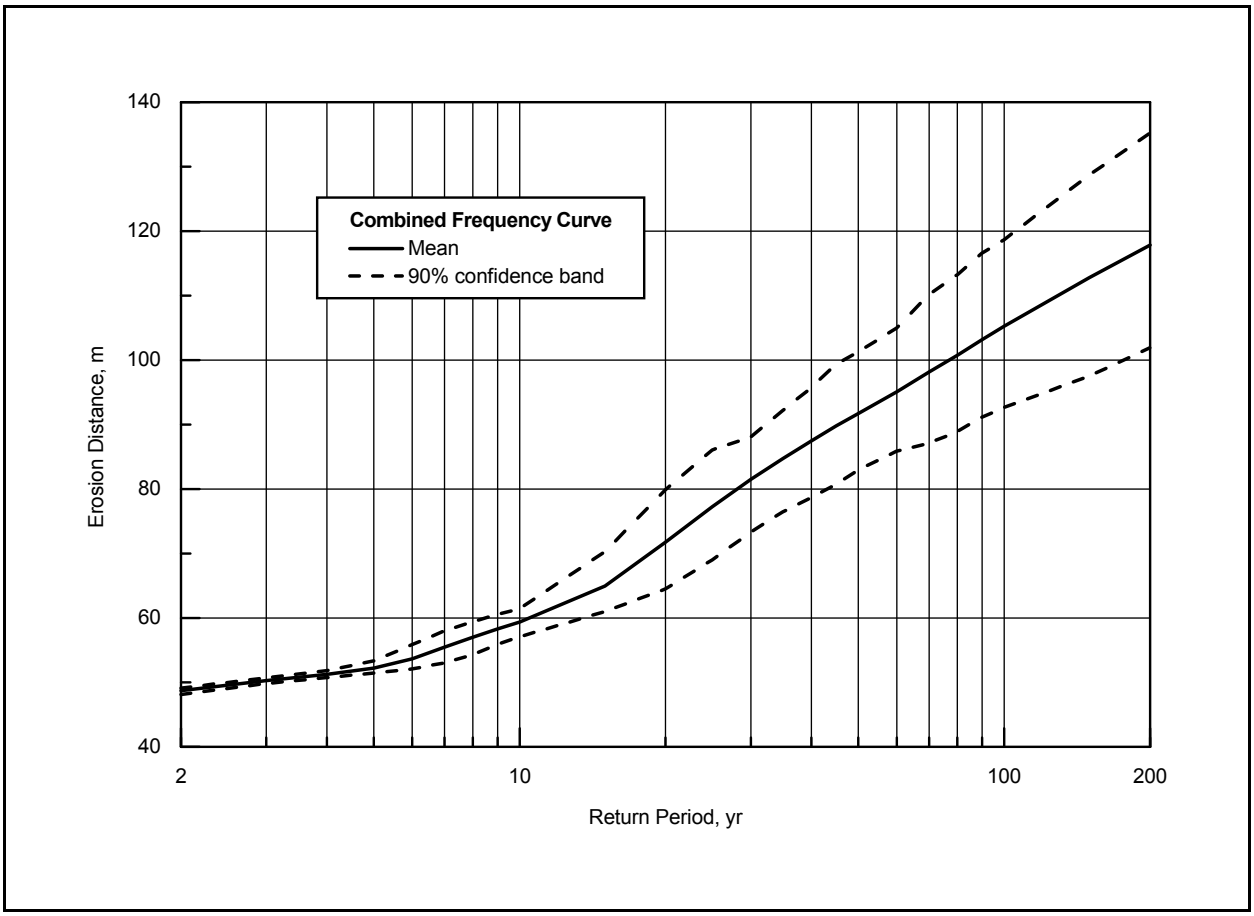

Figure V-4-18. Combined tropical and extratropical erosion-frequency curve

by translating the design profile at elevations between the design berm elevation and the depth of closure (see Figure V-4-14) by an amount equal to the advance nourishment berm width. The sectional fill volume required for initial construction (volume per unit length of shoreline) is calculated as the difference in cross-sectional area between the preproject profile and the modified design profile shape. Example V-4-2 illustrates calculation of sectional fill volume for a case where the preproject profile is in a severely eroded, unnatural, condition.

(b) Advance nourishment beach width, and design berm width, might not have uniform values from reach to reach within the project domain. Variations in the desired level of protection, assessment of long-term fill evolution and renourishment requirements, and consideration of the potential for hot spot formation, will most likely lead to alongshore differences in desired beach width. Therefore, the required sectional fill volume also will vary by reach. Volume calculations for the entire project domain are made by summing results on a reach-by-reach basis, where the volume requirement in a particular reach is calculated as the product of the cross-sectional volume requirement and the length of shoreline in that reach.

(c) For the case of a healthy (sediment-rich), preproject beach profile and a fill material that has a median grain size equal to that of the native beach sand, the volume V per unit length of shoreline required to produce a beach width W can be estimated by

$$V = W\left(B+D_C\right) \tag{V-4-6}$$

EXAMPLE PROBLEM V-4-2

FIND:

Volume per unit length of shoreline required to widen the dry beach by 30 m (at the msl datum), includes both the design berm and advance nourishment. Plot the existing profile and the final design profile.

GIVEN:

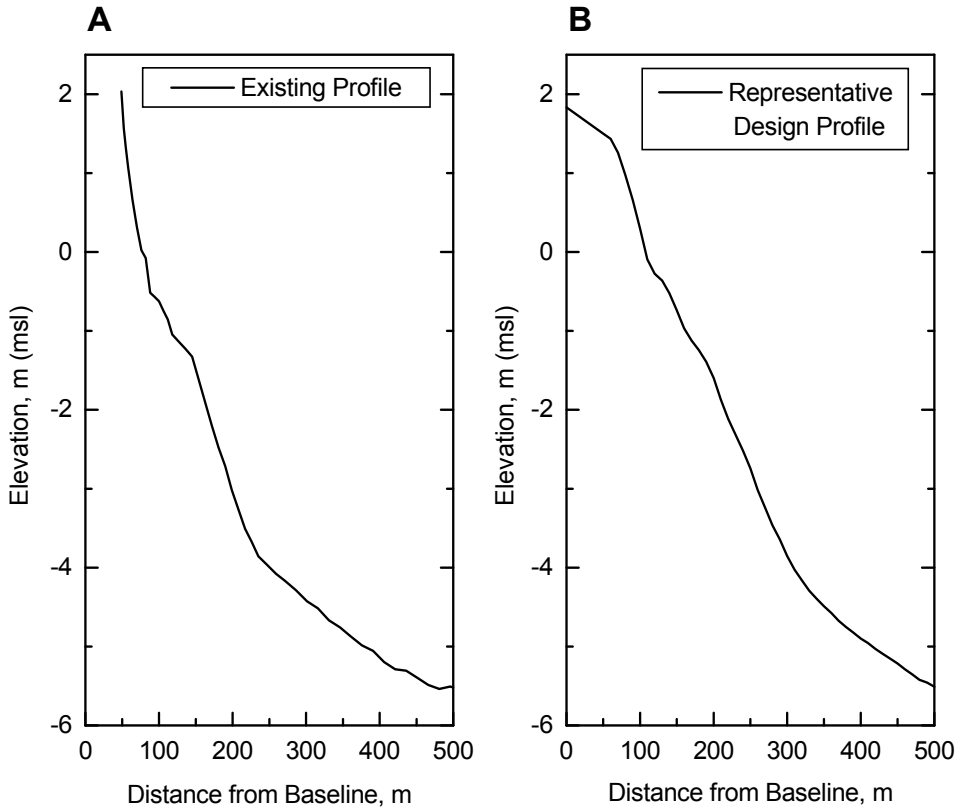
Preproject beach profile is not representative of healthy (sediment-rich) conditions.

Existing condition beach profile (Example Figure A).

Representative design beach profile reflecting healthy (sediment-rich) conditions (Example Figure B).

Berm height of 1.5 m and depth of closure of 5.5 m.

Native and fill sand median grain size are the same.



(Continued)

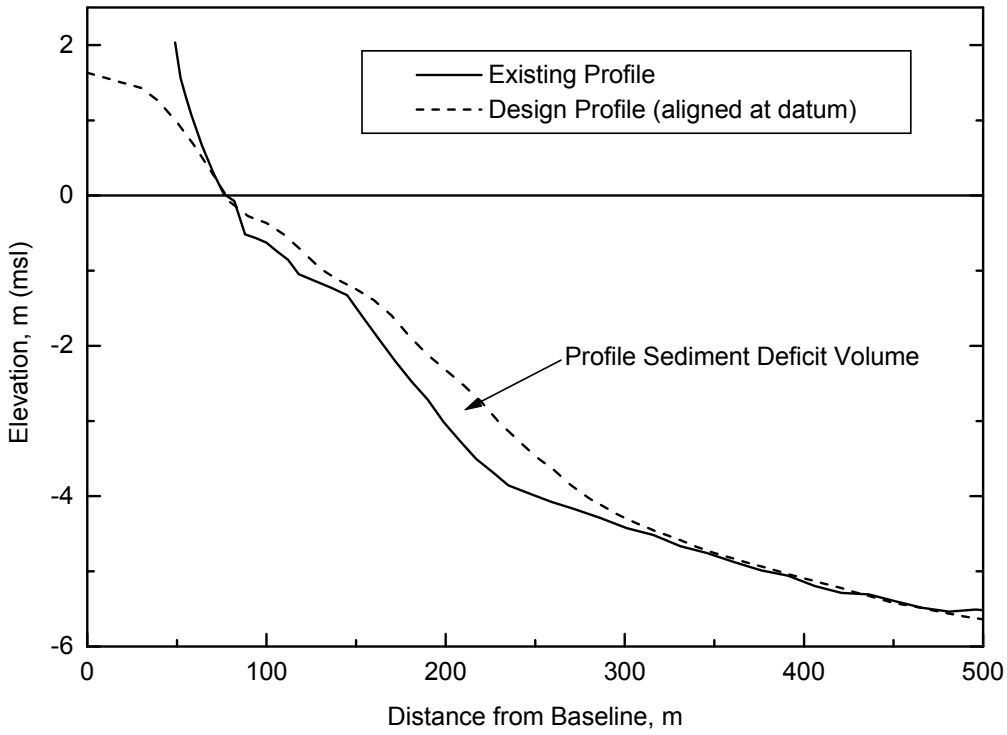
EXAMPLE PROBLEM V-4-2 (Continued)

SOLUTION:

Step 1; Compute sediment deficit volume in existing profile.

Align existing and representative design profile at MSL datum. Compute volume difference between existing and representative design profiles. This volume represents the sediment deficit between the existing condition and the healthy or sediment-rich condition expected to occur after nourishment. The elevation at which the existing and design profiles are aligned will influence the magnitude of the computed profile sediment deficit. In the present example the MSL datum is selected because here beach width is defined relative to this datum. The sediment deficit in the pre-project profile can vary significantly along the project reach. The computed pre-project sediment deficit in the beach profile is 100 m^3/m in this example and is illustrated in Example Figure C. The data manipulations and calculations discussed in this example are automated within the BMAP software (Sommerfeld et al. 1994).

C



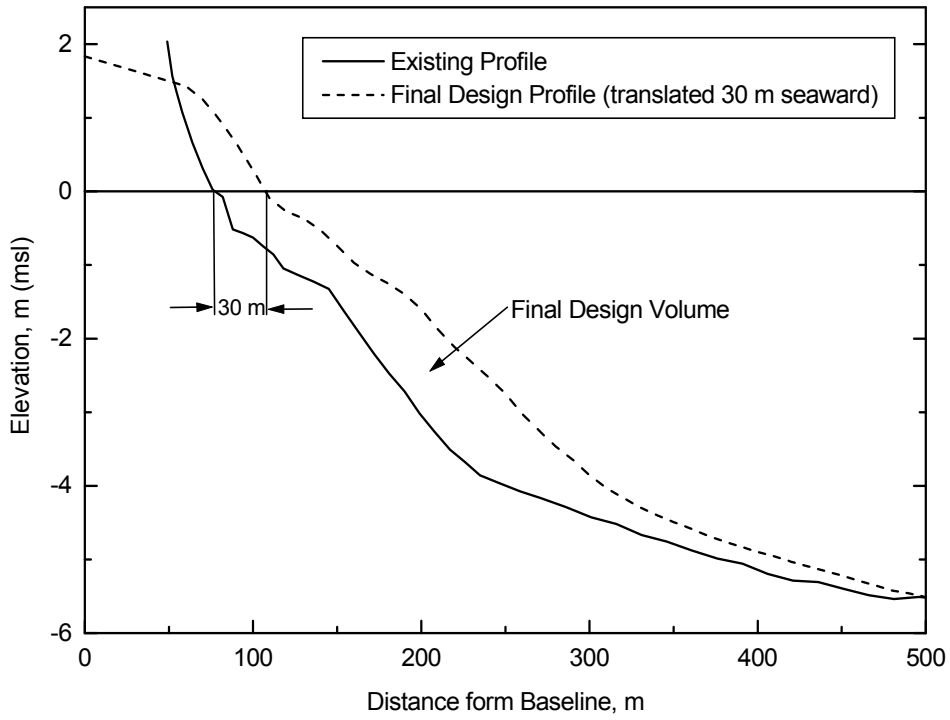
(Continued)

EXAMPLE PROBLEM V-4-2 (Concluded))

Step 2; Compute required sectional fill volume.

Translate the aligned design profile (from Step 1) 30 m seaward to obtain the final design profile. Compute volume difference between the existing and final design profile between the 1.5-m berm elevation and the 5.5-m depth of closure. This volume represents the total sectional fill volume required to advance the dry beach 30 meters seaward at the msl datum. The total sectional fill volume can vary significantly from reach to reach. In the present example, the total sectional fill volume is 298 m^3/m and is illustrated in Example Figure D. Approximately one-third of the total sectional volume was required to offset the sediment deficit associated with the over-steepened erosion-stressed condition of the existing profile.

D



where

B = the design berm elevation

D_C = the depth of closure

Equation V-4-6 is derived by computing the area of the parallelogram formed by translating the existing profile a distance W as shown in Figure V-4-14. Example V-4-3 illustrates this calculation.

EXAMPLE PROBLEM V-4-3

FIND:

Sectional fill volume (fill volume per unit length of shoreline) required to widen the dry beach by 30 m.

GIVEN:

Preproject beach profiles are representative of healthy (sediment-rich) conditions.
Berm height of 2.5 m and depth of closure of 6 m.
Fill material (composite median diameter) same as native beach sand.

SOLUTION:

Equation V-4-6 gives

$$V = 30(2.5 + 6) = 255\ m^3/m$$

(d) Sectional volume computations in situations when the fill and native sediments differ should be made by considering differences between the existing profile and the design profile shape as outlined in Part V-4-1-f-(4) and illustrated in Figure V-4-17. The BMAP software provides capabilities for calculating sectional fill volume in cases where native and fill sediments differ in median grain size.

(e) Equilibrium profile concepts also can be used directly to make preliminary estimates of required fill volume, when the native and fill sediments have differing composite median grain sizes. While not recommended for final fill volume computations, these methods provide valuable insight regarding the implications of using fill material with different grain size characteristics. Dean (1991) defines three basic types of nourished profiles. Figure V-4-19 shows an intersecting profile, where the profile after nourishment intersects the native profile at a depth shallower than the depth of closure; a nonintersecting profile, where the nourished profile does not intersect the native profile before closure depth; and a submerged profile, where after equilibrium there is no dry beach. A submerged profile is a special case of a nonintersecting profile which occurs when insufficient volume is placed to fully develop the underwater equilibrium profile. Dean (1991) shows that whether a profile is intersecting or nonintersecting is determined by the following inequality:

$$W\left(\frac{A_N}{D_C}\right)^{3/2} + \left(\frac{A_N}{A_F}\right)^{3/2} \begin{cases} < 1, & \text{Intersecting profile} \\ > 1, & \text{Nonintersecting profile} \end{cases} \qquad \text{(V-4-7)}$$

- For fill material different from the native beach sand, cross-sectional volume requirements should be estimated with consideration given to the differences in profile slope given by equilibrium profile concepts. Based on theoretical equilibrium beach profile shapes, where A_N and A_F are the A parameters for native and fill sands, respectively (see Table III-3-3 for values of the A parameter for different sand sizes), fill sand that is finer than the native material will always produce a nonintersecting profile according to Equation V-4-7. Fill sand that is coarser than native sand may

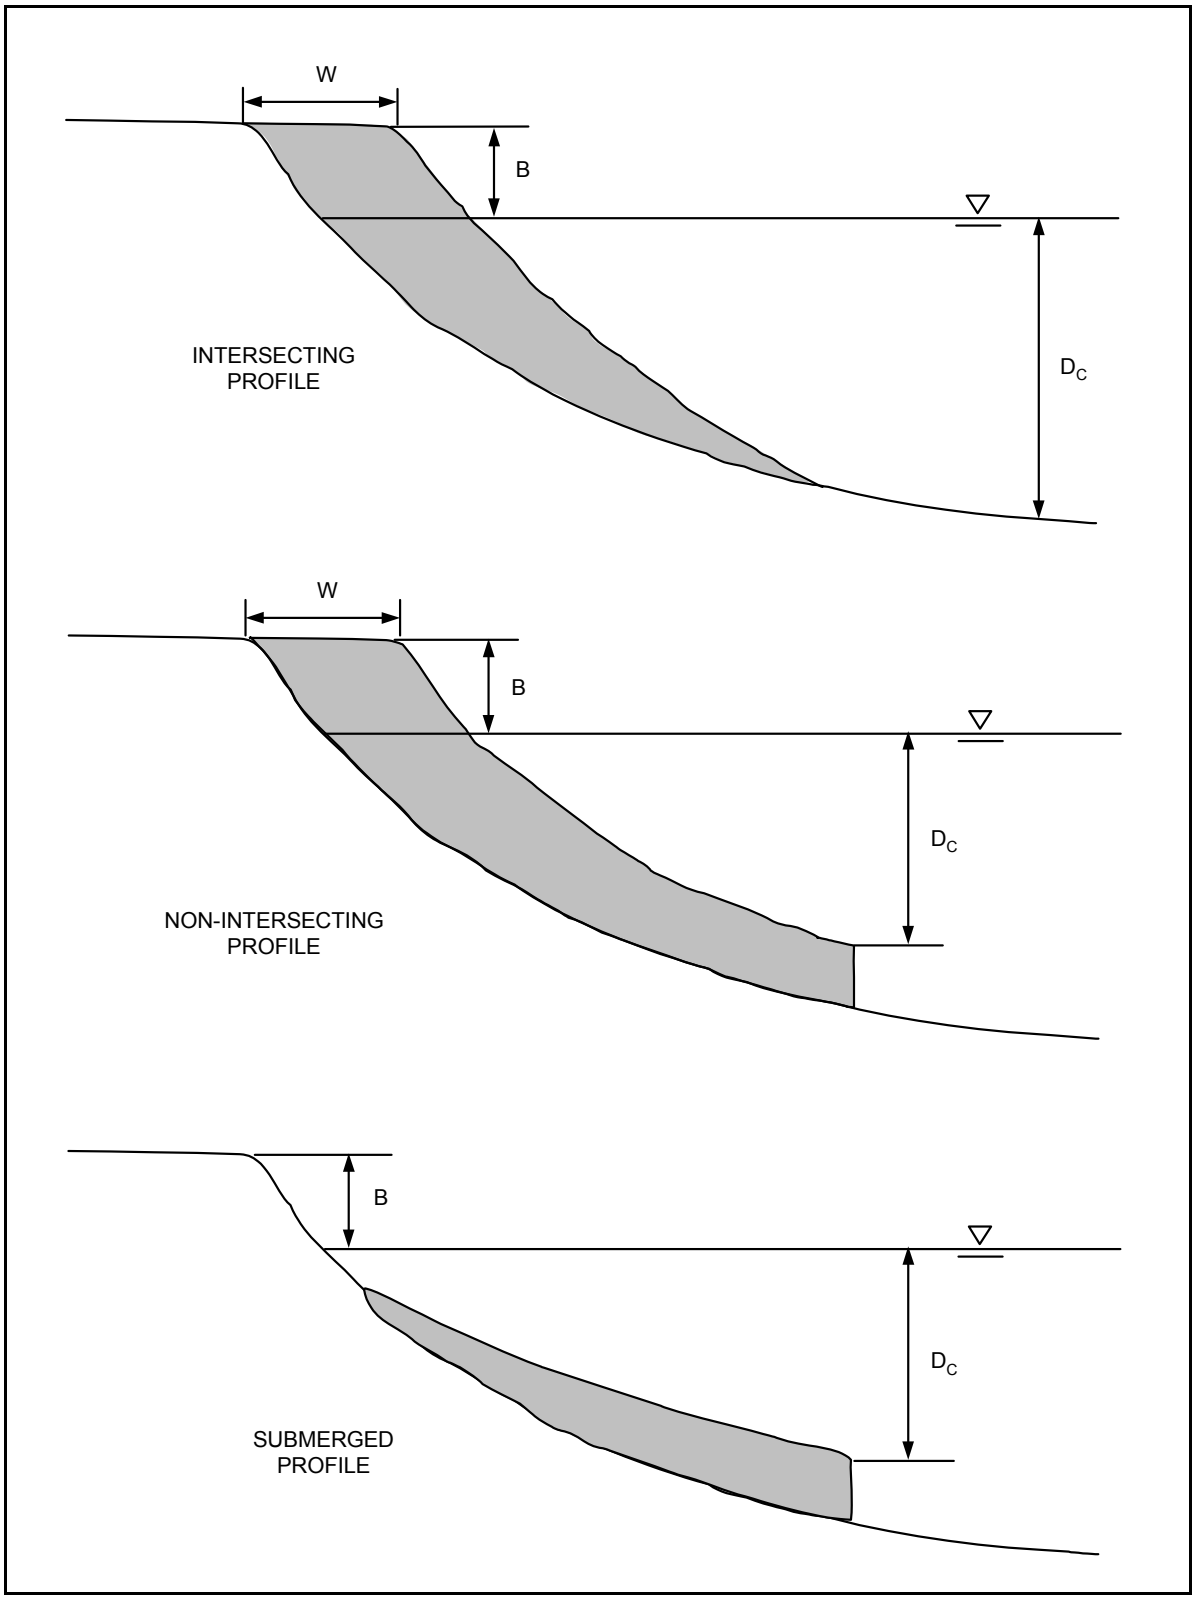


Figure V-4-19. Three basic types of nourishment profiles (adapted from Dean 1991)

produce either an intersecting or a nonintersecting profile. For a nonintersecting profile, the volume of sand per unit length of shoreline that must be placed before there is any dry beach after equilibrium is estimated as

$$V = \frac{3}{5}\left(\frac{D_C}{A_F}\right)^{5/2}\left(A_N - A_F\right) \tag{V-4-8}$$

- If the volume placed is less than that given by Equation V-4-8, a submerged profile is produced after equilibration. Example V-4-4 illustrates volume calculations using Equation V-4-8.

- For nonintersecting profiles with a dry beach after equilibrium (i.e., volume placed is equal to or exceeds that in Equation V-4-8) the volume per unit length of beach required to produce a dry beach of width W may be estimated as

$$V = WB + \frac{3}{5}\left(\frac{D_C}{A_F}\right)^{5/2}\left(A_N\left[1 + W\left(\frac{A_F}{D_C}\right)^{3/2}\right]^{5/3} - A_F\right) \tag{V-4-9}$$

Example V-4-5 illustrates volume calculations using Equation V-4-9.

For intersecting profiles, the volume per unit length of beach required to advance the beach a distance W after equilibriation can be estimated by

$$V = WB + \frac{\frac{3}{5}W^{5/3}A_N A_F}{\left(A_F^{3/2} - A_N^{3/2}\right)^{2/3}} \tag{V-4-10}$$

- It is noted that the depth of closure does not enter Equation V-4-10, because by definition, the nourished profile intersects the native profile landward of the depth of closure (see Figure V-4-19). Example V-4-6 illustrates volume calculations using Equation V-4-10.

- Equilibrium profile methods do not account for a sediment deficit in the preproject beach profile, which is common along erosion-stressed shorelines where beach nourishment projects are typically considered. The methods also only account for volume below the berm elevation. Volume contained in the dune must be added to the estimate. These methods are recommended for quick calculations, and to compliment calculations based on differences between preproject profile shapes and design profiles. They are not recommended for use in computing final sectional fill volume estimates.

- A third method for computing sectional fill volume when fill and native sediments have different grain size characteristics is to translate the healthy, sediment-rich, design profile as shown in Figures V-4-14 and 15, calculate the volume using Equation V-4-6 , and then apply the overfill factor to the volume determined from profile translation (see Part V-4-1-e-(3i) and Example V-4-1). The overfill factor would also be applied to any advance renourishment volume. Dune volume must be

EXAMPLE PROBLEM V-4-4

FIND:

Sectional fill volume that must be placed before any dry beach width is added after equilibrium. Disregard any volume necessary to makeup for a preproject sediment deficit in the beach profile.

GIVEN:

Berm height of 2.5 m and depth of closure of 6 m. Native sand median grain size of 0.26 mm and fill sand median grain size of 0.19 mm.

SOLUTION:

Values of the A parameter for native and fill sand are read from Table III-3-3.

$A_N = 0.117\ m^{1/3}$, $A_F = 0.097\ m^{1/3}$

Profile is nonintersecting because $A_F < A_N$, therefore Equation V-4-8 is applicable.

Equation V-4-8 gives

$$V = \frac{3}{5} \cdot \left(\frac{6}{0.097} \right)^{5/2} \cdot (0.117 - 0.097) = 361\ m^3/m$$

This illustrates that when filling with sand finer than the native beach material, a significant amount of sand must be placed before any dry beach width is produced after equilibrium. Note that the sectional fill volume is 140 percent of the sectional fill volume computed in Example V-4-3, and the present example will produce no additional dry beach width whereas 30 m of additional dry beach width is obtained in Example V-4-3.

added. The overfill method can compliment calculations made using the other methods, but it is not recommended for final fill volume computations.

g. Evaluating project longevity

The longevity of a beach nourishment project is primarily determined by the degree to which the placed sand volume addresses any preproject profile volume deficit, and the rate at which fill material is transported out of the project domain in the alongshore direction, i.e, lateral spreading losses. Wave-driven longshore sand transport processes are the major cause of lateral spreading. Projects tend to be built in erosional areas where waves act to move sand out of the project domain, in a long-term, net sense. In addition to the wave climate and its interaction with the local morphology, there is another important aspect of lateral spreading. The project itself creates a perturbation in shoreline and beach orientation, particularly where the fill transitions into the adjacent beaches. At these transitions, local wave transformation patterns and consequently the longshore sand transport regime are altered, which can lead to high rates of fill loss from the ends of the project (often called end losses). Coastal structures that exist within the project domain, or are built as part of the project, also can impede alongshore sand movement and influence the rate of sand loss. Grain size characteristics of the fill material may be a factor in determining beach-fill longevity. Part III discusses dependency of longshore sand transport on grain size. However, in practice, the role of grain size is not usually considered in evaluating lateral spreading losses.

EXAMPLE PROBLEM V-4-5

FIND:

Volume per unit length of shoreline required to widen the dry beach by 30 m. Disregard any volume necessary to makeup for a preproject sediment deficit in the beach profile.

GIVEN:

Berm height of 2.5 m and depth of closure of 6 m. Native sand median grain size of 0.27 mm and fill sand median grain size of 0.18 mm.

SOLUTION:

Values of the A parameter for native and fill sand are read from Table III-3-3.

$A_N = 0.119\ \text{m}^{1/3}$, $A_F = 0.094\ \text{m}^{1/3}$

Profile is nonintersecting because $A_F < A_N$, therefore Equation V-4-9 is applicable.

Equation V-4-9 gives

$$V = 30 \cdot 2.5 + \frac{3}{5} \cdot \left(\frac{6}{0.094} \right)^{5/2} \cdot \left(0.119 \cdot \left[1 + 30 \cdot \left(\frac{0.094}{6} \right)^{3/2} \right]^{5/3} - 0.094 \right) = 796\ \text{m}^3/\text{m}$$

By comparing with Example V-4-3, it is seen that using the finer material specified in this example requires 3.1 times the volume required using compatible material to generate the same equilibrium beach width. This example illustrates that much higher fill volumes are required when using finer-than-native sand to obtain a given beach width, which is consistent with sand compatibility calculations performed using the overfill ratio (see Example V-4-1).

Although alongshore spreading of fill material represents a loss to the project area, this material is in most cases transported to adjacent beaches. Nearby beaches, particularly those downdrift of the project, realize protective benefits from the neighboring project. Over the life of a beach nourishment project, adjacent beach benefits can be quite significant. If the project is built adjacent to an inlet with navigation channels, the impact of the nourishment project on channel operation and maintenance should be assessed.

(1) Periodic renourishment. Beginning immediately after construction, fill material will be lost from the project due to lateral spreading. Periodic renourishment will be required to maintain the desired beach cross section. It should be recognized by the designer that year-to-year loss rates can deviate from the long-term average erosion rates. In addition to end effects at transitions, losses are significantly influenced by the occurrence of major storms. Annual losses will likely vary from year to year because of the dependency on storm activity. Therefore, while an average renourishment interval and quantity can be estimated, the actual

EXAMPLE PROBLEM V-4-6

FIND:

Volume per unit length of shoreline required to widen the dry beach by 30 m. Disregard any volume necessary to makeup for a preproject sediment deficit in the beach profile.

GIVEN:

Berm height of 2.5 m and depth of closure of 6 m. Native sand median grain size of 0.27 mm and fill sand median grain size of 0.36 mm.

SOLUTION:

Values of the A parameter for native and fill sand are read from Table III-3-3.

$A_N = 0.119\ m^{1/3}$, $A_F = 0.137\ m^{1/3}$

Determine whether profile is intersecting or nonintersecting.

Equation V-4-7 gives

$$30 \cdot \left(\frac{0.119}{6}\right)^{3/2} + \left(\frac{0.119}{0.137}\right)^{3/2} = 0.893 < 1$$

therefore, the profile is intersecting and Equation V-4-10 is applicable.

Equation V-4-10 gives

$$V = 30 \cdot 2.5 + \frac{\frac{3}{5} \cdot 30^{5/3} \cdot 0.119 \cdot 0.137}{\left(0.137^{3/2} - 0.119^{3/2}\right)^{2/3}} = 137\ m^3/m$$

By comparing with Example V-4-3, it is seen that using the coarser fill material specified in this example requires approximately 45 percent less volume than that required using compatible material, to generate the same equilibrium beach width.

required interval/quantity will vary depending on the climatic conditions that occur. Ideally, the need for renourishment will be determined by monitoring performance of the fill. Some level of renourishment, or maintenance such as redistribution of sand within the project domain, is needed when the project design cross section is no longer in place. In this situation, the desired level of protection is compromised. However, the schedule for periodic renourishment may be more fixed, in the sense that budgeting for it may have been set at the outset of the project. If renourishment is needed before the scheduled time, it can be handled as an emergency maintenance action (see Part V-4-1-m). Should permanent changes to the periodic renourishment cycle (volume and/or frequency) be necessary, a reformulation of the project may be needed. Having an adequate project monitoring plan in place is very important. Monitoring data are particularly valuable if the project does not perform as designed. The data can be analyzed to evaluate the nature of the conditions that prompted the need for unexpected renourishment and assess their frequency of occurrence. Analysis of the

monitoring data also can shed light on a design deficiency. Monitoring and analysis of data are discussed in more detail in Part V-4-1-l.

(2) Advance nourishment. Advanced nourishment is the volume of sand that is placed for "sacrificial" purposes during initial construction to maintain the design fill section during the initial renourishment interval (i.e., the time from project completion to the first scheduled renourishment). The magnitude of the advance nourishment should be determined based on results from work done to assess lateral spreading losses and volumetric losses due to long-term shoreline recession, i.e., the historic or background erosion rate. The postproject shoreline erosion rate will be greater than the preproject historic or background erosion rate in those cases where the preproject beach featured a sediment deficit or was otherwise sediment starved. For example, project reaches that feature an armored shoreline may historically exhibit little or no erosion, but can exhibit significant background erosion when replenished with sand fill. Advanced nourishment quantities are included in the initial total construction volume.

(3) Fill parameters affecting lateral spreading. Both simple and detailed methods are available for estimating the rate of alongshore spreading, and identifying renourishment requirements (both volume and interval). Simple methods treat the incident wave climate in a more approximate manner, through use of a representative wave height and neglecting wave direction. They consider the background erosion rate as an input parameter, and they assume the erosion rate is uniform over the project domain. Simple methods are generally most applicable to cases that do not involve coastal structures. On the other hand, detailed methods treat the effects of coastal structures and wave climate more rigorously. They address the issue of alongshore variation in wave conditions that produce the background erosion rates, as well as alongshore variations in erosion rates within the project bounds. Detailed methods treat the directionality of the wave climate. Dominant wave directions become important for projects constructed in the vicinity of engineered structures, littoral barriers, or sediment sinks, such as inlets. Detailed methods consider the actual planform layout of the shoreline and structures, whereas simple methods represent them in an idealized manner. In this section, analytical solutions to the one-line theory of shoreline evolution are examined to reveal the importance of the following beach nourishment design parameters on lateral spreading losses: length of the nourishment project, incident wave climate, and ambient background erosion. The analytical approach is extremely useful in preliminary design and to gain an understanding of the relative importance of these parameters. Detailed methods are also presented later, which rely on the use of numerical models to evaluate project longevity.

(a) Effect of fill length.

- In this section, the effect of beach-fill length (the alongshore extent of the fill) on project longevity will be examined. The influence of length is best illustrated by considering the most simple case of an initially rectangular beach fill constructed on a long straight beach with no background erosion. This situation was first introduced in Part III-2 of this manual where the linearized equation of longshore sediment transport was combined with the equation of continuity to develop the one-line theory of shoreline evolution (see Equations III-2-25 and III-2-26). A number of analytical solutions to this equation were presented. In this section, Equations III-2-31 and III-2-32 will be examined further to extract additional information pertinent to beach nourishment design. Upon close examination of Equation III-2-31 it is seen that the important parameter is

$$\frac{a}{2\sqrt{\varepsilon t}} \tag{V-4-11}$$

where a is one-half the length of the rectangular project, ϵ is the "shoreline diffusivity" parameter defined in Equation III-2-26, and t is time. Here it is seen that if the quantity in Equation V-4-11 is the same for two

different projects their planform evolution would be the same. However, if two projects were exposed to the same wave climate but had different alongshore lengths, then the project with the greatest length would be predicted to last longer (with all other factors being the same). In fact, according to Equation III-2-32 the longevity of a project varies as the square of its length. If more than 50 percent of the placed beach-fill volume remains within the placement area ($0.5<p(t)<1.0$), Equation III-2-32 can be approximated using the following relationship (with an accuracy of ±15 percent).

$$p(t) = 1 - \frac{\sqrt{\varepsilon t}}{a\sqrt{\pi}} \tag{V-4-12}$$

- Example Problem V-4-7 illustrates the importance of project length on project longevity. In this example, a fill with twice the length will last four times as long. The effect of project length on fill longevity is critical for short fills. It is also important in long fills which may be built in stages. For example, construction may be limited to a particular season to avoid turtle nesting season or the tourist season. Therefore it may take 2 or 3 years to complete the work. Projects built in stages will temporarily perform as short fills until the other portions of the project are completed. Actual loss rates from the constructed subreaches will likely exceed losses predicted for the completed as designed project. Any short-term accelerated losses due to construction of the project in stages should be factored into the advance nourishment quantity.

(b) Effect of wave environment.

- The rate of alongshore spreading losses is also a function of the incident wave climate. In Equation III-2-26 it is seen that the shoreline diffusivity term (ϵ) varies inversely with the breaking wave height raised to the 5/2 power. Dean and Yoo (1992) present a method for calculating a representative wave height and period based on assumptions of Rayleigh-distributed wave height, shallow-water linear-wave theory, simplified and linearized wave refraction and shoaling relations, and a constant proportionality between breaking wave height and corresponding water depth. Use of an effective wave height is recommended in the calculation of the shoreline diffusivity term (ϵ). Dean and Yoo (1992) defined the effective wave as one that produces the same spreading of the beach nourishment material as the actual time-varying wave conditions (expressed as pairs of height and period). They provided the following equation to calculate the effective wave height, H_{eff},

$$H_{eff} = \left(\frac{\frac{1}{N}\sum_{n=1}^{N} (K_s H_s^n)^{2.4} \frac{\left(C_{go}^n\right)^{1.2}}{C_*^n}}{\frac{1}{N}\sum_{n=1}^{N} \frac{\left(C_{go}^n\right)^{1.2}}{C_*^n}} \right)^{\frac{1}{2.4}} \tag{V-4-13}$$

where K_s is the proportionality factor between significant deepwater wave height and effective deepwater wave height and is equal to 0.735 (Dean and Yoo 1992), H^n_s is the significant wave height of the n^{th} record in the time series of N wave records, C^n_{go} is the deepwater wave group speed of the n^{th} record, and C^n_* is the wave celerity at breaking of the n^{th} record. The effective wave period T_{eff} is defined as the period corresponding to the expression in the denominator.

EXAMPLE PROBLEM V-4-7

FIND:

The "half-life" of the specified beach fills (time at which 50 percent of the beach-fill material remains within the placement area).

GIVEN:

Both projects have a rectangular planform and differ only in alongshore length. Beach fill A has an alongshore length of 3 km, whereas beach fill B has an alongshore length of 6 km. Both projects are subjected to the same wave environment.

Assume:

$K = 0.77$	$\rho_s/\rho = 2.65$
$H_b = 0.95$ m	$n = 0.4$
$C_{gb} = (g\ h_b)^{1/2}$	$d_b = 2.5$ m
$h_b = H_b/0.78$	$d_c = 6.0$ m
$g = 9.81$ m/s^2	

SOLUTION:

Equation III-2-26 gives

$$\epsilon = \frac{0.77(0.95)^{2.5}\sqrt{9.81/0.78}}{8} \cdot \frac{1}{(2.65-1)} \cdot \frac{1}{(1-0.4)} \cdot \frac{1}{(2.5+6.0)} = 0.03568\ \frac{m^2}{sec}$$

Solving Equation V-4-12 for t and p(t) = 0.5 gives

$$t_{50\%} = \frac{a^2 \pi}{4 \epsilon}$$

Half-life of beach fill A

$$t_{50\%} = \frac{(1500)^2 (3.14)}{(4)(0.03568)} = 49.526 X 10^6 \text{ sec} \cong 1.57 \text{ years}$$

Half-life of beach fill B

$$t_{50\%} = \frac{(3000)^2 (3.14)}{(4)(0.03568)} = 198.102 X 10^6 \text{ sec} \cong 6.28 \text{ years}$$

- Example Problem V-4-8 illustrates the relative importance of the breaking wave height on the expected longevity of a beach-fill project, with all other factors being equal. In this example, a 19 percent increase in breaking wave height resulted in a 35 percent decrease in the project's half-life, which is a measure of fill longevity.

- Differences in longevity are even more pronounced if greater differences in breaking wave height are considered. For example, if the average summer breaking wave height at the project site is 0.6 m, and the average winter breaking wave height is 1.2 m, one would expect that loss rates to be much higher in the winter compared to those in the summer (because of the diffusivity parameter dependence on breaking wave height raised to the 2.5 power). Many beach-fill projects are built during the winter season. The strong dependence of longevity on wave environment helps explain the high rates of lateral spreading loss that can occur during the winter season.

(c) Effect of background shoreline recession.

- The effect of project length and the incident wave environment have been shown to have a significant influence on expected project longevity. The analysis presented to this point has not considered losses due to ambient coastal processes, such as a gradient in the longshore sand transport rate, which tends to produce background erosion at the project site. Equation V-4-12 can be modified to include the effect of a uniform background shoreline recession rate, E , as follows:

$$p(t) = 1 - \left(\frac{\sqrt{\epsilon t}}{a\sqrt{\pi}} + \frac{Et}{\Delta y_o} \right) \qquad 0.5 < p(t) < 1.0 \tag{V-4-14}$$

- Solving Equation V-4-14 for time t yields an expression that predicts the time required for a fraction (1-p) of the material placed to be lost from the project area (or equivalently the time at which a fraction p of the material placed remains in the project area). This expression is provided as

$$t_p = \frac{-m - \sqrt{m^2 - 4ln}}{2l} \qquad for\ \sqrt{\epsilon t}/a < 1.0 \tag{V-4-15}$$

in which

$$l = \left(\frac{E}{\Delta y_o} \right)^2$$

$$m = \frac{2E(p-1)}{\Delta y_o} - \frac{\epsilon}{\pi a^2}$$

and

$$n = (1-p)^2$$

EXAMPLE PROBLEM V-4-8

FIND:

The "half-life" of the specified beach fills (time at which 50 percent of the beach-fill material remains within the placement area).

GIVEN:

Both projects have a rectangular planform with an alongshore length of 6 km. The effective breaking wave height at beach fill A is 0.80 m whereas the effective breaking wave height at beach fill B is 0.95 m.

$K = 0.77$	$\rho_s/\rho = 2.65$	$C_{gb} = (g\ h_b)^{1/2}$	$n = 0.4$
$h_b = H_b/0.78$	$g = 9.81\ m/s^2$	$d_b = 2.5\ m$	$d_c = 6.0\ m$

SOLUTION:

Equation III-2-26 gives: (for beach fill A)

$$\epsilon = \frac{0.77(0.80)^{2.5}\sqrt{9.81/0.78}}{8} \cdot \frac{1}{(2.65-1)} \cdot \frac{1}{(1-0.4)} \cdot \frac{1}{(2.5+6.0)} = 0.02322\ \frac{m^2}{sec}$$

(for beach fill B)

$\epsilon = 0.03568\ m^2/sec$ (see EXAMPLE PROBLEM V-4-7)

Solving Equation V-4-12 for t and p(t) = 0.5 gives

$$t_{50\%} = \frac{a^2 \pi}{4 \epsilon}$$

Half-life of beach fill A

$$t_{50\%} = \frac{(3000)^2 (3.14)}{(4)(0.02322)} = 304.420 \text{X} 10^6\ sec \cong 9.65\ years$$

Half-life of beach fill B

$$t_{50\%} = \frac{(3000)^2 (3.14)}{(4)(0.03568)} = 198.102 \text{X} 10^6\ sec \cong 6.28\ years$$

where Δy_o is the initial dry beach width (after cross-shore equilibration), E is the historical shoreline recession rate and a is the beach-fill half length. Example Problem V-4-9 illustrates the effect of background erosion rate. Comparison of results from this example with results from Example V-4-7 show that the specified background erosion rate decreased the half-life of the fill by about 20 percent. Note that the historical shoreline erosion rate E, may underestimate the postnourishment erosion rate if the preproject beach is armored or otherwise features a deficit in sand volume or sand supply.

EXAMPLE PROBLEM V-4-9

FIND:

The approximate time required for 50 percent of the placed beach fill volume to be lost from the placement area due to alongshore spreading and a background shoreline recession rate of 0.5 m/year.

GIVEN:

Assume the planform of the beach fill is initially rectangular with an alongshore length of 6 km and an estimated offshore width of 50 m (after equilibration).

Assume:	$K = 0.77$	$h_b = H_b/0.78$	$n = 0.4$
	$H_b = 0.95$ m	$g = 9.81$ m/s^2	$d_b = 1.5$ m
	$C_{gb} = (g\ h_b)^{1/2}$	$\rho_s/\rho = 2.65$	$d_c = 6.0$ m

SOLUTION:

Equation III-2-26 gives $\epsilon = 0.03568$ m^2/sec (see EXAMPLE PROBLEM V-4-7)
Equation V-4-15 gives

$$l = \left(\frac{E}{\Delta y_o}\right)^2 = \left(\frac{0.5}{50}\right)^2 = 0.0001 \text{ years}^{-2}$$

$$m = \frac{2E(p-1)}{\Delta y_o} - \frac{\epsilon}{\pi a^2} = \frac{(2)(0.5)(.5-1)}{50} - \frac{0.03568}{(3.14)(3000)^2}(31.536 \text{X} 10^6) = -0.04980 \text{ years}^{-1}$$

$$n = (1-p) = (1-.5)^2 = 0.2500$$

and

$$t_{50\%} = \frac{-m - \sqrt{m^2 - 4ln}}{2l} = \frac{0.04980 - \sqrt{(0.04980)^2 - (4)(0.0001)(0.2500)}}{(2)(0.0001)} \cong 5.07 \text{ years}$$

(4) Shoreline change modeling to estimate advance fill and renourishment requirements. In detailed design, one-line numerical models of shoreline evolution such as the GENEralized model for SImulating Shoreline Change model (Hanson 1987; Hanson and Kraus 1989) are typically used to provide more realistic estimates of project longevity and renourishment requirements than may be possible using the analytical approach discussed previously. Numerical shoreline change models provide the designer with an objective tool for evaluating a variety of potential project design alternatives, which may involve coastal structures in addition to beach fill. The use of numerical models of shoreline evolution for the design, optimization, and comparative evaluation of competing project alternatives has many advantages over the use of the analytical approach. For example, the GENESIS model allows examination of multiple renourishment cycles leading to a complete project life cycle, the effects of beach-fill stabilization structures, the effects of many possible future wave conditions (as defined by the Wave Information Study (WIS) wave hindcast) leading to a suite of possible future shoreline conditions. The numerical approach allows for the evaluation of the project design and its performance within the context of a realistic sediment budget developed for the project reach. Employing a shoreline change model like GENESIS allows the designer to examine project performance under conditions much more representative of the actual project setting than is possible with the analytical approach, and is therefore the recommended approach for final design of major projects.

(a) Simple model application.

- In this section, the GENESIS model is applied in a simplified manner to simulate the evolution of an idealized beach-fill project, throughout an anticipated 50-year project life, to investigate the design issues of advance fill and renourishment requirements. The hypothetical project is 6 km (3.7 miles) long with a design berm width of 20 m (65 ft). Two series of model simulations were performed for each of four renourishment intervals, 3, 5, 7, and 9 years. The first series of simulations were for a hypothetical condition where the project shoreline was subjected to no ambient or background erosion. The second series of simulations were for a project shoreline experiencing a background erosion rate of 0.5 m/year. All simulations were made for the entire 50-year project life. Note that the 3-year renourishment cycle project was simulated as a series of fifteen 3-year cycles plus one 5-year cycle beginning in project year 45. Likewise, the 7-year renourishment cycle project was simulated as a series of six 7-year cycles plus one 8-year cycle, and the 9-year renourishment cycle project was simulated as a series of five 9-year cycles plus one 5-year cycle.

- In the execution of the simulations, the computed shoreline position at the end of each renourishment cycle was used to define the initial shoreline position at the beginning of the next renourishment cycle, except of course in the project area where the required renourishment fill volume was placed with tapered transitions to the existing shoreline adjacent to the project. The incident wave climate was specified as an effective wave condition that approached the project normal to the shoreline and did not change throughout the simulation. The average berm height and depth of closure were specified to be 1.5 and 6 m, respectively, for a total active depth of 7.5 m. The preproject shoreline was straight. The initial construction planform included 2-km-long transitions to the preproject shoreline position adjacent to the project limits, which were added to reduce the rate of end losses from the project. The model was then run for the first renourishment interval, an appropriate nourishment volume was added, the model was run for another renourishment interval, and so on, until the 50-year life was reached. Each prenourishment shoreline within the project limits was advanced seaward a sufficient distance so that the predicted shoreline position at the end of the renourishment cycle was 20 m seaward of the preproject shoreline at all locations within the project, except within 400 m in from both ends of the 6-km-long project. That is, the design width was allowed to be violated only at the lateral limits of the project, and for an alongshore distance of only 400 m. The results of these model simulations bring to light a number of important considerations with respect to beach-fill design.

Plots of the placed advanced fill and renourishment volume throughout the life of each of the projects simulated are shown in Figure V-4-20. Volumes shown in this plot exclude the design fill volume of 960,000 cu m contained within the project limits and small 400-m transitions at the ends of the project. The volume values include the volume contained in the transition zones that are constructed initially, and advance nourishment placed within the project limits needed to see that the design width is not compromised during the first renourishment cycle. As can be seen in Figure V-4-20a, in the absence of background erosion, the required renourishment volume is expected to decrease slightly over the life of the project. With a background erosion rate of 0.5 m/year the required renourishment volume is seen to remain nearly constant throughout the project life. Most project sites experience background erosion.

- Results indicate that the advance fill volumetric requirement is nearly twice the volumetric requirement of subsequent renourishments, and nearly three times as much for the shortest renourishment interval, or 3 years. The advance fill volume includes the volume initially placed in the transition sections. The explanation for this result is that a substantial volume of material is required to provide a natural transition from the adjacent shorelines to the more seaward-advanced project shoreline. This volume of material is required at the time of initial construction, as part of the advanced fill. Without the transition sections, high end losses at the project transitions would have compromised the design berm width over a significant length of the lateral portions of the project. Subsequent renourishments do not require this additional volume because the adjacent beaches are already prograded toward the design beach width. Part V-4-1-h examines the subject of fill transitions in more detail.

- Figure V-4-21 provides plots of the cumulative volume placed for each of the beach nourishment projects simulated. Results indicate that the cumulative beach nourishment volume requirement for a 50-year project life is nearly the same regardless of the renourishment cycle (at least for the renourishment intervals tested, which span the typical range of most beach-fill projects). A detailed examination of the model output indicates that the average annual rate of loss of sand from the project area increases only slightly as the renourishment cycle increases (3 or 4 percent difference between annual loss rates for 3- and 9-year renourishment cycles). Selection of a renourishment cycle for Federal projects is made through an optimization process that optimizes the amortized initial construction costs and the annual cost of periodic renourishment to minimize the total average annual equivalent cost. Selection of renourishment volumes/intervals is typically done based on average expected losses over the life of the project. Selecting a longer renourishment interval, with strict adherence to amortized life-cycle-cost based selection, may reduce flexibility in dealing with annual variations in loss rates, which might be caused by several years of higher than normal storm activity, or design deficiencies discovered within the first few years following construction. From both engineering/design and monitoring/maintenance perspectives, 3- to 4-year renourishment cycles are desirable. If longer renourishment intervals are desired from an economic perspective, it is prudent to plan a short first renourishment interval (about half the optimized interval, or 3 to 4 years, whichever is smaller).

- If the volume remaining within the project area is subtracted from the cumulative placed volume, one can estimate the cumulative spreading losses. In the simulations without background erosion, the cumulative spreading losses range between 2.75 to 2.83 million cu m of sand, depending on the renourishment cycle. However, the simulations that included the effect of a 0.5 m/year background erosion rate indicate substantially higher cumulative losses, between 6.36 to 6.68 million cu m of sand, depending on the renourishment cycle. Some past projects have underestimated renourishment requirements by assuming that a historically based volumetric rate of erosion within the project domain can be used to estimate the required renourishment. This assumption incorrectly neglects the effect of background erosion outside the project on project end losses. For example, the

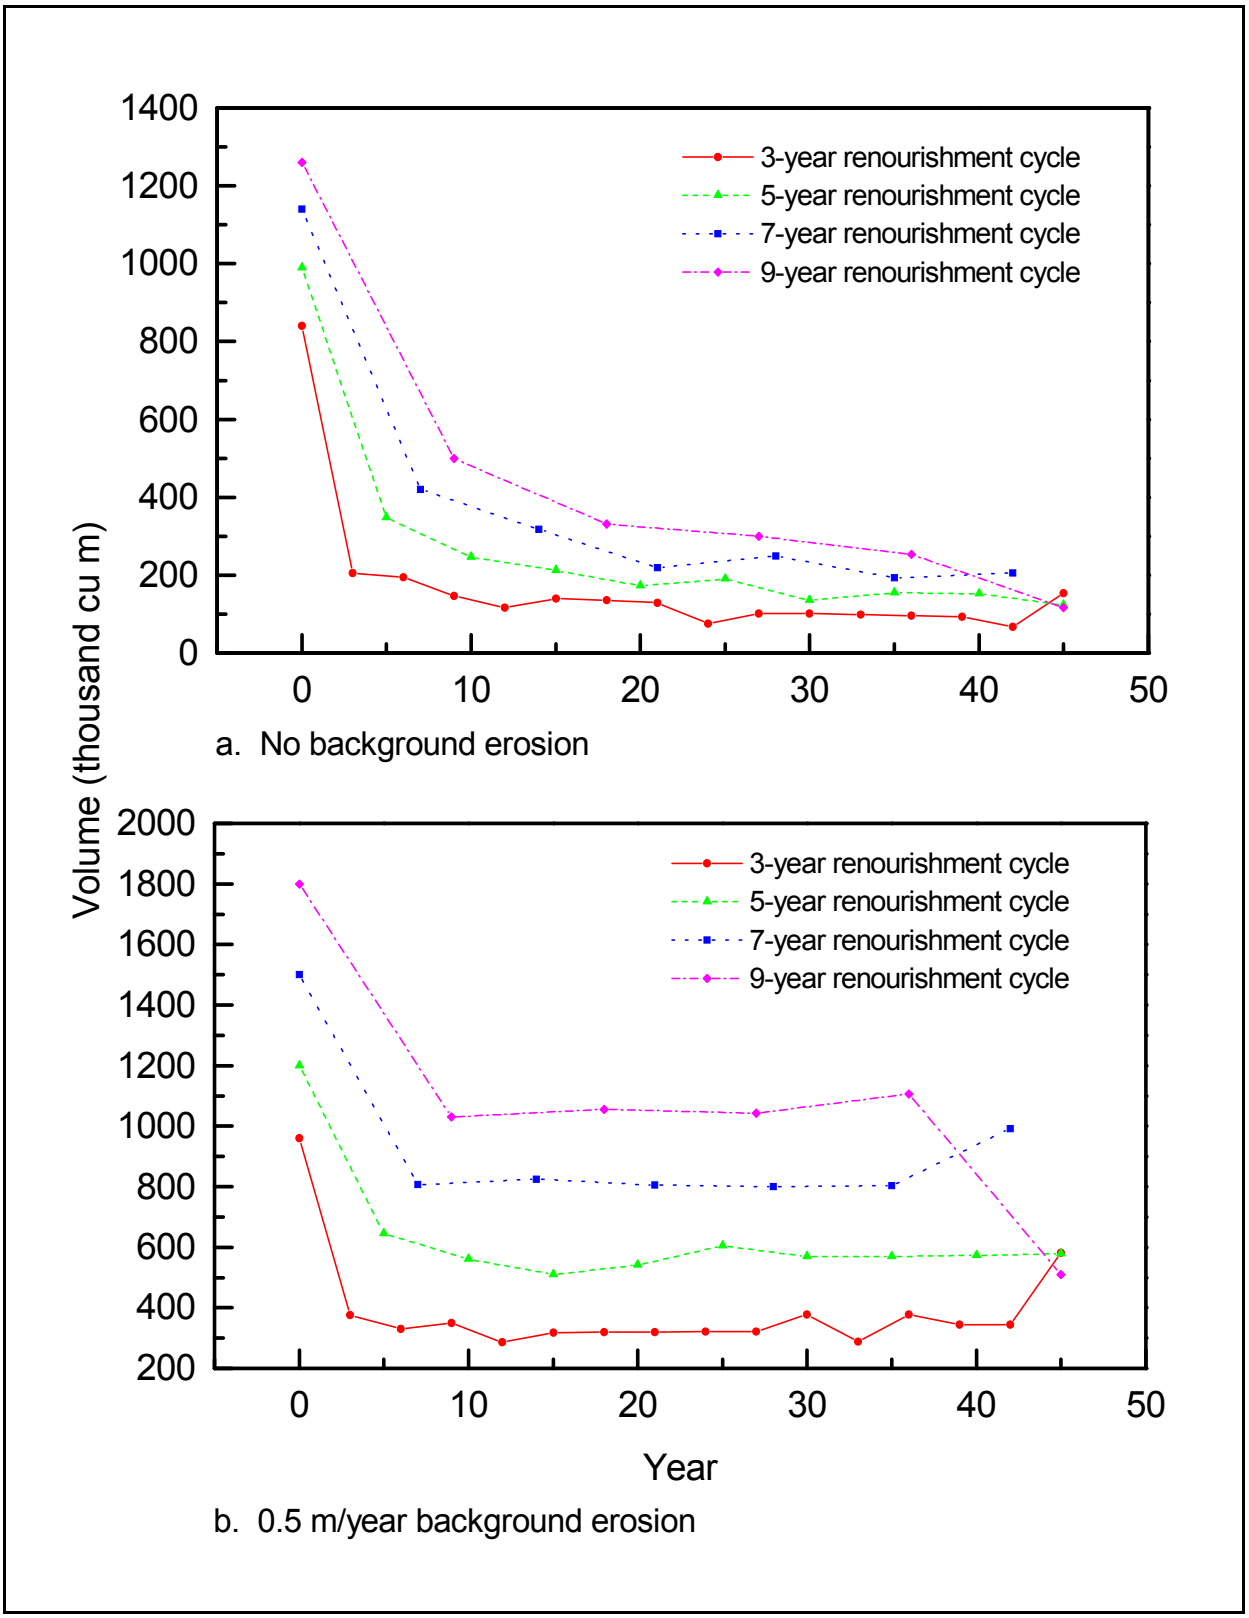

Figure V-4-20. Advanced fill and renourishment volumes

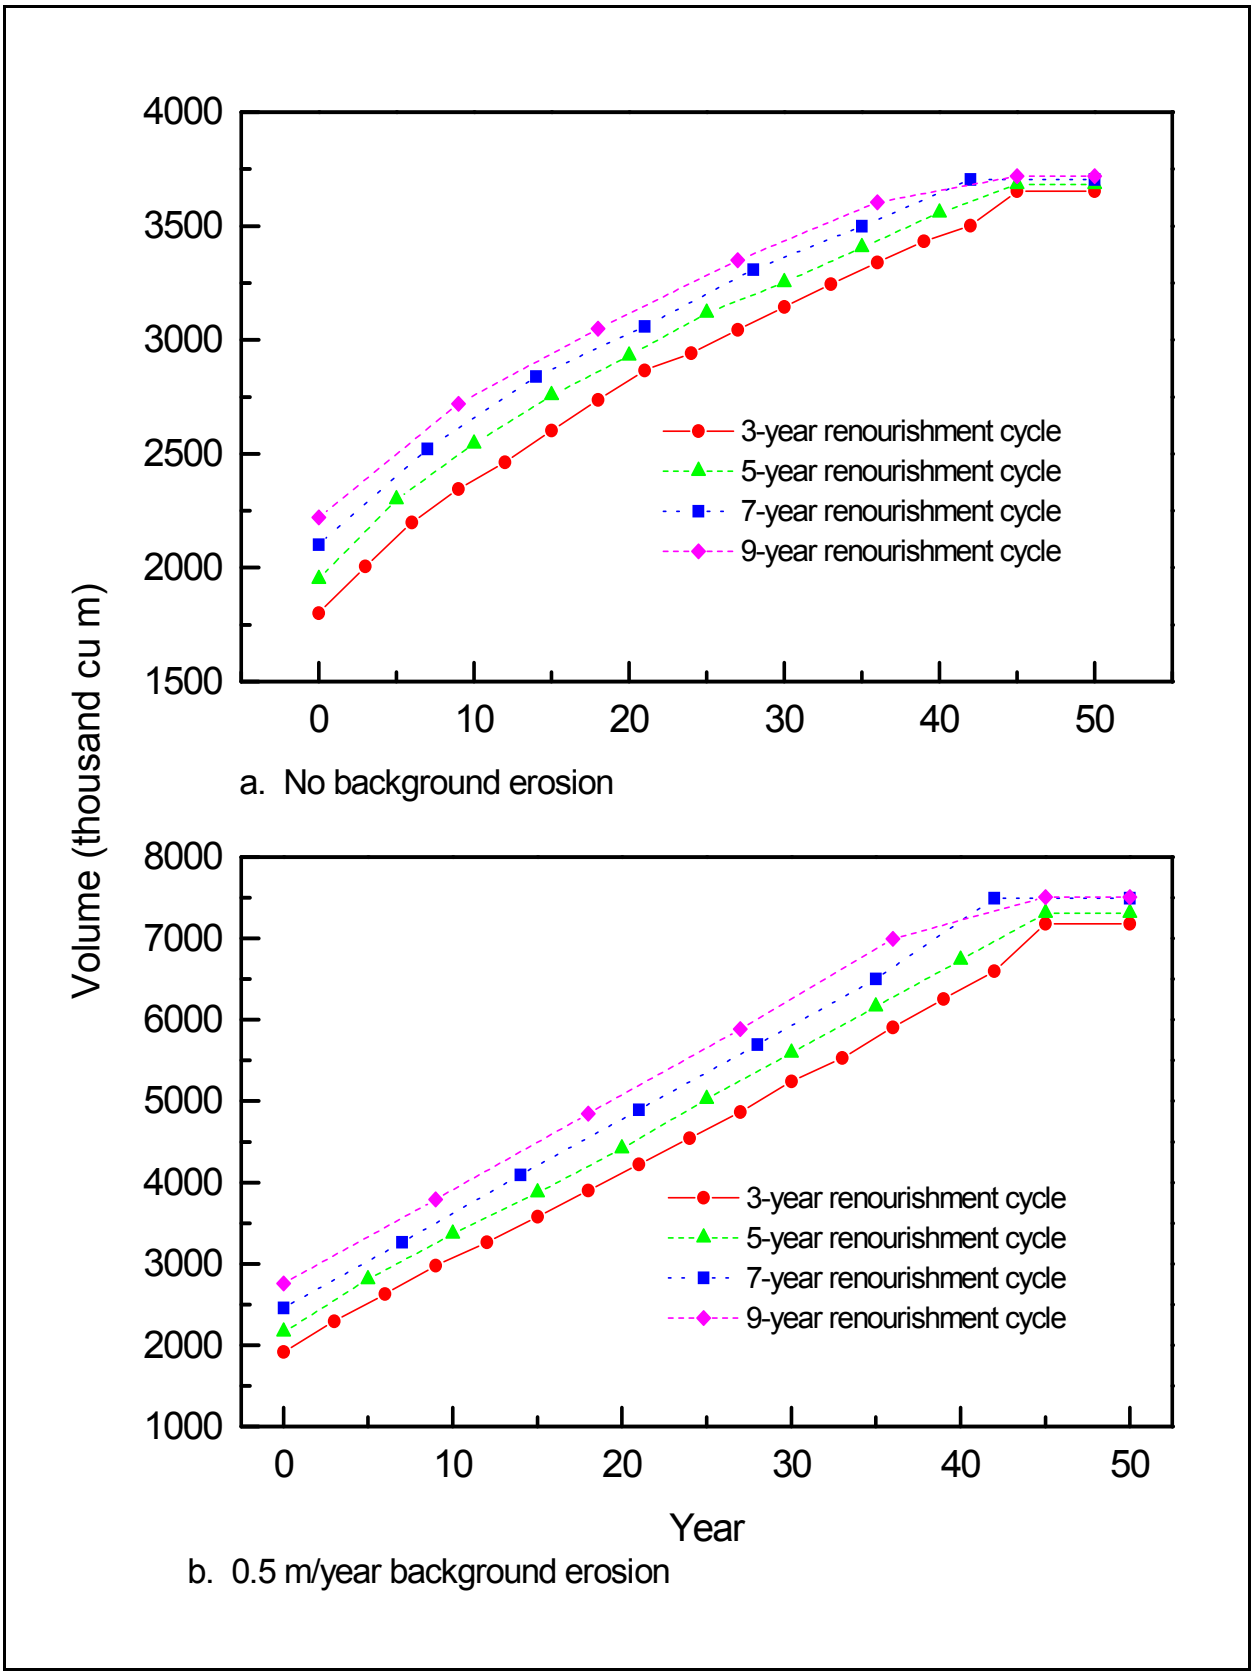

Figure V-4-21. Cumulative beach nourishment volume

volumetric erosion due to a background erosion rate of 0.5 m/year on a 6-km project length with an average berm height of 1.5 m and a depth of closure of 6 m is 1.13 million cu m over a 50-year project life. Adding this volume to the calculated project end loss volume (in the absence of background erosion) of 2.8 million cu m gives a total project volume of 3.93 million cu m which is only about 60 percent of the 6.52 million cu m estimated in the simulations that included a background erosion rate of 0.5 m/year. The explanation for this result is that background erosion outside the project causes the seaward protuberance of the project to become larger each year. At the end of the 50-year project, the design shoreline is 45 m seaward of the adjacent shorelines which are unaffected by the project nourishments; whereas in the absence of background erosion, the protuberance of the design shoreline remains 20 m throughout the 50-year project. The additional nourishment volume is required to provide a natural transition from the eroded adjacent shorelines to the design shoreline. Figure V-4-22 shows the calculated shoreline position at the end of the 50-year nourishment project for each of the project scenarios simulated. It also illustrates the previously discussed requirement for additional nourishment volume in the presence of background erosion. Figure V-4-22 also illustrates the beneficial effects a beach-fill project has on the adjacent shorelines during its lifetime. In the absence of background erosion (Figure V-4-22a) it is seen that the beaches adjacent to the fill project are advanced seaward approximately half the design width for more than a project length on both sides of the fill. With a background erosion rate of 0.5 m/year (Figure V-4-22b) it is seen that the fill project stabilized the shoreline at or seaward of the preproject shoreline position for a distance of approximately one project length on both sides of the fill.

(b) Recommendations for detailed analysis.

- In the previous section, the GENESIS model was applied in a simplified way to estimate volume requirements for an idealized beach-fill project. That application of the GENESIS model was referred to as simplified because the model was not calibrated for the specific project reach nor was a time varying time series of wave information used to represent the environmental forcing. Furthermore, the simplified method of analysis assumes that the project and adjacent beaches can be characterized as long straight beaches with uniform and temporally constant background erosion rates, and that the dominant long-term processes affecting the evolution of the beach-fill project can be captured by examining the alongshore dispersion of the fill by a persistent effective wave condition. However, many if not most projects vary significantly from these assumptions and warrant a more detailed application of the GENESIS model. Gravens, Kraus, and Hanson (1991) and Gravens (1992) provide detailed information concerning the application of the GENESIS model.

- A detailed application involves developing shoreline position and beach profile data sets, analyses of incident wave conditions including detailed nearshore wave transformation, and selection of a time-history of representative wave conditions for use in model calibration, verification, and project forcasting. Typically a detailed wind wave hindcast such as WIS provides the required wave information and serves as the database defining the local and regional characteristics of the offshore wave climate in the vicinity of the project. A long, multiyear record of measured wave data may also suffice.

- A critical aspect of the detailed application is the calibration of the model to site specific project conditions. Calibration involves selection of the domain to be modeled and boundary conditions, evaluation of model accuracy in reproducing historical shoreline change, and net and gross longshore sand transport rates. The calibration and evaluation of the GENESIS model serve to demonstrate the predictive capability of the model at the specific project site. Estimates based on a well-calibrated and verified GENESIS model are considered superior to those based on a simplified application of GENESIS. However, it may be informative to examine the difference between estimates generated

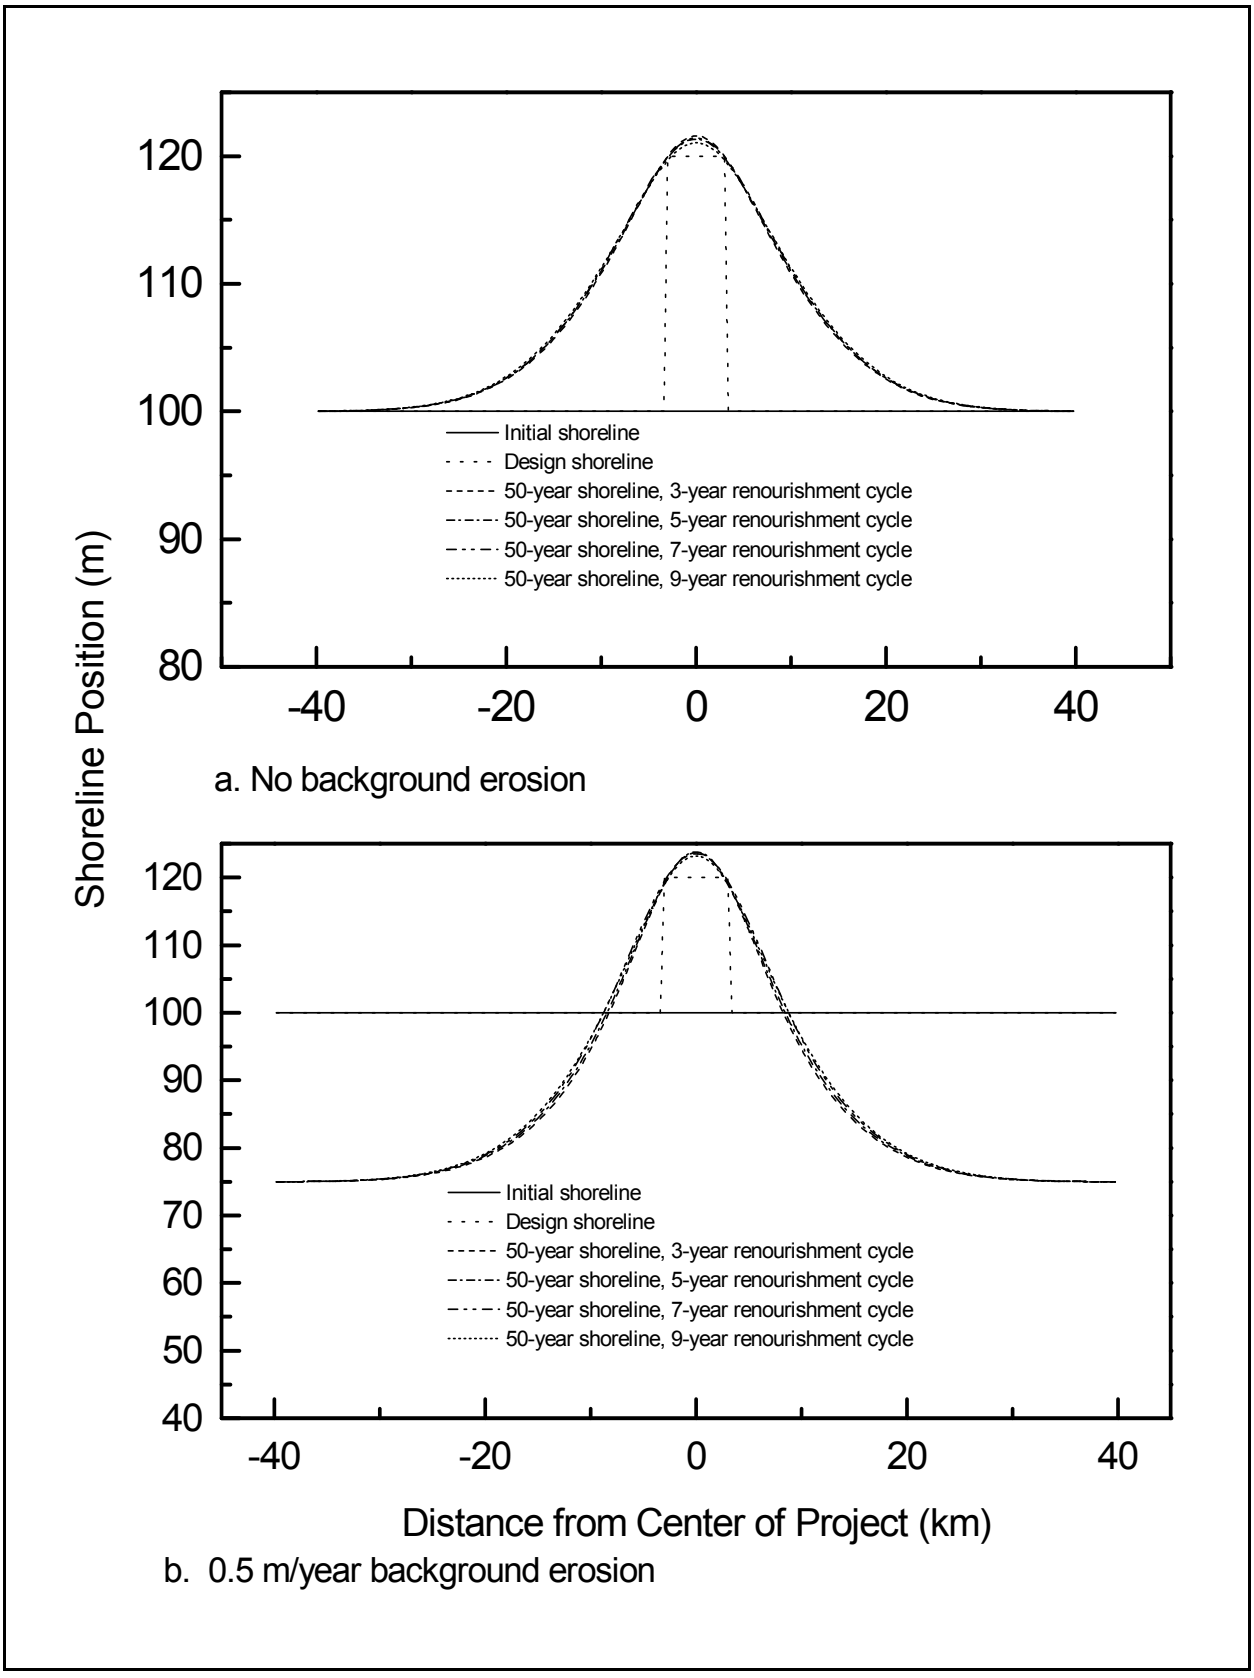

Figure V-4-22. Calculated 50-year shoreline position

through both simplified and detailed applications of GENESIS for a given project to quantify the range of uncertainty between the design methods. Coastal engineering judgement, local coastal experience, and the performance of nearby similarly-situated projects, if any, are important and should be factored into the overall design and specifically the estimates of project volume requirements. The results of a detailed GENESIS model application should always be interpreted in the context of the model calibration and verification. For instance, if the historical rate of erosion was underpredicted in some specific model region of the simulated shoreline in the calibration and verification then it should be expected that the model will continue to underpredict erosion in this area in the simulation of the various design alternatives. Estimates of volume requirements should be adjusted to account for deficiencies in the model calibration and verification.

- One advantage of taking the detailed GENESIS modeling approach in the investigation and prediction of beach-fill project performance is the opportunity to anticipate possible secondary effects that have troubled some past projects. For instance, the excavation of a nearshore borrow area or some preexisting bathymetric feature may significantly alter local breaking wave conditions and result in the development of a localized zone of accelerated erosion along the project shoreline (a hot spot). A detailed application of GENESIS would examine the effects of local bathymetry and project changes in the bathymetry, through the application of nearshore wave transformation models and inclusion of nearshore wave information in the shoreline change calculations. GENESIS model predictions based on this type of data can reveal the potential for the development of shoreline anomalies within the project. Simplified applications of GENESIS or an analysis based on the analytical approach have no chance of revealing possible hot spot development because the processes responsible for their development are ignored or are smoothed over in the analysis.

- If a good calibration of the GENESIS model cannot be achieved because of complex boundary conditions (unstructured inlet, randomly fluctuating shoreline), or insufficient or poor data quality, then a more simplified application of the model is recommended. An alternative to calibrating and verifying the GENESIS model to historical shoreline position data, is to calibrate GENESIS to an accepted existing-condition sediment budget developed through an analysis of the available physical data. In this type of application, a wave time series that reproduces the accepted sediment budget within the model is developed either from hindcast wave information such as WIS, measured wave information, or simply synthesized from observations or general wave and wind information available in a statistical form.

(5) Anticipating hot spots. Hot spots are localized areas within a beach nourishment project that experience a reduction in beach width (corresponding to a loss of sand volume) significantly greater than losses that were predicted and/or are observed throughout the rest of the project. Hot spots are problematic in the sense that the desired level of protection may be compromised locally, whereas the remainder of the project is functioning well. To achieve the desired level of protection, renourishment in the hot spot area may be required on a more frequent basis than the rest of the project. Or, some structural solution may be required to provide the desired level of protection or improve sand retention so that renourishment can be performed on the same schedule as is planned for the rest of the project. Hot spot mitigation measures will probably result in additional unanticipated and undesired costs. The public perception of hot spots that develop shortly after construction can be one of project failure. Therefore, the potential for the occurrence of hot spots should be investigated during the design process. This can be accomplished through, for example, the method used by Smith and Ebersole (1997). The GENESIS model together with detailed nearshore wave conditions can also be used for this purpose (Bodge, Creed, and Raichle 1996).

(a) Hot spots can arise due to a locally strong gradient in longshore sand transport rate, which creates a divergent zone where, in a net sense, more sand is leaving an area than is entering it. Strong longshore transport gradients can develop due to a noticeable change in shoreline/bathymetric contour orientation.

Figure V-4-23 illustrates an example of this type of hot spot at Folly Beach, South Carolina. A beach-fill was constructed along much of the island, and high loss rates were observed locally at the place where the shoreline noticeably changes orientation and creates a convex curve relative to the incident waves (Ebersole, Neilans, and Dowd 1996). Prior to construction of the nourishment project, this area was known as the wash-out area, suggesting an area that previously experienced high erosion rates. Local knowledge or an analysis of historical shoreline change rates may help identify such a zone. However, areas that have historically suffered high sand loss rates may be presently armored with seawalls or revetments, or controlled by some other structures such as groins, thereby pinning the shoreline position and masking the presence of a future hot spot. Any area in which the shoreline has a bulge or convex shape, relative to the incident waves, is a potential candidate for this type of hot spot.

(b) The presence of a submerged offshore shoal, or some other highly irregular bathymetric feature such as an underwater canyon, can also be a cause of erosion hot spots. Morphologic features can alter the propagation of incident waves in a persistent manner, creating strong gradients in net longshore sand transport. Stauble (1994) documented the occurrence of multiple erosional hot spots in a beach nourishment project constructed at Ocean City, Maryland, and hypothesized that the cause of the hot spots was the presence of shore-attached finger shoals that characterize the nearshore bathymetry off Ocean City (see Figure V-4-24). The finger shoals appear as lighter-shaded areas. Stauble also identified corollary cold spots, or areas of unusual sand accumulation, which were formed by the sand that was transported out of the hot spots. Smith and Ebersole (1997) showed that the positions of the hot spots/cold spots were well-correlated to zones of divergent/convergent potential longshore sand transport caused by persistent changes to nearshore wave patterns induced by the shoals. The shoals act to alternately focus and spread wave energy due to the process of wave refraction. Results from the application of a wave transformation model (see Part II-3) were used to compute potential longshore transport rates. Figure V-4-25 shows the variation in transport rates for Ocean City, Maryland. Positive rates are directed to the south, negative to the north. Hot spots correspond to strong uphill gradients (e.g., changes from low southerly transport rates to high southerly transport rates). Cold spots occur at downhill gradients.

(c) Just as natural bathymetric irregularities can lead to the development of a hot spot, an excavated borrow area or a submerged mound constructed out of dredged material can produce the same result. If the manmade feature results in a significant change in bottom relief and is located in water depths where the waves feel the change in depth, persistent longshore sand transport gradients may develop. Hot spots can also form in areas where the incident wave directions are constrained to a narrow window and the area is blocked or sheltered by some land feature or coastal structure, creating a gradient in wave energy and longshore sand transport.

(d) A third type of hot spot can result as a consequence of how a project is designed and built to protect existing structures and infrastructure. Typically beach nourishment projects are built in areas where structures and infrastructure are vulnerable to storm-induced damage. Oftentimes, the project site already has revetments or seawalls that have been built by private landowners. Both protected and unprotected structures may protrude beyond the natural prevailing shoreline position, thereby creating a very irregular, and unnatural, shoreline. It may be difficult to estimate where the prevailing natural shoreline position would be if the structures were not present.

(e) If a project is designed and constructed to "wrap around" protruding structures, in an attempt to create a uniform width of beach in front of each structure, the beach will most likely readjust following construction. The readjustment process will lead to a more stable arrangement of sand in which the design width may not be retained in front of the seaward most structures, whereas the beach width may exceed the design width in other areas. Figure V-4-26 illustrates this process. An offshore depth contour equal to the

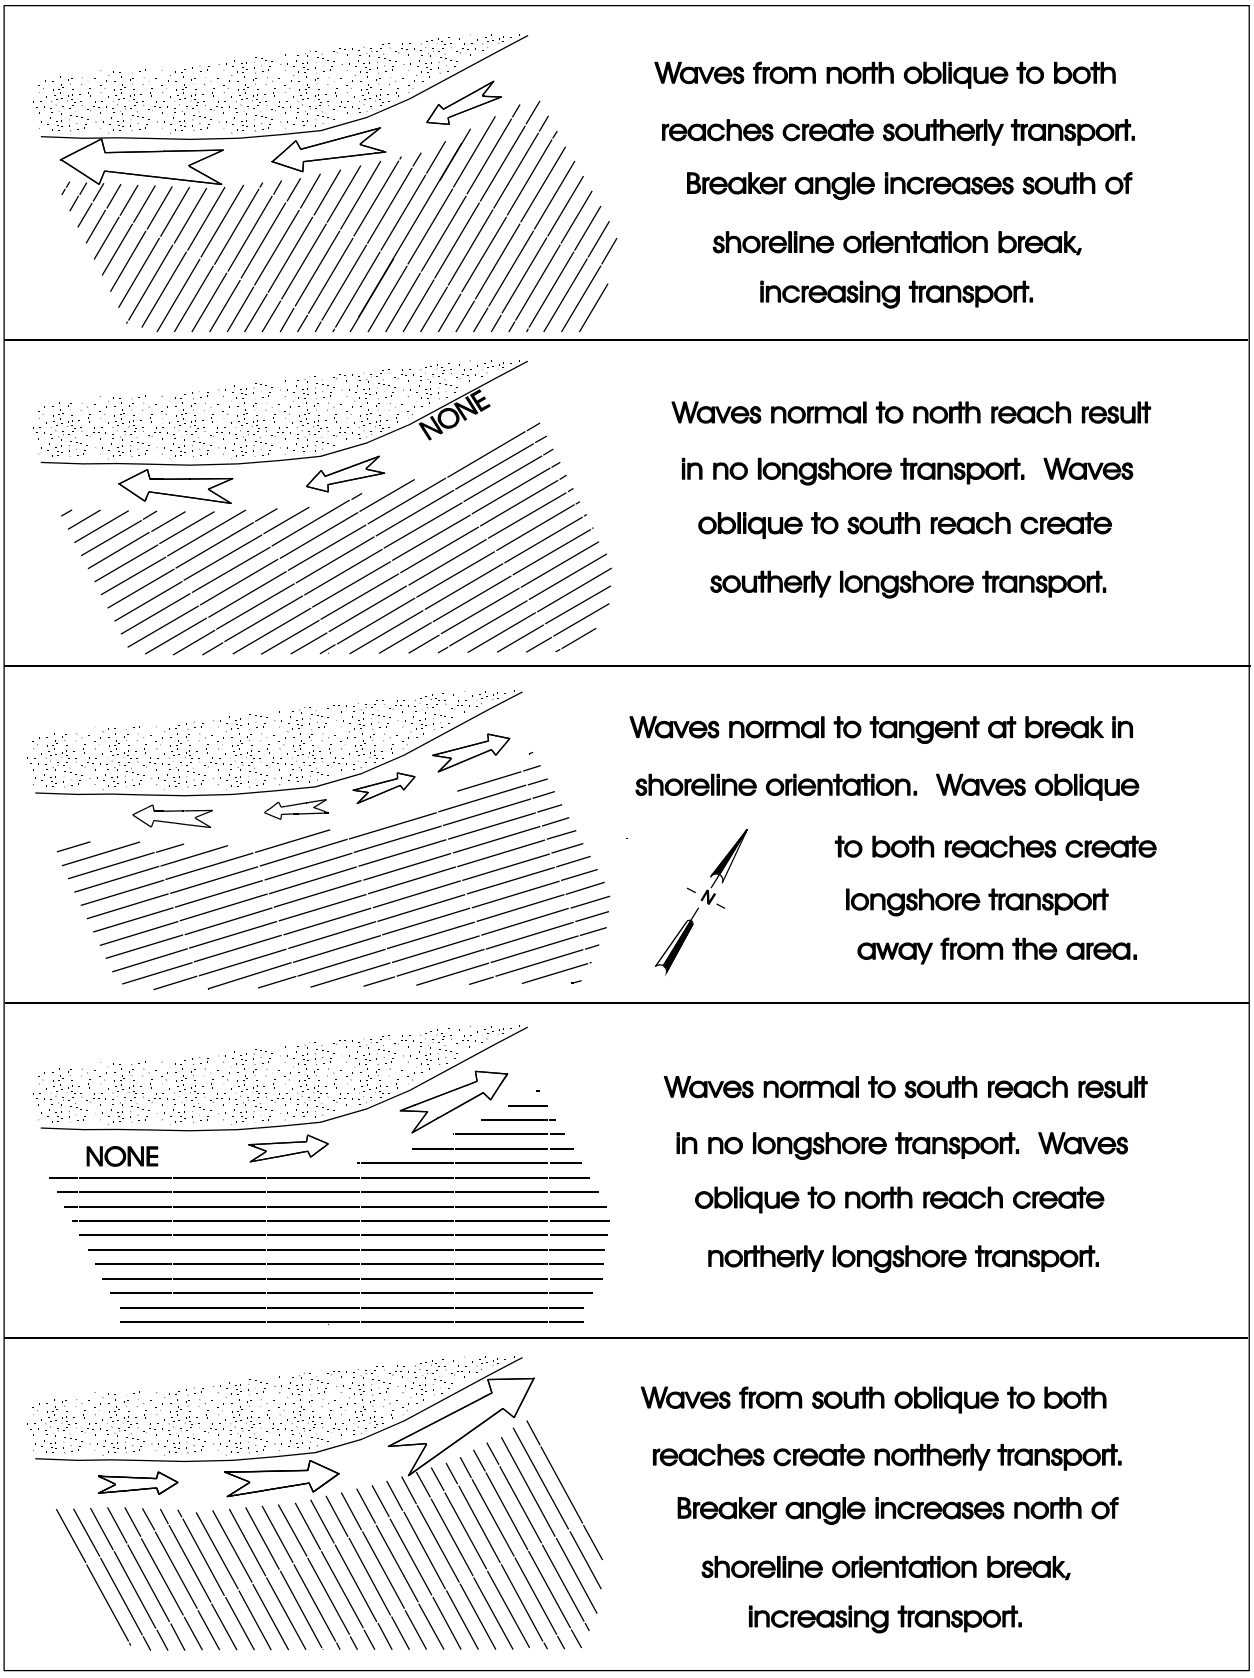

Figure V-4-23. Causes of hot spot formation at a convex shoreline feature

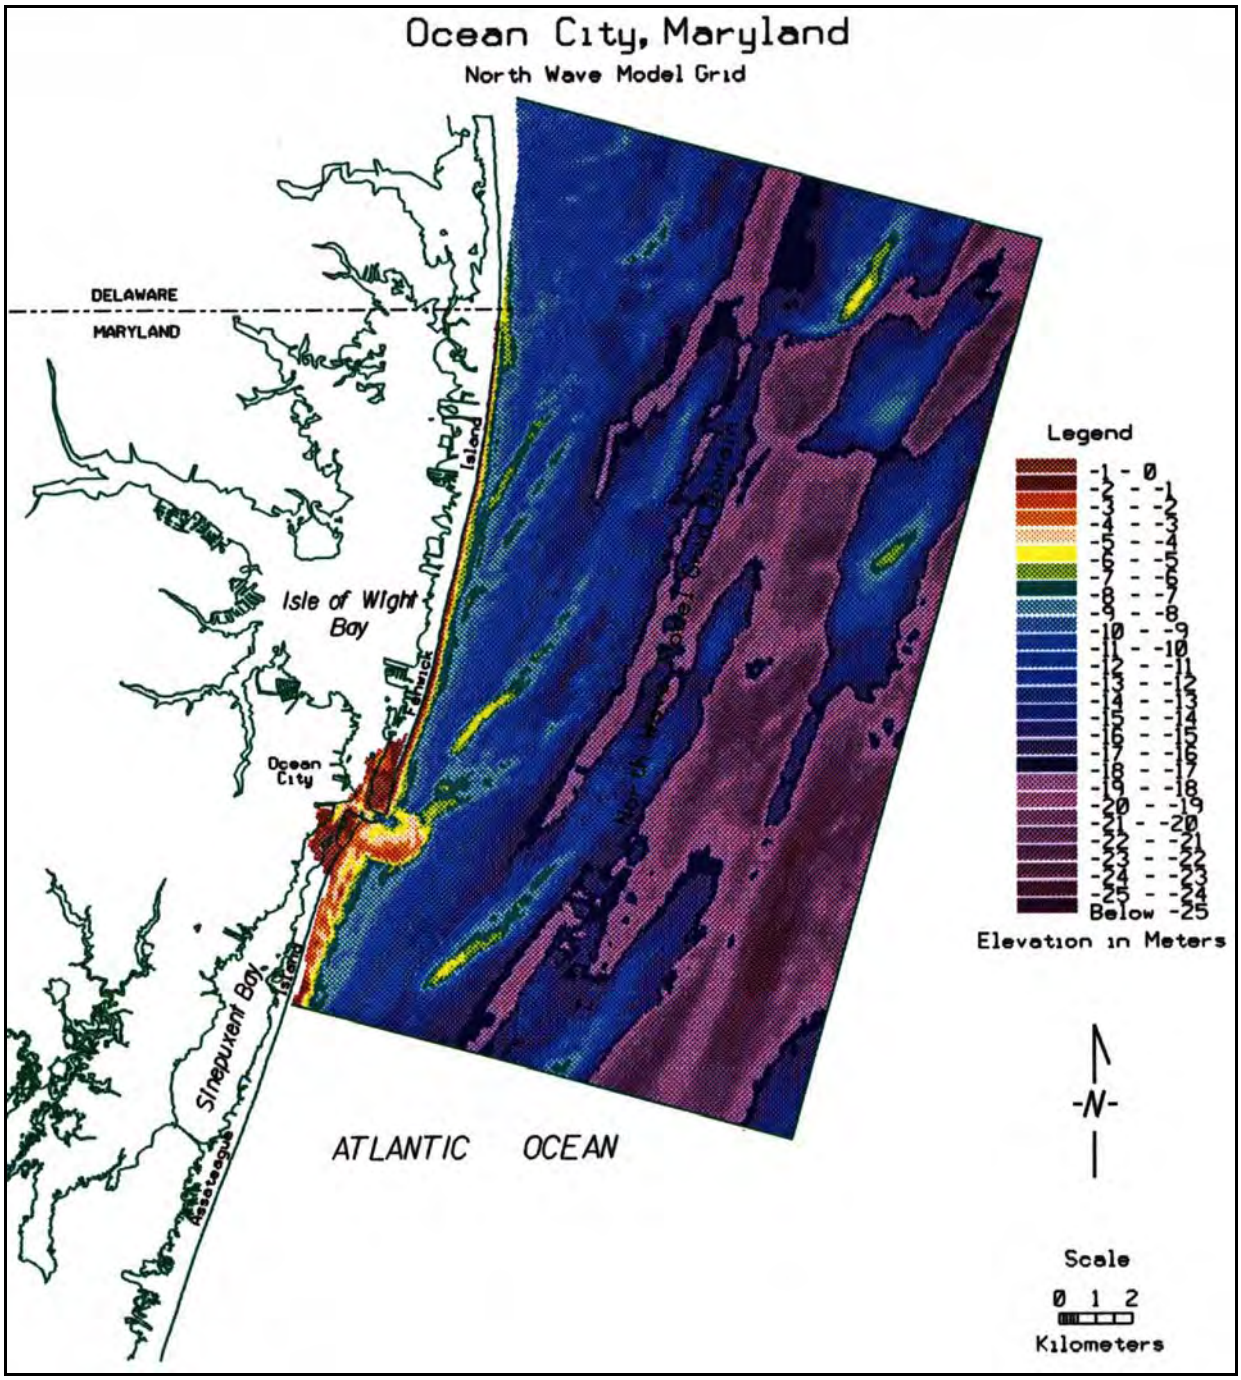

Figure V-4-24. Project shorelines, nearshore bathymetry, wave modeling domain, and position of offshore wave information

breaking wave height associated with frequent storms (2- to 3-m depth contour) may serve as a better indicator of the orientation of the postconstruction, adjusted shoreline.

(f) It may be impossible to maintain the design width in front of some structures without placing a substantially larger volume of sand than is estimated based on "wrapping" the project around the existing structures. It may not be cost-effective to build the entire beach out to the point required to provide the

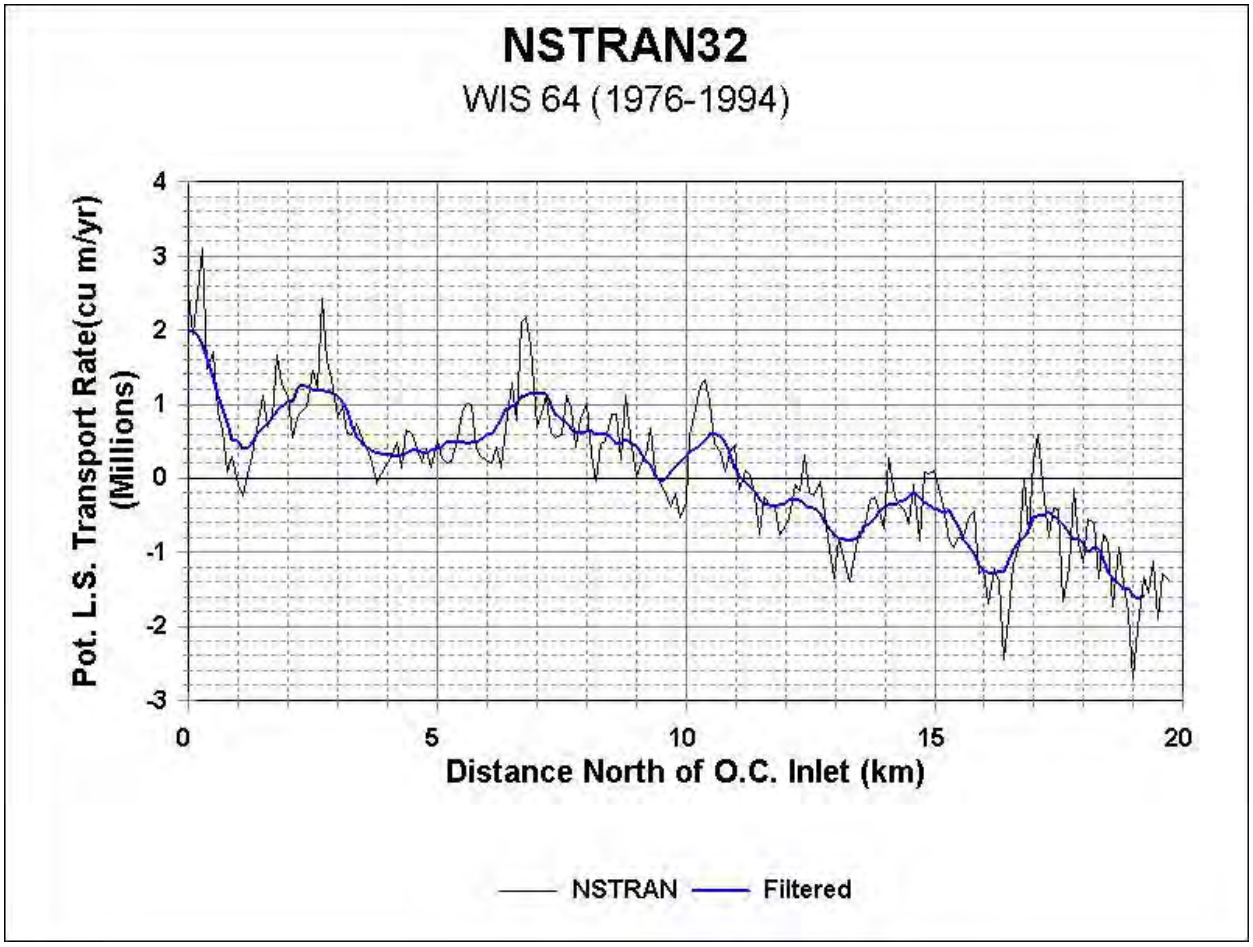

Figure V-4-25. Variations in potential longshore sand transport rates caused by offshore shoals at Ocean City, Maryland

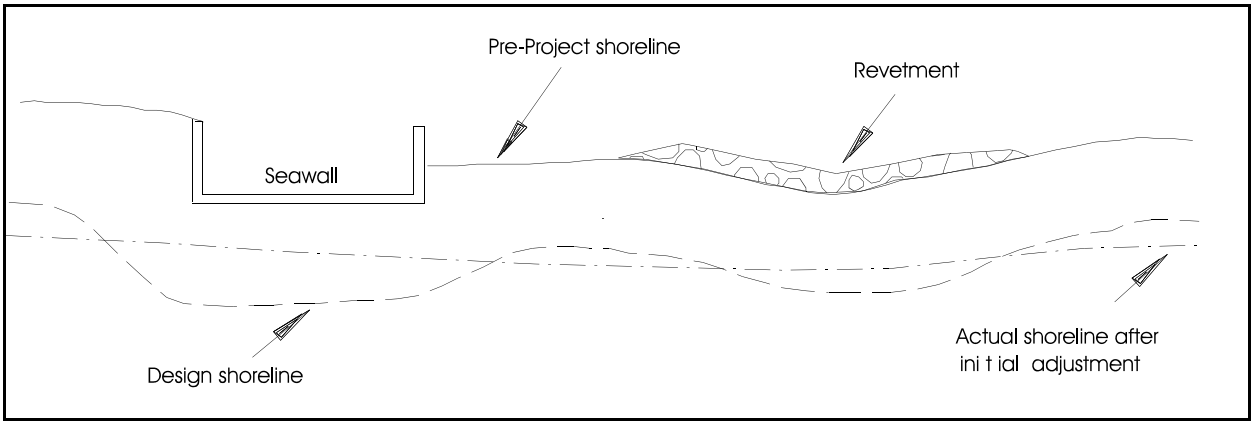

Figure V-4-26. Planform adjustment of a beach-fill project designed to "wrap around" existing coastal structures

desired level of protection to the seaward most structures. If this is the case, other means for achieving the desired level of storm protection in certain local areas, such as more frequent nourishment, use of a feeder beach, a filled groin compartment, or a revetment or seawall, should be considered.

(g) There are probably other less well-understood causes for the development of hot spots. A geologic control such as remnant morphologic feature (relic inlet) with a different sediment composition may cause differential erosion along the project reach. Longshore variation in the sediment characteristics of the borrow material may produce a differential loss rate within sections of the project. However at present, there are no reliable methods for anticipating hot spots caused by these other factors.

h. Fill transitions.

(1) Selection of a method for terminating a beach nourishment project depends on several factors. One important consideration is what lies immediately beyond the project limits. For example, is there an open straight beach or an inlet? On open stretches of coast, transition to the adjacent beach can be accomplished using a fill transition section, which was briefly introduced in the previous section, or using hard structures, such as groins, navigation structures, or breakwaters. Structures placed at the boundaries of a project are called terminal structures. If the project is constructed near an inlet, structures may be desirable to minimize movement of fill material into navigation channels. Hard structures will allow an abrupt termination of the beach-fill section. However, these structures can be costly, and can interfere with the natural longshore transport of sediment along the shoreline. If not designed properly, this interference could result in adverse effects along the unrestored beach and subsequent objections by adjacent-beach property owners.

(2) Another key factor is the purpose for building the project. If the project is built to provide storm protection, what is the reach of shoreline to be protected and what is the desired level of protection within the reach? The desire to maintain a specific design beach width may dictate the design of the transition section. In practice, if a uniform design width is desired for the entire project reach, it will be extremely difficult to maintain that width near the lateral ends of the project, unless a terminal structure is used or the design fill is extended beyond the limits of the design reach. If sand is to be placed outside the design reach, other issues become important. Can the fill provide benefits to the adjacent property, and how will those benefits be factored into the economic justification of design (if at all)? It may be more practical to consider the nourishment project in three sections, one interior section where a desired level of protection will be maintained, and two outer sections of the project where a lesser degree of protection will exist (i.e., the transition sections). In the transition sections, the level of protection will diminish with distance from the main project reach.

(3) If the project is built primarily for recreational purposes, the design goal may be to maximize retention of fill volume within the limits of the project reach. This design objective may dictate whether or not fill transitions are used at all, and if so, how they are designed.

(4) Although sometimes approached as an afterthought in project design, beach-fill termination deserves careful consideration. This is particularly true in terms of its relation to the economics of the project and the level of storm protection that is sought/claimed near the limits of the project. This section discusses use of fill transitions at the ends of a nourishment project. The next section, Part V-4-1-i, discusses use of structures in fill stabilization.

(5) The intent of fill transitions is to minimize the effect of end losses on project integrity. End losses from the main project reach can be reduced by extending the design section past the limits of the reach where protection is desired, or by smoothly tapering the project into the adjacent beaches (i.e., gradually reducing project width from the design width to zero). Tapering the fill ends will decrease the perturbation effects of

the project section. The effect of varying taper length can be estimated with the aid of analytical or numerical shoreline planform response models (Walton 1994; Hanson and Kraus 1989).

(6) The GENESIS model was used in a series of simplified applications to investigate the effect of beach-fill transitions. Figure V-4-27 shows plots of an initial rectangular 6-km-long fill section, and the calculated shoreline at 1-year intervals, for two projects identical in every way except that the project in the top panel has a 400-m-long fill transition and the project in the bottom panel has a 2,000-m-fill transition. The total fill volume is the same in both projects, to allow assessment of how best to utilize a finite volume (or alternatively a fixed cost). The duration for both simulation is 5 years. A single, normally-incident effective wave is considered. The design objective is to maintain a beach width of 20 m throughout the 5-year interval, everywhere within the project reach.

(7) At the end of the 5-year simulation, both projects have beach widths greater than the 20-m design width; and therefore, both projects have satisfied the design objective. It is noted that the average annual volumetric rate of sand loss from the 400-m fill transition project was 148,000 cu m/year; whereas for the 2,000-m fill transition project, the average end losses were 89,000 cu m/year (about a 40 percent reduction in the rate of end losses). However, because approximately 22 percent of the fill volume was placed outside the project reach at the time of construction in the 2,000-m fill transition sections, the percent of total placed fill volume remaining within the 6-km project area is greater for the 400-m fill transition project (58 percent remaining) than for the 2,000-m fill transition project (55 percent remaining). For this case, the example suggests that if there are few or no economic benefits to claim in the transition section, then all the fill volume should be placed within the limits of the project reach (i.e., no use of transition sections). The same conclusion would be reached in this case if maximizing fill volume retention was the primary design goal. However, recall from the previous section that project longevity varies with the square of the project length. Generally, this rule of thumb concerning use of transitions is true for shorter fills. Also, for short fills, it may not be desirable to place sand volume in transition sections which may require a significant percent of the total volume placed within the project.

(8) For longer projects, the design requirement of maintaining the design berm width at the project boundaries throughout the renourishment interval may favor the placement of beach-fill transition sections. Figure V-4-28 provides plots of the initial fill and the calculated shoreline position after 5 years, for 6- and 22-km-long fill projects, with both 400- and 2,000-m fill transition sections. Again, the design berm width is 20 m. In Figure V-4-28a, it is seen that for the 6-km fill project, the 400-m transition project shoreline is seaward of the 2,000-m transition project shoreline after 5 years everywhere within the project domain. However, for the 22-km fill project shown in Figure V-4-28b it is seen that at the project boundaries, the 400-m transition project is landward of the 2,000-m transition project, and more importantly, landward of the design shoreline. This result illustrates the potential value of beach-fill transition sections for long beach-fill projects.

(9) However, even for long projects, the benefit of placing a fill transition section is only realized during the first few years after construction (within the first renourishment cycle, as a rough rule of thumb).

(10) Within only a few years the volume of fill material that has moved from within the project limits onto the adjacent beaches, as a result of alongshore spreading, is likely to be much greater than the volume that was initially placed in the transitions, even with 2,000-m-long transition sections. This conclusion is further illustrated by the results shown in Figure V-4-28, where it is seen that the calculated shoreline position adjacent to the main project after 5 years is for all practical purposes the same for both the project with the 400-m fill transition and the project with the 2,000-m fill transition. The work of Walton (1994) suggests that transition sections have a more lasting significant impact on reducing rates of sand loss from the project only when their length exceeds a value that is 0.25 times the project reach length. In past practice,

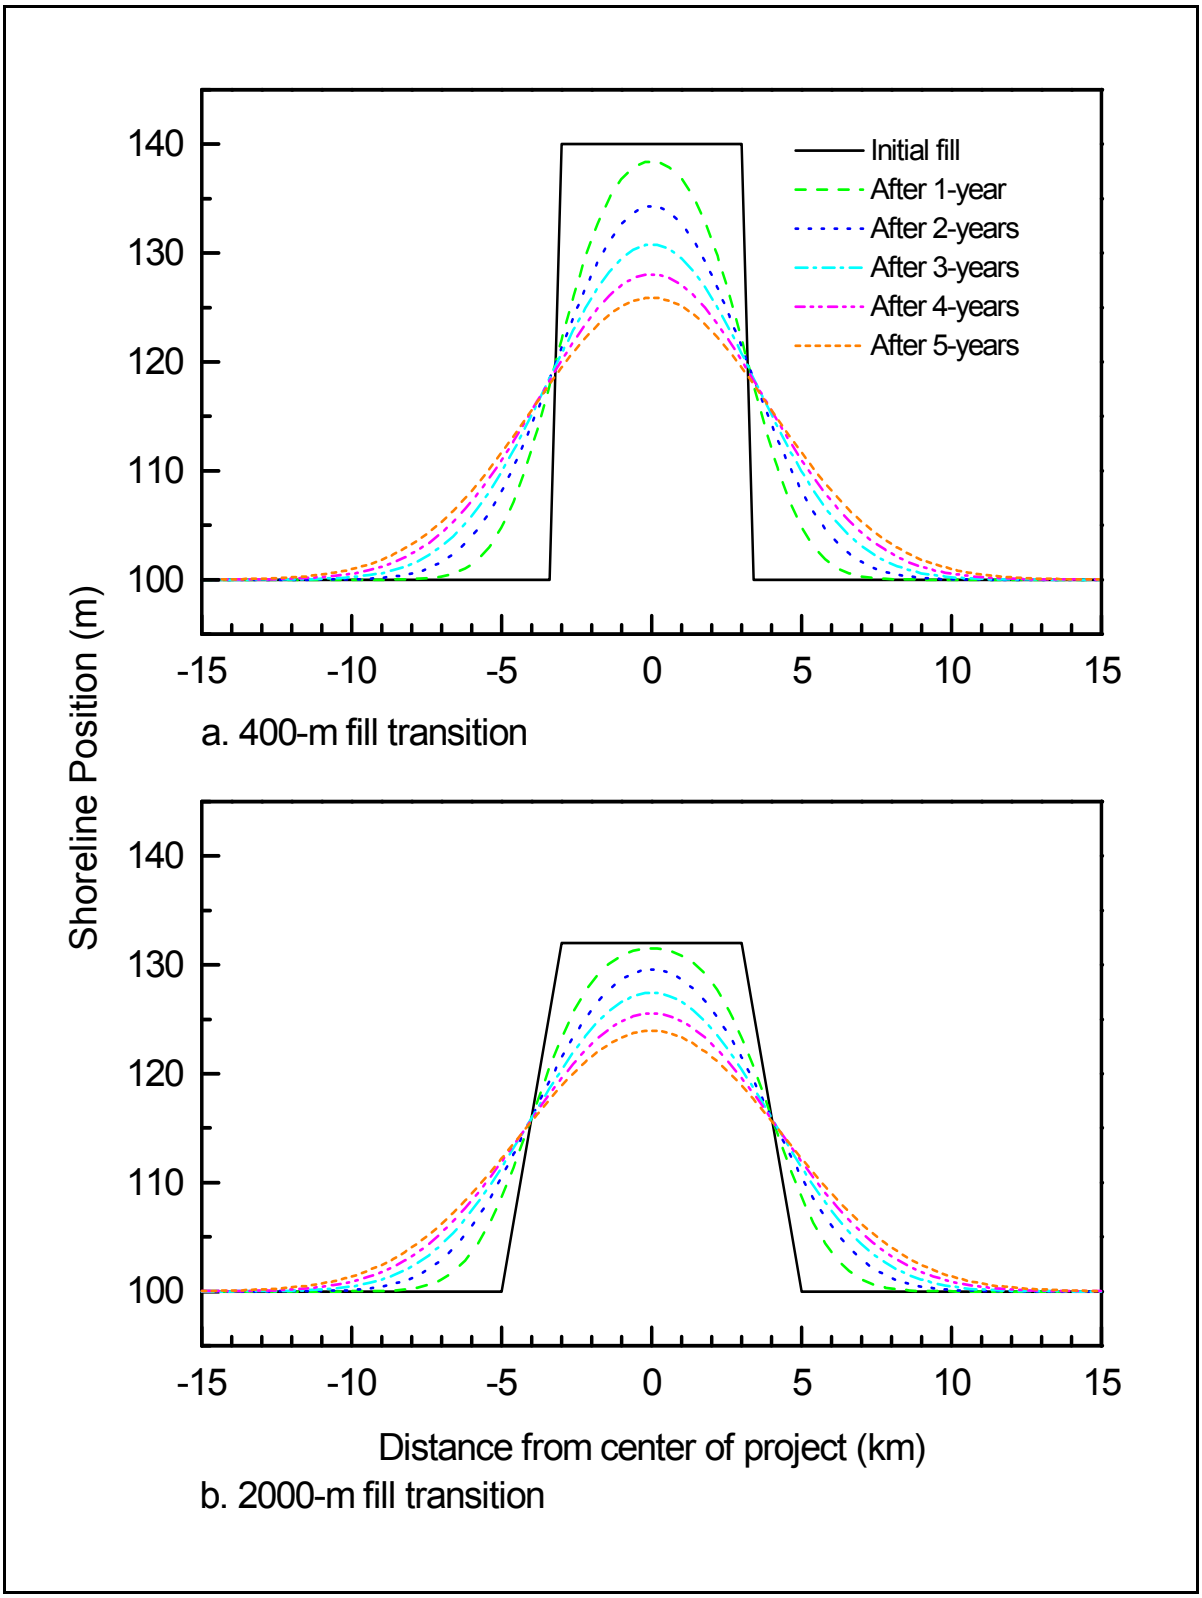

Figure V-4-27. Effect of fill transitions

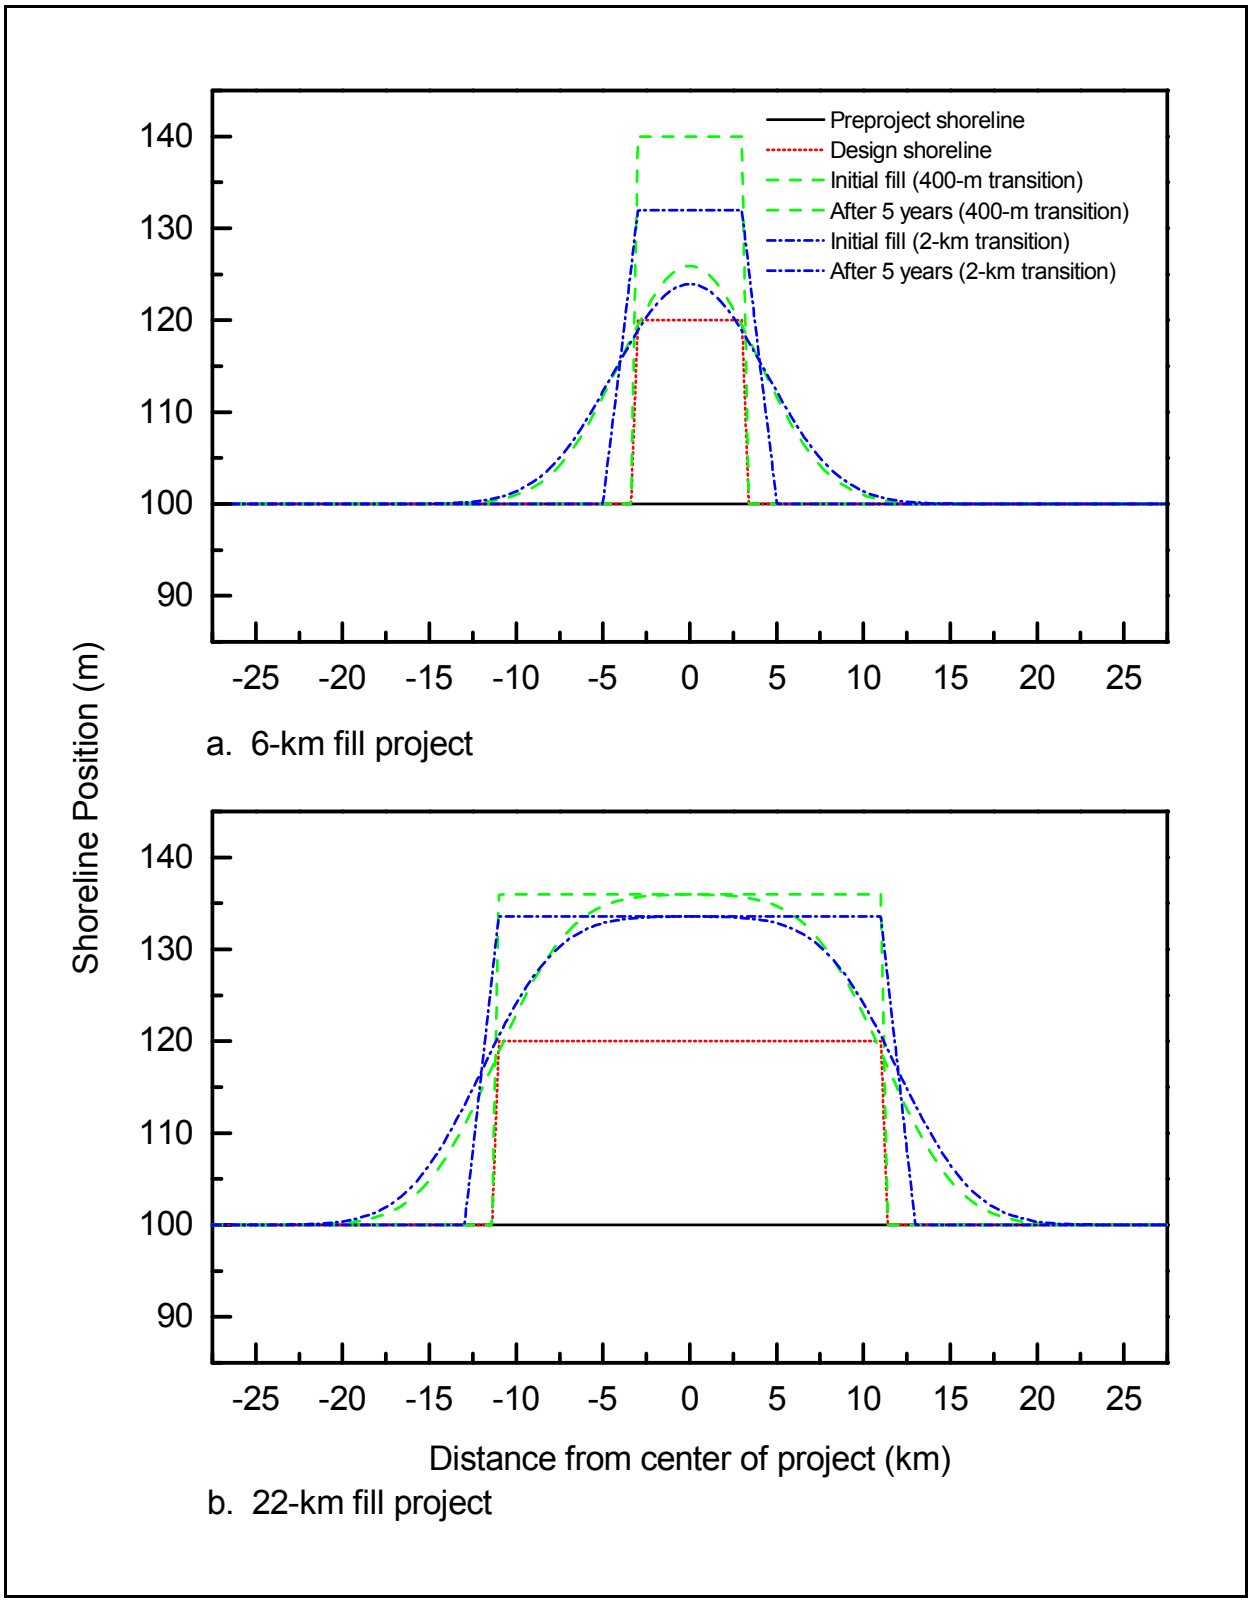

Figure V-4-28. Effect of fill transitions

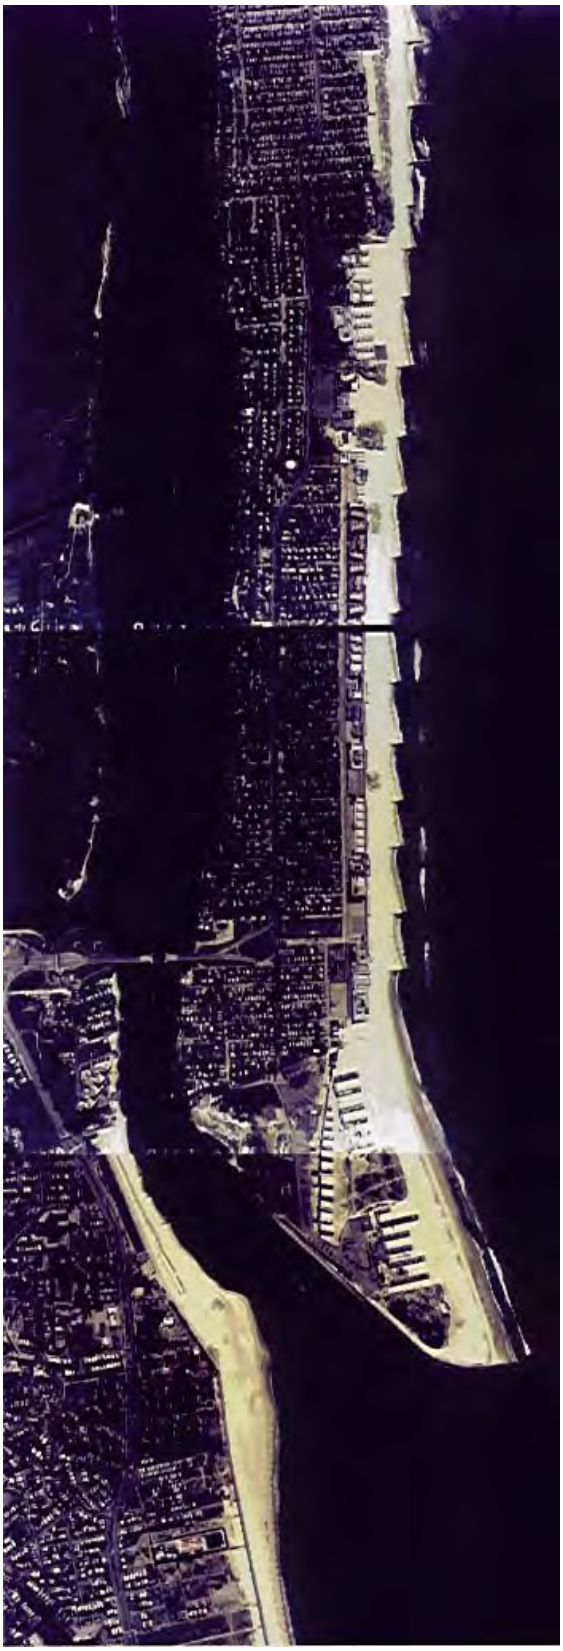

Figure V-4-29. Groin field at Long Beach island, New York

transitions sections have rarely been constructed to this length. In practice, the exact length of the fill transition section does not ultimately matter so long as it is in reasonable proportion to the scale of the project. Typical fill transition lengths for small projects (approximately 1 to 2 km; 100,000 to 200,000 m^3) are on the order of 150 to 300 m (500 to 1000 ft) long, while for larger projects they are on the order of 300 to 600 m (1000 to 1,500 ft) long.

(11) Transition sections do reduce the rate of fill loss from the project; but again, this benefit lasts only for the first few years following construction. Some past project designs have inappropriately estimated the beneficial effects of the beach-fill transitions by computing the reduction in the rate of end loss during the first few years of the project and then projecting these benefits throughout the 50-year project life. The analysis presented here suggests that while benefits associated with reduced loss rates are very high during the first few years, they diminish significantly thereafter.

(12) An analysis of beach-fill transitions should first examine the evolution of the project with transition sections, either tapered sections or lateral extensions of the design section, and then examine evolution of the project with the transition volume distributed within the project economic benefit area. The distribution within the project doesn't have to be uniform, as was the case in the examples shown here. If transitions are a desirable feature, they should be optimized by balancing the reduction in the rate of end losses from the project (which will reduce renourishment costs) with the cost of placing fill volume outside of the project's economic benefit area. Then, costs of the transition sections over the project life should be compared to the cost of using a terminal structure or compartmentalizing the beach-fill material with groins or jetties, including an assessment of any impacts that might be caused by a terminal structure. The most cost-effective approach should be selected. Environmental concerns, land ownership constraints, or other factors may also need to be considered in the selection of the optimum fill transition sections.

i. Beach-fill stabilization measures.

(1) Structures. Different types of structures can be used in conjunction with beach-fill projects to retard fill erosion and thereby reduce periodic renourishment costs. As discussed in the previous section, losses are particularly pronounced at the ends of a project where an offset occurs between the fill section and the adjacent unfilled beach. Structures may be needed in these transition zones to keep fill losses at acceptable levels. In some cases, structures may already be in place on the project beach. Depending on type and location of these structures, it may be advantageous to retain them, and perhaps refurbish them. However, some structures may have a negative effect on the beach, or are undesirable from the standpoint of aesthetics or safety. If existing structures are judged to have a probable negative effect, their removal should be considered. Following is a brief discussion of coastal structures in common use in conjunction with beach-fill projects. A more detailed discussion of their characteristics, effects, and design can be found in Part VI.

(a) Groins.

- Groins are low linear structures which are typically built perpendicular to the shoreline, extending from the beach into shallow nearshore water. Their primary purpose is to trap and retain sand moving in the alongshore direction. Groins can be constructed in groups, or fields, consisting of a series of structures spaced at predetermined intervals along a segment of shore to improve retention of beach-fill material, Figure V-4-29, or as an individual structure intended to provide effective termination of a beach-fill project. Weggel and Sorensen (1991) note that the addition and modification of groins within the Atlantic City, New Jersey, nourishment project, constructed in 1986, improved fill performance when compared to that of previous fills for the same location. The groins acted to retain the fill within the project area and prevented fill losses into the adjacent inlet.

- In the context of beach nourishment projects, the most common use of the groin is as a terminal structure, designed to reduce or eliminate sediment losses out of the project area. The use of a terminal groin is most frequently considered in projects that abut lacks tidal inlets or are adjacent to the beginning or end of a littoral cell. For example, use of a terminal groin at the end of a beach-fill project built next to an unstabilized tidal inlet will not only reduce project end losses but also prevent increased shoaling in the inlet channel caused by deposition of sand lost from the project. Likewise, a terminal groin constructed at the downdrift end of a project built updrift of a submarine canyon can substantially reduce end losses. In both of these cases, the accretionary fillet that develops updrift of the terminal groin can be a renewable source of sediment for maintaining and perhaps renourishing the project. Terminal groins are also appropriate, and should be considered, in projects where the preproject shore lacks existing sandy beach, and in projects where the postproject shoreline will be positioned substantially seaward of the adjacent beaches, particularly in short fills. Federal projects of this type are rare, but private development can often include construction of recreational beaches which depend substantially on terminal structures for their longevity. Figure V-4-30 shows an example of a terminal groin used to terminate a beach nourishment at Oregon Inlet, North Carolina.

Figure V-4-30. Terminal groin, Oregon Inlet, North Carolina

- In littoral cells where there is a dominate net longshore transport direction, a terminal groin centrally located within the cell can exacerbate erosion on the downdrift beach. A terminal groin should not be used within the interior of a littoral cell, unless the downdrift impact of the groin is defined and mitigated. Careful attention must to be given to the design of the groin's profile and length. The terminal groin profile should be a template of the design beach berm and nearshore profile such that the structure blocks littoral transport only to the extent necessary to preserve the design beach cross section, while allowing the ambient net littoral transport to bypass the structure to downdrift beaches. Careful monitoring to assess the structure's impact on the adjacent beaches is recommended. Placing a sacrificial sand fillet downdrift of the terminal groin at the time of initial construction, and perhaps during periodic renourishments, may be necessary to offset any adverse impact to the downdrift beach caused by the groin.

- Groins in general, and groin fields in particular, were commonly used to control erosion and to protect upland development in coastal projects constructed from the 1930s through the 1960s. The experience with groin fields has been checkered with both successes and failures. Groin fields have a proven capacity to provide relief for a local erosion problem by compartmentalization of the shore face and stabilization of the shoreline. However, because the compartments between the groins were rarely filled with beach material at the time of construction, the groin compartments filled over time by capturing, and retaining a portion, if not all, of the longshore sand transport. The result was typically severe erosion downdrift of the groin field. The problem was exacerbated by a chronically increasing deficit of littoral material caused by other upcoast diversions of sand (inlet dredging, breakwaters, hydroelectric dams, etc.). Present coastal engineering knowledge and predictive tools have advanced to the point where competent functional design of groins and groin fields is now possible. However, this design option is often rejected as a matter of policy by many local, state, and Federal agencies with jurisdictional authority.

- Groin fields can provide an effective and economical solution to some coastal erosion problems where shoreline stabilization is the primary project goal. Groins can improve retention of beach fill, but construction of a groin field without concurrent placement of fill is strongly discouraged. As is the case with a terminal groin, groin fields that terminate within a littoral cell, as opposed to at the end of the littoral cell, must provide for sediment bypassing to adjacent shores without interruption. Groin fields should not be terminated in areas with increasing (accelerating) net longshore transport potential. To ensure bypassing, the groin field should be filled during construction and the downdrift groin system should be tapered to provide a smooth transition to the adjacent unprotected shore (see Figure V-4-2). Groin fields have been successfully used together with beach nourishment to stabilize the highly developed southern shorelines of western Long Island at Long Beach Island, New York (see Figure V-4-29). A series of groins were refurbished at Folly Beach, SC, to reduce renourishment requirements for the beach-fill project, which was constructed in 1993 (U.S. Army Engineer District, Charleston, 1987).

- T-head and L-shaped groins are variants of the traditional straight shore-perpendicular groin. These structures include a shore-parallel head section that acts to block and diffract wave energy before it reaches the shoreline. T-head groins can provide a functional improvement over standard groins by reducing the occurrence of rip currents adjacent to the groin and to some extent blocking the offshore movement of sand adjacent to the groin. T-head and L-shape groins are best suited for protecting limited coastal reaches where the mobilizing forces include tidal currents as well as wave-generated currents and where the project objectives are more focused on compartmentalization and stabilization of the coast than on increasing beach width. A series of T-head groins constructed at Ocean Ridge, Florida, downdrift of South Lake Worth Inlet have proven to be effective in local stabilization of the shoreline (U.S. Army Engineer, Charleston, 1987).

(b) Detached breakwaters.

- Detached breakwaters are linear offshore structures generally oriented more or less parallel to the shoreline to which they have no solid connection. They can be built as a single continuous structure or segmented into a series of short sections with gaps. Detached breakwaters provide protection by reducing the wave energy that reaches the shore through dissipation, reflection, and diffraction. Compared to shore-perpendicular structures, such as groins, which provide protection by impoundment of alongshore-moving sediment, detached breakwaters can be designed to allow continued movement of longshore transport through the project area, thus potentially reducing adverse impacts on downdrift beaches. However, as is the case with groins, if fill material is not placed at the time of breakwater construction, then any sediment that accretes in the lee of the breakwaters is sediment that is denied from downdrift beaches, which can be expected to erode. The use of breakwaters for shore protection and in conjunction with beach nourishment in the United States has been primarily limited to littoral sediment-poor regions characterized by a low-energy wave climate. Most projects have been located on the Great Lakes, Chesapeake Bay, or Gulf of Mexico (Chasten et al. 1993). These projects are typically subjected to short-period, steep waves, which tend to approach the shoreline with limited refraction, and generally break at steep angles to the shore.

- While detached breakwaters have several appealing functional characteristics for shore protection, they also have disadvantages that include the following: limited design guidance, high construction and maintenance costs, limited ability to predict and compensate for structure-related phenomena such as adjacent beach erosion, rip currents, scour at the structures base, structure transmissibility, and effects of settlement on project performance. Like groins, detached breakwaters should only be utilized after careful study of the effects they will have on the project area and adjacent beaches.

- Details concerning the uses of detached breakwaters in beach-fill projects and design considerations can be found in Engineer Manual 1110-2-1617, Pope and Dean (1986); Dally and Pope (1986); Rosati (1990); and Chasten et al. 1993. Case studies of interest are contained in Nakashima et al. (1987); Gorecki (1985), and Gravens and Rosati (1994).

(2) Evaluation and optimization of stabilization structures.

(a) As discussed in previous sections, a beach nourishment project requires periodic reconstruction of the beach planform throughout the project life. In this section, use of structures to stabilize a nourishment project and reduce project end losses have been discussed. Structures such as groins and detached breakwaters are comparatively more expensive and permanent than beach-fill material. Project optimization requires an analysis of the cost-effectiveness of incorporating structures to reduce periodic nourishment requirements versus designing the project without the stabilization structures.

(b) During the plan formulation phase of the project, the performance of alternative plans (with and without fill stabilization structures) can be evaluated using a shoreline/beach change model, such as the GENESIS model, to estimate total volume requirements. A model can also provide information for assessing adjacent beach impacts resulting from the inclusion of fill stabilization structures. The effects of structure length and transmissibility can be estimated using the GENESIS model. The physical characteristics of the structure, therefore, can be optimized to best serve specific project requirements and objectives. Physical models can also be utilized to comparatively evaluate the performance of beach-fills with and without structures such as groins and breakwaters (Bottin and Earickson 1984).

(c) Techniques for design of a groin system to reduce beach-fill losses and offshore breakwater design are presented in EM 1110-2-1617. Additional guidance for the functional design of offshore breakwaters for shoreline stabilization is presented in Dally and Pope (1986) and Chasten et al. (1993).

(3) Dune stabilization. Coastal sand dunes are valuable and effective barriers to storm flooding and wave attack; and therefore, they are often an important component of the beach nourishment project. Because of the importance of the dunes to storm protection, and their vulnerability to wind- and wave-induced erosion, it is advisable to stabilize them with sand fences and vegetation. These stabilization measures are relatively inexpensive and serve two beneficial purposes: to enhance the protective nature of the dunes, and to reduce volume losses from the project due to wind blown transport of the fill. Guidelines for estimating the rate of wind blown sediment transport are provided in Part III-4. Beach-fill projects usually involve creating a much wider dry beach, so more sand is available for transport by wind. As a result, if dunes are stabilized with fences and vegetation, they often accrete with time and wind-blown sand losses from the project are minimized.

(a) Fences.

- Various types of fences have been used to create, enlarge, and stabilize coastal dunes. To be successful, the barrier must be porous to wind because a solid barrier creates turbulence that may result in scour rather than accretion. Fencing with a porosity (ratio of area of open space to total projected area) of about 50 percent should be used (Savage and Woodhouse 1969). Open and closed areas should be less than 5-cm in width. The standard slat-type wooden snow fence appears to be the most practical and cost-effective, and it has been widely used for dune stabilization and to promote dune growth. Snow fences are usually installed in single or multiple rows aligned parallel to the shoreline or perpendicular to the predominant wind direction and secured to posts about 3 m (10 ft) apart to improve their stability. If accretion fills the fences, additional fencing can be installed at the new level to promote further growth. Field tests of dune building with sand fences under a variety of conditions have been conducted at Cape Cod, Massachusetts, Core Banks, North Carolina, and Padre Island, Texas. The following are guidelines and suggestions based on these tests.

- Only straight fence alignment is recommended, and the fence should parallel the shoreline. It need not be perpendicular to the prevailing wind direction. Fence will function even if constructed with some angularity to sand-transporting winds. Fence construction with side spurs or a zigzag alignment does not increase the trapping effectiveness enough to be economical (Savage 1962; Knutson 1980). Lateral spurs may be useful for short fence runs of less than 150 m (500 ft), where sand may be lost around the ends (Woodhouse 1978).

- Placement of the fence at the proper distance shoreward of the berm crest may be critical. The fence must be far enough back from the berm crest to be away from frequent wave attack. Efforts have been most successful when the selected fence line coincided with the natural vegetation or foredune line prevalent in the area.

- Dunes are usually built with sand fencing in one of two ways: by installing a single fence and following it with additional single fence lifts as each fence fills (Figure V-4-31); or by installing double fence rows with the individual fences spaced about four times the fence height apart and following these with succeeding double-row lifts as each fills (Figure V-4-32). Single rows of fencing are usually the most cost-effective, particularly at the lower wind speeds, but double fences may trap sand faster at the higher wind speeds.

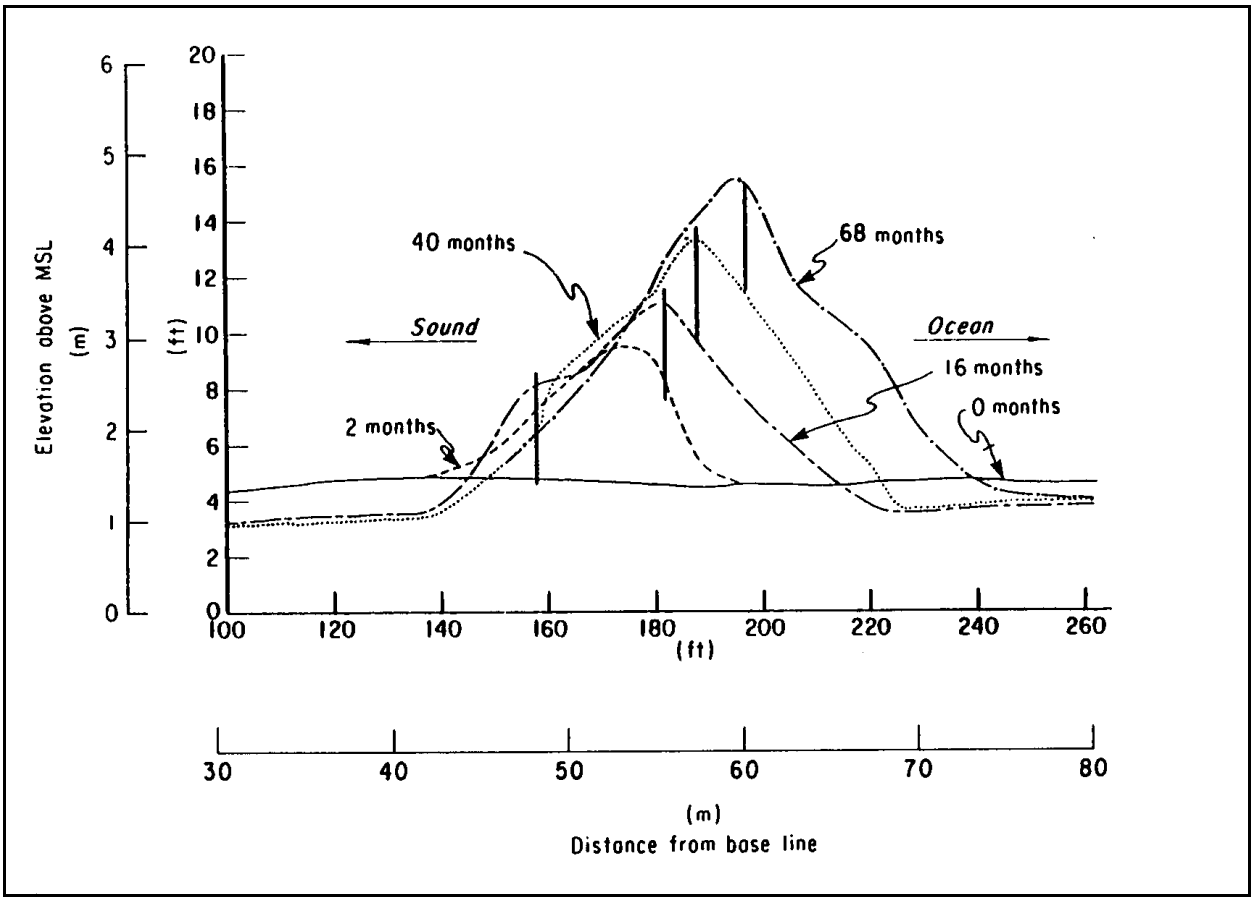

Figure V-4-31. Sand accumulation by a series of four single fence lifts, Outer Banks, North Carolina (Savage and Woodhouse 1969)

- Dune height is increased most effectively by positioning the succeeding lifts near the crest of an existing dune. However, under this system, the effective height of succeeding fences decreases and difficulties may arise in supporting the fence nearest the dune crest as the dune becomes higher and steeper. Dune width is increased by installing succeeding lifts parallel to and about four times the fence height away from the existing fence. The dune may be widened either landward or seaward in this way if the dune is not vegetated.

- Accumulation of sand by fences is not constant and varies widely with the location, the season of the year, and from year to year. Fences may remain empty for months following installation, only to fill within a few days by a single period of high winds. To take full advantage of the available sand, fences must be observed regularly, repaired if necessary, and new fences installed as existing fences fill. With sand moving on the beach, fencing with 50 percent porosity will usually fill to capacity within 1 year (Savage and Woodhouse 1969). The dune will be about as high as the fence. The dune slopes will range from about 1:4 to 1:7, depending on the grain size and wind velocity. The trapping capacity of the initial installation and succeeding lifts of a 1.2-m-high sand fence averages between 5 and 8 cu m/lin m of shoreline (2 to 3 cu yd/lin ft).

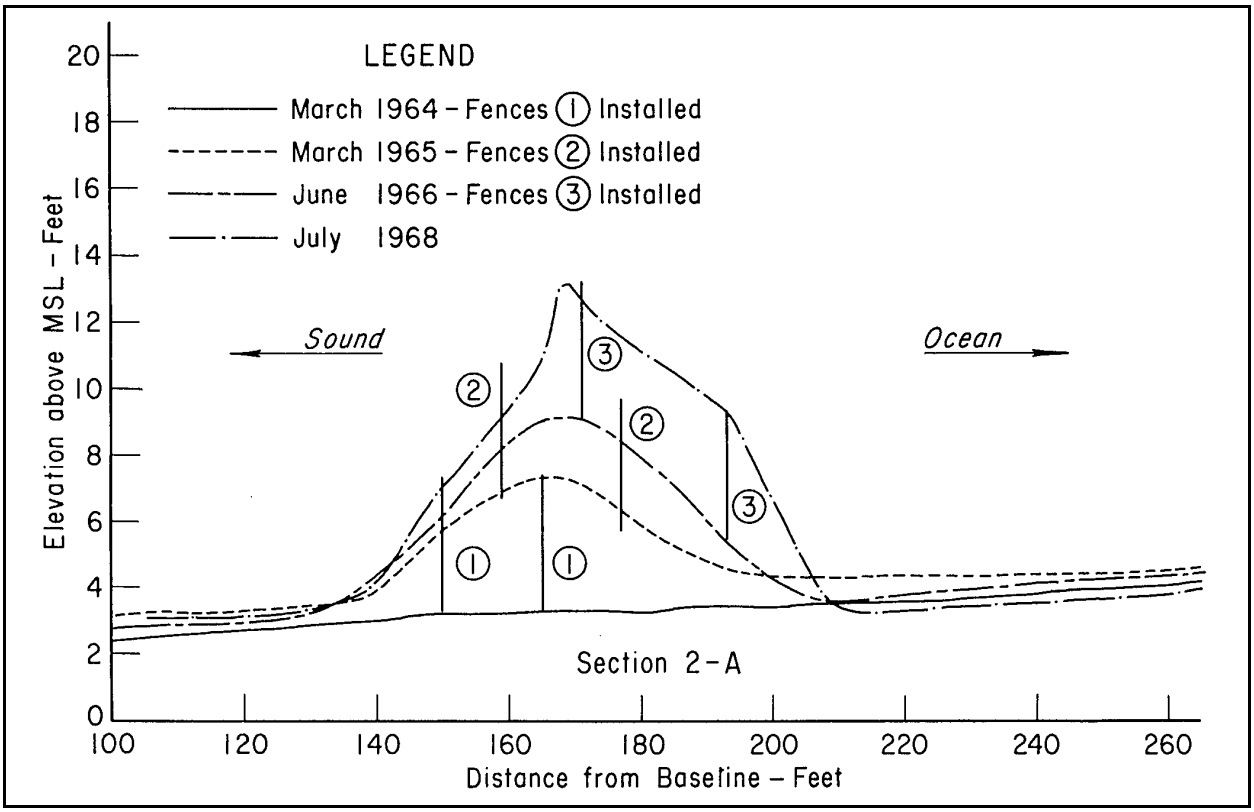

Figure V-4-32. Sand accumulation by a series of three double fence lifts, Outer Banks, North Carolina (Savage and Woodhouse 1969)

- Experience has been that an average of 6 man-hours are required to erect 70 m (230 ft) of wooden, picket-type fence or 60 m (195 ft) of fabric fence when a six-man crew has materials available at the site and uses a mechanical post-hole digger.

- Fence-built dunes must be stabilized with vegetation or the fence will deteriorate and release the sand. While sand fences initially trap sand at a high rate, established vegetation will trap sand at a rate comparable to multiple lifts of sand fence. The construction of dunes with fence alone is only the first step in a two-step operation. Fences have two initial advantages over planting that often warrant their use before or with planting: sand fences can be installed during any season, and the fence is immediately effective as a sand trap once it is installed. There is no waiting for trapping capacity to develop, unlike the vegetative method. Consequently, a sand fence is useful to accumulate sand while vegetation becomes established.

(b) Vegetation. Vegetation is a natural means of shore and dune stabilization that is effective when used under the proper circumstances. Vegetation is relatively economical, and does not detract from, but can enhance environmental quality. On open sea coasts, vegetation is primarily used to enlarge and stabilize dunes. A number of beach grasses and other plants tolerant of a dune environment can be used to create, enlarge, or stabilize dunes. Frequently used species are American beach grass (*Ammophila breviligulata*) in mid- and upper-Atlantic Coast and Great Lakes, European beach grass (*Ammophila arenaria*) on the Pacific Coast, sea oats (*Uniola paniculata*) on the south Atlantic and Gulf Coasts; and the panic grasses (*Panicum amarum*) and (*Panicum amarulum*) on the Atlantic and Gulf Coasts. All of these plants can be propagated by planting suitable stock and are effective in trapping and holding windblown sand. A number of herbaceous and woody plants are also effective in dune areas. The principal considerations in selecting plants

for dune building and stabilization are the suitability of the species for growth in the project area, its probable effects on the existing ecology, availability of stock for transplanting, and economics. Detailed information on suitability of plant species for various regions of the United States, methods of propagation and planting, and protection against disease and physical damage can be found in EM 1110-2-1204, "Environmental Engineering for Coastal Protection"; Knutson (1977); Woodhouse (1978); Savage and Woodhouse (1969); and Knutson (1980). Dune stabilization by vegetation has these advantages. It is capable of growing up through the accumulating dune sand and it can repair itself if damaged, provided the damage is not too extensive and the vegetation was well established prior to being damaged. New plantings will require periodic fertilization the first year or two, and watering the first few months, for the young plants to become well established.

(c) Dune cross-over structures. If newly-constructed or existing dunes are to be stabilized with fences and/or vegetation it is important to protect the stabilization efforts by minimizing traffic through or across the dune. Pedestrian and/or vehicular traffic will damage vegetation and fence lines. Dune walk-over structures for pedestrians and controlled vehicular access points to the beach should be provided in the overall design. Controlled access points provide recreational as well as maintenance access to the beach without damaging the stabilized dune area. Barren low spots (such as caused by trampling) within an otherwise healthy vegetated dune can experience wave overwash and further dune deflation during storms (see Part IV-2). These local areas of overwash and deflation are commonly referred to as a "blow-outs." Blow-outs reduce the dune's reservoir of sand and capability to protect upland areas from flooding. Construction guidelines for dune cross-over structures are provided in U.S. Army Engineer Waterways Experiment Station (1981).

j. Construction issues.

(1) Removal, transfer, and placement of borrow material. Removal, transfer, and placement of borrow material is typically the job for the dredging contractor. However, certain aspects of the dredging work should be understood so that practical design and reasonable specifications can be developed prior to bidding out the dredging job. With regard to the removal and transfer phases of the job, the following points are made:

(a) Offshore borrow areas typically have fine material in the top layers. Hence, if the borrow area is shallow, large losses of fines may occur during the placement operation. Typically, thicker borrow areas are more economical for this reason.

(b) The further offshore the borrow area is located, the more expensive the pumping of material becomes. Direct pumping to the beach may not be economically feasible if the borrow area is located too far offshore.

(c) If a hopper dredge or barge is used to transport fill to the site, many of the borrow material fines are washed out with overflow, hence providing a larger grain size distribution of fill material than that based on in situ samples from the borrow site. This fact and the fact that less dirty material (fines) is provided at the subaerial beach may make this type of placement desirable from an environmental and public satisfaction standpoint.

(d) Borrow areas should not be located too close to shore due to the fact that the equilibrium profile of the beach may be downcut. This could lead to offshore transport of material from the nearshore zone to make up for the deficit. If the borrow site is located too close to shore, and in too shallow water, the irregular bathymetric feature created as a result of the excavation can significantly alter the propagation of incoming waves. This could lead to an erosional hot spot. As a rule of thumb, borrow areas should be located in water depths at least twice the estimated depth of closure (see Part III-3-3-b), or a comparable distance offshore.

(e) For hydraulically-filled projects, there is a minimum practical sectional fill volume. That is, the constructed beach-fill must be of sufficient width for the contractor to erect dikes, move pipeline, and operate equipment for grading the placed fill and building the dune section, etc. Typical sectional fill volumes range from 25 to 63 m^3/m (10 to 25 yd^3/ft) for truck-haul projects and from 75 to greater than 250 m^3/m (30 to greater than 100 yd^3/ft) for hydraulically placed fill projects. Sectional fill volumes between 140 and 215 m^3/m (55 and 85 yd^3/ft) are fairly common; however, Dean and Campbell (1999) recommended a minimum sectional fill volume of 200 m^3/m (80 yd^3/ft) from a performance perspective.

(f) A good overview of various dredging systems which can be applied for beach nourishment from offshore sources is provided by Richardson (1976). If trailing suction hopper dredges are available (loaded draft $\approx$ 9 m for large hopper dredges), long borrow areas may be preferable (for long production runs). Cutterhead pipeline dredges may be more economical where borrow areas are more uniform in dimension (i.e., square) and the deposit is relatively thick (1.5 m or greater) so that the dredge and pipeline do not need to be moved far.

(g) There are four types of material placement for beach-fill purposes. Description and comments on these methods follow:

- Direct placement. In this method, the fill is placed at one time throughout the stretch of shore to be protected. This is the most frequently used method of placement. Usually, fill is pumped as a slurry onto the beach via hydraulic pipeline, then reworked into the desired configuration using earth-moving equipment. Additional pipeline is added in sections to extend the placement zone along the beach. The largest grain sizes in the slurry will settle out closest to the slurry discharge point. Likewise, the finer grain sizes will settle out at greater distances. Hence, locating discharge points in locations of known maximum erosion or hot spot regions may be desirable. Providing a sand dike behind which most of the discharge occurs will reduce loss of fines and provide better water quality in the area.

- Nearshore placement. This method is appealing because large volumes of material can be made available at low costs by hopper dredges or split-haul barges. The principle is that the material, dumped in shallow water is transported towards the beach by wave action. Early tests of this method where the material was dumped in water 6 to 11 m are presented by Hall (1952). In all cases, the results showed that the beaches did not benefit from the dumped sand to any appreciable extent. Hands and Allison (1991) have reviewed a number of offshore dumping projects and found that if disposal depth is less than closure depth, the disposal sediment would be active and move toward the beach. Although nearshore dumping may be more economical, it does not provide the level of protection to upland property that direct placement on the subaerial beach does. It is expected, though, that the nearshore mound will provide some level of wave attenuation. A mound may also change local wave refraction patterns, leading to changes in local longshore sand transport gradients.

- Continuous supply. This method is typically used at a littoral barrier (i.e., navigation channel or inlet) where sand trapped at the updrift side of the barrier is bypassed to the beach on the downdrift side. These operations are more commonly thought of and designed as sand bypassing systems rather than as a method of beach nourishment. The purpose of this approach is to restore the natural flow of littoral transport at the location where such interruption occurs.

- Feeder beaches. Feeder beaches involve the stockpiling of fill at the updrift end of the areas intended to receive the fill as the feeder beach erodes. This method is typically used for smaller projects where sand may be trucked in and/or access to discharge points on the beach is limited. The intent is for the stockpiled material to be distributed by natural littoral processes. Feeder beaches generally work well in areas that serve as a source of material for adjacent beaches. Examples are areas

immediately downdrift from inlets or other man-made structures that form a littoral barrier. An erosional hot spot may be another area where a feeder beach is useful as a means for maximizing sand retention.

- Stockpile. In some projects, sand is stockpiled landward of the primary dune (or elsewhere outside of the normally active littoral system) for use in emergency situations. The intent here is to store a quantity of material at favorable costs at a time when the dredges and equipment are already mobilized. Most often this material is used on an as-required basis to repair or restore dunes following storms, or as fill material to close a breach should one be opened by a storm. Having this material readily available at the time of a breach or when needed to restore an eroded dune line can substantially reduce the time and cost associated with completing the emergency repair. For some projects, it may be possible to anticipate that there will be a need for emergency repairs sometime during the life of the project. In these cases, it may be cost-effective to dredge and stockpile excess material for use in emergency situations at the time of initial project construction.

(2) Construction template.

(a) The construction template is the target cross-sectional profile that the contractor is expected to build to ensure that the proper volume is placed. Two construction approaches are generally used. One is to "over-build" the upper part of the beach profile, stacking the fill material to match the specified template. The second method involves placement of the fill volume over more of the active profile. The over-building method is used most often because of the availability and working limitations of equipment used to place and shape the fill, and the desire to place the material in the most economic manner, which usually means minimizing movement of the discharge point. To a degree, the second construction method involves doing what nature will do on its own anyway, redistribute the volume over more of the active profile. The over-building method relies on wave and current action to redistribute the fill to deeper parts of the active profile.

(b) In the overbuilding method, the dune and/or berm of the design profile is built to the desired elevation. However, the constructed berm width will be much greater than the design berm width for two reasons. First, the volume to be placed includes the advance nourishment volume in addition to the volume needed to create the design profile. Second, and most important, the volume is stacked in the nearshore zone only over a portion of the active depth. Figure V-4-33 shows a typical preproject beach profile, the design profile (which includes a dune), a modified design profile that includes the advance nourishment volume, and the construction template. The construction template reflects a different configuration of the sectional fill volume.

(c) The construction template is usually specified as a simple geometry, like that shown in Figure V-4-33. The dune is usually built with a trapezoidal cross section having the desired crest elevation, crest width, and side slopes (see Part V-4-1-f for guidance on selecting these parameters). The berm may include a gentle slope (1:100) that transitions from the toe of the dune to the seaward end of the berm crest on the design profile. Such a gentle slope is found on many natural benches. Additional material seaward of the design berm that arises from the overbuilding technique should be constructed to the design berm elevation. The design berm is either constructed with a uniform elevation equal to the design crest elevation or with a gentle slope from the toe of the dune to the seaward point on the design berm crest. At the seaward terminus of the constructed berm, the fill should be placed at a constant grade, the upper slope, from the berm crest elevation seaward to the elevation that corresponds to mlw. From this point seaward, the fill is placed on a more gentle slope, the lower slope, in an attempt to match the construction template. Earth-moving equipment can be used to shape the above-water portions of the profile to the desired slope. The submerged portions of the profile are more difficult to control.

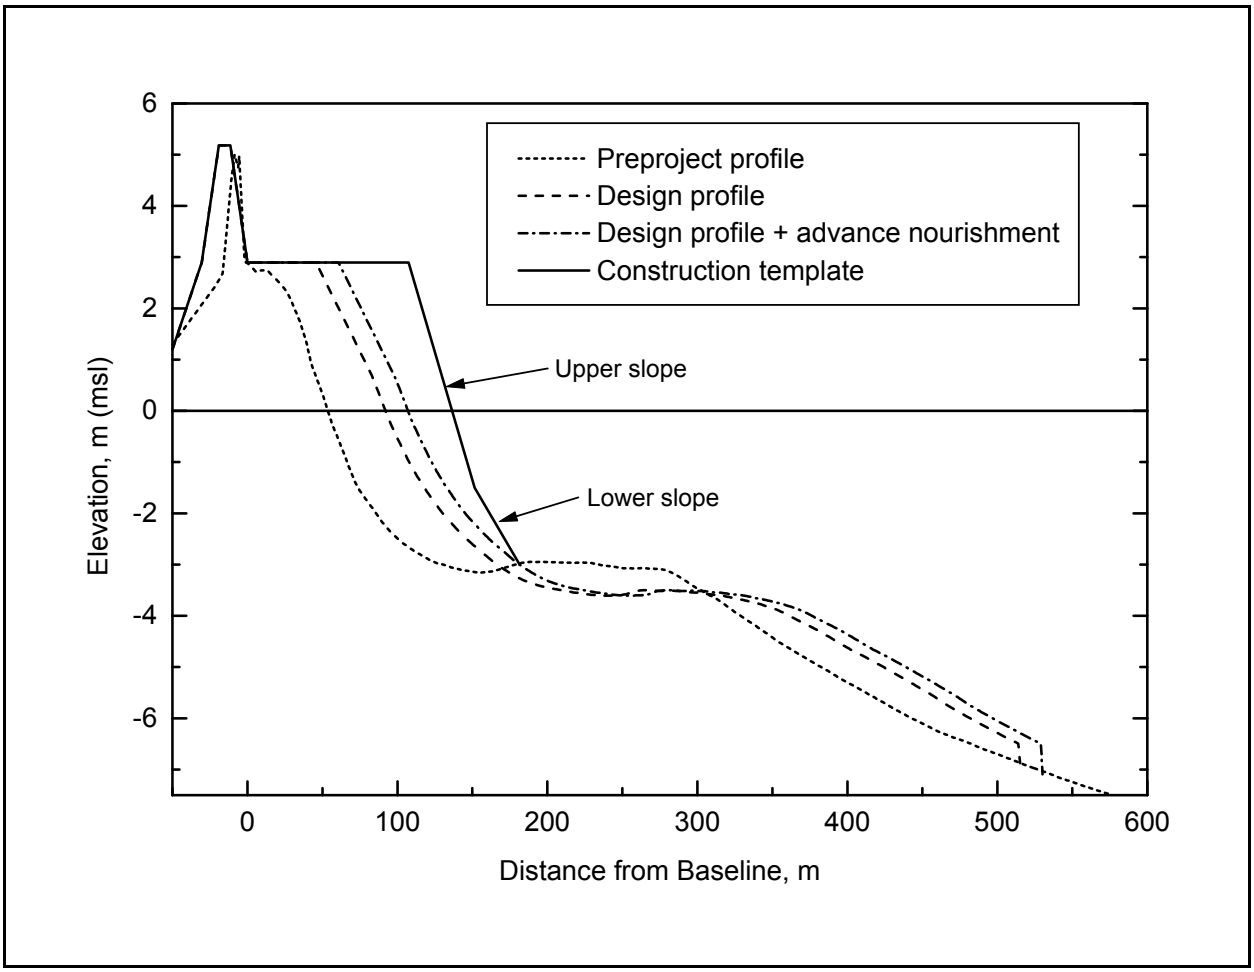

Figure V-4-33. Definition of beach profiles for nourishment projects

(d) To minimize difficulties in constructing the upper and lower slopes of the construction template, they should be defined based on expectations of how the beach will evolve after it is placed. The optimal slopes are primarily a function of the grain size characteristics of the fill and the wave and tide conditions that occur at the site during placement operations. One method for estimating upper and lower slopes involves use of the design profile. Part V-4-1-f-4 discussed methods for estimating the design profile shape. The upper slope of the construction template can be estimated as the average beach slope found on the design profile in the elevation range between the berm crest elevation and the elevation corresponding to mlw. The lower slope of the template can be estimated as an average slope computed from the design profile in the elevation range from mlw to a depth below msl which is approximately equal the typical storm wave height (e.g., 2 to 3 m below msl on the southeastern U.S. coast). The design profile reflects substantial adjustment and equilibration of the placed fill.

- Since the time between fill placement and surveying to assess compliance with the construction template might be short, full equilibration may not be realized. Therefore, the upper and lower slopes of the construction template should be chosen to be slightly steeper than the slopes estimated from the design profile.

- An alternative method is to apply the following rough rules to select both slopes.

Median Grain Size (mm)	Upper Slope	Lower Slope
D_{50} <0.2	1:20 to 1:15	1:35 to 1:20
0.2 <D_{50} <0.5	1:15 to 1:10	1:20 to 1:15
D_{50} > 0.5	1:10 to 1:7.5	1:15 to 1:10

(e) The median grain size corresponds to that of the fill material. Coarser material can be constructed to, and maintain steeper slopes; finer material adjusts to gentler slopes. Additional information on the specification of construction slopes, as a function of grain size, based on design experience in the southeastern United States is provided by Creed, Bodge, and Suter (1999). Example V-4-10 illustrates the procedure for developing a construction template.

(f) During placement, the fill should be monitored to determine actual slopes (particularly the lower slope). Strict adherence to the slope of the construction template is not an absolute requirement if the placed material seeks to attain a different adjusted slope. Adjustments can be made to the berm width of the construction template to allow for differences that occur between assumed and actual slopes. This will prevent unnecessary time being expended to mold the beach in a dynamic region of the profile. Analysis of monitoring data should be performed to ensure the prescribed sectional fill volume (volume per unit length of beach) is placed within the active beach zone. Placement of the prescribed sectional fill volume is more important than exactly matching a construction template.

(g) Scarping is one problem that may be encountered in the overbuilding approach. Scarps may develop at the toe of the fill as waves begin the profile adjustment process. Scarps can pose a threat to human safety, and they also present a problem for nesting sea turtles. Scarps can be mechanically smoothed as part of the construction contract or during regular beach maintenance and cleaning. Designing the berm crest elevation to be equal to the natural berm crest elevation, and selecting an upper slope of the construction template similar to the foreshore slope of the design profile, will minimize the likelihood of severe scarping.

(h) The second construction method involves placing more of the fill offshore, i.e., nourishing more of the active profile rather than stacking the material in the inshore zone. In this method, the target construction template is more or less the design profile. However, emphasis is placed on providing the required volume to the active profile, with less emphasis on achieving an actual construction template. Placement at various points across the profile may be more costly depending on the dredge plant used to construct the project. All material should be placed in depths less than the depth of closure. Accurate surveying is needed to monitor the actual volume of material placed, especially in the deeper portions of the active profile.

(3) Postconstruction profile adjustment. As previously above, construction profiles are generally out of equilibrium with the prevailing coastal processes, and they will begin to change shape during and after placement. This is particularly true for fills placed using the overbuilding method, where sand is “stacked” in the nearshore zone. Sand moved to lower elevations on the profile (eventually down to the depth of closure) is required to create and support the volume of sand visible on the dry beach.

EXAMPLE PROBLEM V-4-10

FIND:

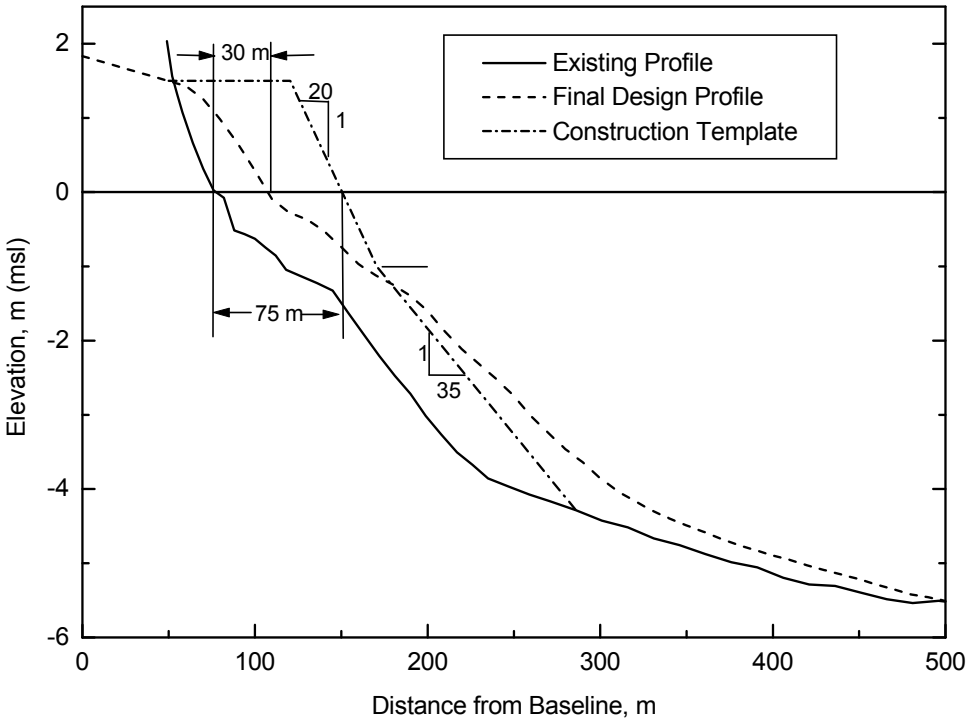
Develop and plot the construction template together with the existing and final design profiles for the design condition discussed in Example V-4-2.

GIVEN:

Existing condition profile (Example V-4-2 Figure A).
Final design profile (Example V-4-2 Figure D).
Sectional fill volume is 298 m^3/m.

SOLUTION:

Develop a schematic construction template with berm elevation of 1.5 m (msl), a 1 on 20 slope from the berm crest to -1 m (msl) and a 1 on 35 slope from -1 m (msl) to the intersection with the existing profile. Translate the schematic construction template such that the volume between the existing profile and the construction template equals the volume difference between the existing profile and the final design profile. The results of this procedure are illustrated below. Note that the msl shoreline is advanced 75 m by the construction template whereas the design condition msl shoreline advances the shoreline only 30 m beyond the existing condition.



(a) The high water levels and more energetic wave conditions that accompany storms are very effective in adjusting the fill. Usually, the nourished profile will adjust to a shape that is much closer to the expected equilibrium shape during the first full winter season, at least on the portions of the profile that are shallower than the typical winter storm wave breaking depth. However, unless very severe storms are experienced during that first winter season, the fill material may not adjust to elevations equal to the depth of closure. Through the life of the project, as more severe storms are encountered, the material will be transported to deeper depths.

(b) For nourishment projects constructed using the overbuilding method, the initial adjustment process and resulting decrease in beach width can be quite dramatic. A rapid decrease in beach width from the constructed width to the design width (including advance renourishment) is often observed, and is to be expected. As a rule of thumb, decreases in beach width of 40 to 75 percent can be expected within a short period of time (months) immediately following construction if the overbuilding method is used. Projects constructed by placing material across much more of the active profile will see less dramatic adjustment in the width of the placed beach.

(c) The public often perceives this dramatic initial adjustment as project failure, particularly in light of the fact that most of the adjustment occurs either during construction or within a few months after construction. Many projects are built during the winter season (storm season) because of environmental windows imposed on the project, or to avoid the heavy beach-use season. A special effort should be made to educate the public and project sponsors regarding the initial adjustment process, and the differences between constructed profiles and design profiles. If the stacking method of construction is used, it should be explained to the project sponsors and beach users (local community) that the project is less expensive to build utilizing this unnatural construction template, and that the beach berm width will be reduced as natural processes redistribute material to the natural/equilibrium profile. Seasonal, cyclical changes in beach width should also be explained, i.e., loss of beach width during the winter storm season, and subsequent beach recovery during the summer. Seasonal changes in beach width will be masked initially by the much larger changes associated with the initial adjustment process.

k. Plans and specifications

(1) Schedules.

(a) Overall start and completion dates. The contractor is required to commence work under a contract within a specified number of calendar days after the date the contractor receives the notice to proceed. Typically, a period of 10 calendar days is specified. The contractor is directed to prosecute the work diligently and complete all work, ready for use, not later than a specified number of calendar days after receipt of the notice to proceed. The time stated for completion also includes final cleanup of the premises. Time needed to complete the work is directly dependent on the scope and extent of the project, and can vary from as little as 60 to 90 days up to a number of years for large projects. For example, the Atlantic Coast of Maryland Shoreline Protection Project, which included the placement of about 3.5 million cu m of beach-fill and dune construction along about 8 miles of shoreline, required completion within 720 days following the receipt of the notice to proceed (Anders and Hansen 1990). For some projects, start and completion dates may be dictated by environmental considerations such as dredging windows or recreational seasons. Sufficient completion time should be provided to avoid excessively high bids from potential contractors. To enforce the specified completion time for a project, liquidated damages are generally required for each day of delay.

(b) Start and completion dates for specific subtasks. Interim start and completion dates may be required for specific subtasks depending on the scope of the project. For example, an interim completion date for

beach-fill placement between designated stations may be required to enable other project features such as revetment or bulkhead construction to proceed.

- Depending on the scope of the project, the contractor may be required to develop a network analysis system for scheduling the work. The system should consist of diagrams and accompanying analyses that show the order and interdependence of activities and the sequence in which the work is to be accomplished by the contractor. In preparing this system, the scheduling of construction is the responsibility of the contractor. The requirement for the system is included to assure adequate planning and execution of the work and to assist the contracting officer in appraising the reasonableness of the proposed schedule and evaluating progress of the work. An example of one of the numerous acceptable types of network analysis systems is shown in USACE Pamphlet EP 415-1-4 entitled "Network Analysis System Guide."

- A preliminary network defining the contractor's planned operations during the first 60 calendar days after notice to proceed should be submitted soon after the notice to proceed. The contractor's general approach for the balance of the project should be indicated. The complete network analysis system consisting of the detailed network analysis, schedule of anticipated earnings as of the last day of each month, and network diagrams should be submitted within a specified number of calendar days after receipt of notice to proceed. The approved schedule should then be used by the contractor for planning, organizing and directing the work, reporting progress, and requesting payment for work that is completed.

(c) Expenditures. The contractor should submit, at monthly intervals, a report of the actual construction progress. The report should show the activities or portions of activities completed during the reporting period and their total value, which serves as the basis for the contractor's periodic request for payment. Payment made should be based on the total value of activities completed, or partially completed, after verification by the contracting officer. An updated network analysis should be used as a basis for partial payment. The report should state the percentage of work actually completed and scheduled, as of the report date, and the progress along the critical path in terms of days ahead or behind the allowable dates. If the project is behind schedule, progress along other paths with negative slack should also be reported. The contractor should also submit a narrative report which should include but not be limited to a description of the problem areas, current and anticipated factors causing delay, the impact of delay, and an explanation of corrective actions taken or proposed.

(2) Specifications.

(a) Boundaries of the project area. The limit of the geographical area available to the contractor must be shown on the project drawings. Except where indicated, the contractor should confine his work to the area seaward of the construction baseline and between the lateral limits of the project. This area does not generally include access, storage, and staging areas. Access routes and storage and staging areas required to perform the work should be provided by and at the expense of the local sponsor. Sponsors are generally given credit for the cost of obtaining the necessary easements and rights-of-way, which count toward their share of project costs. The contractor should coordinate access to the work area and storage and staging area locations with the contracting officer. Unless otherwise approved by the contracting officer, excess equipment should only be stored in approved storage or staging areas, or in temporary areas, in the immediate vicinity of the fill placement site. Operation of grading and other construction equipment should not be permitted outside the work area limits except for ingress and egress to and from the site at approved locations.

(b) Boundaries of the borrow area. All excavation for beach-fill material should be performed within the borrow area limits shown on the project drawings. Excavation in the borrow areas may be restricted to specified elevations depending on the findings of the geotechnical investigations of the borrow site (see

Part V-4-1-e). For offshore sources, the contractor should be required to set appropriate buoys which should meet U.S. Coast Guard standards to delineate the limits of the borrow areas. The contractor should be required to have electronic positioning equipment capable of achieving Class 1 survey accuracy as specified by EM 1110-2-1003, "Hydrographic Surveying." This accuracy is necessary to locate the dredge when operating in the borrow area. The geographical position of the dredge should be continuously monitored at all times during dredging operations. Locations should be determined with a probable range of error not to exceed 15.24 m (50 ft) to avoid violations of the environmental permits and clearances. Position data should be furnished as a part of the daily report of operations. Prior to initiation of any dredging, the contractor should submit for approval his proposed method of determining the dredge's location. Use of Loran-C positioning systems should be avoided, as output coordinates are not typically repeatable from one machine to the next.

(c) Routes between borrow area and project site. Determination of the route and the method used to transport beach-fill material from the borrow area to the fill site should be at the contractor's option. For offshore borrow sources, the contractor should be required to conduct the work in such manner as to obstruct navigation as little as possible. Upon completion of the work, the contractor should promptly remove his plant, including ranges, buoys, piles, and other marks placed by him under the contract in navigable waters or on shore.

- If a pipeline dredge is utilized in a congested navigation area, the pipeline may have to be submerged except at the dredge or at the location of any booster pumps or pumphouse barges. The contractor should maintain a tight discharge pipeline at all times. The joints of the pipeline should be so constructed as to preclude spillage and leakage. Upon development of a leak, the pipeline should be promptly repaired and the dredge may have to be shut down until a complete repair has been made.

- If a submerged pipeline is placed across a navigable waterway, the contractor should notify the contracting officer in writing. Notification should be received in the District Office prior to the desired closure date. This notification should furnish the following: location and depth (over the top of the pipeline) at which the submerged line should be placed; the desired length of time the navigable water is to be obstructed; the date and hour placement or removal should commence; and the date and hour of anticipated completion.

- It is recommended that a statement concerning submerged pipelines similar to the following be included in the dredging contract:

"Submerged Pipelines. In the event the contractor elects to submerge his pipeline, the top of the submerged pipeline shall be no higher than the required dredging depth for a channel for which the pipeline is placed. The submerged pipeline shall be marked with signs, buoys, and lights as required to the complete satisfaction of the contracting officer."

- Complying with this requirement may require that the contractor excavate a trench in the channel bottom. If it is known during the design phase that a submerged pipeline will cross a navigable waterway, then specifications and provision for the contractor to establish (trench) the crossing should be explicitly provided. The equipment necessary to trench the crossing, and the disposal site for the trenched material will, in all likelihood, be different than that required to construct the beach-fill.

- If the contractor elects to use a hopper dredge or pumpout barge, overflow during loading should be permitted to the extent that designated turbidity and water quality standards are met. The contractor should limit the loading to partial loads, if necessary, to meet turbidity and water quality requirements for the overflow during loading. No overflow or spillage should be permitted during transport to the discharge site.

(d) Placement methods. The contractor should be given the option of starting the beach-fill placement operations at any point and proceeding in any direction along the project beach, unless special conditions exist.

- Acceptance reaches, which are segments of beach measured along the construction baseline between designated stations used to monitor construction of the project, should be defined and identified on the project drawings. For the case of the lateral termini, the acceptance reach is the segment of beach, measured along the construction baseline, between the longitudinal limit of fill and the subsequent designated station.

- Once the contractor begins placement in an acceptance reach, placement in that reach should be completed before proceeding to another acceptance reach. Beach-fill placement operations should proceed in an orderly manner from reach to reach. If more than one dredge and/or pumpout facility is utilized by the contractor, more than one beach-fill operation may be accomplished simultaneously. Placement of beach-fill in multiple locations at any one time should only be allowed if adequate inspection is available.

- Prior to initiation of beach-fill operations, the contractor should submit for approval his proposed plan for beach-fill placement. The plan should include the type of dredge plant to be utilized, the location and type of any booster pump facilities to be utilized, and the sequence of work for beach-fill placement. The contracting officer should reserve the right to reject any scenario which, in his/her opinion, might be detrimental to the stability of the in-place beach-fill, might unduly disrupt access to or use of the beach by the public during placement operations, or for any other credible reason. Excavation of sand from the existing beach for use as beach-fill should not be permitted.

- All materials excavated from the borrow areas should be transported to and deposited on the beach or dune area within the specified lines, grades, and cross sections in a controlled manner so as to maximize sand retention within the beach-fill section and minimize losses to the ocean. This should be accomplished in a manner acceptable to the contracting officer and should include, but not be limited to temporary diking where required, control of the discharge pipe direction and velocity of discharge, and control of the sand and water mixture. Temporary diking included within the dune cross section may be left in place and incorporated into the dune structure.

- For dredged borrow sources, fill placement on the beach can be accomplished by a single or double-pipe system. The double-pipe system consists of a yoke attached to the discharge line, and by use of a double-value arrangement, the discharge slurry is selectively distributed to either one pipe or the other, or to both pipes simultaneously. The beach is built by placing the first discharge pipe at the desired final fill elevation and pumping until the desired elevation is reached. By alternating between the two discharge lines, the beach width is built to the full cross section as they advance. The final placement to the design lines and grades can be accomplished using bulldozers.

- The contractor should be required to maintain and protect the beach-fill in a satisfactory condition at all times until acceptance of the work. Prior to placement of beach-fill, the contractor should remove from the work site all snags, driftwood, and similar foreign debris lying within the limits of the beach-fill section.

- The excavated material should be placed and brought to rest on the beach to the lines, grades, and cross sections indicated on the project drawings, unless otherwise directed by the contracting officer. The beach topography is subject to changes and the elevations on the beach at the time the work is accomplished may vary from the design elevations and the resulting beach-fill quantities may vary from that shown in the unit price schedule. To accommodate this situation, the contracting officer should reserve the right to vary the beach-fill cross sections at any location along the beach.

- The contractor should be responsible for any damage caused by excessive discharge water flowing landward from the beach-fill section. However, the plans and specifications should specify that the contractor will construct sand dikes of a minimum length to control water discharge and promote settlement of the slurry's sediment. Where a pipeline is placed on the beach, sand should be placed around the pipe to form a pedestrian ramp over the pipe at street ends and at midblocks or at locations otherwise directed by the contracting officer. All such ramps should be maintained as long as the pipe is in place.

(e) Final project dimensions. The intent of the contract is to place beach-fill to the lines and grades prescribed in the contract. Tolerances should be provided in the template for the practicality of construction. A tolerance of ±0.2 m (0.5 ft) is usually permitted for the dune and berm design sections. However, in light of the critical nature of beach elevation to shore protection and flood damage reduction, the contractor should be required to provide his best efforts in placing material to the designated lines and grades landward of the influence of waves. Persistent over- or underfilling of the construction template to the plus or minus tolerance should not be permitted. It should be considered that the primary goal of nourishment is to place a specified volume of material per unit length of beach. The required dimensions of the construction template, specifically the width of the construction berm, should not be explicitly specified so that the width of the berm can be adjusted during construction to account for the actual foreshore slope the fill acquires during placement.

- Any material placed above the prescribed cross section, plus the allowable tolerance, should not be included in the pay quantities; however, such material may be left in place at the discretion of the contracting officer. In the event that material placed at any prescribed cross section is below the minus tolerance, the contractor should be required to provide additional sand to the level of the beach-fill template.

- Upon completion of all fill operations in any acceptance reach, the beach should be graded and dressed to eliminate any undrained pockets and abrupt mounds or depressions in the beach-fill surface as necessary to comply with tolerance requirements specified. All temporary dikes not incorporated into the dune cross section should be completely degraded.

- Any material deposited in areas other than those designated or approved by the contracting officer should not be paid for. The contractor should be required to remove such misplaced material and deposit it where directed, at his expense.

(f) Calculating fill volume for payment purposes. Options for calculating fill volumes for payment include: tabulation of the fill delivered by truck load from land borrow sources, comparison of pre- and post-dredging surveys for offshore sources, and measurement of in situ volumes after placement. Of these options, the latter is recommended. With this method, acceptance reaches should be used for the purpose of closely monitoring the cumulative amounts of beach-fill placed. Acceptance reaches should also be used to control the timing for pre- and postplacement surveys. Acceptance for payment by the contracting officer of a reach should not be made until all beach-fill placement is made within the acceptance reach and final surveys have been approved. Separate acceptance for the dune portion of the beach-fill may be made for an acceptance reach upon approval of the contracting officer. In no case, however, should the contractor be paid more than

once for sand placed in any space along any acceptance reach should erosion occur before the entire volume of sand is placed. Unless otherwise approved by the contracting officer, acceptance reach stationing should be as shown on the contract drawings.

- Beach fill, satisfactorily placed, may be measured for payment by use of the average end area method. The quantity computations should be verified from survey data submitted by the contractor in accordance with specified procedures. The basis of measurement should be the preplacement cross sections of the beach and dune area taken by the contractor just prior to the placement of fill and a second set of cross sections of the same area taken by the contractor as soon as practicable after completion of beach-fill placement for any acceptance reach. The plans should depict existing conditions and the construction template at intervals along the shoreline not greater than 150 m (500 ft). Measurement for payment is typically surveyed at more frequent intervals, often at about 30-m (100-ft) spacing. Once postplacement surveys have been taken in an acceptance reach, no removal of beach-fill material should be permitted in that reach unless otherwise directed by the contracting officer. Landward of the wave runup limit (in general, landward of the seaward berm crest position), the area of fill material lying above the plus tolerance (an elevation tolerance of less than ± 0.2 m is typical) template should be deducted from the gross area and the net amount used as a basis for payment. Seaward of the wave runup limit, the quantity of fill material used as a basis for payment should be that determined from the area of fill measured between pre- and postfill cross sections, less any material placed seaward of the intersection of the construction template with the existing sand surface (corrected as necessary for the actual slope taken by the fill material, if deemed appropriate by the contracting officer). Compliance with the construction template should be judged reasonably on the submerged portion of the profile. Success of the placement should also consider placement of the required volume of fill per unit length of beach within the active depth (landward of the design depth of closure).

- Payment for beach-fill should be made at the contract price per unit volume. Such payment should constitute full compensation for furnishing all labor and performing all work necessary to excavate, transport, and place beach-fill material, and all other items of work required by the drawings and the specifications for which separate payment is not provided.

- Survey specifications should indicate that the contractor conduct the original and final surveys, and surveys for any interim period, for which progress payments are requested. All these surveys should be conducted under the direction of the contracting officer, unless the contracting officer waives this requirement in a specific instance. The contractor should employ a registered and licensed land surveyor, experienced in land and hydrographic surveying, to perform the work required for quantity surveys. Prior to initiation of any quantitative beach surveys, the contractor should submit to the contracting officer for approval, a description of his method and type of equipment for performing the surveys.

- The contractor should make such surveys and computations as are necessary to determine the quantities of work performed or sand placed. All original field notes, computations, and other records should be furnished to the contracting officer at the work site.

- The contractor should perform his preplacement surveys of an acceptance reach no more than 5 days prior to placement of beach-fill material within that reach. Prior to placement of fill material the contractor should submit to the contracting officer, all field notes, data disc(s), and computations, with sufficient lead time so that control of quantities, and if necessary, adjustment to the berm width can be made.

- Postplacement surveys should be made as soon as practicable after completion of an acceptance reach. The contractor should use the same survey stations that were used in the preplacement surveys. Postplacement surveys for the next reach should not be conducted until the previous reach is accepted by the contracting officer.

- The contractor should prepare and provide to the contracting officer, immediately after completion of an acceptance reach, cross-sectional drawings showing the preplacement conditions, post-placement conditions, and the design beach-fill template for each section surveyed. The survey cross sections should be taken perpendicular to the construction baseline at specified stations, and at the beginning and ending acceptance reach stations. When unusual site or geographical conditions exist, additional stations and elevations should be taken for greater definition. The pre- and postplacement surveys should extend some distance seaward of the intersection of the construction template with the existing sand surface and that distance should be specified. The scale for the plotted cross sections should be on the order of 1 to 60 in the vertical (1 cm = 0.6 m or 1 in. = 5 ft) and 1 to 240 horizontal (1 cm = 2.4 m or 1 in. = 20 ft). All stations and elevation points taken from field books should be clearly indicated on the cross-section plots.

l. Project monitoring and data analysis. Beach fills are "soft structures" which respond dynamically to changing waves and water levels, similar to natural beaches. Physical responses of a beach-fill include post construction adjustment of the placed sand, seasonal variation and storm-induced changes of the beach profile, and seasonal and long-term change of the project planform. Functional performance of a beach-fill requires that the design cross section and planform be maintained over the life of the project through scheduled periodic renourishment, and emergency maintenance and/or renourishment after severe storms. The dynamic behavior of beach-fills together with the need to ensure project functionality over the design life requires that a systematic monitoring plan be established for beach-fill projects.

(1) Monitoring objectives. Primary objectives of monitoring beach-fill projects are to ensure that project functionality is maintained throughout the design lifetime, and to assess project performance. These objectives involve collection, analysis, and interpretation of data to: evaluate the condition of the project in comparison to design specifications; determine maintenance and renourishment volume requirements; document and assess project performance to determine how well it fulfills the protection requirements for which it was designed; evaluate project impacts on adjacent areas; and address performance problems by identifying causes and developing solutions.

The first two activities listed relate primarily to operational monitoring and provide information required to operate and maintain the project. The latter three activities relate to performance monitoring, and measure the success of the project, identify project problems, and provide information for improving the project design.

(2) Physical monitoring components. A physical monitoring plan for a beach-fill project consists of four major components: beach profile surveys, beach sediment sampling, aerial shoreline photography, and wave and water-level measurements. These four components provide information required to document the physical response and condition of a beach-fill project. A recommended schedule of data collection is presented in Table V-4-1. The schedule is divided in two phases. The initial phase is a period of more-intensive monitoring during the first 3 years of the project that focuses on monitoring the performance of the project. During this phase, data are gathered to confirm that the project design is performing as expected and to identify potential design problems such as erosional hot spots, unexpected project impacts, or inadequate design volumes and cross-section dimensions. If problems are identified, the monitoring data provide information for developing solutions and improving project performance based on an understanding of the physical processes. Assuming the project is functioning properly and design/performance deficiencies are addressed, the monitoring plan presented in Table V-4-1 transitions to a second phase after the third year.

Table V-4-1
Physical Data Collection Schedule for Beach-Fill Monitoring

Phase I: Initial Placement and Project Years 1 to 3[1]

Monitoring Component	Initial Placement		Year 1 Following Initial Placement				Years 2 to 3		Years 1 to 3 Poststorm Contingency
	Pre-fill	Postfill	Mar	Jun	Sep	Dec	Mar	Sep	
Beach profile surveys	X	X	X	X	X	X	X	X	X
Sediment sampling	X	X			X				
Aerial photography	X				X			X	
Waves and water levels	Continuous								

Phase II: Nonconstruction Years for Project Years 4 to N (N= Project Life)

Monitoring Component	Even Number Years Following Each Construction	Odd Number Years Following Each Construction	Years 4 to N Poststorm Contingency
	September	September	
Beach profile surveys	X	X	X
Aerial photography		X	

Phase II: Beach Renourishment

Monitoring Component	Renourishment		Year Following Renourishment
	Prefill	Postfill	September
Beach profile surveys	X	X	X
Sediment sampling	X	X	X
Aerial photography	X		X

[1] Following Year 3, decision is made whether to continue Phase I level of monitoring

The second phase of the plan employs an operational level of monitoring to annually assess the condition of the project. This phase of monitoring also provides information for assessing longer term aspects of project performance. Details of the monitoring components and schedules are discussed in the following paragraphs.

(a) Beach profile surveys. Profile surveys provide data which are used to calculate fill volumes and document changes in the beach cross section. Accurate estimates of fill volume are essential during construction to ensure that required design volumes are placed in the construction template, and to verify payment to contractors. Periodic surveying of profile lines over the project lifetime enable calculation of volume of fill remaining in the project bounds and on the subaerial beach and comparison of the present project condition with the required design template.

- Where practical, profile surveys should be conducted using a sea-sled system. Because of the accuracy, simplicity of design, and wide availability of system components, the sea sled is considered to be the best method for profiling beach nourishment projects (Grosskopf and Kraus 1993). An added advantage is that sea-sled surveys can extend from the upper portion of the dry beach out to the depth of closure. In areas where sea-sled surveys are not practical (e.g., in environments with reefs, rock outcrops, submarine canyons, etc.), offshore surveys should be taken by boat with a properly calibrated fathometer and combined with land-based rod and level surveys performed out to wading depth. When using this combined technique, care must be taken to avoid problems in matching the land-based and fathometer surveys.

- Survey locations should be selected to include profiles within the project limits as well as control profiles some distance up and downdrift of the project boundaries to assess benefits or impact on adjacent shorelines due to longshore spreading of the fill. The number and location of profile surveys is site specific and depends on the length of the fill and the degree of longshore uniformity of the beach morphology. On an essentially straight open-coast beach, longshore profile spacing of approximately 300 m should provide adequate resolution for periodic condition profile surveys. Pre- and postconstruction profile surveys are routinely collected at higher resolution, with spacing of 60 m or less, to accurately determine placement volumes for payment purposes. To reduce costs, profile spacing can be evaluated after several monitoring cycles to determine if the number of profile surveys may be reduced while still adequately characterizing the condition of the project.

- Profile locations should be established along a reference baseline from benchmarks that are documented and recoverable in future years. The project baseline should be set at the beginning of a project study, and all surveys should be referenced to this baseline. The surveys should extend across the entire zone of profile change from the upper profile, landward of any dune, out to beyond the depth of closure.

- In practice, exact timing of beach profile surveys depends on the construction sequence and climatic conditions; but in general, surveys should be conducted as indicated in Table V-4-1. Surveys taken immediately prior to and following construction document fill volumes and cross sections. Quarterly surveys taken during the first year following initial construction document the rapid response of the constructed cross section as it forms a more natural shape. Semiannual surveys measured in years 2 and 3 of the project record the ongoing adjustment of the project cross section. After the third year of the project, survey frequency can be reduced to once a year assuming the project is performing satisfactorily. It is recommended that these annual surveys be performed at the end of summer (or the typical period of low-energy wave conditions) to determine project condition prior to winter (or the typical storm season).

- The monitoring plan should include continency plans to collect surveys immediately after severe storms. Poststorm profile data document storm-induced beach change and poststorm condition of the project.

- Site inspections should be performed concurrently with all beach surveys, and at least once each year. Inspections should document any information relevant to characterizing the condition of the subaerial beach (e.g., level of dune vegetation, evidence of modification or addition of fill material by local property owners, effects of storms such as scarping or overwash, presence of poststorm recovery berm, longshore variability in subaerial beach features). Site inspections should include photographs of the beach, taken looking alongshore, to provide a visual record of the project condition.

(b) Beach sediment samples. Sampling is needed to determine sediment characteristics, such as median grain size and grain-size distribution, which affect the beach profile shape and influence fill volume requirements. Sediment sampling is of particular importance when fill and native material have different characteristics. Sampling of beach sediment provides data that can be used to relate project performance to characteristics of the fill material. This information can then be used to evaluate future borrow-material suitability and determine required fill volumes for renourishment.

- Sediment samples should be collected at selected locations within the project area to account for longshore and cross-shore variability in sediment characteristics. The longshore sample spacing should be approximately 900 m, with sampling locations corresponding to the nearest profile lines.

- Sediment sampling should consist of shallow grab samples at various locations across the beach profile including the dune, berm, midtide level, mlw, and three subaqueous samples spaced uniformly out to the depth of closure (Larson, Morang, and Gorman 1997). This sampling scheme documents cross-shore variability of the median grain size and size distribution which influence profile shape.

- Sediment samples should be collected before and after initial construction and each renourishment, and 1 year following each construction. Sediment sampling should be performed concurrently with beach profile surveying.

(c) Aerial shoreline photography. Aerial photography is an essential monitoring component for documenting long-term performance of beach-fills. Aerial photographs provide a visual record of shoreline position, variations in beach planform, condition of the dune and berm, and subaerial beach width; and do so with a total-project perspective that cannot be obtained by ground photography and beach profile surveys alone. Such information is useful for documenting project planform evolution, evaluating project end effects, and identifying erosional hot spots. Aerial photographs, together with beach profile surveys, provide information on the 3-D characteristics of fill behavior that can be used to better assess condition of the project and renourishment requirements.

- Aerial photography should be taken along a single flight line with 60 percent overlap stereo coverage of the entire project area shoreline, including updrift and downdrift control areas. The scale of the photographs should be sufficient to identify shoreline features. An approximate scale of 1 cm equals 50 m is recommended. All photography should be taken near midday and around low tide to reduce shadows and reflections and to provide the maximum area of exposed intertidal beach.

- Aerial photography should be performed before initial placement and after each construction to document the preproject and postnourishment shoreline. During the first 3 years, aerial photographs should be taken annually to record initial planform spreading and shoreline response to measured wave conditions. After the first 3 years, aerial photographs should be taken once every 2 years between construction and in the year following each construction. It is recommended that aerial photographs be collected in September (prior to the storm season) when the beach is typically in its most-accreted condition. During this time, effects of storms on the observed shoreline are minimized, allowing easier assessment of fill condition from year to year and providing a more consistent measure of long-term project performance.

(d) Wave and water level measurements. Waves and water levels are the principal hydrodynamic forcing parameters controlling beach-fill evolution. Storm waves and water levels erode the upper part of the beach and redistribute sand across the profile. Over the longer term, wave-driven longshore processes reshape the planform and produce shoreline retreat along the project. Establishing a cause-and-effect

relationship between actual waves and water levels and measured beach response is essential for understanding project behavior and formulating solutions when problems occur.

- Wave and water level data also provide valuable information for evaluating project design tools and techniques. Application of design tools with monitoring data may enable more accurate assessment of renourishment intervals and quantities and refinement of the project design to improve performance throughout the remainder of the project life.

- Wave and water level data should be collected using a directional wave gage. The gage should provide a continuous record of information from which significant wave height, peak wave period, peak direction, and mean water level can be determined. Water level (depth) measurements from the gage should be compared with area NOS tide gages or other sources to establish vertical datum control. The wave gage should be placed offshore of the center of the project outside the breaking zone. A depth of 10 m is typically sufficient for gage placement. Hemsley, McGehee, and Kucharski (1991) and Morang, Larson, and Gorman (1997) provide further guidelines for collecting wave and water level data.

- Wave data collection should begin prior to project construction and continue for at least 3 years from the time of initial placement. After 3 years, a decision should be made whether to continue data collection based on sufficiency of information obtained in evaluating project performance. At a minimum, data collection should continue long enough to capture at least one significant storm erosion event and to accurately assess trends in project behavior.

(e) Physical monitoring data analysis. A systematic data analysis plan should be developed as part of the monitoring activities. Pre- and postconstruction beach profile surveys should be analyzed to compute constructed fill volumes and verify compliance with construction template specifications. Sand samples should be analyzed to develop composite measures of median grain size and size distribution from which design profile shapes and fill volumes can be estimated for future construction. Seasonal profile surveys collected during Phase I of the monitoring plan should be used together with aerial shoreline photography to document initial fill adjustment and short-term project behavior. If problems arise such as excessive project erosion rates, erosional hot spots, or unanticipated impacts to adjacent shorelines, a coastal processes study should be performed with the monitoring data to identify causes and develop solutions. Poststorm profiles collected after major erosion events should be analyzed together with storm wave and water level data to verify project performance in light of design criteria. Analysis of Phase II monitoring data should focus on assessing project condition and renourishment requirements. The existing cross section should be compared with the design cross section to identify when dune heights or berm widths fall below design specifications. Shoreline data should be analyzed to determined long-term erosion rates and spreading losses for the project which can be used to fine-tune future renourishment activities.

(3) Borrow area monitoring. Monitoring procedures for the borrow area will depend on the type of borrow area being used. Borrow area types include offshore, inlet shoals, sand traps, bay or lagoons, and terrestrial sources. The principal purpose for monitoring borrow sites is to evaluate borrow fill suitability, borrow area bathymetry, continuing changes in the morphology and sediment characteristics, and biology of the area after completion of the borrow operation. Data collection should include bathymetric and sub-bottom surveying, sediment coring and surface sampling, and biological data acquisition. Baseline data should be collected prior to excavation and periodically thereafter. This section primarily addresses borrow sites in water-covered areas. Terrestrial borrow sites generally exhibit little or no change in topography and sediment characteristics after completion of the borrow operation.

(a) Bathymetric and bottom profiling. Once a borrow site is selected, removal of material from the borrow site will affect its morphology. The nature of the modification depends on whether the material was

obtained by excavating a thin superficial layer over a large area or deep pits in a comparatively small area. One objective of borrow site monitoring is to determine to what extent marine processes restore the original morphology or create new forms. For this reason bathymetric surveys are needed to monitor the site after the borrow operation.

(b) Borrow area sampling scheme. Borrow area sampling time and collection requirements are presented in Table V-4-2. The borrow area monitoring does not require data collection as often as the project site, however a minimum of 1 year between sampling is recommended.

Table V-4-2
Borrow Area Bathymetry and Sediment Sampling Scheme

Year	Times/year	Number of Samples
pre	1	Cores to characterize borrow material and access fill suitability. Bathymetry and subbottom sampling covering expected borrow sites and control areas.
post	1	Surface sediment grab samples to characterize postdredging borrow area sediment distribution. Bathymetry of postdredged surface to assess volume removed.
last	1	Cores to characterize infilling sediment grain size distribution. Bottom surface bathymetry to determine infilling volume.

(c) Changes in processes. Changes in bathymetry due to offshore borrow operations can modify the characteristics of incoming waves. These changes are primarily related to refraction and bottom friction. Dredging fill material from ebb tidal shoals is a likely source of wave modification because these shoals lie close to the shore and their crests are at shallow depths.

- During preproject planning and design, these factors will have been evaluated on the basis of theoretical considerations and indicate wave modification judged to be acceptable. However, it is possible that unforeseen effects may occur. These will usually be indicated by accelerated erosion or accretion of the project beach and/or adjacent shore areas. During postproject monitoring, any unusual erosion or accretion of the project area or adjacent beaches should be investigated with the possibility that it is resulting from modification of offshore borrow sources.

- Another type of process modification can occur where inlets and associated shoals are dredged for borrow material. The strength and distribution of tidal currents in the inlet and shoal areas can be altered by the removal of material. In such cases, provisions should be made for current observations as well as bathymetric and sediment data.

(d) Borrow area data analysis. Analyses should include evaluation of temporal borrow changes, determination of the rate and volume of borrow area infilling, and identification of current patterns in the borrow area channel or basin in cases where inlet shoals are excavated.

(4) Biological monitoring. The excavation and placement of fill material usually impacts the biology of the area that is directly involved. Biological impacts may also be created in adjacent areas from the turbidity created by the excavation process. For this reason, biological surveys of both the beach and borrow area should be performed. Monitoring of the borrow site should include assessment of the infauna, sea grasses, reefs, or other biologically sensitive areas adjacent to the borrow area. The beach project area may also have environmentally sensitive areas such as sea turtle nesting sites, bird nesting areas, beach organisms, nearshore reefs, and sea grasses. Biological sampling should consist of grab samples of the borrow area and quadrate samples of the beach areas to identify the infauna of the borrow and fill locations. Monitoring turbidity in the borrow site and in the surf zone of the fill area may be necessary to assess the impact of

dredging and dumping of fill material on the local biota. A more detailed outline of biological sampling can be found in EM 1110-2-1204, "Environmental Engineering of Coastal Shore Protection."

Data analysis should evaluate fluctuations in the flora and fauna in the beach-fill and adjacent nearshore area, effects of turbidity on fauna at the beach-fill and borrow site, and the effects of the borrow operation on the borrow site organisms. The time and extent of recovery of native organisms should be verified and compared to that of control areas. The absence of native or appearance of new organisms should also be verified and documented.

(5) Structure monitoring. If structures are a component of the project, a periodic inspection and survey report of the structures needs to be performed to assess the condition of the structures. This is especially important after a large storm that might do damage (functional or otherwise) to the structure. If damage is sustained by the structure(s), adequate photography of the structure should be taken to describe the damage and the extent of repairs that will be necessary. As damage photography is best compared to "design built" photography, a baseline set of photography for each structure in the project should be made as soon as possible after the structures are built. Damage photography for any damaged structure should be taken from the same locations as the baseline photography if reasonable and feasible.

At the time of structure inspection, the critical wave conditions (height, period, direction, etc.) under which the structure was damaged (if damaged) or exposed to (if not damaged) should be noted in the report/survey. A detailed survey of the structure may be needed. Last, an assessment of the structure's present and future effectiveness should be made.

m. Operations and maintenance

(1) Purpose. The beach-fill and any structures built for local shore protection, access, and any visitor facilities, must be operated and maintained to obtain the anticipated project benefits. In addition to periodic renourishment, the following types of maintenance work will be needed: mechanical redistribution of sand within the project area, grading, and periodic removal of debris from the project area. Performance and condition monitoring are needed throughout the economic life of the project. As discussed in the previous section, project monitoring and analysis is essential to assuring the project is providing the intended storm protection. In Federal beach nourishment projects, an Operations and Maintenance (O&M) manual specific to the project is prepared upon completion of the initial project construction. The purpose of an O&M manual is to present detailed information to assist the responsible parties in operating and maintaining the project, and to describe the periodic nourishment and monitoring aspects of the project.

(2) Scope of O&M manual. This section will present a possible outline for an O&M manual and briefly describe the contents of each section. A sample outline is provided in Figure V-4-34. The outline should be modified as necessary to meet the specific needs of the project. The manual is divided into four parts. Part I presents general information about the project. Part II provides essential operation and maintenance information necessary to ensure the desired performance of the project. Part III describes the periodic nourishment and monitoring of the project, while Part IV presents information concerning responsibilities of parties involved in the project.

(3) Introduction. This section of the O&M manual provides a concise summary of pertinent information related to the project and generally includes the information discussed in the following paragraphs.

(a) Authority. Cite the authority(ies) which authorized the project construction.

(b) Location. Describe the project location relative to nearby urban centers, water bodies, or other geographic or demographic features. Give the north, east, south, and west project boundaries.

Figure V-4-34. Sample Operations and Maintenance manual outline

(c) Brief description. Describe the major features of the project such as dune and berm elevations, widths, and slopes. Give the grain size characteristics of the fill, volume of material placed, type and characteristics of any structures, and lengths of fill, including transitions. Make reference to the availability and location of as-built plans. The anticipated periodic renourishment volume and interval should be briefly discussed.

(d) Protection provided. Discuss the protection provided by the project and if practicable, identify the storm parameters, or combinations thereof, for which the project is expected to limit inland or upland damages to a minor and acceptable level. Alternatively, the expected project response-frequency curves developed from the analysis of the with-project condition could be provided as indicators of expected project responses resulting from the passage of coastal storms.

(e) Local cooperation. Federal beach-fill projects are constructed and maintained by both the Federal government and one or more levels of local government. The partnership established between the various involved parties is detailed in a local cooperation agreement (LCA). The O&M manual should include a copy of the LCA in an appendix and reference to that appendix should be made in this section of the O&M manual. The summary should identify the local sponsor and those represented by the sponsor if more than one entity is involved. The cost-sharing arrangement for periodic nourishment and project monitoring should be stated and the technical document that supports the LCA and cost-sharing agreement should be cited.

(f) Construction history. Review the contracts used in constructing the project indicating the contractor, contract number, award and completion dates, any significant events or circumstances encountered, and the volumes of materials involved.

(4) Operations and maintenance. This part of the O&M manual presents information on general duties and procedures to assist local interests with their responsibilities for operation and maintenance of the beach-fill project (see ER 1110-2-2902, "Prescribed Procedures for the Maintenance and Operation of Shore Protection Works").

(a) Management. The local person or persons that will be responsible for project administration, maintenance, and general operational responsibilities should be identified. The appointment recommendation and approval procedures should be stated.

(b) Duties. Delineate the project management duties related to the project as outlined in ER 1110-2-2902. Some of these duties (in Federal beach-fill projects) include the following: maintain public ownership and use of the beach which formed the basis of Federal participation; prevent unauthorized trespass or encroachment onto the project; ensure alterations are approved by the District Engineer; ensure pedestrian and vehicular traffic are confined to designated access and use areas; and conduct periodic inspections, and operate and maintain the project as specified in this manual.

(c) Periodic inspections. Routine or emergency inspection plans should be identified. The size of the inspection team may vary from the person in charge up to a team of three or four depending on the scale and complexity of the project. Timing and number of routine inspections should be stated along with the features to be inspected, what information to record, and how and when it should be reported. A set of inspection forms should be developed to help ensure needed information is obtained. Inspection procedures to be followed before and after significant storm events should also be included. Notification from the District or some other mechanism should be included to trigger pre- and poststorm action.

(d) Reports. An inspection report is to be completed by the inspection team for each inspection to ensure that no part of the protection project is overlooked. Any item requiring repairs should be noted. Satisfactory items should also be indicated. A completed and signed set of inspection forms, plus any

pertinent photographs taken during the inspection or monitoring effort, will accompany and provide the basis for the report content. In the event that repairs have been made, either temporary or permanent, the nature and date of the repair are pertinent and should be included. The address to which the reports are to be submitted should be given along with the timing of the reports. All reports should indicate project deficiencies discovered during the inspection, and the scheduled remedial measures to correct the reported deficiencies.

(e) Improvements or alterations. Drawings or prints of proposed improvements or alterations are to be submitted to the District Engineer sufficiently in advance of initiation of the proposed construction to ensure that the absence of his approval does not delay construction. As-built drawings will be furnished to the District Engineer and maintained with the original plans.

(f) Project features. This part of the O&M manual provides detailed description of the features and their operational and maintenance requirements. The section will typically cover such features as the dune, beach berm, transitions, crossovers and access ways, and, if included as part of the project, groin(s), nearshore breakwater(s), seawalls(s), and bulkhead(s).

(5) Periodic nourishment. This section of the O&M manual provides procedures for monitoring the condition of the beach-fill portion of the storm protection project, analyzing the monitoring data, evaluating when nourishment will be required, and determining the volumes of nourishment needed. The project must be periodically nourished to ensure that the desired protection is provided throughout its life.

(a) Scope. Refer to the design document and LCA to define periodic renourishment, its anticipated volume, and interval of placement. Explain the concept of advanced nourishment. Discuss the parameters and conditions that will trigger a nourishment event. Direct quotes from the design document provide credibility for the need to renourish the project. If "renourishment is triggered when, in effect, the project reaches its design configuration" is quoted from the design document, then those responsible need to understand that the design section is the minimum section required to provide the protection and not the maximum section desired or constructed. It should be emphasized that the profiles discussed are based on the configuration of the project beach that is expected once the beach has reached its equilibrium state. In most cases, this will be quite different from the configuration shown on the plans and specifications or the profile that was actually constructed. The issue of postconstruction profile adjustment should be discussed, as well as what is to be expected in terms of beach width decreases through time. Expected seasonal changes should also be discussed.

(b) Monitoring. There are various components that need to be considered to understand the performance of a beach-fill project and subsequent nourishment requirements. To ensure that the project is providing at least the design level of protection, knowledge of the project conditions via project monitoring is imperative. Consequently, a monitoring program is designed as part of the periodic nourishment of the project. For Federal projects, the monitoring program is typically administered by the Corps Engineering Division. Data collected during project monitoring will be used to assess the condition of the beach-fill and to determine when to initiate a nourishment operation. Part V-4-1-l provided guidance on the collection of beach profile surveys, sediment samples, aerial photographs, wave data, etc., and additional guidance can be obtained from EM 1110-2-1004, "Coastal Project Monitoring." The application of these monitoring efforts to the project comprise the remaining topic items to be covered in this section of the O&M manual.

(c) Nourishment. Moving material from the foreshore to the higher berm and/or dune area, or from an accreting area within the project limits to an unusually eroded area, is considered maintenance. Artificially adding new material to the beach-fill project is considered renourishment. The need for renourishment is addressed by determining the protection provided by the existing beach-fill project.

(d) Routine monitoring analysis. The O&M manual will require routine inspection and survey of the beach-fill project. Routine analysis will compare existing profile shapes to the design profile shapes. Of specific importance in the comparison of the existing profile with the design profile is the dune elevation and width and the berm elevation and width. If the comparison indicates that the existing condition dune and berm sections are substandard as compared to the design profile, a more detailed and thorough analysis is initiated to determine, for the overall project, the extent of the deficiency and the level of risk associated with delaying nourishment until the next scheduled renourishment. Based on the results of the detailed analysis a decision is made as to whether or not to initiate a project nourishment action or if maintenance (redistribution of sand within the project area) actions can be implemented to alleviate or minimize a localized problem.

(e) Poststorm analysis. This analysis focuses on the protective features of the beach-fill project located on the upper backshore portion of the beach consisting of the dune and/or storm berm. Generally these features, once eroded, are not soon replaced by nature during poststorm beach recovery and therefore must be replaced by maintenance or nourishment of the project beach.

- Inspection and damage assessment will be conducted as soon as possible after the passage of a significant storm. A joint District and local inspection team will assess the project area. Ground photography will be obtained at a minimum and, if warranted, aerial photography and/or video will be obtained to document the poststorm conditions. The inspection will assess the visible part of the project (i.e., dune/berm erosion, damaged fence, destroyed vegetation, etc.)

- If the extent of upper beach erosion is judged to have compromised the integrity of the project, more extensive data collection and analysis will be required. Beach profile surveys should be immediately initiated at the monument locations as described in the monitoring program. Due to the expediency required in reacting to a storm event causing damage to the project and/or upland development, it is recommended that an Indefinite Delivery Type Contract (IDTC) for poststorm surveying be established and maintained.

- Using the water level and wave height data from offshore gages, or other sources, along with other physical data such as storm duration, wind speed and direction, the storm severity should be estimated. Severity should also be assessed in the context of the beach erosion the storm caused, and should include assessment of key project response parameters such as dune crest lowering, landward extent of vertical erosion threshold, volume eroded above National Geodetic Vertical Datum (NGVD), overwash extent and volume, etc. This information should be provided to the local sponsor and used to document the amount of damages that the project prevented. These findings should be reported in an “annual flood damages prevented” report. After collection and analysis of the survey data, a preliminary cost estimate of emergency maintenance and nourishment costs will be made for local use and possible budgeting purposes.

(f) Poststorm maintenance. Using the survey data, volume calculations will be made which will determine the quantity of sand required to restore the dune and/or berm to its design configuration. An assessment will be made as to the vulnerability of specific areas to additional damage during subsequent storms. Appropriate emergency maintenance actions will be identified and performed. Survey data will be used to determine a source of sand within the project boundaries to be used for the repairs. Once the design is completed and a source of material identified, a construction cost estimate will be prepared. Construction will be undertaken by the local sponsor or they may contract with the District to prepare and manage the contract.

(g) Poststorm nourishment. If the above design and survey data indicate a need to obtain material from an outside source and the District and local sponsor determine the vulnerability analysis warrants such action,

an out-of-cycle nourishment contracting procedure will be initiated and the proposed contract will be immediately advertised for bids. Design analysis will determine the required sand quantities and placement areas and the associated construction templates. Construction plans and specifications and cost estimates will be prepared, as well as related contract documents. Advertisement and award of the contract should be accomplished as soon as possible to allow as much flexibility as possible in scheduling the construction.

(6) Responsibilities. This section should define the roles and responsibilities of organizations and organizational elements for implementing the provisions of the O&M manual.

V-4-3. Definition of Symbols

Δy_o	Initial dry beach width (after cross-shore equilibrium) [length]
ε	Shoreline diffusivity parameter (Equation III-2-26) [length^2/time]
$\sigma_{\varphi b}$	Standard deviation of a borrow sediment sample (Equation III-1-3) [phi units]
$\sigma_{\varphi n}$	Standard deviation of a native sediment sample (Equation III-1-3) [phi units]
φ	Sediment grain diameter in phi units (φ = -log$_2$ D, where D is the sediment grain diameter in millimeters) [phi units]
a	Beach-fill half length [length]
a	One-half the length of the rectangular project [length]
A_F	Nourishment material scale parameter (Table III-3-3) [length$^{1/3}$]
A_N	Native sediment scale parameter (Table III-3-3) [length$^{1/3}$]
A_S	Vessel submerged cross-section area (= BT)[length^2]
B	Design berm elevation [length]
B_R	Channel blockage ratio [dimensionless]
C^n_{go}	Deepwater wave group speed of the nth record [length/time]
C^n_*	Wave speed at breaking of the nth record [length/time]
D_{50}	Median grain size [length]
D_C	Depth of closure [length]
E	Historical shoreline recession rate [length]
H_{eff}	Effective wave height [length]
H^m_s	Significant wave height of the nth record in the time series of N wave records [length]
K_s	Shoaling coefficient [dimensionless]
$M_{\varphi b}$	Estimated mean grain size of a borrow sediment sample (Equation (III-1-2) [phi units]
$M_{\varphi n}$	Estimated mean grain size of a native sediment sample (Equation (III-1-2) [phi units]
R_A	Beach nourishment overfill factor [dimensionless]
R_J	Beach nourishment factor [dimensionless]
t	time
T_{eff}	Effective wave period [time]
V	Volume of material per unit length of shoreline required to produce a beach width of W (Equation V-4-6) [length^3/length]
W	Beach width [length]
W_{add}	Added distance of translation (Equation V-4-5) [length]

Chapter V-5
Navigation Projects

V-5-1. Project Assessment and Alternative Selection

a. Introduction

(1) Purpose. The purpose of this chapter is to present information and procedures that help in coastal navigation project planning and design. Both deep-draft ports and small boat harbors are included. Navigation channels, turning basins, anchorage areas, and related structures are discussed. Other areas of port and harbor design, such as docks, facilities, terminals, and other land-side requirements, are not included. These areas are generally nonfederal concerns.

Guidance for navigation projects has traditionally been focused on deep-draft project requirements. Modified guidance based on experience has evolved for shallow-draft projects. This chapter follows a similar philosophy, focusing on deep-draft projects with supplementary material for shallow-draft projects, as appropriate. The chapter provides fairly comprehensive coverage, but it is intended to complement, rather than replace, Engineer Manuals 1110-2-1613, "Hydraulic Design Guidance for Deep-Draft Navigation Projects" (USACE 1998), and 1110-2-1615, "Hydraulic Design of Small Boat Harbors" (USACE 1984).

(2) Contents. This section gives an overview of issues and considerations important in assessing navigation projects and in defining and selecting project alternatives. Since navigation projects are designed to satisfy requirements of a target group of vessels, an understanding of vessel types and behavior is given in Part V-5-2. Determination of design vessel and transit conditions is also discussed. Data needs and sources are reviewed in Part V-5-3, with appropriate reference to other CEM chapters. Part V-5-4 is devoted to a brief discussion of economic analysis, which is crucial to every navigation project. Development of navigation project features is addressed in Parts V-5-5 through V-5-8. Features included are channel depth, width, and alignment, turning basins, anchorage areas, navigation-related structures, and aids to navigation. Post-project activities are discussed in Part V-5-9, including operation, monitoring, and maintenance. Part V-5-10 gives a description of physical and numerical modeling tools and specialized field studies which can assist in planning and designing effective navigation projects. A number of specific project examples are presented to illustrate the capabilities and applications of model and field studies. References are given in Part V-5-11.

(3) Relationship to other chapters and parts. Part V provides general guidance on the Planning and Design Process (Part V-1) and Site Characterization (Part V-2), including data needs and sources and monitoring. Part V also contains chapters with more detailed guidance on particular project types frequently encountered in the U.S. Army Corps of Engineers (USACE). This chapter addresses navigation projects. Part V-6, Sediment Management at Inlets/Harbors, is an important complement to this chapter. It deals with sediment processes in the vicinity of inlets and harbor entrances, engineering methods for managing sediment processes to prevent negative project impacts and/or achieve positive benefits, and project experience and lessons learned. Other chapters of particular relevance are Part II-6, Hydrodynamics of Tidal Inlets; Part II-7, Harbor Hydrodynamics (including a section on vessel interactions); and Part VI, Design of Coastal Project Elements, which provides guidance for the detailed structural design needed for navigation and other coastal projects.

b. Port and harbor facility issues

(1) Motivation. Ports and harbors are vital to the nation. Since ports handle about half of U.S. overseas trade by value and nearly all by weight, waterborne commerce directly affects prosperity and richness of life in the United States. Ports and harbors are also vital for military applications because a large percentage of military goods are transported by ship. Finally, harbors provide launching and berthing facilities for commercial fishing boats and a large number of recreational boaters.

(a) The term *harbor* describes a relatively protected area accessible to vessels. The term *port* indicates a location where ships can transfer cargo. A port may be located in a protected harbor or it may be exposed, such as single-point mooring facilities used for petroleum products.

(b) Ports and harbors must be located so that vessels can penetrate coastal waters and interface with land. Ideally, vessels have a relatively short travel distance between port/harbor areas and open water. Vessels must have sufficient water depth and protection to safely enter and exit the harbor/port area. Thus, a well-maintained, clearly identified channel through any shallow areas is needed.

(c) The requirements for access and protection in harbors and ports often lead to dredged channels and engineered structures, such as jetties and breakwaters. These project features can impact dynamic coastal processes and lead to a range of coastal engineering concerns.

(2) Deep- versus shallow-draft projects. The terms *deep-draft* and *shallow-draft* are often used to distinguish between major commercial port projects and recreational or other small boat harbor projects. USACE definitions for these terms are based on authorized navigation project depth:

- Deep draft Channel depth greater than 4.6 m (15 ft)
- Shallow draft Channel depth less than 4.6 m (15 ft)

Defining depth for a deep-draft harbor can vary with context. For example, Federal cost-sharing rules are based on a 6.1-m (20-ft) minimum depth for deep-draft projects. The harbor maintenance tax system is applied to projects with depth greater than 4.3 m (14 ft), while inland fuel taxes apply in shallower-depth projects, excluding entrance channels. Deep-draft U.S. ports serve commercial seagoing ships, Great Lakes freighters, Navy warships, and Army prepositioning ships. Shallow-draft harbors typically serve pleasure craft and fishing boats. The term *small craft* is often used synonymously with *shallow draft*. As part of its mission, USACE has had responsibility for maintaining over 200 deep-draft coastal ports and over 600 shallow-draft harbors. Issues involved in shallow-draft navigation projects have similarities but also significant differences from those in deep-draft projects. For example, shallow-draft boats are typically small and are strongly influenced by wind waves and swell. Thus, wave criteria for safe transit of entrance channels and safe mooring areas are more demanding than for deep-draft vessels. However, large ships typically maneuver with difficulty in confined areas, and channel width is a critical component of deep-draft channels. Deep-draft harbors are more prone to harbor oscillation concerns because resonant periods of moored ship response are typically in the same range as harbor oscillation periods. Flushing is an important issue in many shallow-draft harbors, where numerous users in a confined area can potentially lead to deterioration of water quality. Flushing is usually less critical in deep-draft projects, which require wider entrances and more careful monitoring of vessel discharges. These issues are addressed later in the chapter.

(3) Organizations related to navigation projects. USACE navigation projects involve other organizations, as well. For example, the U.S. Coast Guard is responsible for installing and maintaining the aids to navigation needed to mark Federal channels. Often state and local organizations, such as port authorities, are

part of a navigation project team. Some organizations and acronyms often encountered in navigation projects as team members or information resources are listed in Table V-5-1.

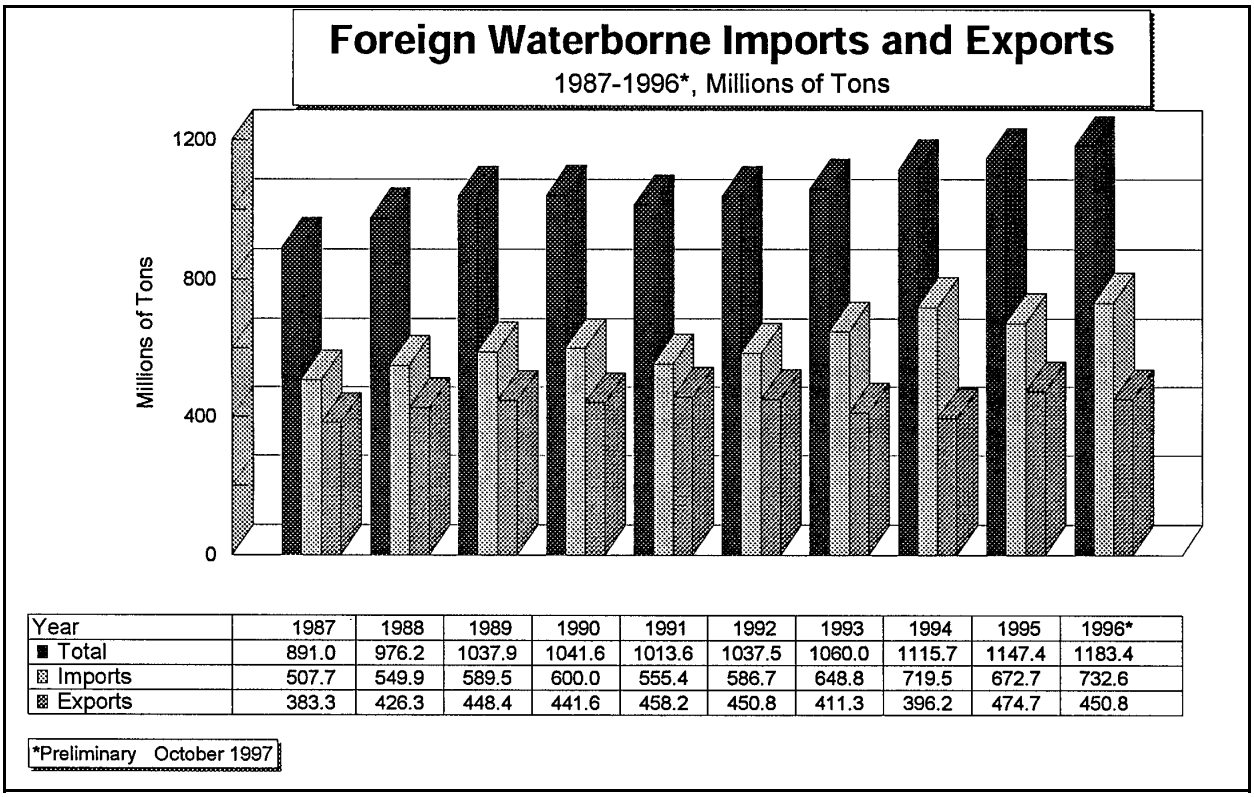
Table V-5-1
Organization Acronyms Related To Navigation Projects

Acronym	Organization
AAPA	American Association of Port Authorities
ABS	American Bureau of Shipping
ASCE	American Society of Civil Engineers
EPA	U.S. Environmental Protection Agency
NAVFAC	U.S. Naval Facilities Engineering Command
NOAA	U.S. National Oceanic and Atmospheric Administration
PIANC	International Navigation Association (formerly, Permanent International Association of Navigation Congresses)
USACE	U.S. Army Corps of Engineers
USCG	U.S. Coast Guard

(4) Trends in port and harbor development. Demand for harbor and port facilities continues to increase while coastal population and other utilization of the coast increases. These competing interests intensify pressures to find mutually agreeable solutions to coastal land and water use. Annual foreign waterborne tonnage (between U.S. and foreign ports) during the years 1987-1996 indicates a clearly increasing trend (Figure V-5-1). Major U.S. ports continue to increase in size and serve larger ships. Dramatic increases in container traffic and a recent trend for container ships to exceed Panama Canal size constraints have helped fuel the need for deeper ports and expanded, modernized terminals. Open terminals and offshore ports have helped accommodate large tankers and bulk carriers, in some markets.

(a) With pressure to serve larger ships, many U.S. ports are faced with costly infrastructure upgrades. Deeper and wider channels, turning basins, and berthing areas are needed. Disposal of large quantities of dredged material, which is often contaminated after many years of harbor operations, can be a major and expensive problem. Dock bulkheads often need to be rebuilt to maintain structural strength in deeper water and with likely higher design loads from ship berthing and apron cargo handling. Landside infrastructure must be capable of efficiently handling cargo from larger ships. This requirement often leads to bigger gantry cranes, single-purpose terminals, larger stockpiling areas, new rail facilities, etc.

(b) Demand for small-craft berthing space is also increasing, mainly to serve recreational boaters. Thus, there is a continuing economic incentive for expansion of existing small-craft harbors and development of new harbors.



Year	1987	1988	1989	1990	1991	1992	1993	1994	1995	1996*
Total	891.0	976.2	1037.9	1041.6	1013.6	1037.5	1060.0	1115.7	1147.4	1183.4
Imports	507.7	549.9	589.5	600.0	555.4	586.7	648.8	719.5	672.7	732.6
Exports	383.3	426.3	448.4	441.6	458.2	450.8	411.3	396.2	474.7	450.8

Figure V-5-1. Foreign waterborne imports and exports (USACE Waterborne Commerce Statistics Center)

c. Preliminary planning and design elements.

(1) Federal coastal navigation projects are focused on channels and maneuvering areas to allow vessels to transit confined nearshore areas and use ports or harbors. Structures needed to accomplish navigation objectives are also included. Preliminary planning and design may include the following considerations, most of which are discussed in subsequent sections of this chapter:

(a) Site characterization.

(b) Design criteria.

(c) Defining vessel requirements.

(d) Entrance channel configuration.

(e) Inner harbor configuration.

(f) Navigation structures.

(g) Harbor and channel sedimentation and maintenance.

(h) Physical and numerical modeling.

(2) Helpful supplementary references for deep-draft projects include McBride, Smallman, and Huntington (1998); PIANC (1997a, 1997b, 1995); Tsinker (1997); Gaythwaite (1990); Turner (1984); Quinn (1972); and U.S. Navy design manuals. For small-craft projects, references include ASCE (1994), Tobiasson and Kollmeyer (1991), State of California (1980), and Dunham and Finn (1974). References with coverage of both deep-draft and small-craft harbors include Herbich (1992) and Bruun (1990). U.S. Army guidance for military ports is given by USACE (1983).

d. Policy considerations. Federal cost-sharing guidelines are a key concern in U.S. navigation projects. Prior to 1986, the Federal Government paid 100 percent of costs for navigation channel deepening and widening. Under present guidelines for *commercial* harbors, the nonfederal share of general navigation feature construction costs is 10 percent for project depth not exceeding 6.1 m (20 ft), 25 percent for project depth greater than 6.1 m (20 ft) but not exceeding 13.7 m (45 ft), and 50 percent for project depth exceeding 13.7 m (45 ft). The nonfederal sponsor must also pay: (1) an additional 10 percent of construction costs that are cost-shared, and (2) for project depths greater than 13.7 m (45 ft), 50 percent of operation and maintenance costs associated with general navigation features. For *recreational* navigation projects or separable recreational elements of commercial navigation projects, the nonfederal share is 50 percent of construction costs and 100 percent of operation and maintenance costs. Partnering between commercial, recreational, and military interests should always be examined. Cost-sharing guidelines are fully described by USACE (1996).

V-5-2. Defining Vessel Requirements

a. Deep-draft ships and shallow-draft vessels.

(1) Vessel dimensions. Navigation projects are designed to accommodate vessels of a desired size. Key vessel dimensions are length, beam (width), and draft. These dimensions are defined in several different ways to characterize the curved, three-dimensional vessel form. Vessel dimensions, especially for commercial ships, are often presented in terms of standard acronyms defined in Table V-5-2. Terms are explained in the following paragraphs.

(a) The shape of a typical commercial ship is depicted in Figure V-5-2. The LOA is an important measure of length for evaluating ship clearances in confined navigation project areas. For example, a turning basin would be sized based on the design ship LOA. The LBP is a more meaningful measure of the effective length for concerns such as ship displacement and cargo capacity.

(b) Definitions of design draft, freeboard, and beam are illustrated in Figure V-5-3. Molded beam is the maximum width to the outer edges of the ship hull, measured at the maximum cross section (usually at the ship waterline at midship). Design draft is the distance from the design waterline to the bottom of the keel. Ship *depth* is a vertical dimension of the hull, as shown in the figure, and it should not be confused with ship *draft*.

(c) Draft may not be uniform along the vessel bottom for both deep- and shallow-draft vessels. For example, draft near the vessel stern (aft) is often greater than near the bow (fore). Two useful indicators of such variations are:

trim - difference in draft fore and aft

list - difference in draft side to side

Table V-5-2
Acronyms Commonly Used to Describe Ship Size and Function

Acronym	Explanation
LOA	Length overall
LBP	Length between perpendiculars (measured at DWL)
LWL	Length along waterline (usually similar to LBP)
DWL	Design waterline (usually represents full load condition)
B	Beam (maximum width of ship cross section)
D	Draft
D_s	Depth of vessel's hull
FB	Freeboard (=D_s - D)
DT	Displacement tonnage (fully loaded)
l.t.	Long ton; = 1016 kg (2240 pounds)
m.t.	Metric ton: = 1000 kg (2205 pounds); ≈ 1 l.t.
LWT	Lightship weight (empty)
DWT	Dead weight tonnage (= DT - LWT)
GRT	Gross register ton; 1 register ton = 2.83 cu m (100 cu ft) of internal space (may also be stated in cubic meters)
GT	Gross ton
NRT	Net register ton
NT	Net tons
OBO	Ore/bulk/oil combination carrier
TEU	20-ft equivalent units; standardized 6.1 m x 2.4 m x 2.4 m (20 ft x 8 ft x 8 ft) container units

(d) *Maximum navigational draft* (the extreme projection of the vessel below waterline when fully loaded) is needed for navigation channel depth; *mean draft* is preferred for hydrostatic calculations. *Waterline beam* (width of the vessel at the design or fully loaded condition) is needed for navigation channel width.

(e) Maximum dimensions of the above-water part of a vessel are also critical to ensure adequate clearance. *Maximum beam* is the extreme width of the vessel. For a vessel such as an aircraft carrier, maximum beam is much larger than waterline beam. *Lightly loaded draft* is the minimum vessel draft for stability purposes, from which vertical clearance requirements, such as clearance under bridges, can be determined.

(2) Cargo capacity. Cargo capacity of commercial ships is generally indicated by DWT or, in the special case of container ships, by TEU. Units of measure for weight are usually long tons or metric tons (Table V-5-3). Cargo capacity also provides a convenient indicator of ship size, since ship dimensions for a particular type of ship (e.g. tanker) are usually closely correlated with capacity.

(a) Port duties and shipping costs are often figured in terms of register tons, a measure of *volume*. The GRT indicates total internal volume of the ship; NRT indicates volume available for cargo. The GRT is equal to NRT plus volume of space devoted to fuel, water, machinery, living space, etc. The terms GRT and NRT are currently used for older ships, but the terms GT and NT are favored for newer ships. The LWT

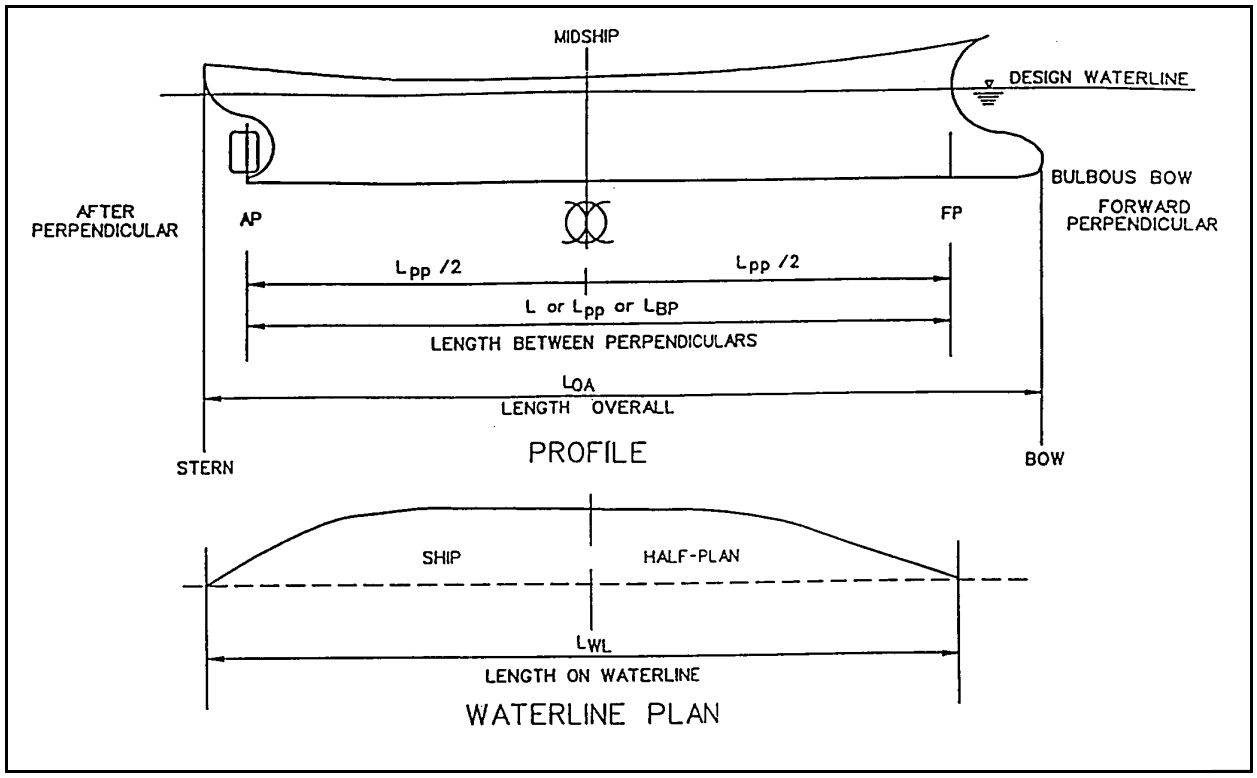


Figure V-5-2. Ship length definitions

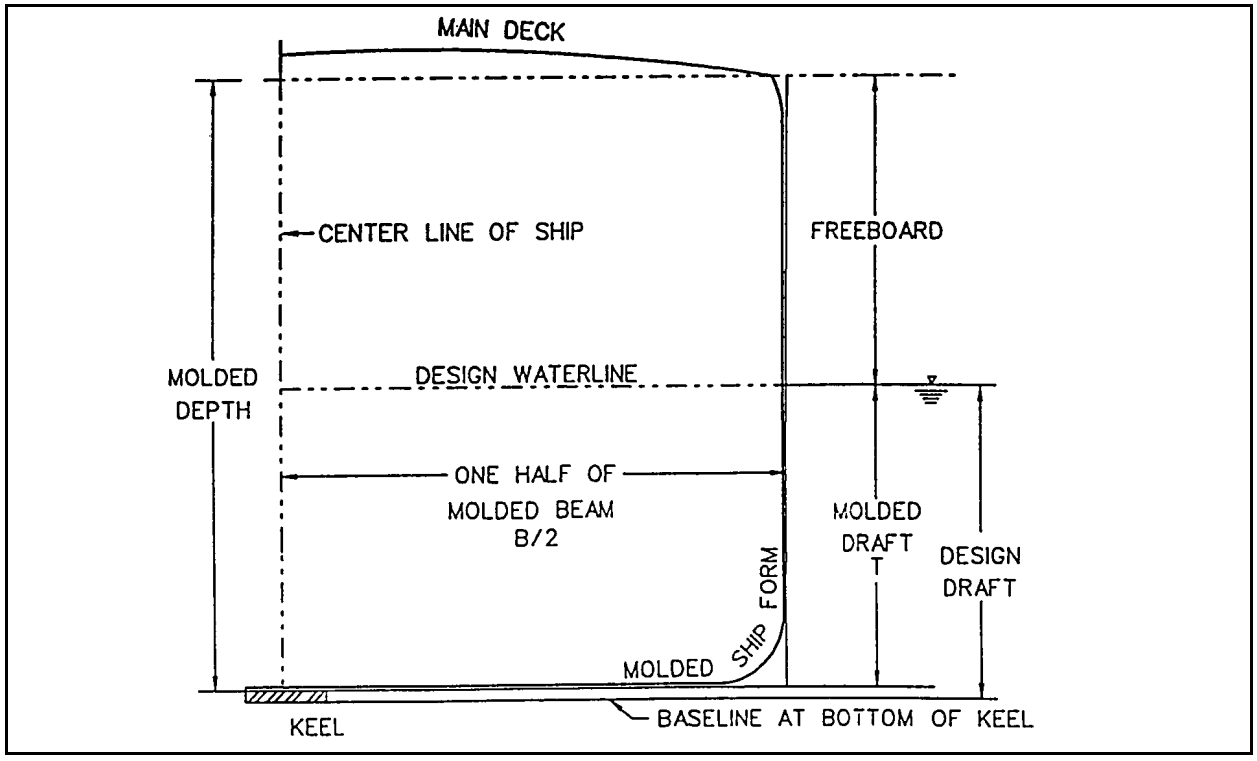

Figure V-5-3. Midship-section molded-form definitions

is the minimum weight a ship can have, such as the weight to be supported in dry dock. In operation, even unloaded ships rarely reach the LWT, as they often take on water, or *ballast*, to increase stability.

(3) Restrictions. Canal and lock sizes can impose distinct restrictions on ship size. The Panama Canal and Suez Canal are the two most critical for oceangoing traffic (Table V-5-3). Ships sized to meet the Panama Canal restrictions are known as *Panamax* vessels. They constitute an important vessel class for navigation projects because many commercial ships fit within the confines of the Panama Canal. Economics associated with some cargos, most notably crude oil, have resulted in ships that cannot pass through the canal. These ships are sometimes referred to as *Post-Panamax* vessels.

Table V-5-3
Canal Restrictions on Ship Size

	Restriction		
Canal	**Draft**	**Beam**	**Length**
Panama	12.0 m (39.5 ft)	32.2 m (105.75 ft)	289.6 m (950.0 ft)
Suez	16.2 m (53.0 ft)	64.0 m (210 ft)	No restriction

(4) Vessel characteristics. Vessels cover a wide range of sizes and shapes. Deep-draft vessels, especially the larger ships that typically dictate navigation project dimensions, may represent a small number of specific ship designs to serve specialized needs and routes. Therefore, deep-draft vessel characteristics are usually presented as a sampling of individual, named vessels. Characteristics of some representative large ships from the world merchant fleet are given in Table V-5-4. Most U.S. ports have controlling depths between 10.7 m (35 ft) and 12 m (40 ft). The deeper ports can accommodate Panamax vessels, but access by larger ships is limited. Common vessel types are briefly reviewed in the following paragraphs. In contrast to deep-draft projects, shallow-draft vessels are usually numerous and their characteristics can be discussed in statistical terms. Also, other factors besides individual vessel characteristics, such as volume of traffic, may be critical to a shallow-draft navigation project.

(a) *Tankers* carry liquid bulk products. Crude oil is by far the most common liquid bulk cargo. Economies of scale have strongly affected tanker design because of the volume and uniformity of product and consistent level of demand. Large tankers are often classified by size (Table V-5-5). The larger vessels far exceed Panamax size, but most can use the Suez Canal in ballast. Loaded tankers less than about 50,000 DWT require a draft of 12 m (40 ft) or less and can enter many U.S. harbors. Supertankers can use partial loading and/or tidal advantage to access U.S. harbors. Navigation projects in the United States generally cannot accomodate the drafts of loaded VLCC and ULCC class tankers. The largest tankers, too big to enter any of the major world ports, ply dedicated trade routes between offshore port facilities.

(b) *Liquid Natural Gas (LNG)* and *Liquid Propane Gas (LPG)* carriers have a highly volatile cargo at very low temperature. They require highly specialized terminals and special safety considerations.

(c) *Dry bulk carriers* carry a wide range of cargoes such as ore, coal, and grain. Size is generally less than 150,000 DWT.

(d) *Combination bulk carriers* are specially configured to carry both liquid and dry bulk cargo. The most common combination is ore/bulk/oil, or *OBO*. Vessel size ranges from 50,000 DWT to 250,000 DWT.

(e) *General cargo ships* carry a wide variety of cargoes packaged in the form of pallets, bales, crates, containers, etc. *Break-bulk* cargo refers to *individually* packaged items that are stowed *individually* in the ship. Size is typically 12,000 to 25,000 DWT.

Table V-5-5
Large Tanker Classes

Name	Approximate Size	Approximate Draft
Supertanker	50,000-150,000 DWT	11-18 m (35-60 ft)
Very Large Crude Carrier (VLCC)	150,000-300,000 DWT	18-24 m (60-80 ft)
Ultra Large Crude Carrier (ULCC)	Greater than 300,000 DWT	24-30 m (80-100 ft)

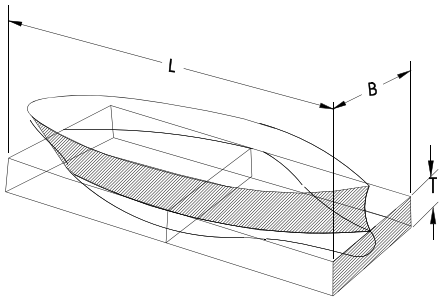
(f) *Container ships* are designed to carry cargo packaged in standardized steel container boxes. These ships, increasingly dominant in world trade, travel at high speed, and rely on fast turnaround times at port. Container ship speed and size are correlated. The larger container ships cruise at speeds of 46 km/hr (25 knots). Capacity is expressed in twenty-foot equivalent units (TEU), the number of 20-ft-long containers that can be carried. Ships with 4,000-TEU capacity reach loaded drafts of about 12 m (40 ft). Until fairly recently, container ship sizes were constrained by the Panamax limit. Since economics of shipping and terminal facilities have favored a Post-Panamax size, container ships have rapidly increased in scale. The largest container ships in present operation exceed 8,000 TEU, and have limited access to U.S. ports. Vessels of 15,000 TEU are under consideration. These Post-Panamax ships have necessitated new, longer-reach gantry cranes and other new or updated terminal facilities to handle the longer, wider ships and large volumes of cargo.

(g) Other vessel types include: *LASH* (Lighter Aboard Ship), *SEABEE*, and *BARCAT* vessels, designed to transport barges; *Ro/Ro* (Roll on/Roll off) carriers, essentially large, oceangoing ferries that load and unload wheeled cargo (trailers and/or vehicles) via ramps extending from the vessel; conventional ferries; passenger vessels; barges; etc. The *Integrated Tug/Barge (ITB)* is a special adaptation of barge design in which the barge resembles a vessel hull and a tug can be linked to the barge stern to form, in effect, a single vessel. ITB applications are usually dry and liquid bulk cargo transport.

(h) U.S. military vessels generally have maximum drafts of less than 12 m (40 ft). Nimitz class aircraft carriers have maximum draft of 12.5 m (41 ft). U.S. Navy vessel characteristics are available on the Internet (http://www.nvr.navy.mil) and in the NAVFAC Ships Characteristics Database soon to be on the Internet.

(i) Shallow-draft vessels are typically recreational or small fishing vessels. Recreational boats in the United States can range in length from about 3.6 m to 60 m (12 ft to 200 ft), but they are commonly 9-14 m (30-45 ft) in length with beams of 4.6 m (15 ft) or less. Recreational boats often have features protruding from the bow or stern. Although such features may not be included in the nominal boat length, they should be considered as needed in sizing harbor channel and dock clearances. Shallow-draft vessels may be driven by either engine power or sail. In comparison to powerboats, sailboats have narrow beam and require large maneuvering space when under sail.

(5) Form coefficients. Vessel shape is conveniently represented in terms of simple parameters known as *form coefficients*. The most important of these is the *block coefficient*, defined and illustrated in Figure V-5-4. This coefficient usually represents the fully loaded ship. Values of the block coefficient can normally range from around 0.4 for tapered-form, high-speed ships, such as container ships and passenger ferries, to 0.9 for box-shaped, slow-speed ships, such as tankers and bulk carriers. Small craft, sailboats, and power boats, respectively, represent forms with relatively low and high block coefficient.



Block coefficient definition

Block coefficient (C_B) = Ratio of the volume of displacement to the volume of a rectangular block having a length, beam, and draft equal to that of the ship.

$$C_B = \frac{\nabla}{LBT}$$

L = Length between perpendiculars

T = Draft to the designed waterline, or molded ship draft

B = Beam amidships at the designed waterline, or molded beam

∇ = Volume of displacement of molded ship form at draft T

Figure V-5-4. Block coefficient definition

(6) Ship speed. Typical transit speeds in deep-draft channels are between 9 and 18 km/hr (5 and 10 knots). Vessel speed in navigation projects often represents a balance between several important considerations, as follows:

(a) Considerations favoring higher vessel speed:

- *Economics*. Vessel productivity increases when transits are faster; loaded vessels may be able to use high tide levels to advantage.

- *Vessel control*. Vessel control in the presence of wind, waves, and/or currents improves when vessel speed is higher.

- *Convenience*. Particularly for small craft, operators and passengers usually prefer quick transits.

(b) Considerations favoring lower vessel speed:

- *Wake effects*. Vessel wakes, directly related to vessel speed, can endanger other vessels and operations and erode banks.

- *Reduction of bank and bottom effects, ship resistance, ship-ship interactions*. Vessels may need to limit speed to avoid creating dangerous, speed-induced pressure differences. The effects are due to constricted clearance between the vessel and other obstacles, such as the bottom, side banks, another vessel in transit, and moored vessels.

- *Safety*. As long as vessels maintain adequate control, lower speeds are generally safer. Typically, vessel speed relative to the water must be at least 4 knots for both deep-draft vessels and small craft.

(7) Maneuverability. Commercial ships are designed primarily for optimum operation in the open ocean. Many of them maneuver poorly in confined areas. A successful navigation project must accommodate the ships using it. Ships are controlled by propellers and rudders at the stern. Some ships are also equipped with bow thrusters or bow and stern thrusters, which aid in control, especially at low speeds. Often, one or more tugs are needed to assist ships in some phases of entering and leaving a port. Control is especially crucial when ships slow to turn, dock, or attach tugs. A navigation project objective is to design ports and approach channels so ships can maintain adequate speed and control and navigate under their own power as much as reasonably possible. Small craft generally respond to engine, sail, and rudder control much more readily than deep-draft vessels. However, as with deep-draft vessels, small craft can encounter conditions in which control is difficult. Factors contributing to loss of control include slow vessel speed, following currents, waves, and cross-wind. Sailboats traveling under sail require extra maneuvering space.

b. Vessel operations. Deep-draft navigation projects are built or improved to enhance safety, efficiency, and productivity of waterborne commerce in U.S. ports and harbors. Shallow-draft projects embody similar concerns and often public recreational access as well. An understanding of vessel operations is critical to successful navigation project design.

(1) Navigation system. Port and harbor operations can be viewed as a system with three main components, as follows:

- Waterway engineering: Navigation channels, environmental factors, dredging and mapping services, shore docking facilities.

- Marine traffic: Operational rules, aids to navigation, pilot and tug service, communications, and vessel traffic services.

- Vessel hydrodynamics: Vessel design, maneuverability and controllability, human factors, navigation equipment.

(a) These components are closely interrelated in a navigation project. Tradeoffs between investment in the components are normal procedure, particularly in deep-draft projects. Thus, for example, channel design is strongly influenced by ship sizes and available accuracy of aids to navigation.

(b) Overall economic optimization of a navigation system can be a complex process. It typically involves crucial tradeoffs between initial investment (e.g. channel dimensions), maintenance, and operational use. For example, a channel that is wide enough for two-way traffic will cost more to dredge and, possibly, to maintain than a one-way channel of the same depth. However, the two-way channel may significantly reduce the amount of time ships must queue while waiting for access to the channel.

(2) Typical operations. Methods of operation must be considered in developing a navigation project. For deep-draft ships, operations depend on interactions between a pilot, captain, crew, and, often, one or more tug captains. On arrival at the entrance to a port, a ship typically is met by a local pilot. The pilot boards the ship near the seaward end of the entrance channel. Boarding is usually accomplished by pulling a small pilot boat next to the ship long enough for the pilot to mount a rope ladder and climb up to the ship deck, a potentially hazardous maneuver during high waves. Local tug services are contacted if needed, and plans finalized for the ship transit. Many tug companies also provide a tug pilot to accompany the local pilot and assist in the tug-aided final phase of transit and docking.

(a) The pilot is stationed on the ship bridge. The pilot effectively takes control of the ship during transit, issuing rudder and engine commands as well as course orders. Transit to a port generally follows a series of straight segments connected by turns. Turn angles greater than about 30 deg require special care because they involve varying currents and changing ship speed and position relative to banks and prevailing wind. Port entrance channels can be especially troublesome due to crosscurrents, waves, shoaling, and wind effects.

(b) A large ship in a confined channel can be difficult to control because ships do not respond quickly to rudder and engine commands. Turning may be sluggish. Bank effects and encounters with passing ships can introduce forces to turn the ship away from the intended travel direction. Such factors, along with human and environmental variability, result in variations in a ship's *swept path* (the envelope of all positions in the channel over which some part of the ship has passed). The swept path is illustrated by a ship simulator study example of ship position at short time increments during transit around a turn, up a channel, and through a turning basin to a dock (see Part V-5-10b for additional discussion of this simulation study) (Figure V-5-5).

(c) The ship must slow down well before approaching the berth or terminal, usually with the assistance of tugs when ship control is lost (at speeds below 6-7 km/hr or 3-4 knots). Often, the ship must pass other port facilities at very slow speed to prevent waves and moored vessel damage. As the ship approaches its berth, tugs typically take full control and push the ship against the dock face while mooring lines are made fast. When the ship departs, operations during a typical outbound run are similar to the inbound run, except in reverse sequence.

(d) Pilots and captains take care to avoid contact between the ship and bottom. However, ship motions and bottom conditions are not entirely predictable, and bottom contact occasionally occurs. Typical consequences are hull abrasion and propeller and rudder damage. Propeller/rudder damage reduces or removes ship control, leaving the ship vulnerable to further damage. It is also costly to repair. Therefore, pilots tend to be very protective of the ship stern when maneuvering in confined channels and turning basins.

(e) Ships may transit in fully loaded, partially loaded, or in ballast condition. The loading condition influences operational concerns. A fully loaded ship has a relatively large fraction of its volume submerged. Hence it is susceptible to currents, shoals, and other bottom influences. A ship in ballast generally has generous bottom clearance, but has a relatively large exposure to wind forces. Some types, including container ships, ferries, and Ro/Ro vessels, have large wind exposure, even in a loaded state.

(f) Sometimes ships approach port with loaded drafts greater than the channel depth, stop in an anchorage area, and offload to smaller vessels (*lighters*). Ships may fully unload to lighters or partially unload to reach an acceptable draft, after which they continue into port.

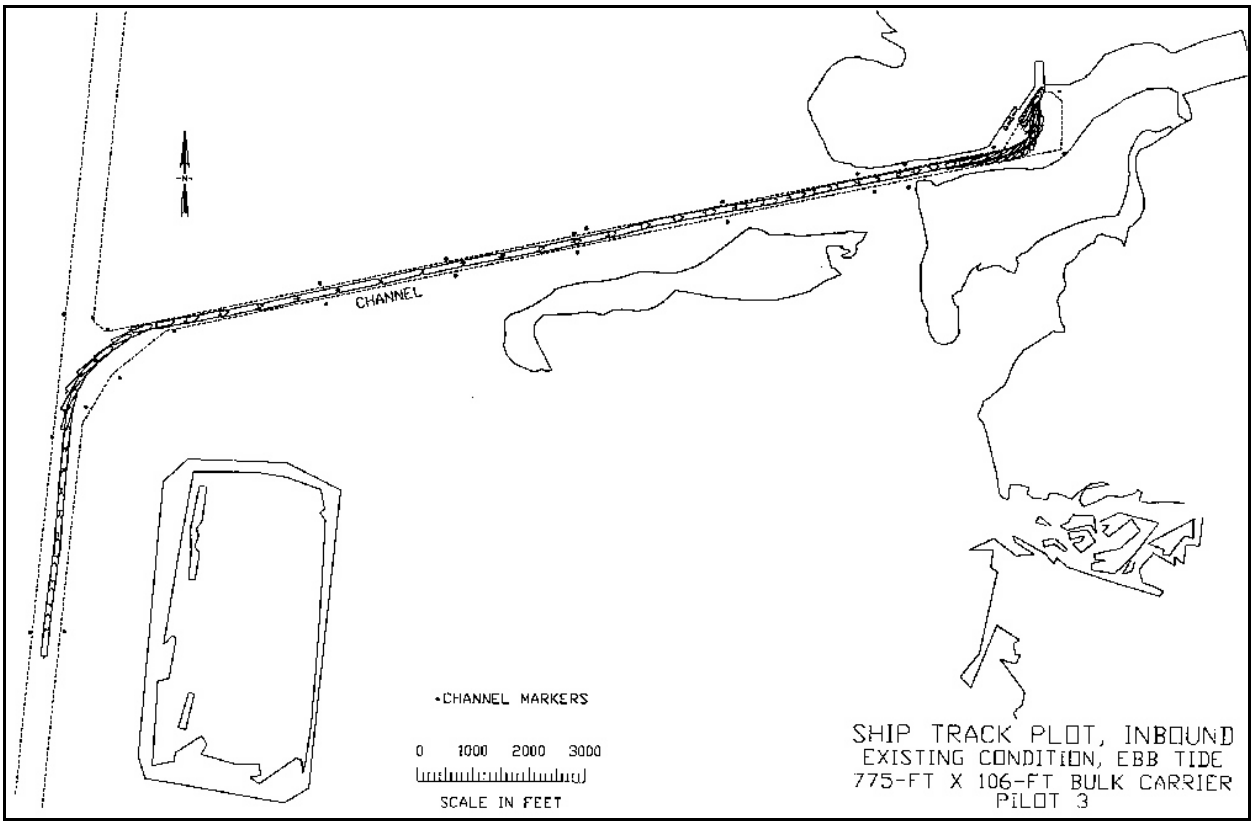


Figure V-5-5. Example ship track, Alafia Channel, Florida

(g) Deep-draft entrance and interior channels are designed for either one-way or two-way traffic. When a ship is entering a port with a one-way channel, any outbound ships must wait until the channel is clear. Two-way channels may accommodate inbound and outbound traffic simultaneously. They may also provide generous horizontal clearance for single ships when passing ships are absent.

(h) For small craft, operational concerns can vary significantly depending on the type of harbor. Small craft travel under their own power, controlled by an operator whose level of expertise and experience can range from novice to seasoned professional. Power boats are typically driven by one or two engines. Sailboats may be equipped with small auxiliary engines for transiting congested harbor areas and for emergency use, but they usually travel under wind power. Depending on wind speed and direction relative to desired travel direction, sailboat operators often must follow a zig-zag course. Small craft operators may take advantage of bays and other protected areas for fishing, sailing, etc., when available, especially if waves along the open coast are rough.

(i) Small craft typically exit the harbor for fishing and/or recreation and return to the same harbor, often on the same day. The number of vessels concurrently using a small-craft harbor during high traffic times can be greater than for deep-draft ports. Level of usage is often affected by holidays, weather, fishing or charter schedules, work schedules, etc. For example, a recreational harbor can be expected to have a higher volume of traffic during fair weather and weekend or holiday times. These same conditions are likely to result in a greater percentage of inexperienced operators and, possibly, a lower level of attention to navigation safety.

(3) Shallow-water, restricted channels. Vessels operating in restricted navigation channels can experience a variety of effects (Figure V-5-6). Large, loaded ships can block much of the channel cross section

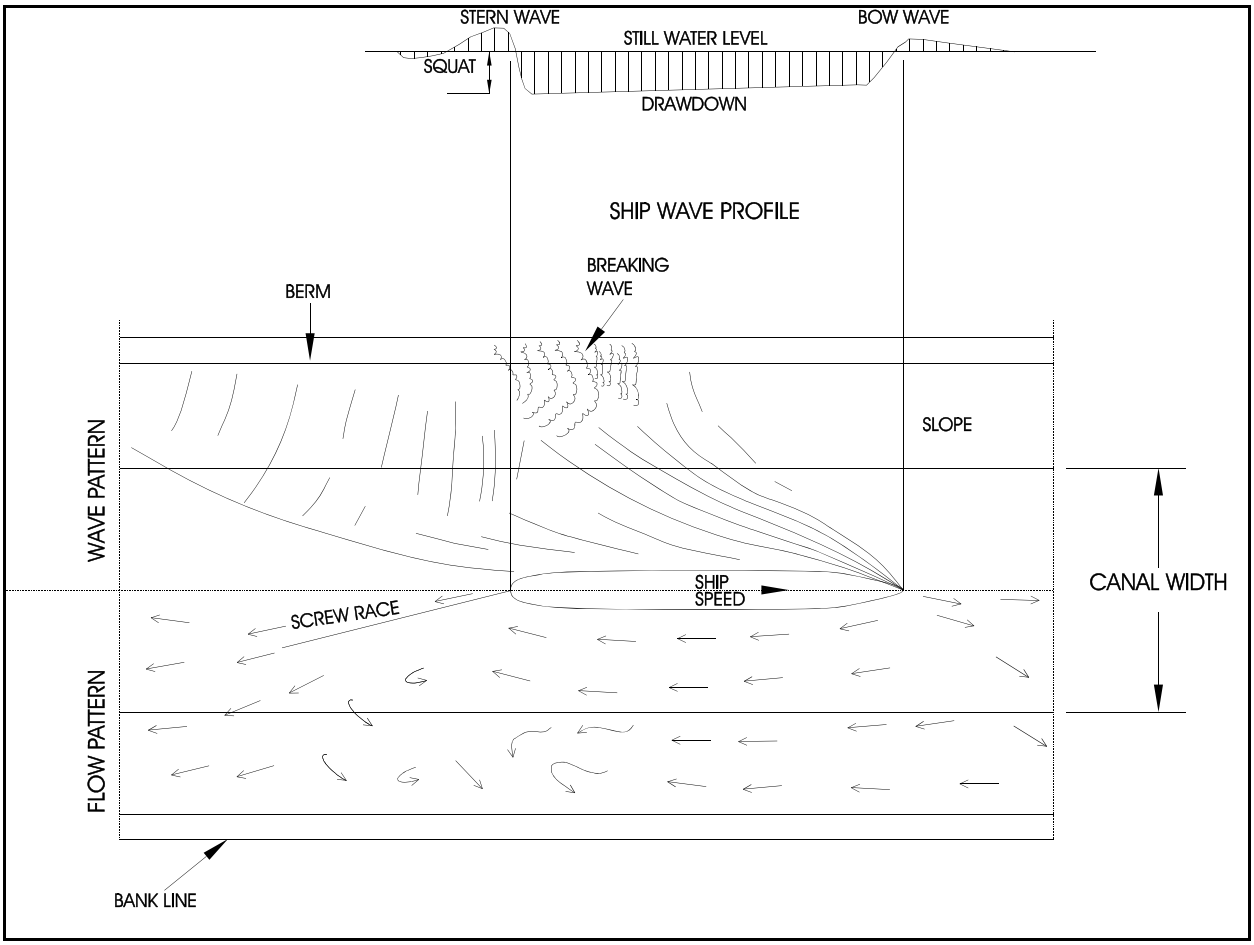

Figure V-5-6. Ship wave and flow pattern in a canal

and encounter very significant hydrodynamic resistance. Much of the water in the channel cross section must flow around the passing ship through highly confined space under the hull and between the hull and channel side slopes. Also, the ship experiences resistance due to the waves it creates as it moves forward.

(a) A moving vessel in a shallow waterway drops in the water relative to its at-rest level. The drop, referred to as *squat*, is due to a reduction in pressure exerted by water flowing around the moving vessel. Squat includes an overall lowering of the vessel *(sinkage*) and a motion-induced trim. Squat further reduces clearance between the vessel hull and the bottom.

(b) The maximum speed a vessel can attain in shallow water is significantly reduced from the typical deepwater speed. An important parameter governing shallow-water effects on a moving vessel (both deep- and shallow-draft vessels) is the depth Froude number

$$F_h = \frac{V}{\sqrt{gh}} \qquad \text{(V-5-1)}$$

where

F_h = channel depth Froude number

V = vessel speed

h = depth of channel or shallow-water area

g = acceleration due to gravity; = 9.80 m/sec^2 (32.2 ft/sec^2)

(c) Consistent units must be used for V, h, and g in the equation. Vessel resistance becomes very high as F_h approaches unity. In practice, a normally self-propelled merchant ship would never operate at F_h greater than about 0.6.

(d) The effect of a restricted, shallow *channel* configuration is to further increase wave effects, squat, and vessel resistance. Relative channel restriction is characterized by the *channel blockage ratio*

$$B_R = \frac{A_C}{A_S} \tag{V-5-2}$$

where

B_R = channel blockage ratio

A_C = channel cross-section area

A_S = vessel submerged cross-section area, = BT

B = vessel beam at midship

T = vessel draft

(e) The channel blockage ratio is illustrated in Figure V-5-7 for the extreme case of a canal with vertical sides. In this case, $A_C = Wh$, where W is channel width. The limiting ship speed for self-propelled vessels in a canal, represented as F_h, is shown as a function of B_R in Figure V-5-7. Typical B_R values range from 2 for very restricted cases to 20 or more for open channels, giving F_h values between 0.2 and 0.7. This effect significantly limits vessel speed in restricted channels. The limit is known as the *Schijf limiting speed*. For example, with B_R = 3 at a 12-m (40-ft) water depth, the maximum ship speed is 11.9 km/hr (6.4 knots). In practice, a ship's engine would not have enough power to drive the ship at the Schijf limiting speed.

(f) Bank effects in a channel can make ship control more difficult by creating suction and/or higher pressures along vessel hulls when vessels are off the channel center line. Forces may differentially affect vessel bow and stern and act to turn the vessel toward a potentially hazardous crosswise position relative to the channel. Bank effects become stronger as *channel overbank depths* (water depth of the natural bottom adjacent to the channel) decrease. Pilots sometimes take advantage of bank effects to assist in turning. Similar differential pressure effects arise when ships pass in a channel and when a ship passes a moored ship adjacent to the channel.

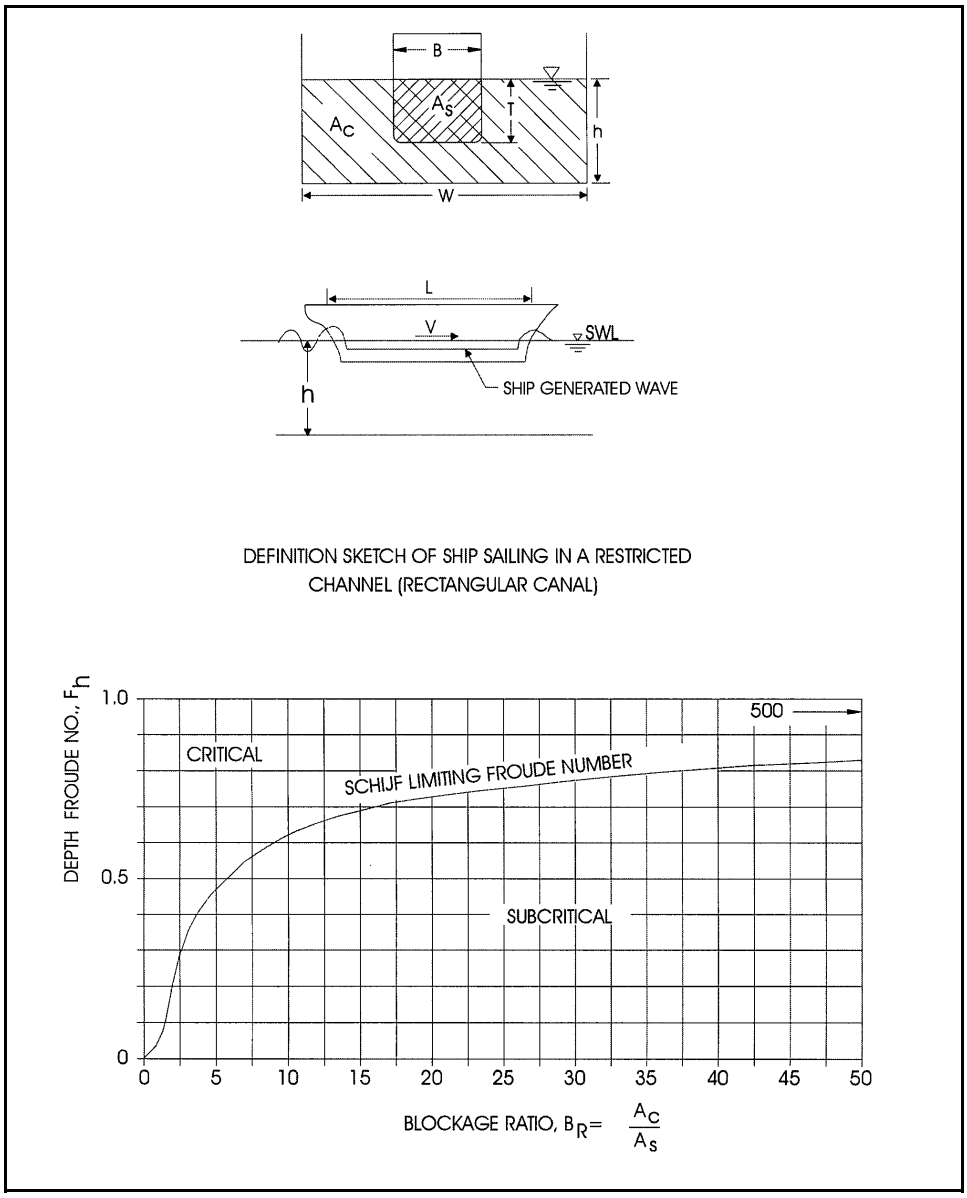

Figure V-5-7. Ship-limiting speed in a canal

(4) Ice navigation. Winter conditions along northern sea coasts, estuaries, and large lakes can cause ice to be an occasional, if not chronic, concern for safe and efficient navigation (PIANC 1984, USACE 1990a). About 42 percent of the earth experiences temperatures below freezing during the coldest month of any year (Figure V-5-8). The presence of ice is accompanied by longer nights and increased fog and precipitation (Figure V-5-9). Shipboard mechanical equipment, instruments, and communications apparatus are less efficient and more prone to failure in cold temperatures. Aids to navigation become less effective, and maneuvering in ice is much more difficult. Navigation projects in northern areas should be designed with consideration of these difficult conditions.

(a) Sea ice nomenclature and map notation symbols are defined by the World Meteorological Organization (WMO 1970). Ice thickness and structure are key concerns. *Multi-year ice*, sea ice more than 1 year in age, can be over 3 m thick, but it is found only in the Arctic Ocean and its marginal seas and near Antarctica.

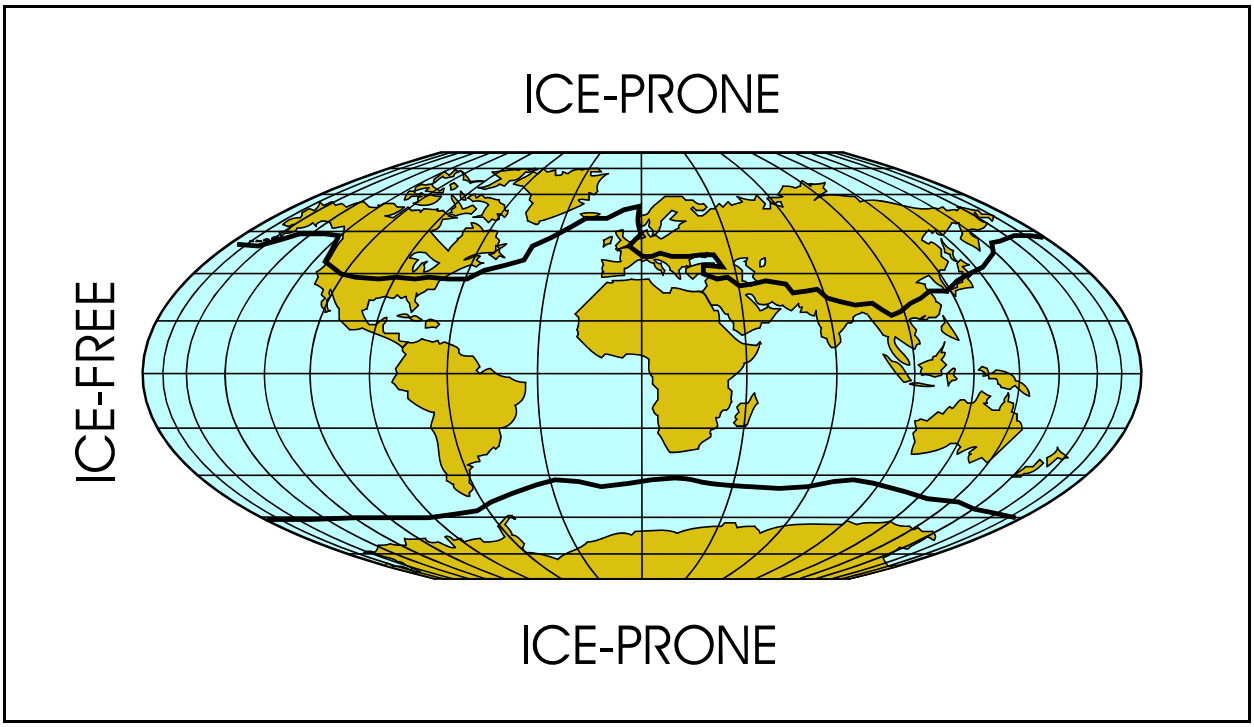

Figure V-5-8. Cold regions of the world

Figure V-5-9. Fog over frozen waterway (photograph, courtesy of Orson P. Smith, University of Alaska, Anchorage, Alaska)

First-year ice is generally classified as *young ice* (0-10 cm), *thin* (10-30 cm), *medium* (30-70 cm), or *thick* (70-120 cm).

(b) Ships that regularly navigate icy waters must have exceptional structural strength and propulsion power for safety of the crew, equipment, cargo, and environment. Special hull, propeller, and rudder designs reduce resistance and help clear lanes. Icebreakers may be needed to escort ice-strengthened cargo vessels or to periodically clear shipping routes. Shallow- and deep-draft ice-strengthened ships are in service around the world, classified for ice navigation by the ABS or several other agencies in Canada, Russia, and Europe.

(c) Factors to be considered for ship operation in ice rather than temperate conditions are:

- Ship maneuverability is retarded.
- Ice forces can divert ships from their intended course.
- Darkness is more common.
- Low visibility is more common (fog and precipitation).
- Winds can be very strong.
- Visual aids to navigation are less effective.
- Shipboard instruments are more prone to malfunction.
- Assistance or rescue by tugs is more difficult.
- Crews are more strained and fatigued in the face of these challenges.

c. Design considerations. Deep-draft navigation projects are typically formulated to provide safe and efficient passage for a selected ship under specified transit conditions. The design ship and transit conditions may be selected to represent the "maximum credible adverse situation," the worst combination of conditions under which the project would be expected to maintain normal operations. A project that successfully accommodates this situation can be expected to perform well with a full range of smaller ships and less difficult transit conditions. If future needs require it, the project may also accommodate ships larger than the design ship under milder transit conditions than the design scenario. Shallow-draft navigation projects are designed to safely accommodate the variety of small craft anticipated during the project design life, typically around 50 years.

(1) Design vessel. For deep-draft projects, the design ship or ships are selected on the basis of economic studies of the types and sizes of the ship fleet expected to use the proposed channel over the project life. The design vessel or vessels are chosen as the maximum or near maximum size ships in the forecast fleet based on the characteristics (length, beam, draft) of the ships being most representative of the potential economic advantage to be found in the forecast ship fleet.

(a) For small craft projects, the design vessel or vessels are selected from comprehensive studies of the various types and sizes of vessels expected to use the project during its design life. Often, different design vessels are used for various project features. For example, sailboats, with relatively deep draft, may determine channel depth design; and fishing boats, with relatively wide beam, may dictate channel width design.

(2) Design transit and mooring area conditions. Operational conditions selected for design can strongly affect a navigation project. A deep-draft project should be designed to allow the design ship to pass safely under design transit conditions. Normally, extreme events are not considered in specifying design transit conditions. Ship operators can usually suspend operations during these rare events without undue hardship. Some important exceptions for which extreme events may need to be considered include ships under construction or in repair facilities, inactive vessels, and USCG vessels.

(a) Operational factors to be specified for design transit include:

- Wind, wave, and current conditions.
- Visibility (day, night, fog, and haze).
- Water level, including possible use of tidal advantage for additional water depth.
- Traffic conditions (one- or two-way, pushtows, cross traffic).
- Speed restrictions.
- Tug assistance.
- Underkeel clearance.
- Ice.

(b) The use of tidal advantage in specifying design transit conditions allows for reduced channel depth, since the design ship would be constrained to transit during a high tide level. Channel length and vessel speed determine vessel transit time. The channel must provide the necessary water depth during at least the transit time period. If tidal advantage is included in design, the optimum design depth may be based on an analysis of water level probabilities, costs (vessel delays, dredging and disposal, etc.), and benefits.

(c) Normal operational conditions are strongly influenced by individual, local pilot, and pilot association rules and practices. For example, pilots usually guide a transit only when conditions allow adequate tug assistance. There may be operational wind, wave, or current limitations on the ability to safely moor a ship at a terminal or berth. Turning operations and maneuvering into a side finger slip may be limited by tide level and current conditions, including river outflow. Energetic wave conditions at the seaward end of the entrance channel may prohibit pilots from safely transferring between the pilot boat and ship. Such operational limitations may well be controlling factors in determining whether or not a safe transit is possible, and navigation project design should be consistent with these limitations.

(d) Design transit conditions for small-craft projects include vessel maneuverability (particularly if parts of the project will accommodate vessels under sail), traffic congestion, wind, waves, water levels, and currents. Design wave criteria are usually expressed as significant wave height, in probabilistic terms, for the entrance and access channels and mooring areas. Typical criteria are:

- Mooring areas: Significant wave height will not exceed 0.3 m (1 ft) more than 10 percent of the time.
- Access channels: Significant wave height will not exceed 0.6 m (2 ft) more than 10 percent of the time.

(e) Final design criteria for small-craft projects should be determined on the basis of economic optimization of the complete project (Part V-5-4).

V-5-3. Data Needs and Sources

a. Introduction. Planning and design of a navigation project are based on a wide range of information about the project area. The necessary data and sources are briefly reviewed in this section. More detailed information about data types and sources is given in Part V-2, "Site Characterization," and Part II-8, "Hydrodynamic Analysis and Design Conditions."

b. Currents. Currents in navigation channels and other project features can strongly affect vessels. Currents may also be important in navigation structure design. Currents of concern are usually tidal circulations or river flows.

c. Water levels. Water levels are essential for determining design depth in channels and other navigation areas. Water level variations are usually due to tides, river discharge, or lake levels. NOAA predicts tides and tidal currents at primary reference stations by the method of harmonic analysis. Phase and amplitude corrections to reference station predictions are available for many other secondary stations (NOAA *Tide Tables* and *Tidal Current Tables*, annual). Interpolation between secondary stations is often practical, if no major constrictions or confluences are present. Commercial software is available that can predict tides at hourly intervals at secondary stations. A similar analysis can be performed by applying the methods of Harris (1981).

d. Wind. Wind forces can strongly influence both vessels under way and moored vessels. Often an airport wind station located in the general area of a project can be used as a source of representative wind data.

e. Waves. Waves can have a major impact on navigation in exposed channels, particularly vertical excursions of the vessel and channel depth requirements. Deep-draft vessels respond to wave periods typically found in exposed ocean and Gulf of Mexico waters. Small craft respond to a wide range of wave periods, and waves can be especially troublesome if they break in the channel. Waves are also important for navigation structure design and for predicting channel shoaling.

f. Water quality. Water quality and potential changes in water quality may become issues for projects creating more enclosed harbor areas, where circulation and flushing may be reduced as a result of the project.

g. Sediments. Sediment characteristics in project and adjacent areas are needed. Bottom materials in any areas to be dredged are especially important. Sediment quality can dictate disposal options and costs ranging from beneficial uses such as beach fill to confined or capped disposal of contaminated material.

h. Bathymetry and sediment transport processes. Bathymetry and sediment transport processes are needed to determine baseline conditions, optimum project location, initial dredging quantities, channel shoaling rate and maintenance needs, and potential project impact on adjacent shorelines. Methods for predicting channel sedimentation are reviewed by Irish (1997).

i. Ecological processes. Navigation projects can have an impact on ecological processes. Baseline conditions may need to be established.

j. Local coordination. Local people familiar with the project area and/or using an existing project regularly can provide valuable insight about present conditions and impact of any modifications.

(1) Pilot interviews. Deep-draft navigation project planners/designers should develop strong coordination with local pilot groups. Pilot interviews can be used to determine users' opinions about existing

channel navigation safety, suitability of design transit conditions, and feasibility and safety of proposed channel design alternatives.

(2) U.S. Coast Guard. The local USCG office should also be contacted early in the project development to solicit their views on channel dimensions and alignment for safe navigation. They can also provide guidance on placement of aids to navigation.

(3) Accident records. Marine accident records are available from the USCG annual compilation of casualty statistics in an automated system called Coast Guard Automated Main Casualty Data Base (CASMAIN). Accident data on existing navigation channel projects proposed for enlargement or improvement should be studied. USCG and National Transportation Safety Board special investigation reports are available for some accidents, which can provide insight on navigation problems.

V-5-4. Economic Analysis

a. A number of alternatives can usually be defined to meet navigation design requirements. Alternatives should generally include a range of channel depths, since depth is one of the major cost-determining parameters. For example, a proposed navigation channel may suffice for the design ship and design transit, but lead to undesirable ship delays and queueing because of heavy ship traffic and limited channel capacity. The adaptability of each alternative for meeting future navigation requirements should also be considered. The final design is usually selected from among the alternatives to maximize economic benefits. USACE navigation project evaluation procedures are described by USACE (1990b).

b. A complete design approach includes consideration and optimization of the full navigation system described in Part V-5-2.b. The comprehensive design process, beyond the scope of this chapter, is discussed by PIANC (1997a).

c. For economic optimization, the cost of each alternative design is estimated. Costs associated with all the elements of developing and maintaining the project should be included. Normally, several alternative channel alignments and widths, as well as depths, are represented. Navigation structures may also be part of some or all alternatives. Costs include initial construction (dredging, dredged material disposal, aids to navigation, breakwaters, jetties, etc.), replacement cost, and operation and maintenance.

d. Benefits for deep-draft projects are determined by transportation savings, considering ship trip time (including loading/unloading time, which may include lightering), cargo capacity, and delays due to project limitations. Benefits are evaluated by determining the transportation costs per ton of commodity for each increment of channel depth. Transportation costs are based on ship annual operating cost for each type of ship, including fixed cost and annual operating expenses. Data on ship operating costs are periodically compiled by the USACE Water Resources Support Center. Benefits may result from:

(1) Use of larger ships.

(2) More efficient use of large ships.

(3) More efficient use of present ships.

(4) Reductions in transit or delay times.

(5) Lower cargo handling costs.

(6) Lower tug assistance costs.

(7) Reduced insurance, interest, and storage costs.

(8) Use of water rather than land transport mode.

(9) Reduction of accident rate and cost of damage.

e. The USACE evaluation procedure to estimate navigation benefits includes nine individual steps (Figure V-5-10). Accurate projection of commodity movements over the proposed alternative project design (steps 3 and 7) is key to evaluation. Details of the procedure are given by USACE (1990b).

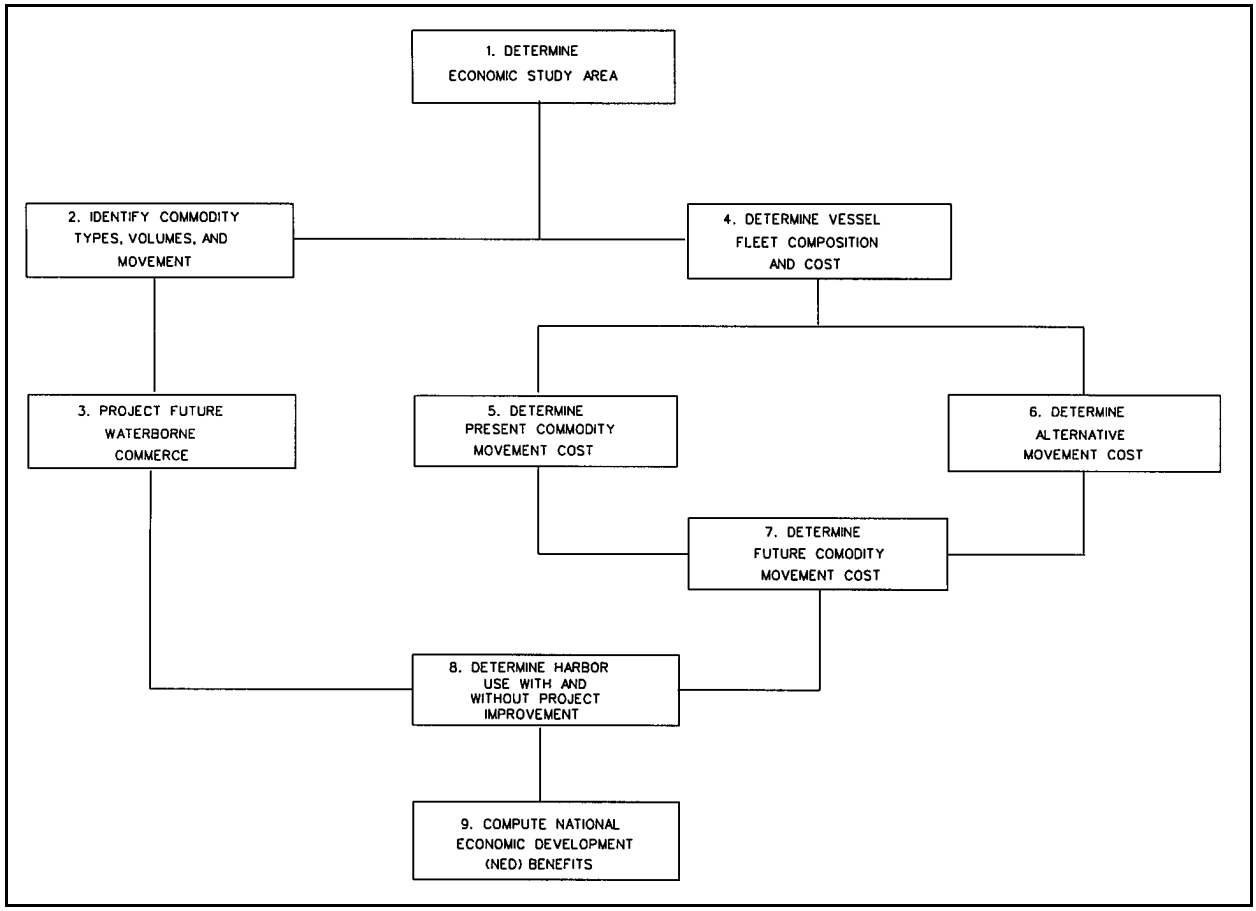

Figure V-5-10. Deep-draft navigation benefit evaluation procedure

f. Small-craft harbor projects follow a similar economic optimization procedure. Generally, several entrance channel and basin configurations are identified as alternatives. The alternatives should provide varying protection and accommodations so an optimal alternative can be selected. The cost for each alternative is estimated, including initial cost, maintenance cost, and social and environmental aspects. Benefits are also estimated. The alternative that maximizes net benefits (difference between benefits and cost) is usually the preferred project plan. After the alternative with optimal level of protection and size has been determined, then the most economical way of providing that protection and size should be developed.

V-5-5. Channel Depth

a. Introduction. Channel depth is a key factor in the cost and usability of a navigation project. It should be adequate to accommodate present and expected traffic. Typically it is chosen on the basis of economic optimization. The design channel depth need not be constant throughout the project. It can, and often does, vary in segments as needed to allow the design vessel or vessels to make safe and efficient transits in a cost-effective project.

(1) Vessels navigating in shallow water encounter a variety of channel cross sections over the length of a navigation project. Since channel cross section can significantly affect natural processes and vessel behavior, it is useful to define characteristic types (Figure V-5-11). A *canal* has an enclosed cross section with exposed land adjacent to both sides of the channel. A *trench* is a deepened passage with submerged overbanks on either side. A *fairway* is a passage with no lateral constraints.

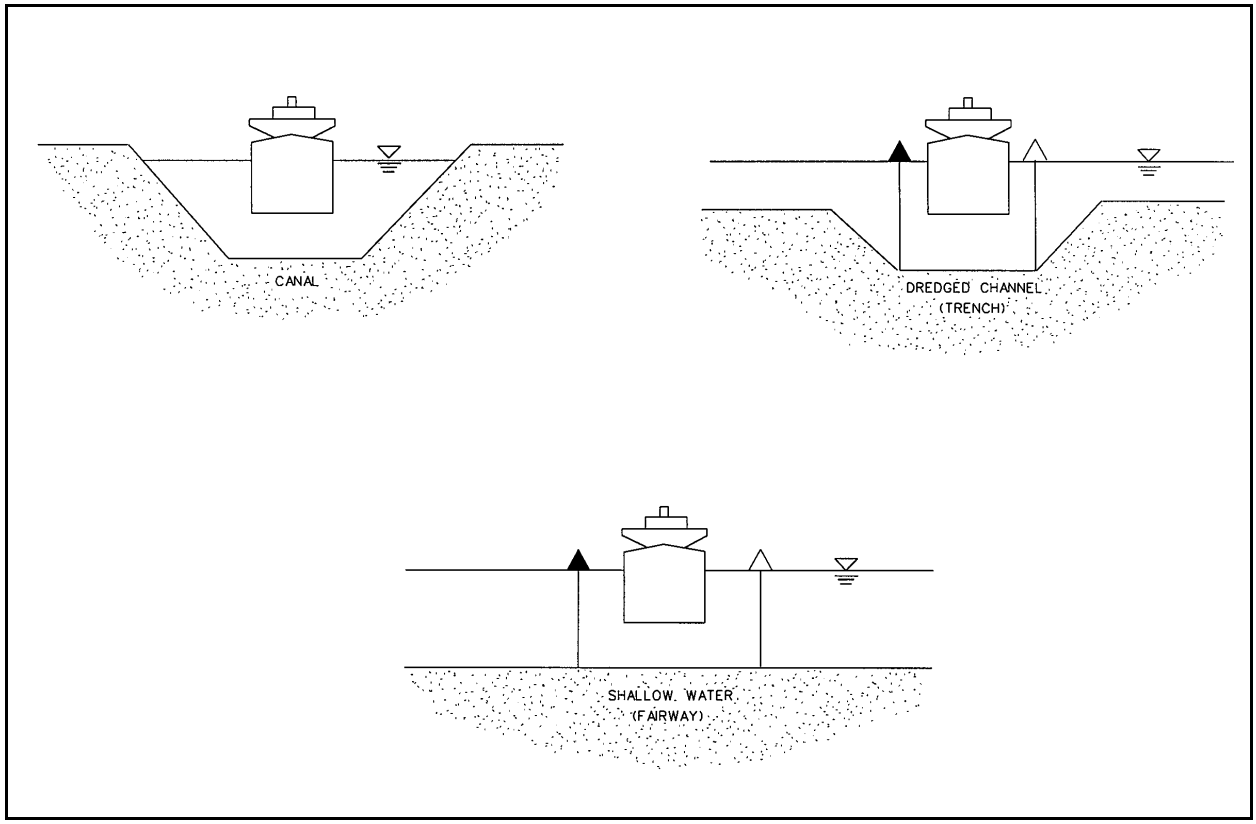

Figure V-5-11. Definition of channel types

(2) Channel depth for both deep- and shallow-draft navigation projects may be determined by figuring a depth increment for each of the important factors affecting vessel underkeel clearance requirements and adding those to the design vessel draft (Figure V-5-12). This depth, required for safe vessel passage, provides a basis for Congressional authorization of Federal channel depth, referred to as the *authorized channel depth*. The dredged channel depth, or *contract depth*, generally exceeds the authorized depth to accommodate potential sedimentation and maintain navigability. In some projects, consideration must also be given to the *permitted depth*, the extreme dredging depth permitted by regulators. The same factors generally apply for both deep- and shallow-draft projects, but their relative importance and estimation procedures differ somewhat, as discussed in the following paragraphs.

b. Effect of fresh water. The nominal draft of seagoing ships usually represents the seawater environment. When ships enter channels and ports in brackish or fresh water, ship draft increases due to the lower water density. The draft increase between ocean and fresh water is 2.6 percent. In USACE practice, a maximum depth allowance of 0.3 m (1 ft) may be included for this effect (Table V-5-6) (see Figure V-5-12). This maximum allowance corresponds to the draft increase between ocean and fresh water for a vessel with an 11.6-m (38-ft) draft. The freshwater effect is generally not considered in small craft navigation projects.

Table V-5-6
Depth Allowance for Freshwater Effect

	Allowance	
Port Location	**m (ft)**	**Percent**
Brackish water	0.15 (0.5)	1.3
Fresh water	0.3 (1.0)	2.6

c. Vessel motion from waves. Vessel vertical motion in response to waves must be considered in design of channel depth at exposed locations (see Figure V-5-12). Entrance channel design depth is typically greater than interior harbor channel depth because of the need to accommodate wave-induced vertical vessel motions. Wave effects tend to increase as wave height increases and decrease with longer vessel length. Maximum vessel response occurs with wavelengths approximately equal to vessel length. Most deep-draft ships are relatively unaffected by very short-period waves but respond when periods are longer than around 6-8 sec.

(1) Vessel motions that affect channel depth are roll, pitch, and heave (Figure V-5-13). Roll is most important when waves are perpendicular to the vessel travel direction (*beam seas*). Pitch and heave are most important when the vessel and wave travel directions are colinear (*head sea* or *following sea*). These motions can have a large impact on deep-draft channel depth requirements. For example, a pitch angle of 1 deg increases the extreme excursion of a 300-m- (1000-ft-) long ship by 2.7 m (9 ft). A 5-deg roll of a ship with a 46-m (150-ft) beam can increase extreme excursion by 2.1 m (7 ft).

(2) Vessel response to waves depends on the combined effects of:

(a) Wave height, period, wavelength, and propagation speed.

(b) Wave direction relative to vessel.

(c) Vessel length and beam.

(d) Vessel speed.

(e) Natural periods of vessel roll, pitch, and heave.

(f) Vessel draft and underkeel clearance.

(g) Channel depth and overbank depth.

(h) Wind and currents (speed and direction relative to vessel).

(i) Pilot strategy.

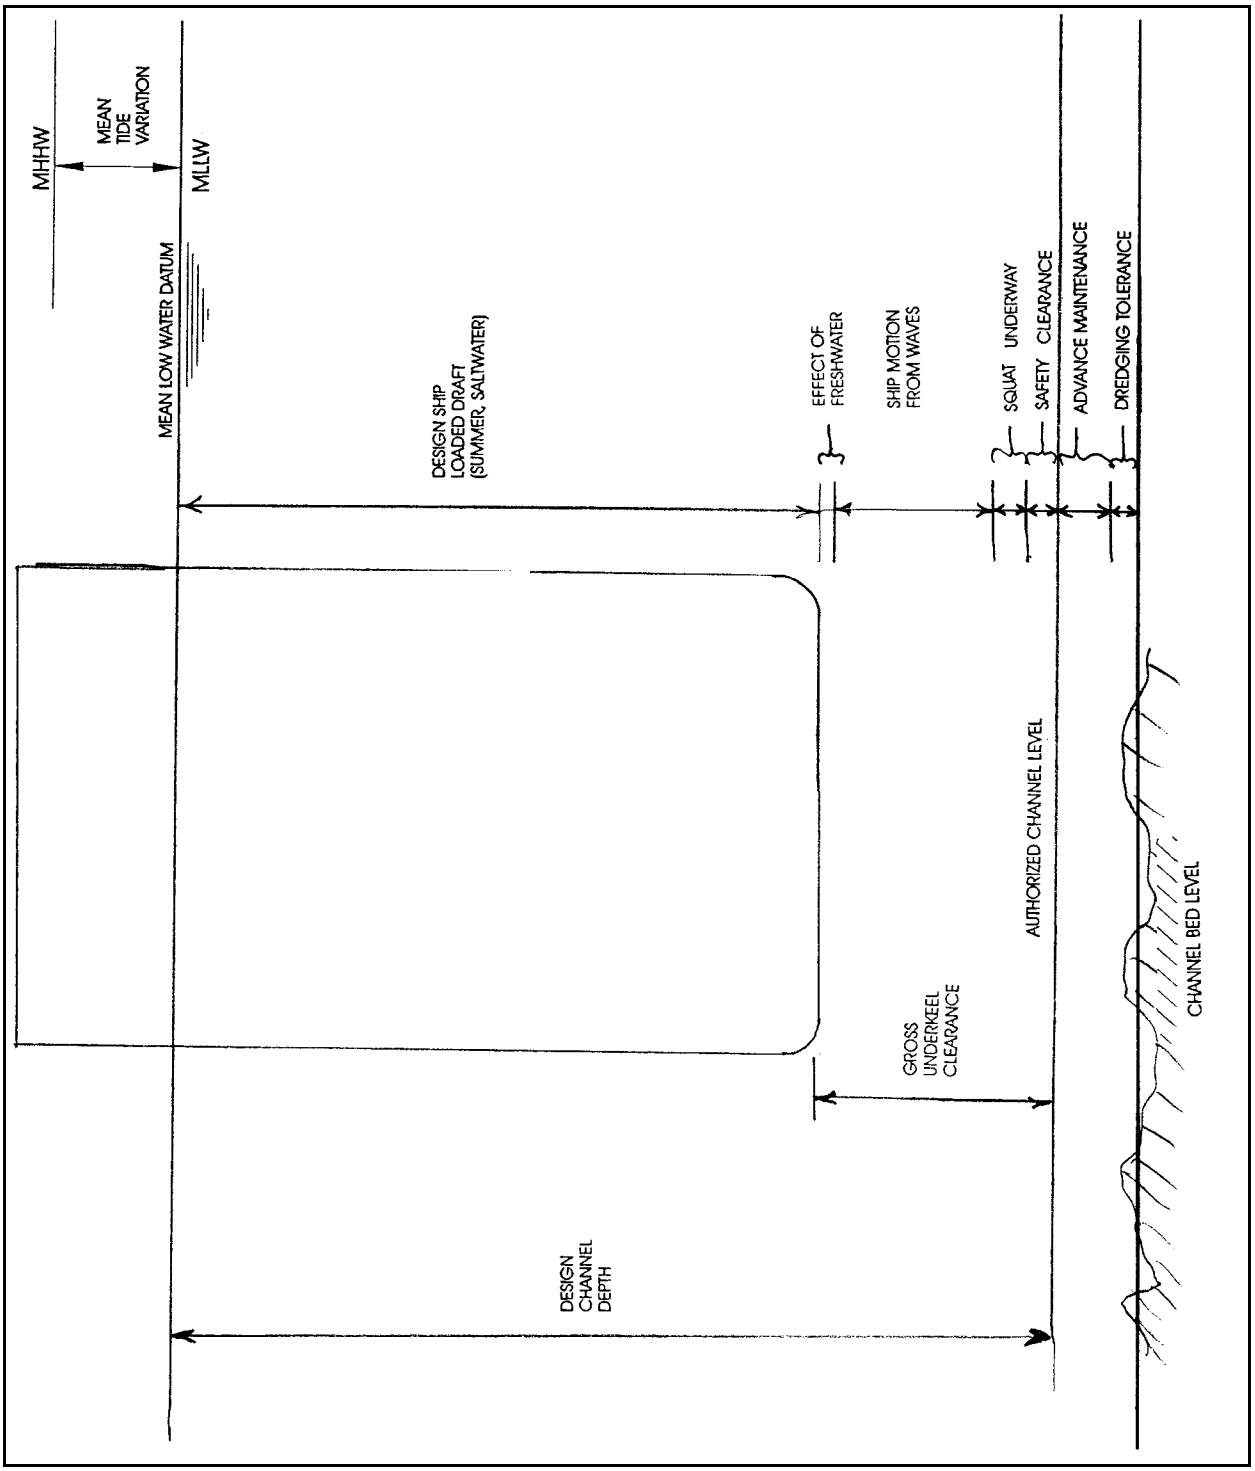

Figure V-5-12. Channel depth allowances

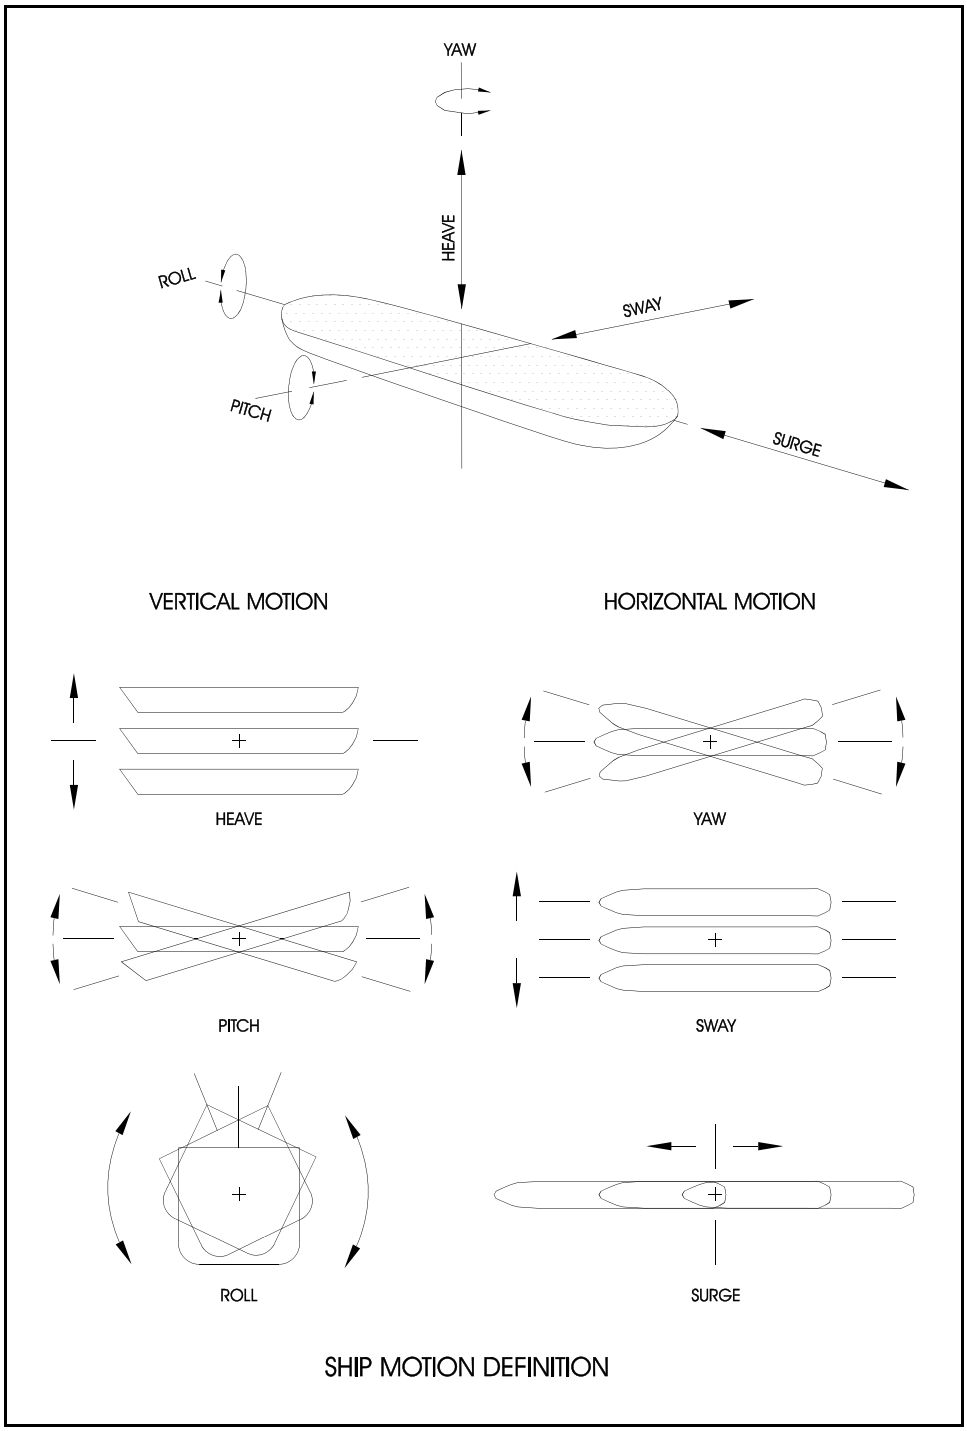

Figure V-5-13. Ship motion definitions

(3) Many of these factors, most notably wave height, vary as a vessel transits a channel. The net effect of these factors on a vessel is difficult to estimate analytically. The design objective is to achieve a channel depth that allows the design vessel to transit the project with a very low probability for any damaging contact with the channel bottom.

(4) For deep-draft projects, the depth allowance needed to accommodate wave-induced ship motions is a major concern for which no easy, accurate solutions are available. Because of the magnitude of depth allowance for waves in many exposed entrance channels and because waves are highly variable, even within a specified sea state, it is prudent for final design to review existing data for similar ships and, in many cases, to conduct studies to develop realistic estimates. Options include (Part V-5-10):

(a) Analytic studies, using strip theory or other theoretical calculation methods as developed by naval architects.

(b) Interactive, real-time ship simulator studies.

(c) Physical model studies, using radio-controlled, free-running scaled ship models with wave response measurements.

(d) Direct, onboard ship measurements while transiting through the entrance channel.

(5) An example of physical model studies to aid in probabilistic navigation channel design is presented in Section V-5-10.b.(1).

(6) Direct field measurements of ship motion are a valuable addition to channel design studies, but extreme conditions controlling design are not easily captured. Field measurements are dependent on available ships and environmental conditions during the limited duration of the measurement program. Figure V-5-14 provides an example of results from a large field measurement program in a high-wave-energy entrance channel. Data were collected over a 2-year period at the mouth of the Columbia River, at the Oregon/Washington border (Wang et al. 1980). The *average* ratio of ship bow/stern response amplitude to wave amplitude on each transit varied between about 0.5 and 2.0 over 29 instrumented voyages.

(7) Simple general guidelines for minimum depth clearance requirements in channels influenced by waves are given by PIANC (1997) as

$$\frac{Water\ depth}{Ship\ draft} \geq 1.3 \qquad \text{when } H \leq 1\text{m (3.3 ft)}$$

$$\frac{Water\ depth}{Ship\ draft} \geq 1.5 \qquad \text{when } H > 1\text{m (3.3 ft) and wave periods and directions are unfavorable}$$

where H = wave height

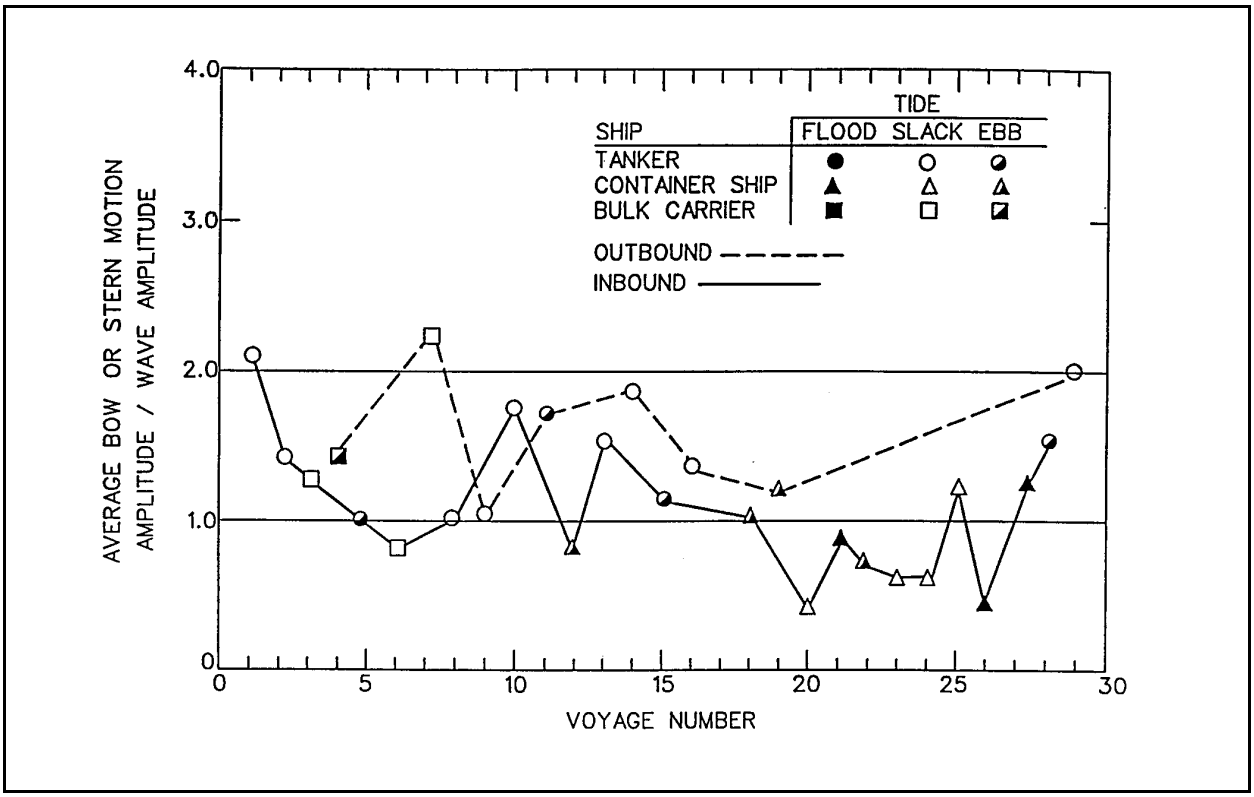

Figure V-5-14. Ship motion response, mouth of Columbia River

(8) For small recreational craft, a depth allowance for waves is also important but difficult to estimate accurately. As with deep-draft vessels, model and measurement studies may be conducted; but such project-specific studies are usually impractical for small-craft channel design. Small craft length and beam are often small relative to wavelengths important for design. It is realistic to consider the maximum vertical drop experienced by a small boat in a wave to occur when the boat is fully contained in the wave trough. The magnitude of this drop below the Swl is then the wave amplitude $H/2$. In practical design, typically one-half the design significant wave height is used.

d. Vessel squat. A depth allowance for squat experienced by vessels under way is included in channel depth design (see Figure V-5-12). The amount of squat experienced by a vessel depends strongly on speed and relative blockage of the channel cross section by the vessel. A small, fast-moving boat in a small channel may experience as much or more squat than a large, slower-moving ship. Squat increases when ships meet and pass in a channel because the total blockage is increased. Squat is an important consideration in both deep- and shallow-draft navigation projects. As with vertical vessel motion due to waves, squat is difficult to estimate accurately and is a subject of present research.

(1) Simplified methods for estimating squat are available. The method presented here is based on equations for squat in fairway and canal channel configurations, with a simple interpolation between these limiting cases to accommodate trench configurations (USACE 1998). A definition sketch of parameters is given in Figure V-5-15.

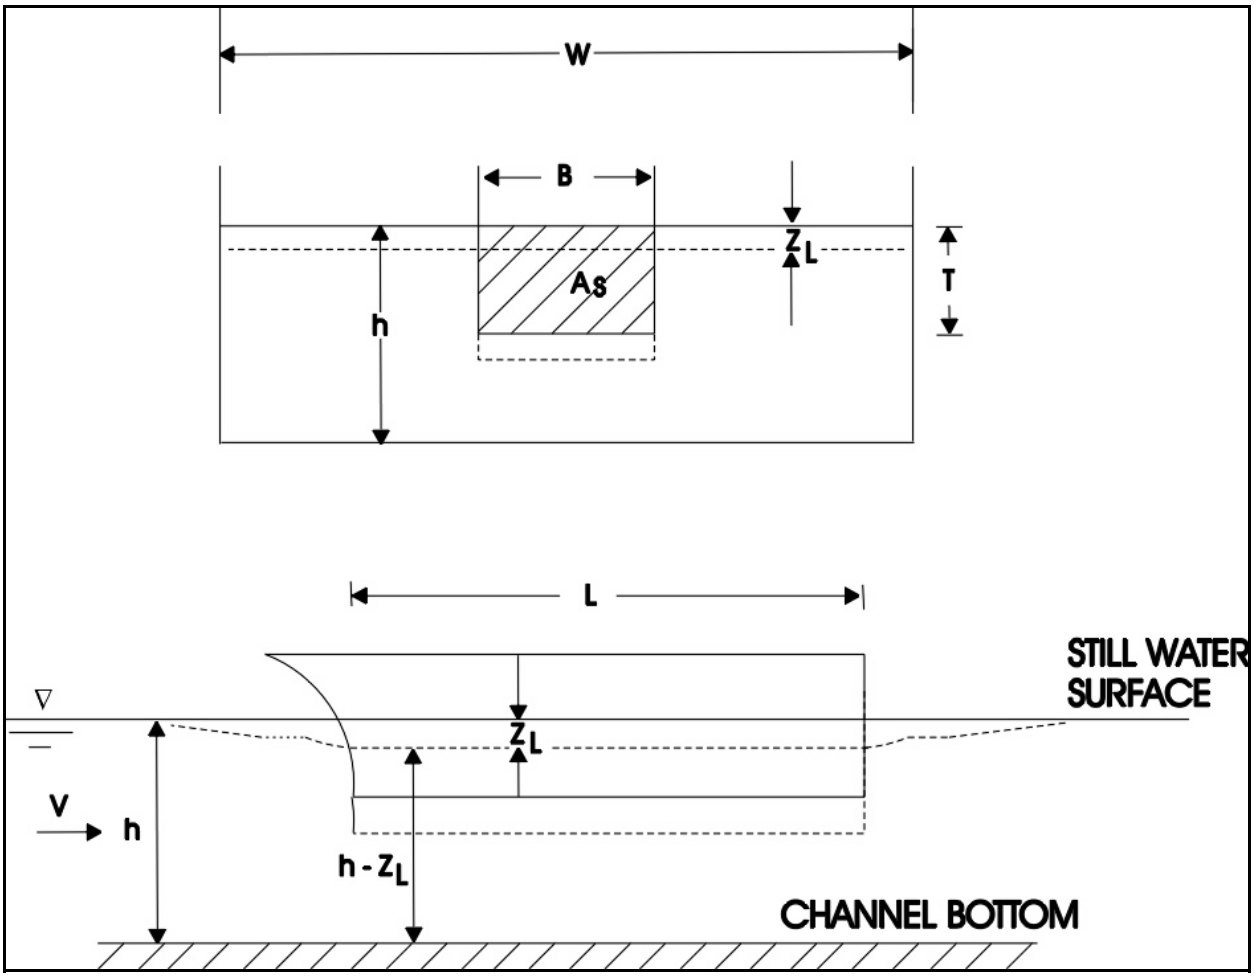

Figure V-5-15. Squat analysis definition

(2) Squat in a fairway can be estimated as (Norrbin 1986)

$$Z = 0.2125\, C_B \frac{B}{L} \frac{T}{h} V^2 \qquad V \text{ in knots, } Z \text{ in ft (fairway)} \tag{V-5-3}$$

$$Z = 0.01888\, C_B \frac{B}{L} \frac{T}{h} V^2 \qquad V \text{ in km/hr, } Z \text{ in m}$$

where

Z = maximum ship squat

C_B = block coefficient (Figure V-5-4)

B = ship beam at midship (Figure V-5-15)

T = ship draft (Figure V-5-15)

L = ship length (Figure V-5-15)

h = depth of shallow-water area (Figure V-5-15)

V = ship speed

This equation is applicable when Froude numbers are less than 0.4.

(3) Squat in a rectangular canal can be related to the Schijf limiting Froude number, which corresponds to the Schijf limiting speed (Part V-5-2-b-(3)). The limiting Froude number is given by (Huval 1980)

$$F_L = \frac{V_L}{\sqrt{gh}} \simeq \left\{ 8 \cos^3 \left[\frac{\pi}{3} + \frac{1}{3} \cos^{-1} \left(1 - \frac{1}{B_R} \right) \right] \right\}^{\frac{1}{2}} \quad \text{(rectangular canal)} \tag{V-5-4}$$

where

F_L = Schijf limiting Froude number

V_L = Schijf limiting ship speed in squat analysis

g = acceleration due to gravity; = 9.80 m/sec^2 (32.2 ft/sec^2)

h = depth of canal (Figure V-5-15)

B_R = channel blockage ratio (Equation V-5-2 and Figure V-5-7)

(4) Maximum ship squat at the Schijf limiting Froude number is given by

$$Z_L = h \left[\frac{F_L^2}{2} \left(F_L^{1/3} - 1 \right) \right] \quad \text{(rectangular canal)} \tag{V-5-5}$$

where

Z_L = maximum squat at Schijf limiting Froude number

An approximate analysis for nonrectangular canal cross sections can be made by replacing the channel depth by a cross-section mean depth.

(5) Trench channels can assume a variety of shapes, including asymmetric overbank depths and different lane depths in two-way channels (Figure V-5-16). The trench configuration is intermediate between the fully

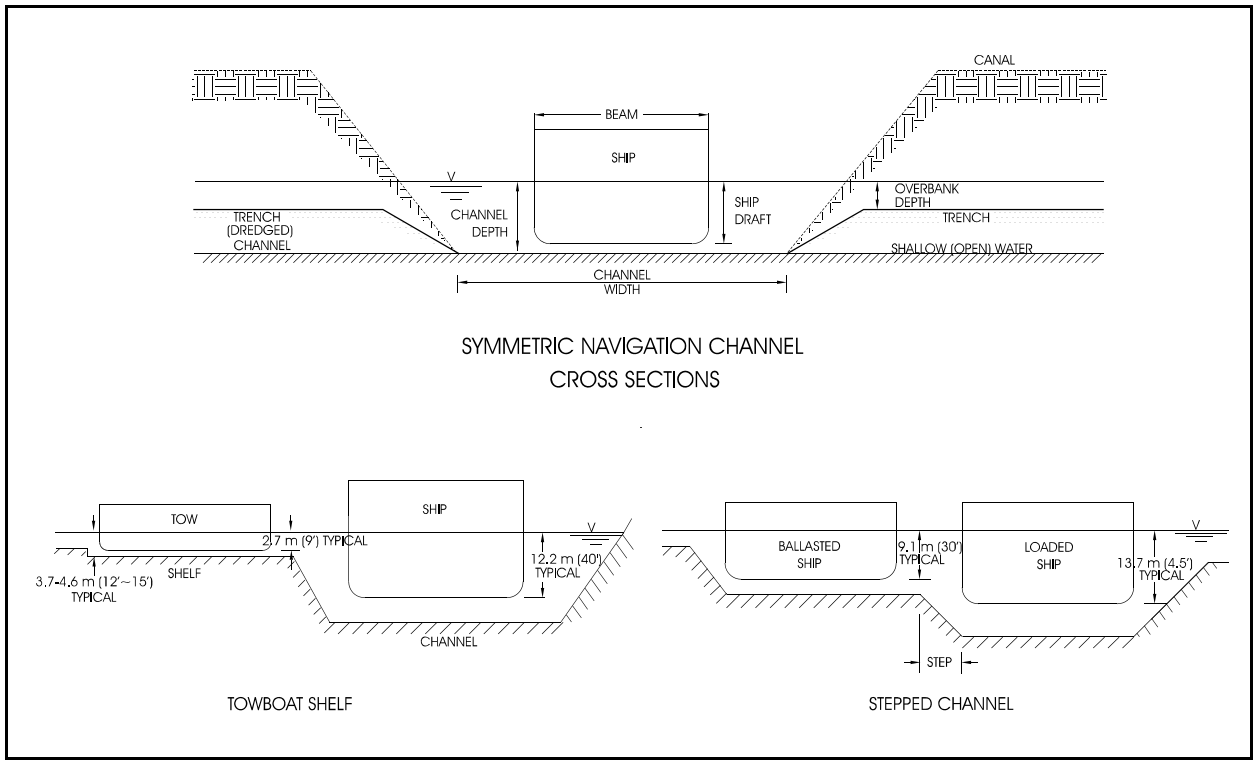

Figure V-5-16. Example channel cross sections

open fairway and fully restricted canal configurations. A first approximation to squat may be made by interpolating between those two extremes, based on the ratio of average overbank depth-to-channel depth (Figure V-5-17)

$$Z_T = \left(\frac{h_1 + h_2}{2h} \right) Z + \left(1 - \frac{h_1 + h_2}{2h} \right) Z_L \qquad \text{(trench)} \tag{V-5-6}$$

where

Z_T = maximum squat in a trench channel

h_1, h_2 = overbank depths

Computational results from a computerized version of this model illustrate squat variation with ship speed and channel type (Figure V-5-18) (Huval 1993). The figure illustrates how a narrow, confined channel can significantly increase squat and, hence, required channel depth.

(6) Squat for small recreational craft is generally less critical than for large displacement, deep-draft ships. However, it should be included in channel design. The usual procedure is to use a fixed depth allowance for squat in entrance channels, where boat speed is relatively high, and a smaller fixed allowance for interior areas, where boat speed is generally low (Table V-5-7).

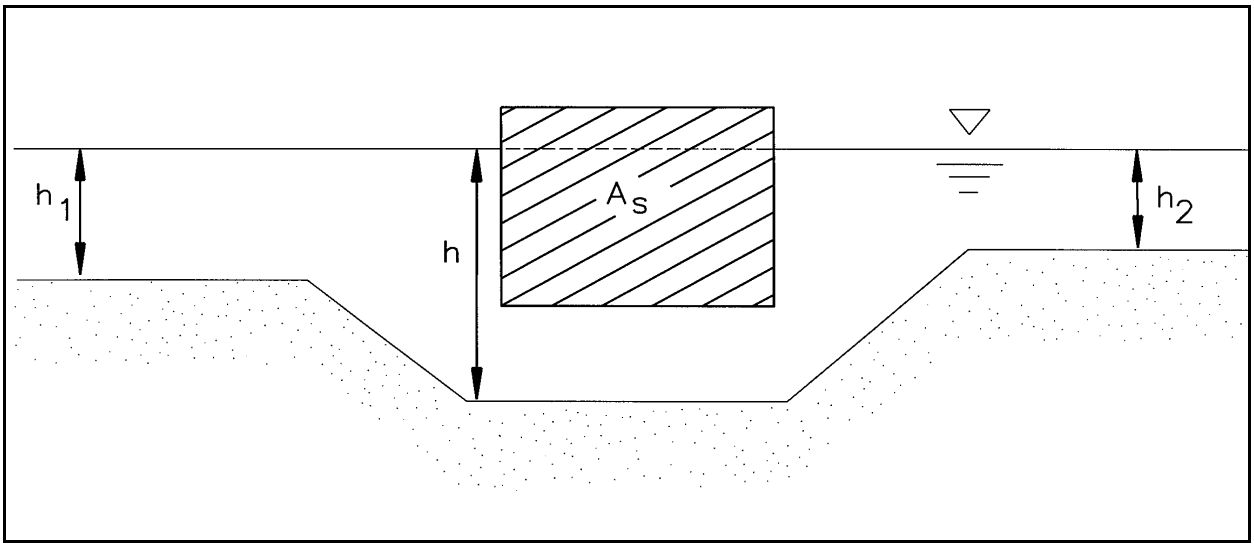

Figure V-5-17. Trench channel definitions

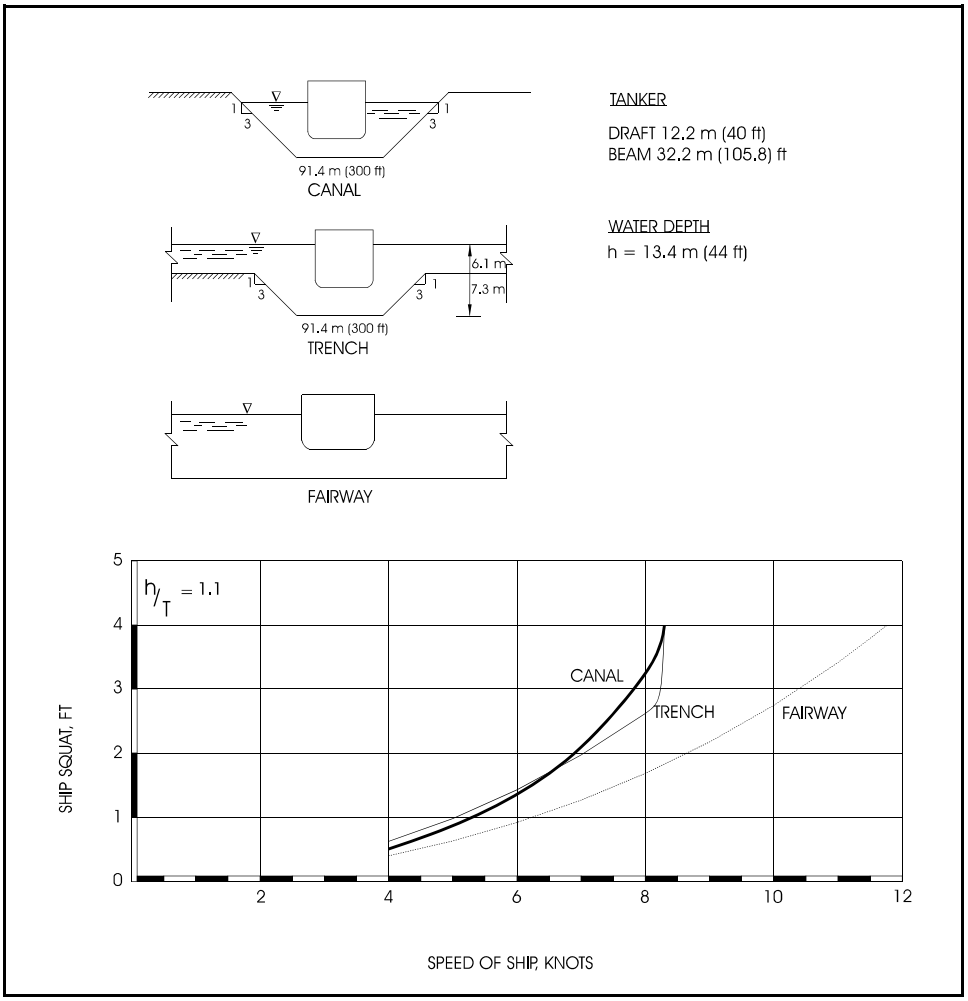

Figure V-5-18. Example squat calculations

Table V-5-7
Squat Allowance for Small Recreational Craft

Location	Allowance
Entrance channels	0.3 m (1.0 ft)
Interior channels, moorage areas, turning basins	0.15 m (0.5 ft)

e. Trim. Deep-draft ships often operate with trim for a variety of reasons. For example, ships may be loaded or ballasted to lower the stern a small amount deeper than the bow, which can improve maneuverability. Ships under way tend to change from the static trim. Small craft in motion can experience significant trim, with the bow rising high and stern dropping low in the water. Because vessel trim conditions are mainly determined by operational decisions, a channel depth allowance for trim is not included.

f. Shallow-water effects. Even when deep-draft ships have sufficient channel depth to avoid hitting bottom, they may experience adverse safety and efficiency effects due to small underkeel clearance. Steering and turning become significantly more difficult, more power is required to maintain speed, and potential for bottom scour and bank failure increases considerably as propeller speed is augmented. Ship cooling systems may ingest benthic organisms or sediment if intakes are too near the bottom. Although these effects can be significant, no depth allowance is included in general channel design to lessen their impact. In some cases, it may be prudent to quantify the location and size of cooling system intakes, evaluate the impacts of small clearances, and perhaps impose a minimum clearance as an added constraint on project design. For example, the U.S. Navy requires a 1.5-m (5-ft) clearance beneath aircraft carrier intakes.

g. Safety clearance. To protect vessel hull, propellers, and rudders from bottom irregularities and debris, a channel depth allowance for safety is included (Table V-5-8). A larger clearance is needed when the channel bottom is hard, such as rock, consolidated sand, or clay (see Figure V-5-12).

Table V-5-8
Safety Clearance

Bottom Type	Minimum Safety Clearance
Soft	0.6 m (2 ft)
Hard	0.9 m (3 ft)

h. Advance maintenance. An additional increment beyond the channel design depth is added to maintain reliable navigable depth between dredge events. This depth increment is to provide for accumulation and storage of sediment. The depth allowance for advance maintenance should be determined by considering several different increments and choosing that which minimizes total channel maintenance cost. Dredge mobilization costs and safety concerns must be balanced against the tendency for a deeper channel to shoal more rapidly. A sediment trap near the entrance may be an economic alternative to reduce advance maintenance requirements in the channel. Depth increments of 0.6-0.9 m (2-3 ft) are normal advance maintenance allowances (see Figure V-5-12).

i. Dredging tolerance. Another depth increment is added beyond the design channel depth to compensate for the inherent mechanical inaccuracies of dredges working in the hostile environment of adverse currents, fluctuating water surface, and non-homogeneous bottom material. A dredging tolerance of 0.3-0.9 m (1-3 ft) is typical (see Figure V-5-12).

j. Tidal shoals and ship transit concerns example. Coastal entrances, bays, and river estuaries typically have meandering natural channels and intermittent shoals. When deeper ship drafts are anticipated, the impact of tidal shoals on schedules and/or margin of safety must be evaluated. Increasing design channel depth over the shoals may eliminate tidal constraints altogether or just improve access to a more economical level. The question, "How deep is deep enough?" must be answered by weighing transportation cost savings against the cost of channel excavation and maintenance. The following example illustrates considerations involved in answering this question and developing an optimum design channel depth.

(1) The example port is located in an estuary, 35 km from the ocean entrance (Figure V-5-19). At a distance of 30 km from port, ships must pass over a shoal with controlling depth of 8 m below mllw (*Shoal 1*). At a distance of 10 km from port, ships encounter another shoal with controlling depth of 7 m below mllw (*Shoal 2*). The port itself has 13 m depth mllw, which is about the average depth available between the two shoals. The diurnal tidal range between mllw and mhhw in this example is amplified from 3 m at the ocean entrance to 4 m at the port, which might correspond to tides in a gradually narrowing bay. Conversely, friction in narrow river estuaries often results in reduced tidal ranges upstream. Tidal datums (e.g., mllw and mhhw) also change as the tidal wave is transformed by the waterway.

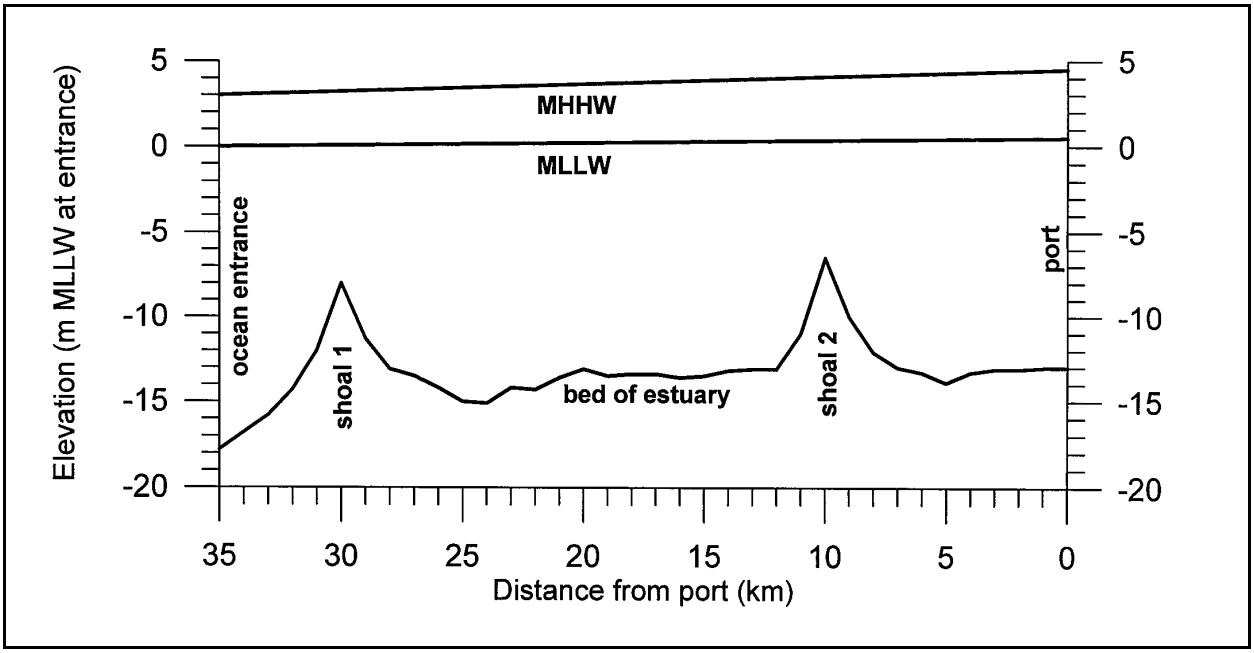

Figure V-5-19. Hypothetical route to a port at the head of an estuary (cross section along channel center line)

(2) The distribution of tidal water levels is estimated by using NOAA primary and secondary tide station data (Part V-5-3). Interpolation between secondary stations is often practical, as needed, if no major constrictions or confluences are present. Figure V-5-20 illustrates the predicted distribution of hourly depths for 1 year at the shallower shoal, Shoal 2. A similar analysis can be performed by applying the methods of Harris (1981).

(3) River discharges and wind-induced water level changes affect water depth over the shoals. Waterway confluences or constrictions and hydrodynamic effects of the shoal itself affect water levels in the vicinity. Seasonal or storm-related changes in elevation of the shoal crest can also affect the depth available to ships. These complications may call for a program of site-specific water level measurements. Numerical modeling

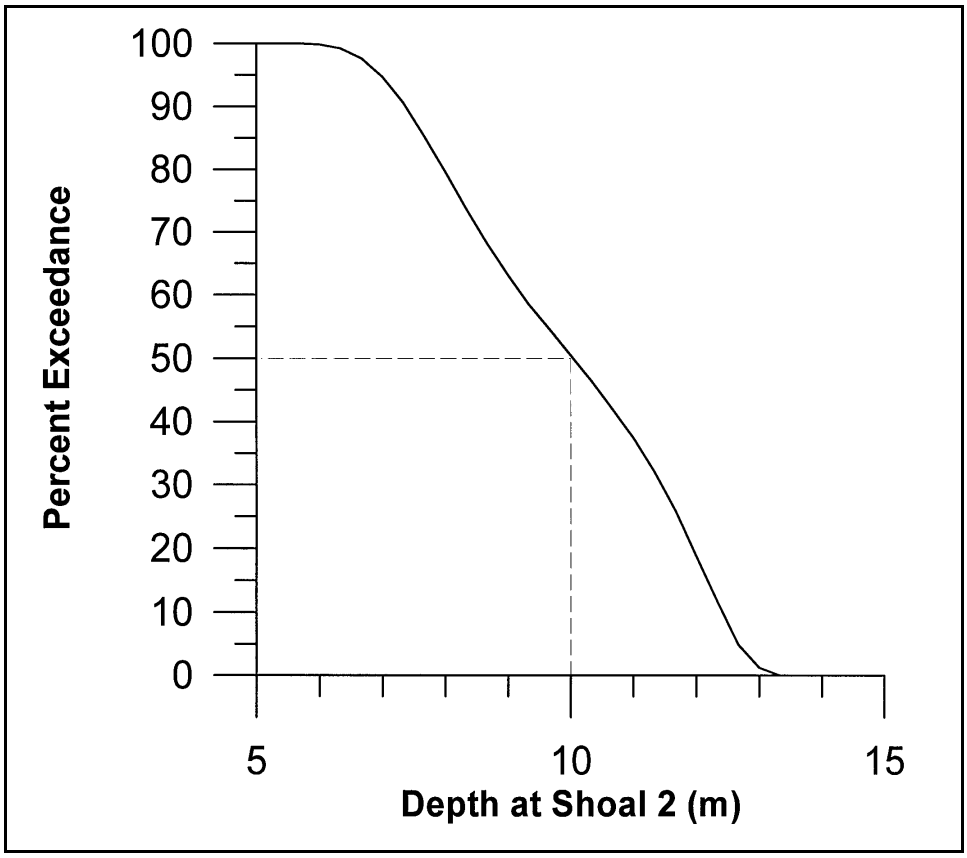

Figure V-5-20. Hypothetical distribution of depths for Shoal 2

of historical conditions (hindcasting) may also be effective for precisely describing water level changes. Figure V-5-21 illustrates water level variations on the main branch of the lower Fraser River near Vancouver, British Columbia, Canada, including tidal and river discharge variations (Ferguson 1991). The transect begins at the river mouth at Sand Heads and continues 35 km up the estuary to New Westminster. Shaded areas show the impact of river outflow on water level for two tide levels (high and low tide). River outflow has little impact on water level at the mouth, but significant impact up into the estuary, especially at low tide. River outflow can add up to 2 m to low tide water depth along this channel. It also affects current. With high river outflow, water level at New Westminster becomes nearly constant over the tidal cycle. Similar processes may need to be considered at the example port.

(4) Figure V-5-20 indicates that ships approaching the example port with draft and keel clearance requirements for a minimum 10-m depth must wait until the upper half of the tidal cycle to cross Shoal 2. Since ships generally arrive on schedules independent of the tide, roughly half the ships of this draft will be delayed. Time spent waiting for the tide, or more likely spent at slow speed offshore, will vary from one arrival to another. Time will also be lost on departure, since ships loaded and ready to depart will have to wait for favorable tide. Deeper ships will lose more time. The shoals of the example are about an hour's sailing apart, so the dangerous possibility exists of crossing one shoal on ebb tide only to find insufficient depth at the second.

(5) The variability of arrival and departure times, ship draft and speed, and water depths is difficult to resolve by multi-variate probability analysis based only on recorded port data. Port arrival and departure times and drafts are usually recorded, but details of shoal-related delays are not. Historical and future delays

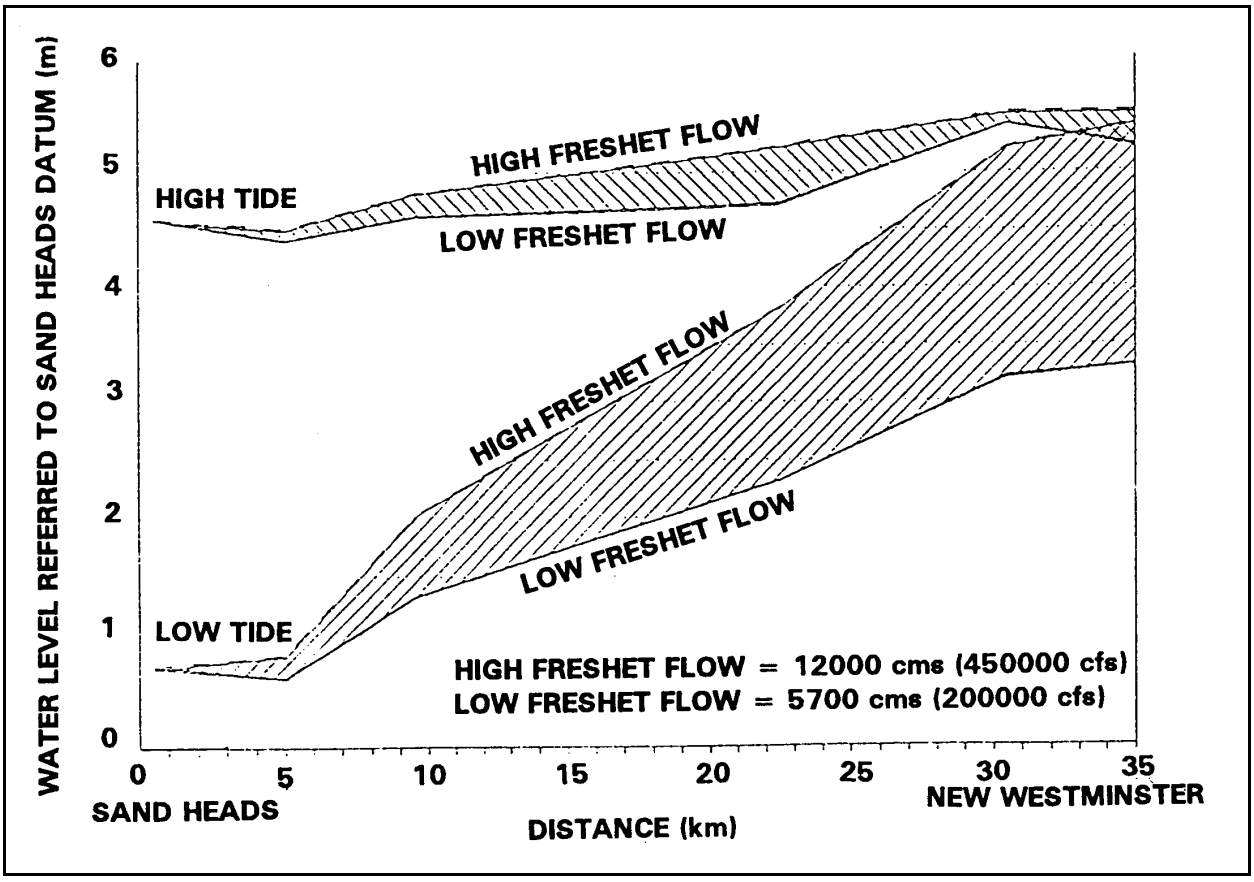

Figure V-5-21. Range of water levels in Fraser River, British Columbia (after Ferguson 1991)

can often be estimated more accurately with numerical simulations. For example, a risk-based system for evaluating channel depth requirements (and for evaluating operational transit safety when coupled with real-time field environmental measurements) is discussed by Silver (1992) and Silver and Dalzell (1997).

(6) Figure V-5-22 illustrates the conceptual approach of a computer program for time-and-motion simulations which applies predicted tides and tidal currents, historical or projected ship cargoes, drafts, and arrival times at the ocean entrance, and cargo transfer rates at port. The same model can simulate ship transit times with various dredged channel geometries. Waiting times are computed as the difference between transit time simulated across the shoals and transit time without shoal restrictions.

(7) Randomly occurring combinations of variables affecting transit times, such as strong winds, river discharge- and wind-induced depth changes, high waves, low visibility, and ice conditions can be added using a Monte Carlo approach. This method requires enough repeated simulations of the same input variables with random values of stochastic variables to encounter the full range of combined extremes. Statistics of transit time, waiting time, and associated costs can be computed from these data. A more complete discussion of vessel traffic flow simulation models is given by PIANC (1997a).

(8) Ship costs are generally proportional to operating time, either under way or at berth. Reductions in time navigating the port approach, at the dock, and departing translate into cost savings. Other cost factors include impacts of ship arrivals on longshoremen, mechanical equipment, and cargo staging at the port. Transportation costs without channel improvement must be estimated as a baseline against which to measure cost-effective optimization of channel excavation. The savings realized by a range of excavation depths and

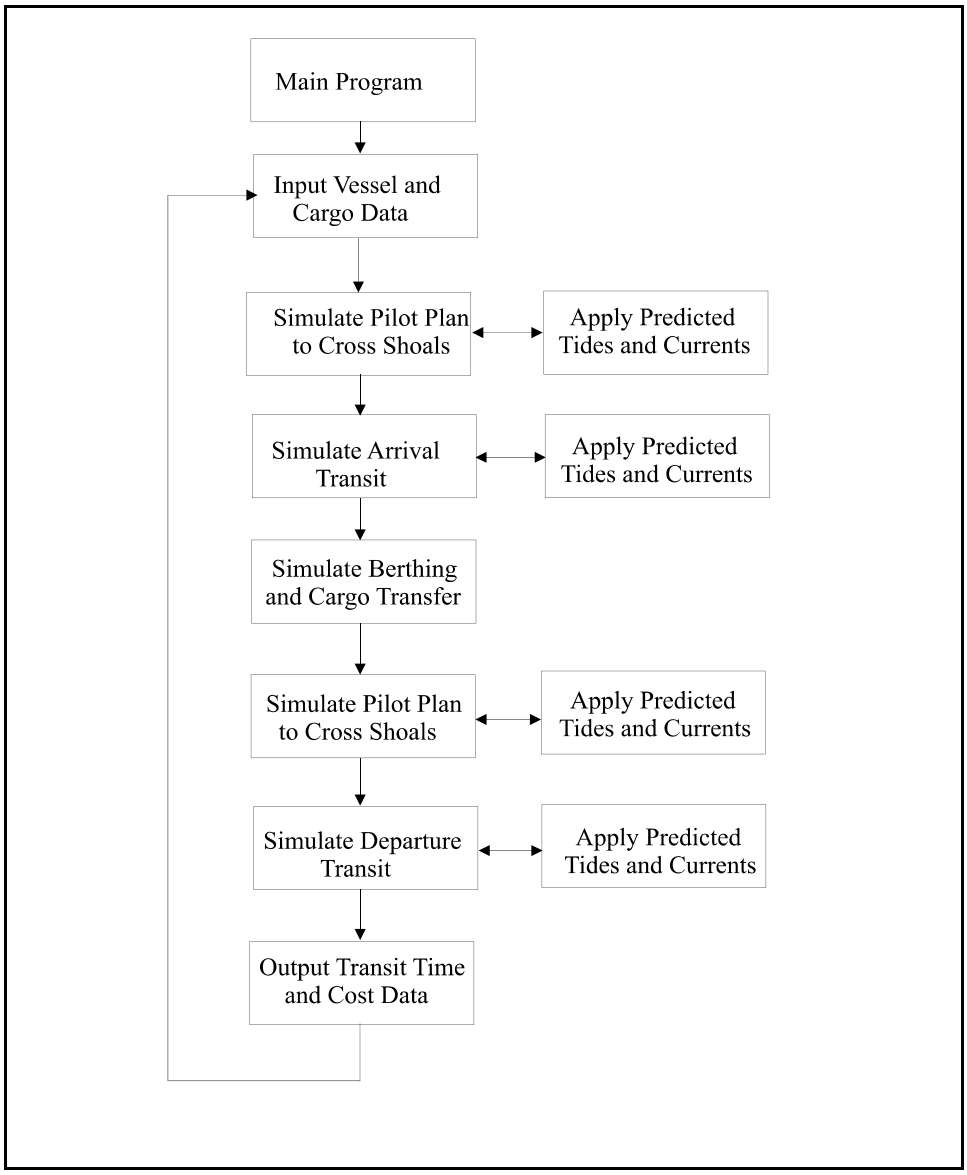

Figure V-5-22. Components of a ship transit simulation program

channel configurations should be compared with corresponding dredging and disposal costs. The ideal optimum will achieve the maximum net savings, but environmental quality effects, financial capabilities, and user preferences can affect the final project design.

V-5-6. Channel Alignment and Width

a. Alignment. Navigation channels are normally aligned as much as possible with natural channels in the pre-project bottom contours. This approach has several important advantages: initial and maintenance dredging are usually minimized; and currents typically take this path in line with the channel, a preferred condition for navigation. The effect of predominant winds and waves, as well as currents, on navigation should be considered. A channel oriented in line with these forces typically serves navigation best.

(1) A straight channel is preferred over a channel with bends. If turning is required, straight reaches with turns between channel segments are preferred over curved alignments. This type of alignment allows the channel to be clearly marked with aids to navigation. Straight segments in a deep-draft channel should be at least five times the length of the design ship. Few turns and small turning angles are best for navigation. Typically, the number of turns introduced in the channel alignment must be balanced against the turning angles to achieve an optimum alignment for navigation purposes. Both deep- and shallow-draft channels should be aligned so that vessels can maintain speed and controllability through areas where they are exposed to potentially damaging winds, waves, and currents. This consideration generally precludes sharp turns in exposed areas.

(2) The entrance channel to San Juan Harbor, Commonwealth of Puerto Rico, helps illustrate the difficulty of turning large ships in design transit conditions (Figure V-5-23). The exposed entrance, or "bar," channel makes a 57-deg turn into Anegado Channel just inside the harbor entrance. A ship simulator was used to model navigation channels in the harbor (Webb 1993). Local pilots from San Juan Harbor conducted simulation runs with two design ships, a tanker and a container ship. Ship tracks from inbound runs with the tanker are shown, where the ship hull outline is plotted at short intervals along each run. The variability of ship track and differences in pilot strategy for making the turn are evident in the figure. Ship track plots such as this clearly show the ship's swept path relative to channel boundaries. The envelope of multiple ship tracks gives valuable information about the navigability of the channel being simulated.

(3) Channel alignment option studies should consist of selecting several alternate routes when viable alternatives are available. Construction and maintenance costs are developed for each alternative. A comparison of annual project costs and benefits then determines the optimum channel alignment.

b. Inner channels (protected waters and harbor areas).

(1) Width. Harbor access channels leading from the bar or entrance channel to the port or harbor area are referred to as *interior channels*. For straight deep-draft channels, the required channel width is based on the following factors, listed in decreasing order of importance:

(a) Traffic pattern (one-way or two-way).

(b) Design ship beam and length.

(c) Channel cross-section shape.

(d) Current speed and direction.

(e) Quality and accuracy of aids to navigation.

(f) Variability of channel and currents.

- Design channel width is defined as the width measured at the bottom of the side slopes on each side of the channel at the design depth. For one-way deep-draft channels, channel width has traditionally been figured as the sum of a maneuvering lane width and bank clearance increments on either side (Figure V-5-24). For two-way channels, an additional maneuvering lane and a ship clearance lane dividing the two lanes of traffic are added. The required width for each increment was given as a factor applied to the design ship beam (Table V-5-9). Factors vary with ship controllability and judgment. Special judgment is required when vessels are exposed to yawing forces.

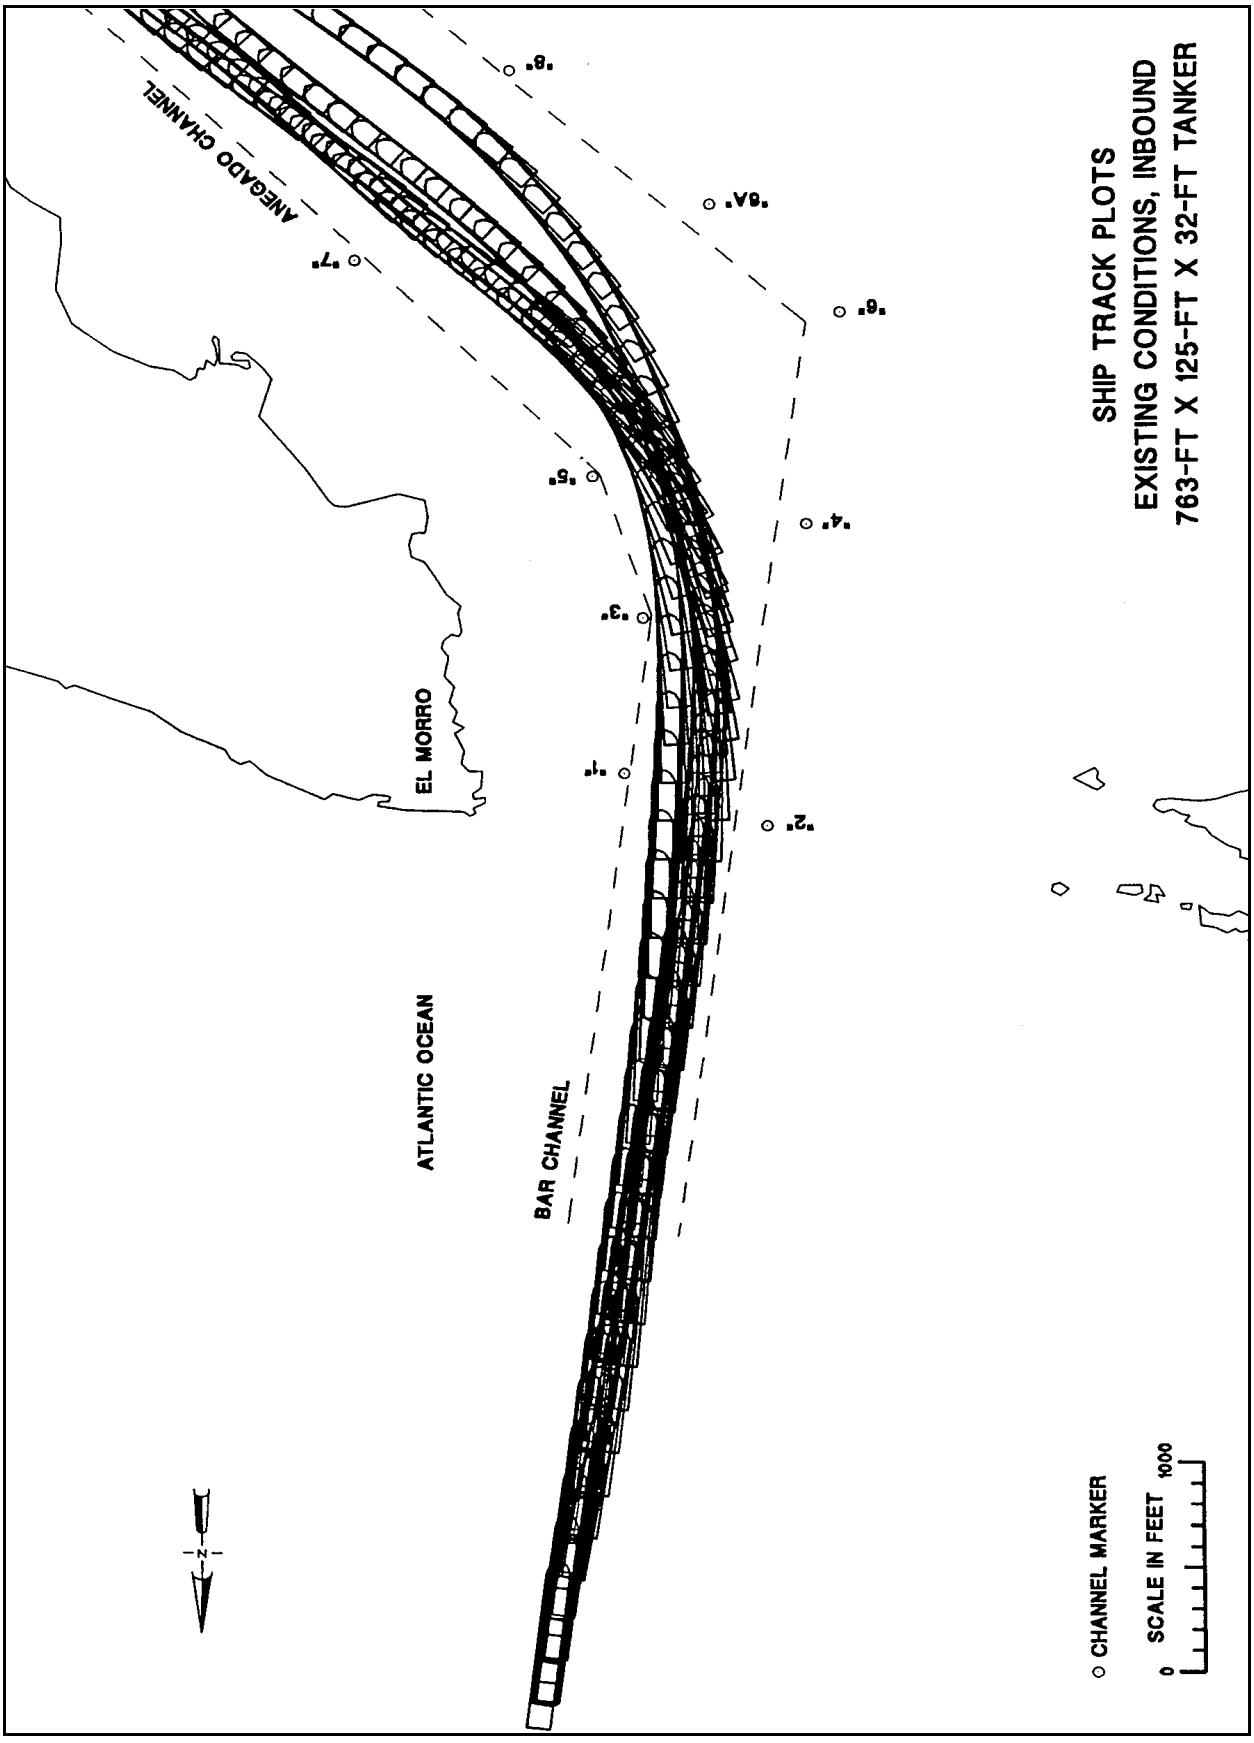

Figure V-5-23. Ship simulation of deep-draft entrance channel, San Juan Harbor, Commonwealth of Puerto Rico

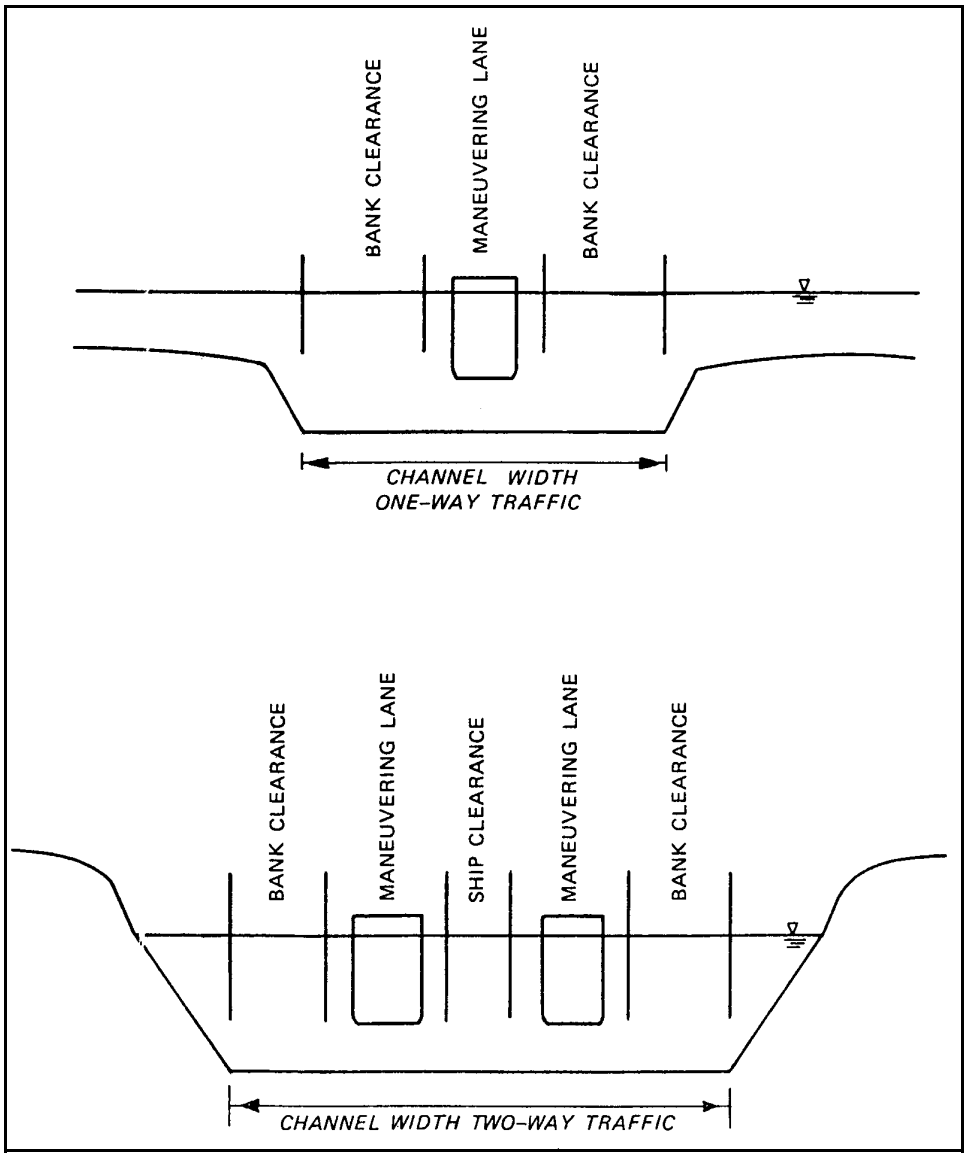

Figure V-5-24. Traditional interior channel width elements

Table V-5-9
Traditional Criteria for Deep-Draft Channel Width Design[1]

	Vessel Controllability			
Location	**Very Good**	**Good**	**Poor**	**Channels with Yawing Forces**
Maneuvering lane, straight channel	1.60	1.80	2.00	Judgment[2]
Bend, 26-deg turn	3.25	3.70	4.15	Judgment[2]
Bend, 40-deg turn	3.85	4.40	4.90	Judgment[2]
Ship clearance	0.80	0.80	0.80	1.00 but not less than 30 m (100 ft)
Bank clearance	0.60	0.60+	0.60+	1.50

[1] Criteria expressed as multipliers of the design ship beam; i.e., W = (factor from table) × B
[2] Judgment is based on local conditions at each project.

- Professional pilots control ships in a way that makes the traditional channel width divisions illogical. For example, they routinely move the ship off center line to use bank effects as a cue in determining ship position. Also, they sometimes use bank effects to assist in turning. Guidance for deep-draft channel width is best expressed as a total channel width based on the design ship beam (e.g., Figure V-5-25). The quality of aids to navigation, type of channel cross section, and current strength impact the required width. Experience with ship simulator studies has indicated that traditional channel width design criteria are overly conservative. Interim guidelines have been developed based on simulator studies (USACE 1998) (Tables V-5-10 and V-5-11). If current speeds are greater than 2.9 m/sec (3.0 knots), design channel width should be developed with the assistance of a ship simulator study (Part V-5-10).

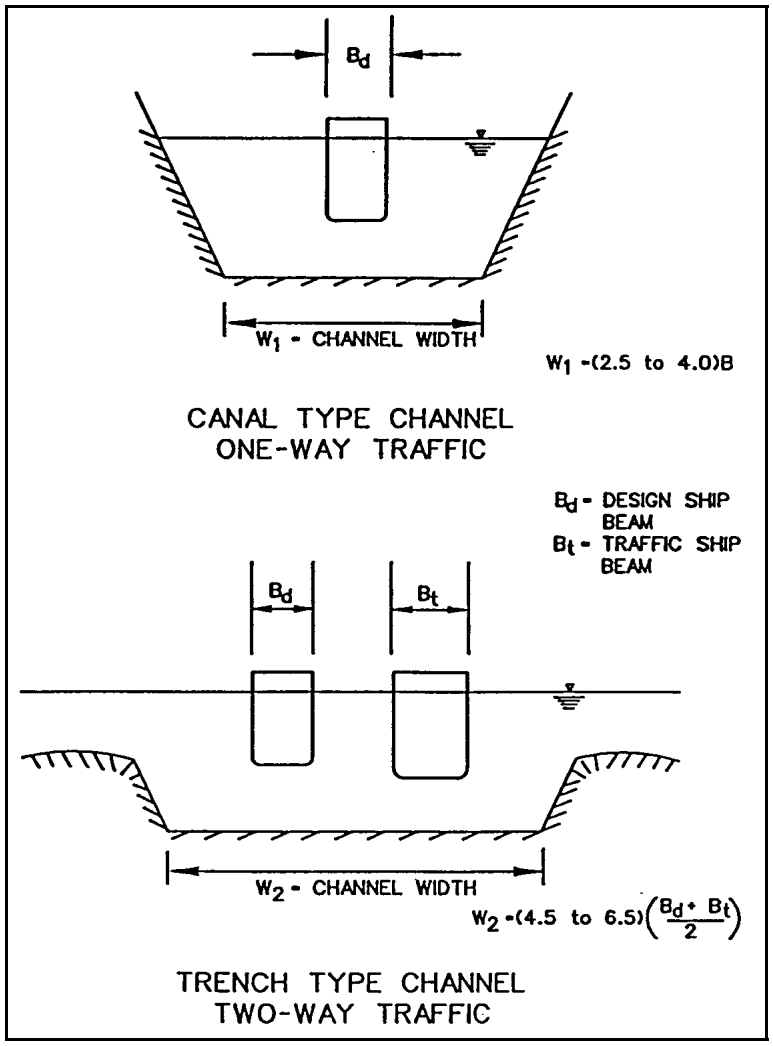

Figure V-5-25. Interior channel design width

- Navigation is more difficult when channel cross section (overbank depths, channel depth and width) varies significantly. Bank effects and currents become less predictable and extra care is needed for vessel control. Table V-5-10 gives channel width factors for a somewhat challenging navigation scenario, with variable cross section and average aids to navigation, and for an ideal scenario with constant cross section and excellent aids to navigation. These two scenarios bracket most channel design projects likely to be encountered in the United States.

Table V-5-10
One-Way Ship Traffic Channel Width Design Criteria[1]

Channel Cross Section	Maximum Current: 0.0 to 0.3 m/sec (0.0 to 0.5 knots)	0.3 to 0.8 m/sec (0.5 to 1.5 knots)	0.8 to 1.5 m/sec (1.5 to 3.0 knots)
Constant Cross Section, Best Aids to Navigation			
Shallow	3.0	4.0	5.0
Canal	2.5	3.0	3.5
Trench	2.75	3.25	4.0
Variable Cross Section, Average Aids to Navigation			
Shallow	3.5	4.5	5.5
Canal	3.0	3.5	4.0
Trench	3.5	4.0	5.0

[1] Criteria expressed as multipliers of the design ship beam; i.e., W = (factor from table) × B

Table V-5-11
Two-Way Ship Traffic Channel Width Design Criteria[1]

Channel Cross Section	Maximum Current: 0.0 to 0.3 m/sec (0.0 to 0.5 knots)	0.3 to 0.8 m/sec (0.5 to 1.5 knots)	0.8 to 1.5 m/sec (1.5 to 3.0 knots)
Constant Cross Section, Best Aids to Navigation			
Shallow	5.0	6.0	8.0
Canal	4.0	4.5	5.5
Trench	4.5	5.5	6.5

[1] Criteria expressed as multipliers of the design ship beam; i.e., W = (factor from table) × B

- Shallow-draft interior channels should be designed to safely handle the expected volume of two-way traffic. Traditional guidance for channel width is the same as for deep-draft channels (Table V-5-9). However, an approach that takes account of the traffic congestion may be preferable. Small-craft channel design guidance is being reevaluated in present research studies. Present recommended simple guidance is a minimum width, generally based on average vessel beam, and an additional width increment based on the number of boats using the project (ASCE 1994, Dunham and Finn 1974)

$$W = W_{\min} + 0.03\ N_B \quad \text{in meters (interior channels)}$$
$$W = W_{\min} + 0.10\ N_B \quad \text{in feet} \qquad \text{(V-5-7)}$$

where

W = design small-craft channel width

W_{min} = minimum width; = 5 B or 15 m (50 ft), whichever is greater

B = average beam

N_B = number of boats using the project

Thus, an interior channel serving 500 small boats with average beam of 5 m would have a minimum width of 5*5 + 0.03*500 = 40 m.

(2) Berthing areas. Although entrance and interior harbor channels and turning basins are usually part of federal navigation projects, berthing areas are typically nonfederal concerns except in military harbors. Normally, a berthing area must have sufficient depth to accommodate the design vessel to be using the berths, which may be smaller than the design vessel for sizing harbor channels, under all or nearly all expected water levels. Typically the design water level for berthing areas is extreme low water. Berthing areas must have sufficient space for safe maneuvering of the appropriate design vessel, often with tug assistance in deep-draft facilities. Guidance for sizing berthing areas to provide adequate access may be found in other references (e.g., Tsinker (1997), Gaythwaite (1990), and U.S. Navy (1981) for deep-draft ports; ASCE (1994), Tobiasson and Kollmeyer (1991), Dunham and Finn (1974), and State of California (1980) for small-craft harbors).

(3) Special considerations due to ice. Increased navigation difficulties in areas with ice may introduce special considerations for channel depth and width. Policies of pilot associations, shipping companies, or vessel insurance underwriters may call for additional keel and bank clearances beyond those allowed in temperate ice-free conditions. These groups and other marine interests, such as the USCG, NOAA, and military operators, should be solicited in the planning process for their views on these matters.

(a) The magnitude and direction of ice forces on ships are random in nature. These forces are combinations of impacts and frictional resistance. Impacts of wind- or current-driven ice forces can be oblique to the course of the ship, causing a sudden diversion. Ship response to such a diversion is slowed by additional oblique impacts and frictional resistance.

(b) Design width for a channel that will be navigated with ice should be increased by as much as 50 to 100 percent over the conventional width. Design depth may also need to be increased. The conventional ice-free design depth including either a standard wave allowance or an additional 0.5-m depth increment, whichever is greater, should be used. Wave allowance can be neglected in ice navigation because ice usually suppresses waves.

c. Entrance channels. Entrance channels are generally wider than interior channels because of many factors complicating navigation at entrances, particularly waves and currents. Intensified waves and currents at entrances make navigation difficult, but they also result in potentially treacherous sediment movement and dynamic shoaling patterns. Often vessels navigate this difficult environment in close proximity to rock or concrete breakwater or jetty structures. Loss of control can result in disastrous collision with these solid structures.

(a) Because of the complexity of processes and vessel responses in entrance channels, experience at the project site or related sites can be an especially helpful guide to determining an acceptable channel width. The traditional simple design approach is to use the guidance in Table V-5-9, choosing factors for a level of

vessel controllability appropriate to the difficulty of the particular entrance channel. Deep-draft entrance channel width design can benefit significantly from comprehensive physical model studies, navigation simulation studies, and field measurements of ship motions (Part V-5-10).

(b) For small-craft harbors, entrance channel width should be a minimum of 23 m (75 ft) (ASCE 1994). Guidance in Table V-5-9 has traditionally been applied. These factors typically exceed those for interior channels, leading to a widened entrance channel design. Small-craft harbor entrance channel design is the subject of a present research study.

(c) USACE practice in southern California, where sailboat usage is accommodated in design, is a minimum width of 90 m (300 ft). Consideration is also given to the number of boats using the project. USACE practice is to increase channel width over the 90-m (300-ft) minimum if the number of boats exceeds 1,000.

$$W = 90 + 0.03\,(N_B - 1000) \quad \text{in meters}$$
$$W = 300 + 0.1\,(N_B - 1000) \quad \text{in feet} \tag{V-5-8}$$

Thus, an entrance channel serving 2,000 small boats would have a minimum width of 90 + 0.03*(2,000-1,000) = 120 m (300 + 0.1*(2,000-1,000) = 400 ft), based on practice in southern California.

d. Turns and bends. Channels with turns and bends are more difficult to navigate than straight channels. Vessel control is reduced and width of the vessel swept path (the envelope around ship hull positions in the horizontal plane) is naturally increased when turning. Therefore, additional width is required in turns and bends for large vessels. Key parameters in a turn are defined in Figure V-5-26. The recommended configuration for widening a turn in a deep-draft channel depends on the deflection angle (Figure V-5-27 and Table V-5-12). Bank conditions, not included in the simple guidance presented here, are important in turn design since pilots often use them to assist in turning.

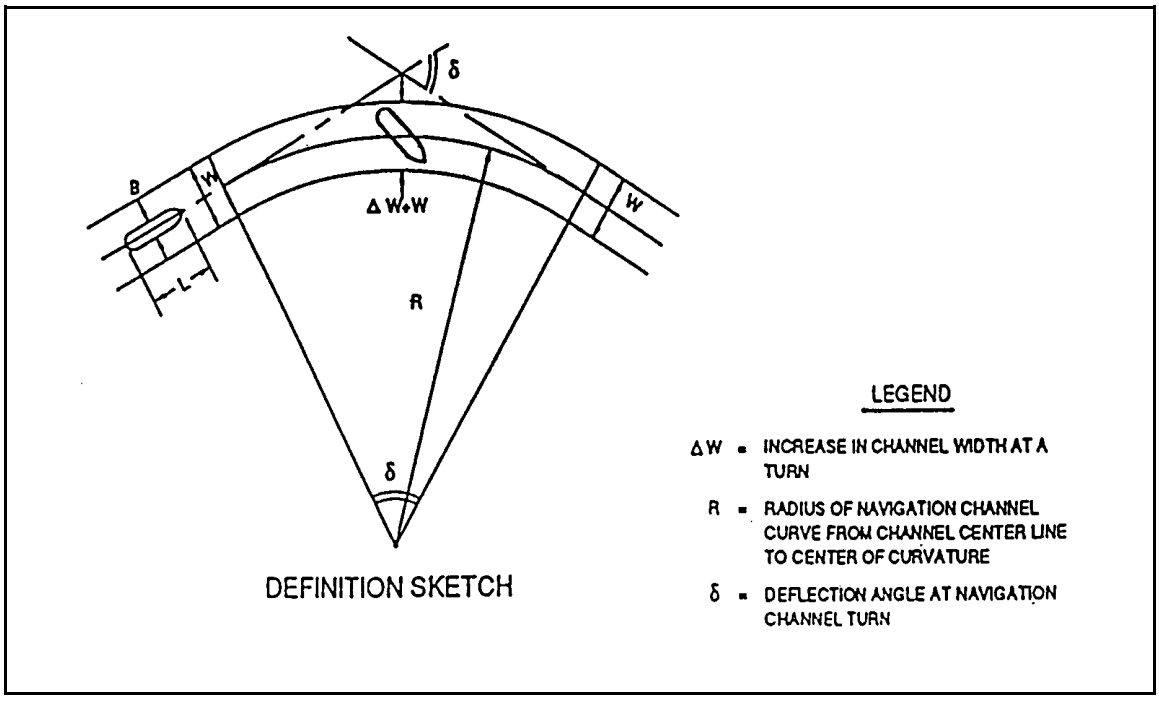

Figure V-5-26. Definition of parameters in channel turn

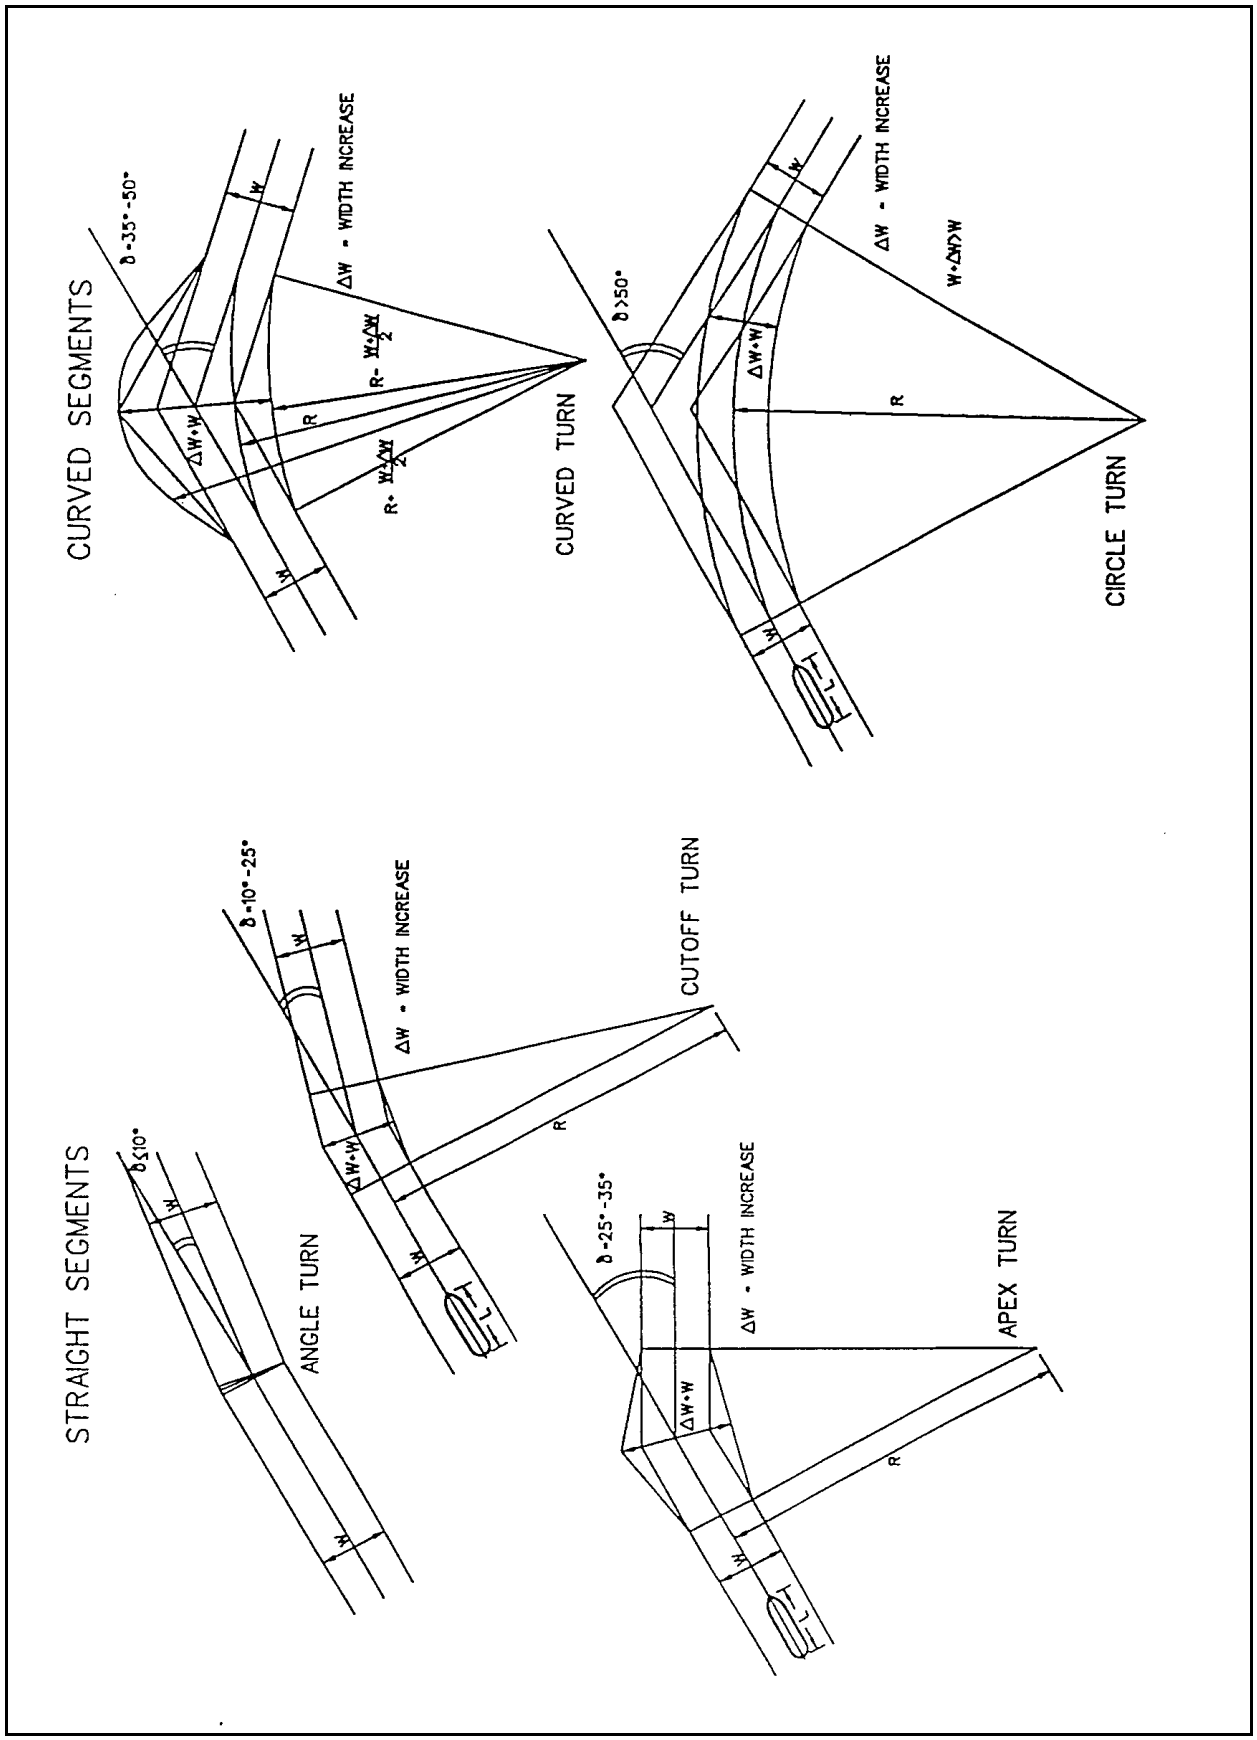

Figure V-5-27. Channel turn configurations

Table V-5-12
Recommended Deep-Draft Channel Turn Configurations

Turn Angle, deg	R/L[1]	Turn Width Increase Factor[2]	Turn Type
0-10	0	0	Angle
10-25	3-5	2.0-1.0	Cutoff
25-35	5-7	1.0-0.7	Apex
35-50	7-10	0.7-0.5	Curved
>50	>10	0.5	Circle

[1] R = curve radius; L = design ship length (see Figure V-5-26).
[2] Expressed as a multiplier of the design ship beam; i.e., ΔW = (factor from table) × B

(1) Apex or cutoff configurations are commonly used because they are simple, easily defined shapes that serve most channel turn requirements. They are easiest to control for dredging, easiest to mark with aids to navigation (usually with two range marker pairs and buoys), and easiest to monitor for maintenance. Some dimensions that are useful for computer drafting are included in Figure V-5-28. Turns should be placed, when possible, in locations easily visible for range markers. A drawback to the apex and cutoff methods is that they can produce difficult current patterns for navigation. In high current areas and/or canals, turns with parallel circular arcs gradually transitioning from straight channel segments into the turn may be warranted.

(2) The impact of channel turns on currents and shoaling and vessel response to wind and waves can be significant. The navigability of a turn design and its shoaling tendencies may merit study with numerical models and a navigation simulator.

(3) Small craft are sufficiently maneuverable that extra channel width in turns is generally not as critical as for deep-draft ships. For large turn angles in the presence of difficult conditions, extra maneuvering space should be provided. A typical situation would be a sharp turn in an exposed entrance channel.

V-5-7. Other Project Features

a. Turning basins. Turning basins are generally provided to allow vessels to reverse direction without having to go backward for long distances. Turning basins provide the extra width needed to comfortably turn. Turning basins are usually located at the upstream end of interior access channels. In long channels accommodating many dock facilities, an extra turning basin may be placed at the upstream end of each group of docks. In normal operations, larger ships turn with pilot and tug assistance.

(1) The minimum turning basin size should allow a turning circle with diameter of 1.2L, where L is the design ship length (Figure V-5-29). Turning difficulty increases significantly when currents are present. If current speed exceeds 0.5 m/sec (0.5 knot), turning basin diameter should be increased as indicated in the figure. If current speed exceeds 0.8 m/sec (1.5 knot), a circular shape no longer suffices. The turning circle should be elongated in the current flow direction, as shown in the figure. Dimensions of the high-current turning basin configuration should be determined with a ship simulator (Part V-5-10). If turning operations will include ships with high sail areas and design wind speeds of greater than 12.9 m/sec (25 knots), a ship simulator design study is also needed.

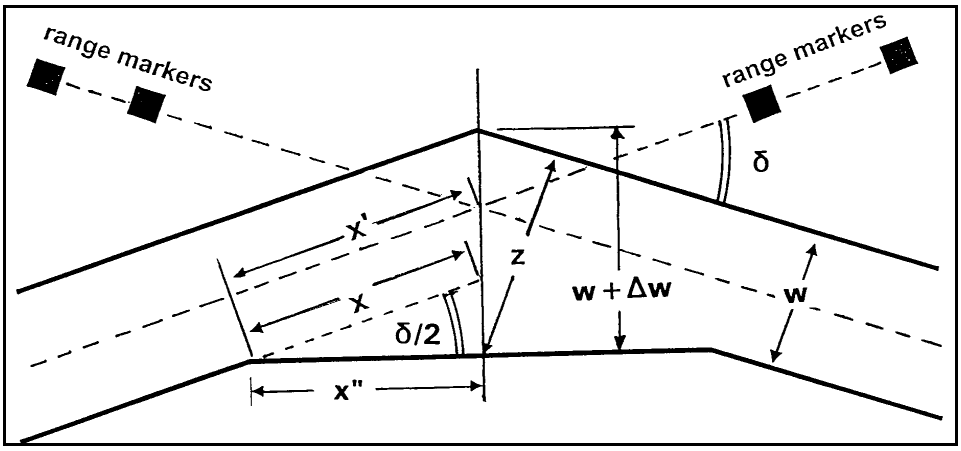

Figure V-5-28. Layout of apex-style turn

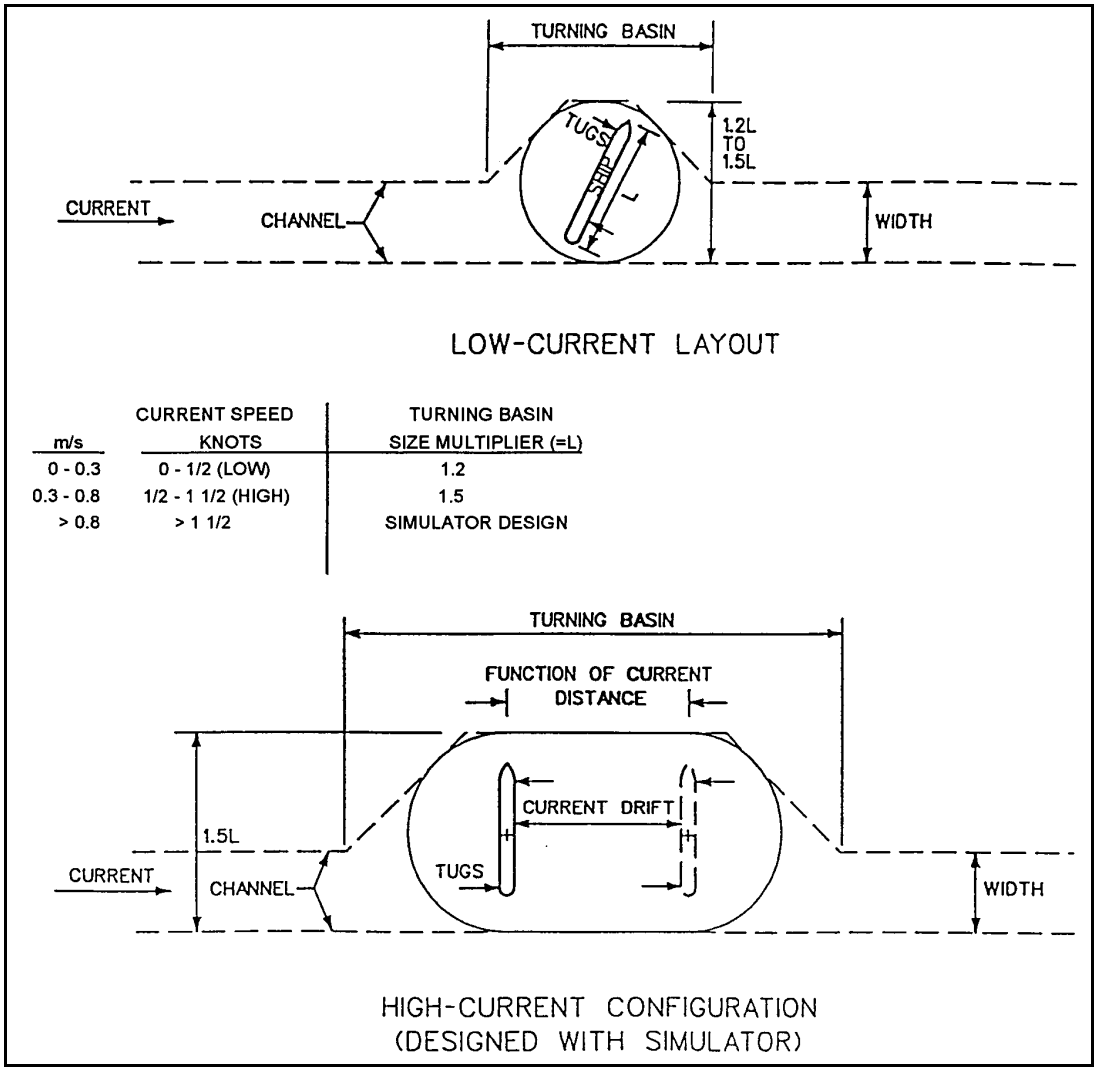

Figure V-5-29. Turning basin alternative designs

(2) Turning space for small boats should be sufficient to allow turning without backing or assistance. The required space depends on the types of boat using the project, but the design channel width usually accommodates turning.

(3) Turning basin design depth normally matches the adjacent channel depth. Turning basins tend to trap sediment because they are wider and typically have lower currents than the navigation channel. Also, being located at the upstream end of the navigation channel, the turning basin is often the first dredged area to intercept river-borne sediment. The potential shoaling problem may be reduced by careful choice of turning basin location and shape to reduce sediment availability and promote flushing.

b. Moorage/anchorage areas. Anchorage areas are provided in some deep-draft ports, typically near the entrance, to accommodate ships awaiting berthing space, undergoing repairs, receiving supplies and crews, awaiting inspection, and lightering off cargo. Anchorage areas may also serve as a refuge for ships during severe storms, since most facilities are designed with the assumption that no ships will be in port during a hurricane or typhoon. Ships may be anchored at the bow and allowed to swing freely or be moored against fixed dolphins. Design guidance is given in Figure V-5-30. Guidance for free-swinging anchorage is approximate, based on a 15-m (50-ft) depth and design ship length of 213 to 305 m (700 to 1,000 ft). The fixed mooring alternative requires a much smaller area for each ship than the free-swinging alternative. If available space is limited or dredging is required, fixed mooring may be the preferred design. Design guidance is available from the U.S. Navy (1998).

c. Basin flushing and water quality. Water quality within a harbor is often a concern with local, state, and Federal agencies. Water quality in a harbor depends on three key factors: quality outside the harbor, substances introduced into the water inside the harbor, and exchange of water between the inside and outside. Although outside water quality is typically beyond the scope of a navigation project, harbor design and operation can have a major impact on the other key factors. Contaminants introduced inside a harbor may include sewage discharge, shower/dishwashing water, bottom paint leaching, fuel and oil spillage, and deck and hull washing. Persistent contaminants may affect bottom sediments as well as water quality, which can increase future dredging costs.

(1) Water movement within a harbor is often restricted by the perimeter design. The extent to which the basin is enclosed, placement of the opening(s), and basin shape all affect water movement in the harbor. Tide, wind, and river flows can help promote circulation in a harbor and exchange between harbor and outside water. For example, a large tidal prism combined with a small low-tide volume gives excellent flushing in a harbor. Flushing processes in harbors are discussed in Part II-7.

(2) Many harbors are located in areas where natural water movement is relatively weak, a desirable condition for navigation but a potential problem for basin flushing. For example, when outside water has a high content of treated sewage, a typical concern, then water should not remain trapped anywhere in the harbor for many days. Methods to promote flushing and prevent stagnation include gaps between perimeter structures and shore, openings within the perimeter structure itself (e.g., segments, baffles, culverts), overlapping wave protective structures to act as scoops to passing water flow, and mechanical agitation. A harbor entrance centrally located along the perimeter is usually preferred over an entrance at one end, which may lead to stagnation at the opposite end.

(3) The flushing characteristics and water quality in a harbor can be predicted with physical and numerical models, as discussed in Part II-7. Both water exchange rates and oxygen or other chemical constituent reactions and replenishment rates should typically be addressed.

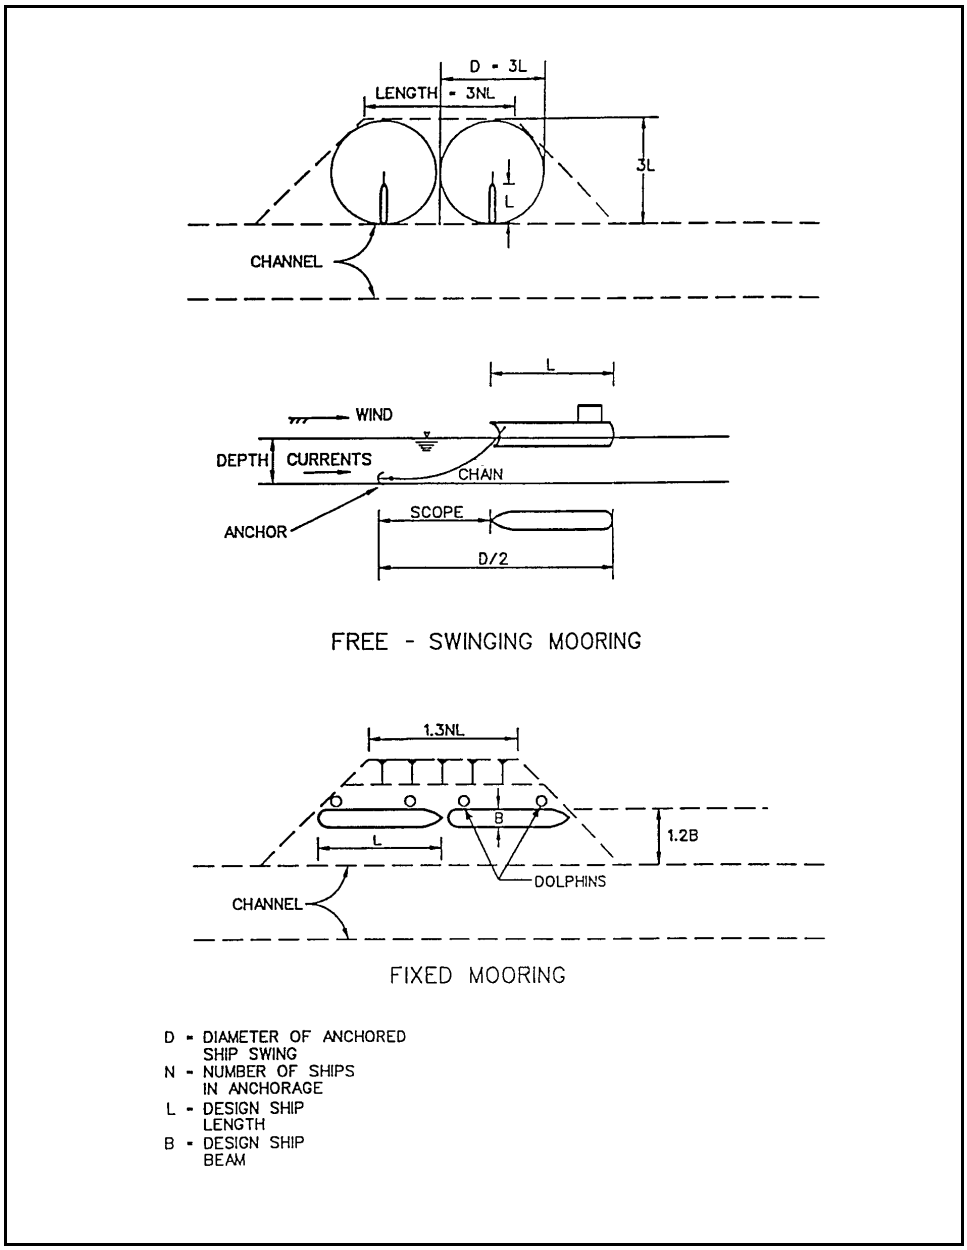

Figure V-5-30. Alternative anchorage designs

d. Navigation structures. Often a navigation project requires one or more engineered structures to accomplish its objectives. Structures can serve a variety of purposes. However, their presence also establishes a major hazard for vessels. Hence, a navigation structure must be designed with regard to several functional concerns. Basic types of structures and functions involved in navigation projects are briefly discussed in this section. Sediment processes and management at inlets and harbors are discussed in Part V-6. Detailed guidance on structure design is given in Part VI.

(1) Breakwaters. Breakwaters are used to protect a harbor, anchorage, basin, or area of shoreline from waves. Breakwaters reflect or dissipate wave energy and thus prevent or reduce wave action in the protected area. Breakwaters must be designed to effectively serve competing requirements for wave blockage and safe vessel passage from fully exposed waters through a constricted entrance into tranquil harbor waters.

(1) For navigation projects, breakwaters are frequently shore-connected and constructed to provide calm waters in a harbor (Figure V-5-31). Shore-connected breakwaters allow access from land for construction, operation, and maintenance, but may have an adverse impact on water quality or sediment movement along the coast.

Figure V-5-31. Harbor with shore-connected breakwater, Waianae Small Boat Harbor, Oahu, Hawaii (June 1980)

(2) If the harbor to be protected is on the open coast and predominant wave crests approach parallel to the coast, a detached offshore breakwater may be a good option. Water quality is preserved with this type structure, but access for construction and maintenance is more difficult than for a shore-connected structure. Offshore structures are sometimes used to provide protection to existing harbor entrances (Figure V-5-32). Accumulation of sediment in the lee of an offshore breakwater must be considered in design (Part V-6).

(3) Many breakwater systems utilize a combination of breakwater types to protect anchorage or mooring areas, such as a shore-connected and a detached structures (Figure V-5-33). Some structures have been constructed with arrowhead entrance configurations, but experience has shown them to be of questionable benefit, and some have been modified to improve performance. The cellular arrowhead breakwater configuration in Figure V-5-33 was modified by adding an overlapping rubble-mound extension to the seaward end of the shore-connected breakwater. In some cases, the primary breakwaters do not provide sufficient protection, and interior breakwaters are needed (Figure V-5-34).

(4) Most breakwaters built on open coasts of the United States are of rubble-mound construction. It is important for harbor tranquility to design such structures to be high enough to prevent excessive wave overtopping and sufficiently impermeable to deter wave transmission through the structure. However, some wave overtopping and/or transmission may be beneficial for harbor flushing. Other structural types include

Figure V-5-32. View of offshore detached breakwater used to protect harbor entrance, Marina del Rey, California (August 1966)

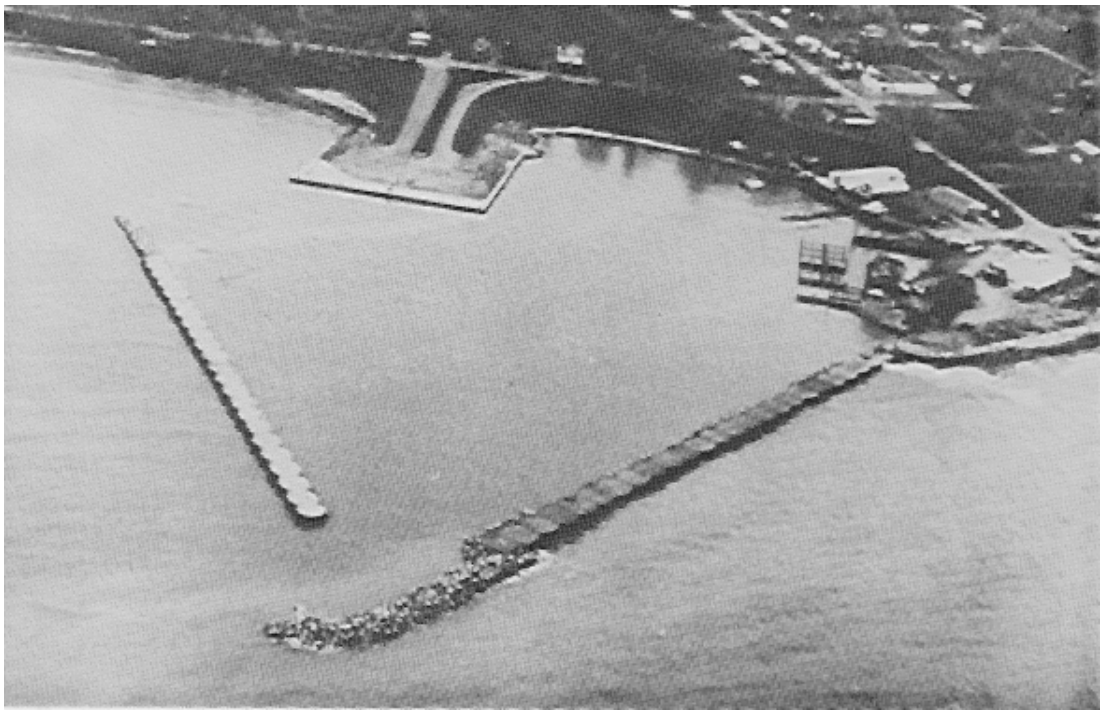

Figure V-5-33. Harbor with both shore-connected and detached breakwaters, Barcelona Harbor, New York (April 1986)

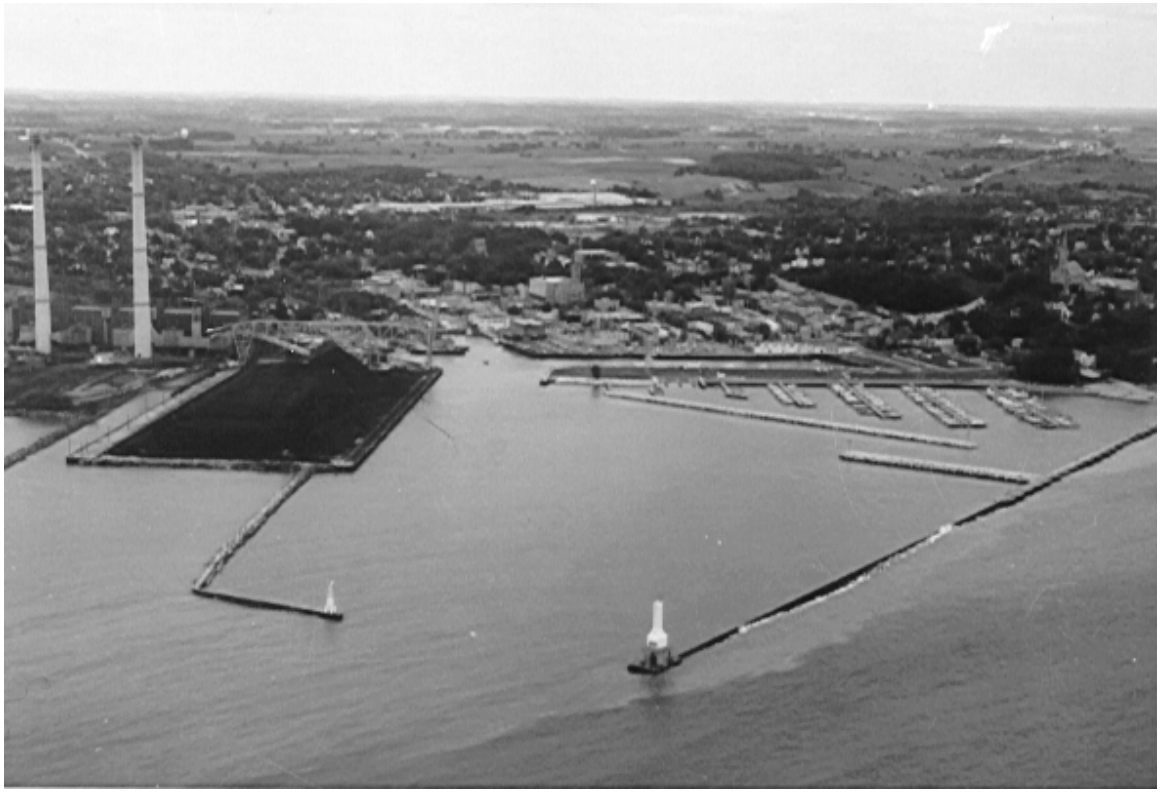

Figure V-5-34. Inner breakwater provides protection to small-craft mooring area, Port Washington Harbor, Wisconsin (September 1983)

concrete caisson, timber crib, sheet pile, cellular steel sheet pile, composite (rubble-mound with concrete cap for stability, etc.), and floating.

(5) The optimum layout of breakwaters for harbor protection is difficult to determine because of the complex conditions typically involved. Waves refract on approaching the entrance, often in the presence of shoals as well as a navigation channel. Wave energy propagates through the entrance, diffracts, and reflects from inner harbor structures. Currents are usually present due to tides, wind, waves, and river flows.

(6) Because they can accurately reproduce many of the complex, interacting hydrodynamic effects on a harbor, physical models provide the most reliable method for optimizing breakwater layout (Part V-5-10). Physical modeling and subsequent monitoring of prototype performance has led to general guidance relative to harbor layout (Bottin 1992). Lessons learned relative to navigation entrance channel and mooring area protection in small boat harbors are:

(a) *Align entrances toward a perpendicular to the incoming wave crests.* It is very dangerous for small craft to travel parallel to high incoming wave crests (*beam seas*). Harbors should be designed to minimize the chance of this condition.

(b) *Block wave energy from the harbor*. It is preferable to prevent wave energy from entering a harbor than to try to dissipate excessive wave energy once inside. Energy entering a harbor can be minimized by using overlapping breakwaters at the entrance, reducing entrance width, minimizing breakwater overtopping, and using impermeable breakwater cores. Breakwaters seaward of the entrance may also be incorporated into a design. If the harbor is at a river mouth, care must be taken to prevent upstream flooding due to flow restriction and/or ice jamming in the harbor.

(c) *Absorb wave energy inside the harbor if necessary*. When physical limitations or costs prevent blocking sufficient wave energy out of the harbor, some energy can be absorbed inside the harbor with judiciously placed rubble slopes and/or spending beaches. Concrete absorber units (e.g. *igloos*) can also be helpful. For long-period wave energy, absorbers installed along harbor slips are essentially ineffective.

(d) *Anticipate Cross Currents on Reefs*. Waves breaking across reefs generally result in very strong currents alongshore. These currents may be hazardous to small craft entering and navigating channels cut through the reef and into harbors. Breakwaters may be used to deflect these currents offshore away from the entrance (Figure V-5-35). Currents also tend to enter the harbor through the entrance. These currents can be used to advantage by laying out interior channels to promote circulation and flushing, as was done with the aid of physical modeling for Agana Small Boat Harbor, Territory of Guam.

Figure V-5-35. Breakwaters protecting small boat harbor from waves and wave-generated crosscurrents on reef, Agana, territory of Guam (May 1978)

(e) *Locate Harbor Facilities and/or Boat Ramps Away from the Entrance Opening*. Wave energy propagating through and diffracting around entrance structures can affect nearby facilities. Facilities can be given further protection by including interior breakwater structures or revetted moles. Although these structures can be very effective, they are expensive and can limit future expansion.

(f) *Avoid vertical walls in high-energy areas of the harbor*. Vertical wall breakwaters and harbor structures are highly reflective. Waves reflecting off entrance structures can result in very confused and hazardous navigation conditions. Reflections inside harbors can cause hazardous anchorage and mooring conditions. Reflected waves from vertical structures have also been found to induce erosion.

(g) *Orient entrances away from the direction of predominant longshore transport*. It is very desirable to promote natural sand bypassing of the harbor entrance. Entrances facing the predominant longshore transport direction are likely to serve as a sediment trap. A typical successful design consists of an outer curved breakwater that overlaps a short shore-connected structure (e.g. Figure V-5-31). The shorter

downcoast structure helps to prevent sediment moving along the shoreline opposite to the dominant direction from coming into the entrance.

(h) *Consider Using Segmented Structures*. Segmented breakwaters are effective in providing wave protection while still allowing tidal circulation through the breakwater openings. They can be effective substitutes for floating or baffled breakwaters. Segmented rubble absorbers inside a harbor, as opposed to a continuous absorber, also have proven to be effective in terms of both performance and cost.

(2) Jetties. A jetty is a shore-connected structure, generally built perpendicular to shore, extending into a body of water to direct and confine a stream or tidal flow to a selected channel and to prevent or reduce shoaling of that channel. Jetties at the entrance to a bay or a river also serve to protect the entrance channel from storm waves and crosscurrents. When located at inlets through barrier beaches, jetties help to stabilize the inlet.

(a) Jetties are usually built in pairs, one on either side of an entrance (Figure V-5-36). Sometimes, jetties are used in combination with a breakwater (Figure V-5-32). A single jetty may also be used, located on the updrift side of the entrance. A disadvantage of the single jetty is that the navigation channel is unconfined and will likely migrate. A typical single jetty problem is the case of an impermeable jetty where the navigation channel migrates to a position immediately beside the jetty, with consequent threats of passing vessels colliding with the structure and undermining of the structure itself. Some jetties have been designed with a low-crested weir section near shore to pass sediment into a deposition basin (Part V-6). The semi-protected waters of the deposition basin are then periodically dredged and sediment is bypassed to the downdrift beach.

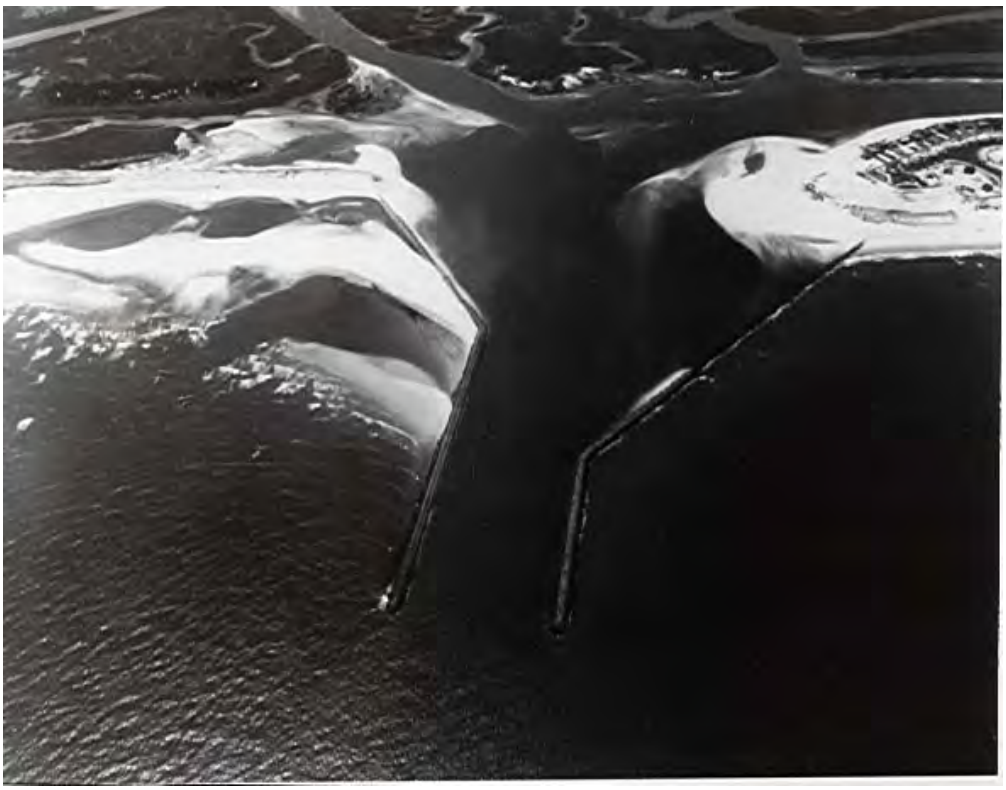

Figure V-5-36. Dual jetty configuration at a tidal inlet, Murrells Inlet, South Carolina (March 1982)

(b) Though jetties have a different function than breakwaters, jetty structural design is similar to breakwaters. Most jetties built on open U.S. coasts are rubble-mound structures. Materials used for jetty construction include stone, concrete, steel, and timber. Unlike breakwaters, jetties are usually designed to allow some wave overtopping. Also, jetty cores may be lower and more permeable than breakwater cores, provided the jetty sufficiently blocks passage of sediment into the navigation channel.

(c) Jetties should be designed to use available construction materials efficiently and effectively to accomplish functional objectives without adversely impacting other physical processes or the environment. Jetties at river or creek mouths, not considering tidal effects, should be spaced close enough together to allow normal river currents to maintain required navigation depths, yet far enough apart to prevent backwater effects and flooding upstream during high river flows. In cold regions, jetties should be oriented to avoid contributing to ice jamming in the entrance, which could cause upstream flooding. In some cases, overlapping jetties have proven to contribute to natural sand bypassing, and they reduce wave energy entering the mouth and lower reaches of the stream. If large quantities of sediment are moving in the area, sand bypassing schemes should be included in the design (Part V-6).

(d) Jetty layout in tidal areas is much more difficult. Interaction of wave-induced currents and tidal currents, sometimes with freshwater discharges, through an inlet connecting the ocean with an embayment, is very complex. A fairly uniform distribution of flow across the entrance is one objective. Dual jetties of equal length usually serve best. The jetties should be parallel if practical; otherwise training dikes or spurs should be added to divert or concentrate flow through the desired channel alignment. If jetty spacing is too wide, shoaling and channel meandering are likely to occur. If jetty spacing is too narrow, structure toes may be undercut and hazardous navigation conditions may occur.

(e) Parallel jetties tend to confine flood and ebb flow, raising flow velocities and providing adequate sediment flushing into the flood and ebb deltas. Arrowhead jetties frequently allow channel shoaling and meandering because ebb flow is not confined enough to produce nondepositional velocities in the widest area between jetties. Barnegat Inlet, New Jersey, is an example where both jetty configurations have been used (Sager and Hollyfield 1974; Seabergh, Cialone, and Stauble 1996) (Figure V-5-37). Arrowhead jetties were built in 1939, and a new south jetty, nearly parallel to the north jetty, was built in 1991. As another general alternative for jetty layout, curved jetties may be designed to produce nondepositional velocities, but flow concentrations on the outside of the curve may cause jetty undermining and a difficult channel alignment for navigation (McCartney, Hermann, and Simmons 1991).

(f) Jetties should be long enough to prevent littoral transport around the jetty ends and into the navigation channel. Jetty orientation for navigation purposes should ensure that the channel is approximately aligned with the approach direction of the more severe waves. Typically, a jetty alignment perpendicular to shore serves this purpose. The ideal jetty alignment for navigation is often a poor alignment for sheltering interior areas from waves. However, waves lose a significant amount of energy in traveling between parallel jetties (energy loss increases with jetty length) or passing through an entrance gap between breakwaters or jetties (Part II-7). The height of waves traveling between parallel jetties may be estimated by treating the jetty entrance as a breakwater gap (Melo and Guza 1991). The inter-jetty propagation distance corresponds to the normal interior distance from the gap and wave height can be estimated from height diffraction contours as given in Part II-7.

(g) Spacing between dual jetties should be determined with consideration of tidal processes, wave protection requirements, river flood discharge requirements, and safe navigation requirements. Jetty spacing for tidal concerns depends on the tidal prism volume or the actual tidal flow exchange through the inlet. Relationships between minimum cross sectional area required at inlet throats as well as detailed design of jettied entrances are presented in Part II-6. Wave protection requirements of interior shorelines and facilities

(a) Arrowhead jetties (November-December 1965)

(b) Parallel jetties (June 1996)

Figure V-5-37. Jetty types, Barnegat Inlet, New Jersey

are specific to each project. A rule of thumb for safe deep-draft navigation is that an entrance width equal to the design ship *length* is satisfactory for two-way traffic. An overbank area between the channel and jetty is needed to protect the structure toes.

(3) Training dikes. Training dikes serve to direct current flow in a desired path. A common application is the use of training dikes interior to a jettied inlet to confine currents to the navigation channel and help prevent channel shoaling and erosion of nearby banks and shores. Dikes are usually constructed of stone, timber pile clusters, or piling with stone fill.

(4) Wave absorbers. Wave energy that penetrates into small boat harbors through entrances or by transmission or overtopping of breakwaters may create serious problems for navigation in interior channels, moored boats, and bank erosion. Excessive wave energy in deep-draft ports can cause similar problems. Wave absorbers are sometimes constructed inside harbors to dissipate this short-period wave energy. Absorbers are generally placed in harbor areas with high concentrations of wave energy.

(a) Beaches are the most effective wave absorbers. Beach slopes dissipate most wind wave and swell energy and reflect very little energy. However, beaches also occupy a relatively large area and may not be practical. More commonly, rubble slopes serve as wave absorbers in navigation projects. For best efficiency, a stone wave absorber should have a rock layer thickness equal to three times the representative diameter of individual rocks used and porosity should be about 30 percent (LeMéhauté 1965).

(b) Sometimes rubble slope absorbers are integrated into a dock to provide wave dissipation without interfering with harbor use. Typical applications are an armored slope under a pile-supported dock face or an absorbing quay wall (PIANC 1997b) (Figure V-5-38). Another approach is a perforated wall along the dock face with a vertical solid-wall fill some distance behind the dock face (Figure V-5-39). The optimum porosity for the perforated wall should be around 30 percent and the optimum set-back of the solid wall should be about one tenth of the wave length to be absorbed (LeMéhauté 1965). Molded concrete wave absorber units may also be used along a vertical dock face. Such units have proven effective in model tests for a Great Lakes site (Bottin 1976) (Figure V-5-40), but have not been used in U.S. harbors.

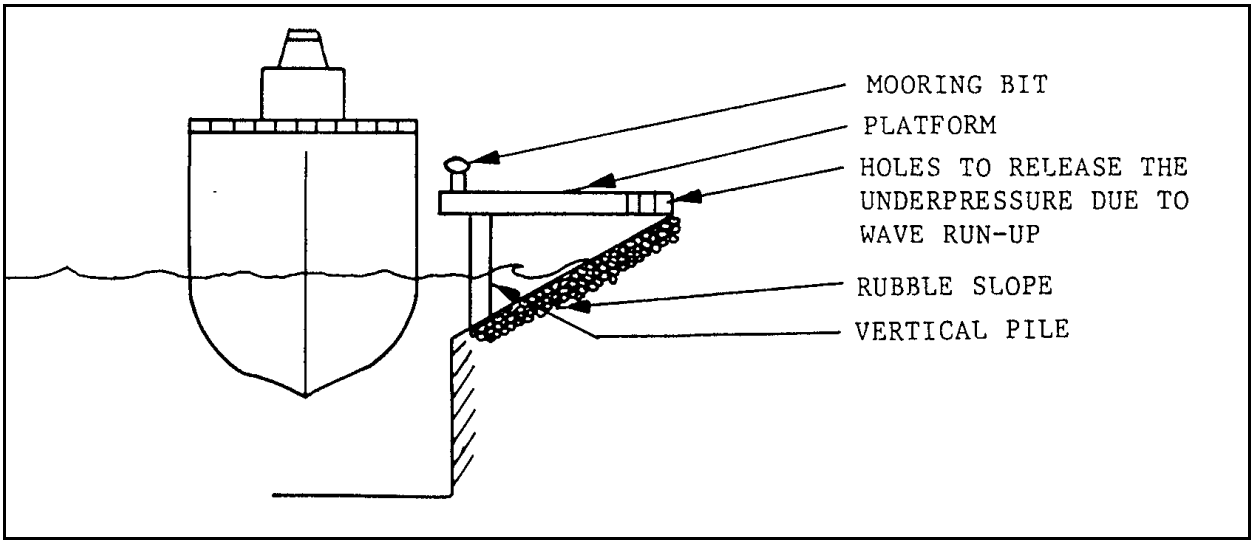

Figure V-5-38. Rubble wave absorber at a dock

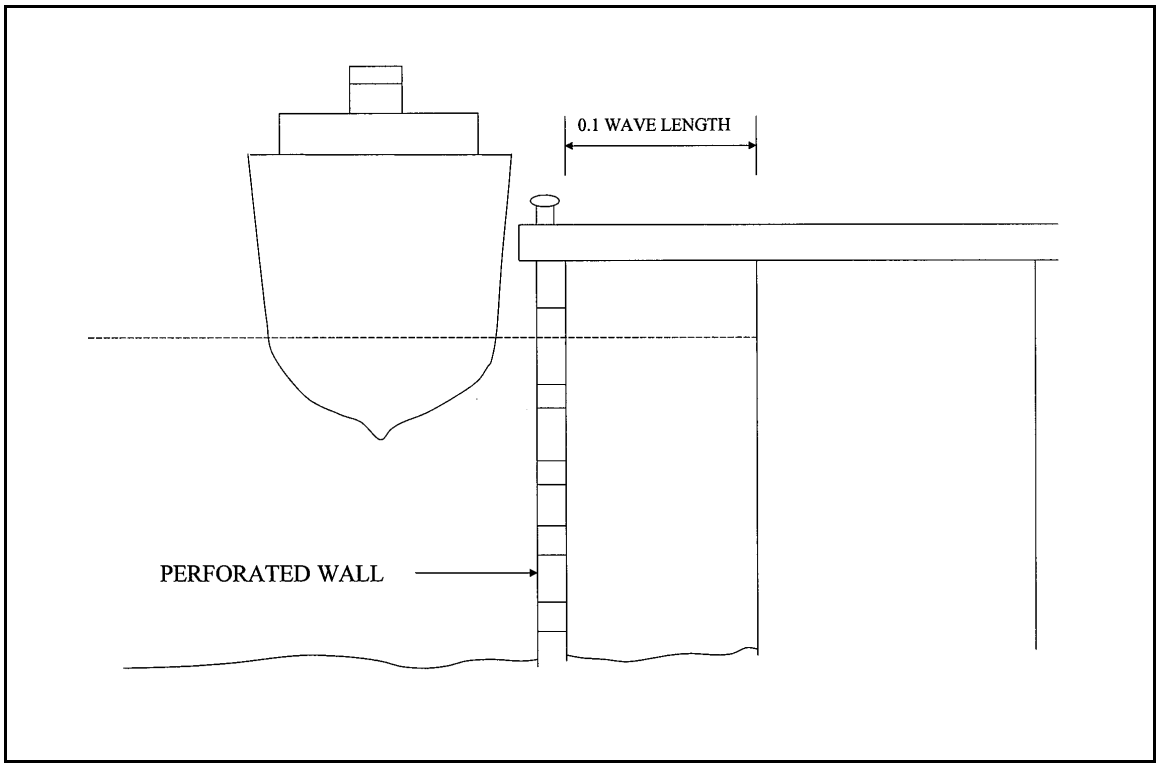

Figure V-5-39. Perforated wall wave absorber at a dock

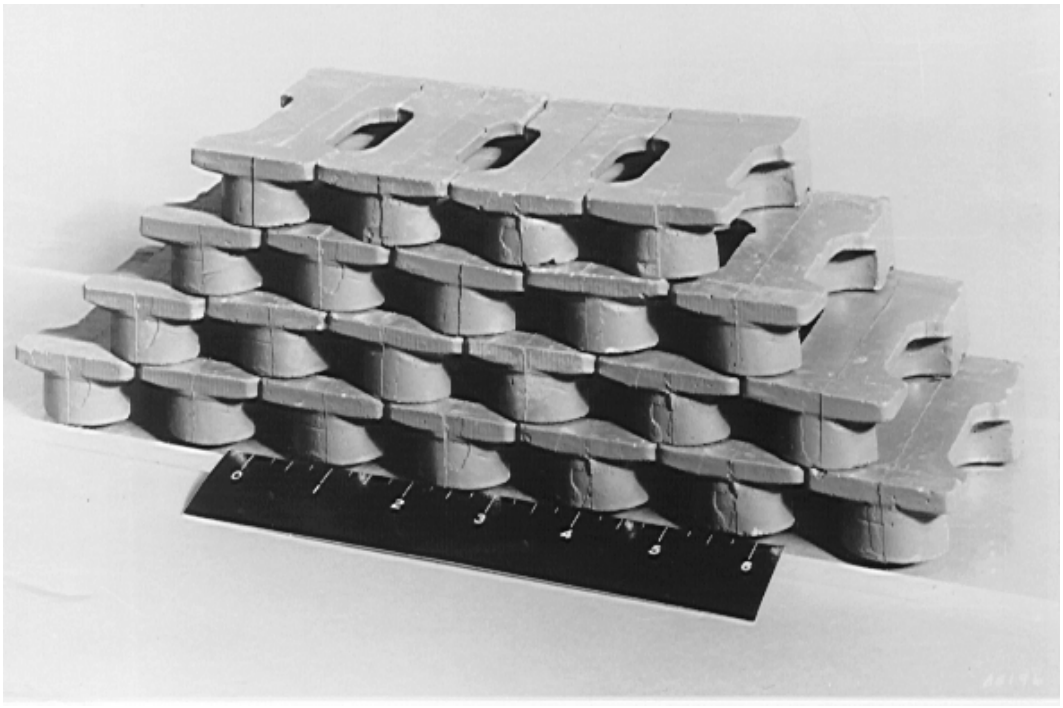

Figure V-5-40. Stacked Igloo model wave absorber units

(5) Revetments, seawalls, and bulkheads. Though not actually navigation structures, revetments, seawalls, and bulkheads are included in, or adjacent to, most harbors. They are briefly reviewed here and discussed in detail in Parts V-3, VI-2, and VI-7. In general, vertical structures are classified as either seawalls or bulkheads, according to their function, while protective materials laid on slopes are called revetments. A seawall is a massive structure that is designed primarily to reduce wave energy and provide wave protection along coastal property. Bulkheads are retaining walls whose primary purpose is to hold or prevent backfill from sliding while providing protection against light-to-moderate wave action.

(a) Revetments, seawalls, and bulkheads are structures placed parallel, or nearly parallel, to the shoreline to separate a land area from a water area. The purpose of the structure dictates which type is used. In harbors, these structures may improve or worsen wave conditions and land access to beaches, depending on the location and design.

(b) Vertical structures (seawalls and bulkheads) are useful as quay walls or docking/mooring areas. Because of potential wave reflection problems, bulkheads to provide vessels with direct access to shore should only be placed in areas with little exposure to wave energy. Wave reflection from vertical structures may create hazardous conditions for small craft, erosion of adjacent shorelines, and beach profile changes.

(c) Revetments are typically less reflective than vertical structures. Rubble revetments may be effective wave absorbers but may hinder access to a beach. Smooth revetments built with concrete blocks generally present little difficulty to pedestrians, but are more reflective than rubble revetments.

(d) On seawalls and bulkheads, convex-curved face and smooth slopes are least effective in reducing wave runup and overtopping. Concave-curved face structures are most effective for reducing wave overtopping when onshore winds are light. Where the structure crest is to be used as a road, promenade, or other such purpose, concave-curved may be the best shape for protecting the crest and reducing spray. If onshore winds occur with high waves, a rubble slope should be considered to reduce runup and overtopping. A stepped-face wall provides the easiest access to beach areas from protected areas, and reduces the scouring of wave backwash. Some seawalls and bulkheads may create access problems and may require the building of stairs.

V-5-8. Aids to Navigation

(1) Aids to navigation are the markers and signals vessels require to safely use a navigation project. The navigation safety of a project is directly related to the clarity and visibility of aids to navigation. Channel design must be planned so that the layout, dimensions, and alignment facilitate clear marking. A reduced width may be possible in a well-marked channel as compared to a poorly marked channel, so a tradeoff between channel widening cost and aids to navigation cost should be considered in design.

(2) The U.S. Coast Guard is responsible for the design, establishment, and maintenance of all aids to navigation in Federal interstate waters (U.S. Coast Guard 1981, 1988a, 1988b). Figure V-5-41 gives two examples of typical devices used to mark U.S. navigation channels. They are uniquely identified by color, shape, and number or letter. They may also include lights, sound, radar reflectors, and electronic signals. Beacons are fixed structures, generally on pilings in shallow water up to about the 5-m (15-ft) depth. Buoys are floating, anchored to the bottom with a chain connected to a concrete block. They mark channel boundaries, hazards, and channel curves or turns, especially in areas where water depth makes beacons impractical. Height above the water, and hence visibility, is more limited for buoys than for beacons. Another limitation of buoys is that their location relative to the channel is imprecise. It can vary over a small distance because buoys are free to move about the anchor point in response to environmental forces.

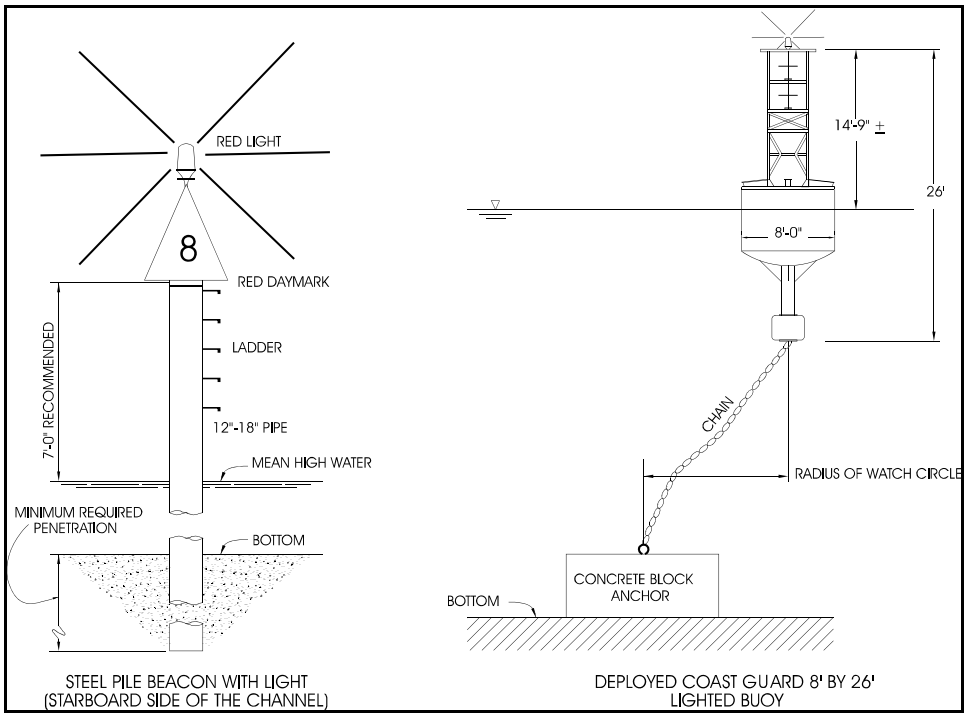

Figure V-5-41. Examples of aids to navigation

(3) Occasionally, buoy/anchor systems are completely moved out of position by strong environmental forces or by vessel impacts. Buoys are also susceptible to sinkage or drifting if mooring connections are lost.

(4) The channel marking system used in U.S. Federal waters is nearly standardized. Conventions for color, shape, numbers/letters, and light characteristics are well-established. Left and right channel sides are relative to an inbound vessel coming from open water into a harbor. Basically, the left side of the channel is signified by green (paint color and/or lights), squares, and odd numbers (Figure V-5-42). The right side is signified by red, triangles, and even numbers. Numbering begins at the seaward end of the channel.

(5) Ranges are pairs of fixed structures usually aligned with the channel center line at one or both ends of straight reaches. They are usually on shore or in very shallow water. The rear marker is always higher than the front marker. They are typically marked with rectangular signs, designated by letters, high-intensity lights, and red and white vertical stripes, as indicated in Figure V-5-42. By observing the placement of front and rear markers relative to each other, mariners can determine vessel position relative to the channel center line (Figure V-5-43).

(6) Additional important aids to navigation along the seacoast include major lights and sea buoys. One or more major lights are located near each harbor entrance. The high-intensity, well-maintained lights are located on fixed structures or towers at heights of up to 60 m (200 ft), sufficient to be visible over a long distance. Electronic aids to navigation are often collocated with major lights. Sea buoys are large, easily visible buoys marking the ocean end of most deep-draft harbor entrance channels. A typical sea buoy is 12 m (40 ft) in diameter and 9 m (30 ft) or more in height, with high-intensity light, electronic aids, and a sound signal. Sea buoys are usually located in deep water on the channel center line extended 2 to 4 km (1 to 2 miles) seaward beyond the channel's seaward end. Often the sea buoy marks an area where inbound ships await local pilot assistance.

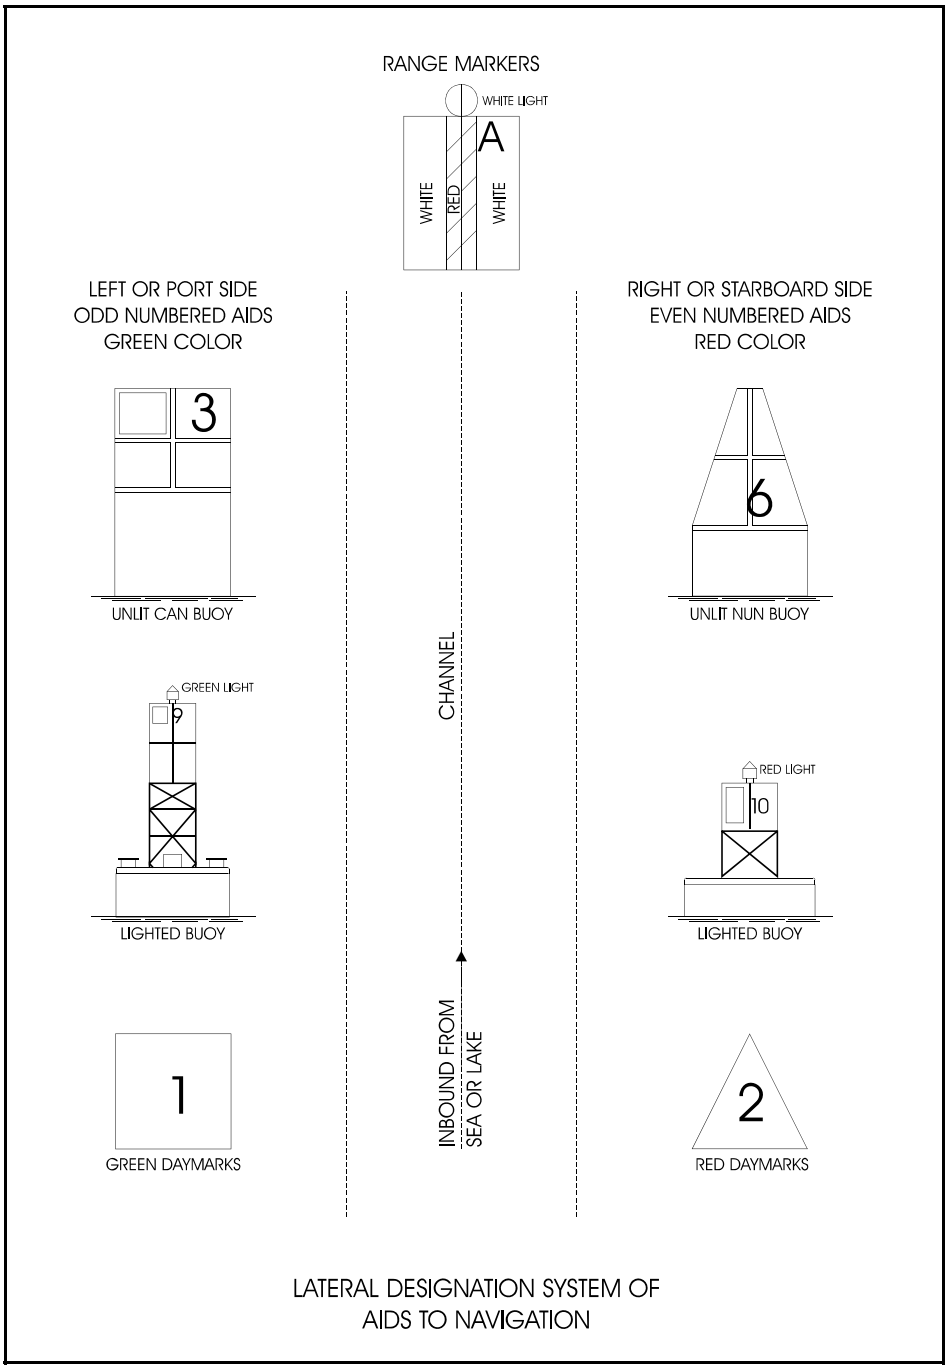

Figure V-5-42. Designation system of aids to navigation

(7) Aids to navigation are normally placed along straight channel reaches so that at least two on either side are always visible. This consideration leads to a practical maximum spacing of about 2.3 km (1.25 n.m.). Range markers must be visible along the entire reach. Practical limitations on range marker height, visibility through fog, and earth curvature effect on line of sight dictate that straight channel reaches should be no longer than about 8 to 10 km (5 to 6 miles). It is good practice to have redundant aids to navigation, such as both range markers and side channel markers, to ensure that failure of a marker will not create a navigation crisis.

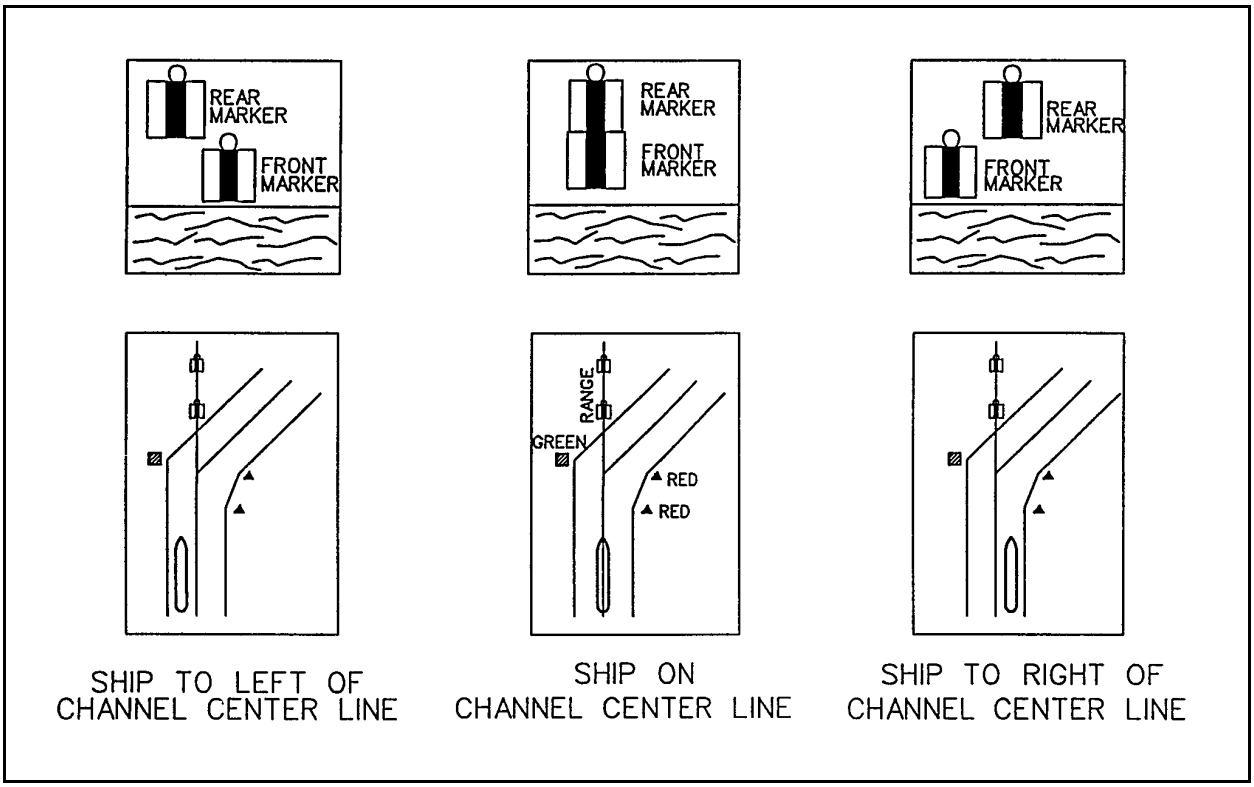

Figure V-5-43. Use of ranges for channel position

(8) An example deep-draft navigation channel at Brunswick Harbor, Georgia, is shown in Figure V-5-44 (Huval and Lynch 1998). The entrance channel begins near a sea buoy in exposed Atlantic Ocean waters, passes between St. Simons and Jekyll Islands, makes a severe turn to pass behind Jekyll Island, and continues with additional turns up the Brunswick River to port facilities at Brunswick. The channel also passes under the Sidney Lanier Bridge. Navigation buoys and range markers are shown.

V-5-9. Operation, Monitoring, and Maintenance

a. After a navigation project has been designed and constructed, operation and maintenance are required to sustain safe and efficient use of the project. Operation and maintenance requirements and costs can be substantial. They are typically estimated with care and optimized against initial construction costs in planning and designing a navigation project. Anticipated maintenance costs are based on predictions of physical changes after the project is constructed.

b. A completed navigation project must be monitored to ensure safe operation and to plan for maintenance activities as needed (see Part V-2-17). Monitoring typically includes hydrographic surveys, beach profile surveys, tide and wave data collection, and navigation structure condition surveys. Surveys are typically done on a planned schedule, such as annually, and before and after periods of maintenance and repair. Surveys should be analyzed comparatively to determine rates of erosion, shoaling, and structure deterioration.

c. Often, periodic dredging to maintain project depths is the major maintenance need. Maintenance dredging intervals depend on factors such as shoaling rate, dredge availability, and dredge mobilization costs.

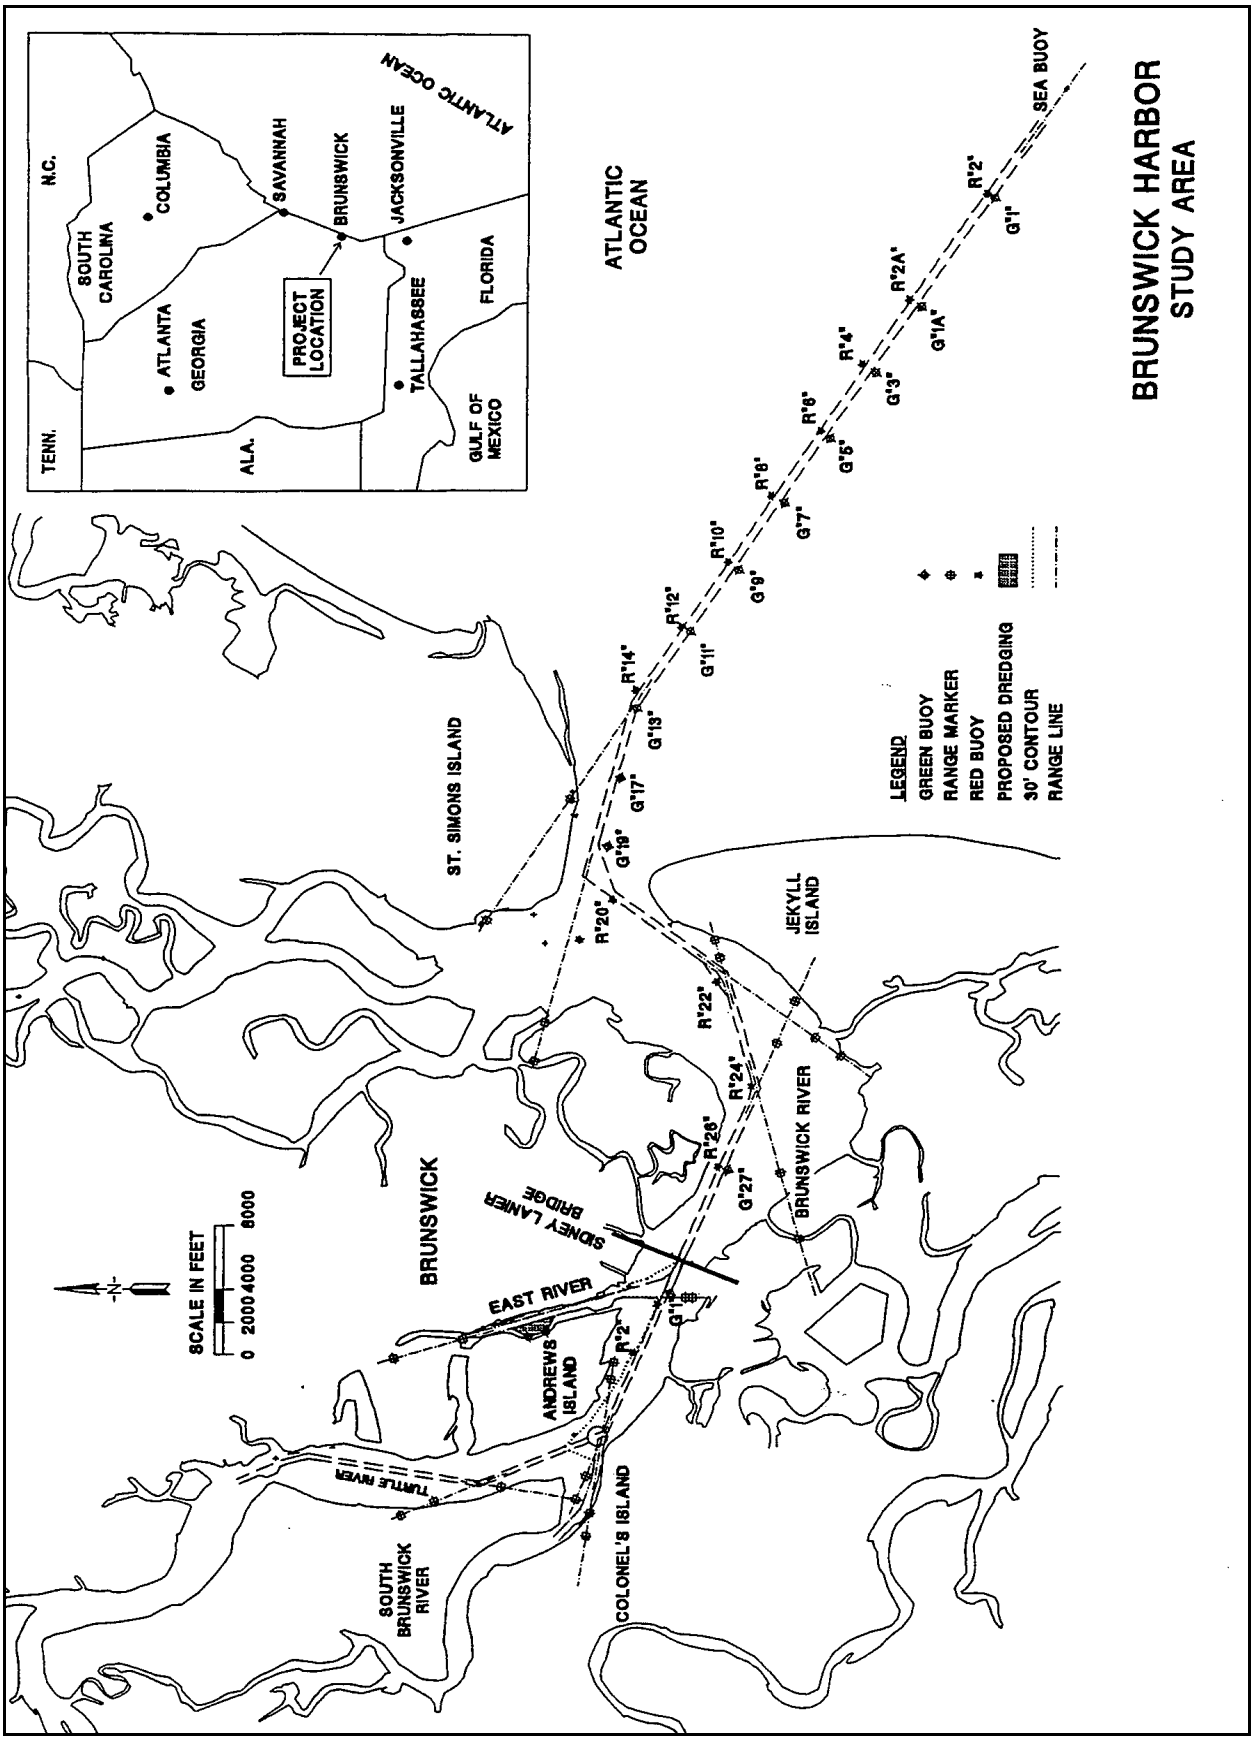

Figure V-5-44. Deep-draft navigation channel, Brunswick Harbor, Georgia

d. Typical maintenance intervals are on the order of 1-3 years at some projects, but maintenance needs are often strongly influenced by storm events. However, environmental forces impacting a navigation project are highly variable. The number and intensity of storms affecting a project each year can only be predicted in terms of probabilities. A single severe storm can cause major shoaling and structure damage. Consequently, monitoring and maintenance activities may occasionally need to respond quickly to maintain project integrity.

e. Project performance should be assessed, based on monitoring data. Actual project performance should be evaluated relative to project expectations during original design. In particular, actual maintenance costs should be compared to those originally predicted. Coordination with local interests, including boaters, pilots, port authorities, etc., should also be part of project performance assessment. Monitoring, maintenance, and performance assessment should continue at an appropriate level for the life of the project.

V-5-10. Model and Specialized Field Studies

a. Harbor modeling. Physical and numerical harbor models are important design tools that can help the designer: Locate the project to ensure maximum wave protection; locate and design breakwaters and/or jetties to provide adequate protection and maintain entrance navigation channels; and locate, orient, and dimension navigation openings to provide vessels safe and easy passage into and out of a harbor without sacrificing wave protection; position spending beaches and other forms of wave absorbers inside the project area. Physical and numerical modeling tools are helpful in developing and optimizing harbor designs. When compounded with problems caused by nearby or adjacent rivers, and/or shoaling problems resulting from littoral transport, and/or harbor oscillation problems relative to long-period wave energy, the designer encounters difficulty in obtaining adequate answers strictly by analytical means. One or both of these tools should be applied when a study has large economic consequences. Even small harbor studies generally benefit from model studies.

(1) Physical modeling as a design tool. Hydraulic scale models are commonly used to plan harbors and to design and lay out breakwaters, jetties, groins, absorbers, etc., to obtain optimum harbor protection and verify suitable project performance. A detailed description of physical modeling related to coastal ports and harbors is given by Hudson et al. (1979). Physical hydraulic model studies may be used to study the following:

- The most economical breakwater and/or jetty configurations that will provide adequate wave protection and navigation channel control for vessels using the harbor.
- Wave heights in the harbor.
- Undesirable wave and current conditions in the harbor entrance.
- Proposals to provide for harbor circulation and/or flushing.
- Qualitative information on the effects of structures on the littoral processes.
- Flood and ice flow conditions.
- Shoaling conditions at harbor entrances.
- River flow and sediment movement in rivers that may enter in or adjacent to the harbor.

- Long-period oscillations (Part II-7).
- Tidal currents or seiche-generated currents in the harbor (Part II-7).
- Inlet entrances.
- Remedial plans for alleviation of undesirable conditions as found necessary.
- Possible design modifications to significantly reduce construction costs and still provide adequate harbor protection.

(a) To ensure accurate reproduction of short-period wave and current patterns (i.e., simultaneous reproduction of both wave refraction and wave diffraction), undistorted models (i.e., vertical and horizontal scales are the same) are necessary for harbor studies. Physical hydraulic models are designed and operated in accordance with Froude's model law (Stevens et al. 1942). Scale relations commonly used for undistorted physical models are shown in Table V-5-13. A scale of 1:100 is used for illustrative purposes.

Table V-5-13
Typical Physical Model Scales for Harbors

Characteristic	Dimension[1]	Scale Relations
Length	L	L_r = 1:100
Area	L^2	$A_r = L_r^2$ = 1:10,000
Volume	L^3	$\forall_r = L_r^3$ = 1:1,000,000
Time	T	$T_r = L_r^{1/2}$ = 1:10
Velocity	L/T	$V_r = L_r^{1/2}$ = 1:10
Roughness (Manning's coefficient, n)	$L^{1/6}$	$n_r = L_r^{1/6}$ = 1:2,154
Discharge	L^3/T	$Q_r = L_r^{5/2}$ = 1:100,000
Force (fresh water)	F	$F_r = L_r^3 \gamma_r$ = 1:1,000,000
Force (salt water)	F	$F_r = L_r^3 \gamma_r$ = 1:1,025,641

[1] Dimensions are in terms of length (L), time (T), and force (F).

(b) Selection of a suitable model scale is an important step in model design. It involves a trade-off between scale effects and construction costs. For short-period wave studies, the model area generally includes enough offshore area and bathymetry to allow waves to refract properly on approaching the harbor and enough upcoast/downcoast area to allow the littoral current to form. Model waves must be large enough to be free from excessive friction and surface tension and to be measured with reasonable accuracy. Typical scales are between 1:75 and 1:150. For long-period wave studies (periods longer than about 25 sec), larger prototype areas are generally needed to include relevant interactions with bay or coastal shelf bathymetry. Also, long-period waves tend to reflect from model basin boundaries and the model harbor should be far from these boundaries. Long-period wave studies usually require distorted-scale models, with unequal horizontal and vertical scales. For example, a USACE model of Los Angeles/Long Beach Harbor, in use since the 1970's has a vertical scale of 1:100 and a horizontal scale of 1:400.

(c) Small-scale models must be constructed very accurately to reproduce conditions in the prototype. The model should reproduce underwater contours to model wave transformation. Shoreline details and irregularities also are important to simulate diffraction, runup, and reflection. The model bed should be as

smooth as possible to minimize viscous scale effects. However, models involving estuary tidal flows and/or river flows typically require the addition of bottom roughness in those areas to correctly simulate flow conditions. When a model involves breakwater or jetty structures, model armor and underlayer stone sizes are adjusted, based on previous research and experience, to reproduce prototype transmission and reflection characteristics. Structure stability is generally not reproduced in harbor models.

(d) The reproduction of river discharges and steady-state tidal flows often is required in wave action model studies. These flows generally are reproduced using circulation systems (i.e., for a river discharge, water is normally withdrawn from the perimeter of the model pit area and discharged in a stilling basin that empties into the upper reaches of the river and flows downstream in the model).

(e) Reproducing the movement of sediment in small-scale coastal model investigations is very difficult (Hudson et al. 1979). Ideally, quantitative, movable-bed models best determine the effectiveness of various project plans with regard to the erosion and accretion of sediment. This type of investigation, however, is difficult and expensive to conduct and entails extensive computations and prototype data. In view of these complexities and due to time and funding constraints, most models are molded in cement mortar (fixed-bed) and a tracer material is selected to qualitatively determine the degree of movement and deposition of sediments in the study area. In past investigations, tracer was chosen in accordance with the scaling relations of Noda (1972), which indicates a relation or model law among the four basic scale ratios: horizontal scale, vertical scale, sediment size ratio (d_{50} model tracer material divided by d_{50} prototype sediment), and relative specific weight ratio. These relations were determined experimentally using a wide range of wave conditions and bottom materials, and they are valid mainly for the breaker zone. This procedure was initiated in the mid-1970's, and has been successful in reproducing aspects of prototype sediment movement as evidenced by the performance of completed projects that have been studied (Bottin 1992). Currently, research is being performed to better understand aspects of sediment movement and improve methods to model it, and scaling relations have been developed for mid-scale, two-dimensional model tests (Hughes and Fowler 1990).

(f) After model construction, representative test conditions must be selected. Wave height and period characteristics, direction of wave approach, and frequency of occurrence are typically needed. Refraction analyses are normally required to transform deepwater waves to shallow water at the location of the model wave generator. From this point, model bathymetry will transform the waves to the harbor area. Still-water levels (swl's) are also important test conditions. Normally more wave energy reaches a harbor with the higher swl's. Lower swl's may result in more seaward movement of longshore sediment (i.e. around a jetty head), since the breaker zone would be moved farther offshore. Dominant movement of wave-induced currents and sediment transport patterns are required for verification of the model. River discharge and/or tidal flow information is also required, if applicable to the study.

(g) Data collected in a physical model include time series measurements at selected points of water surface elevation and, when needed, current. Spatial current patterns and velocities can be estimated by timing the progress of weighted floats over known distances on the model floor. Photographs and videotapes of experiments in progress provide valuable visual documentation of wave transformation patterns, wave breaking, sediment movement, etc.

(2) *Example: Dana Point Harbor, California*. Dana Point Harbor, located on the southern California coast about 64 km (40 miles) southeast of the Los Angeles/Long Beach Harbors, is an example of a small craft harbor designed with the aid of physical modeling (Figure V-5-45). The harbor occupies a small cove in the lee of Dana Point. The harbor consists of a 1,676-m- (5,500-ft-) long west breakwater, a 686-m-(2,250-ft-) long east breakwater, and inner harbor berthing areas partially enclosed by the shoreline and mole sections. The harbor encloses an area of about 0.85 sq km (210 acres) and provides berthing facilities for about 2,150 small boats.

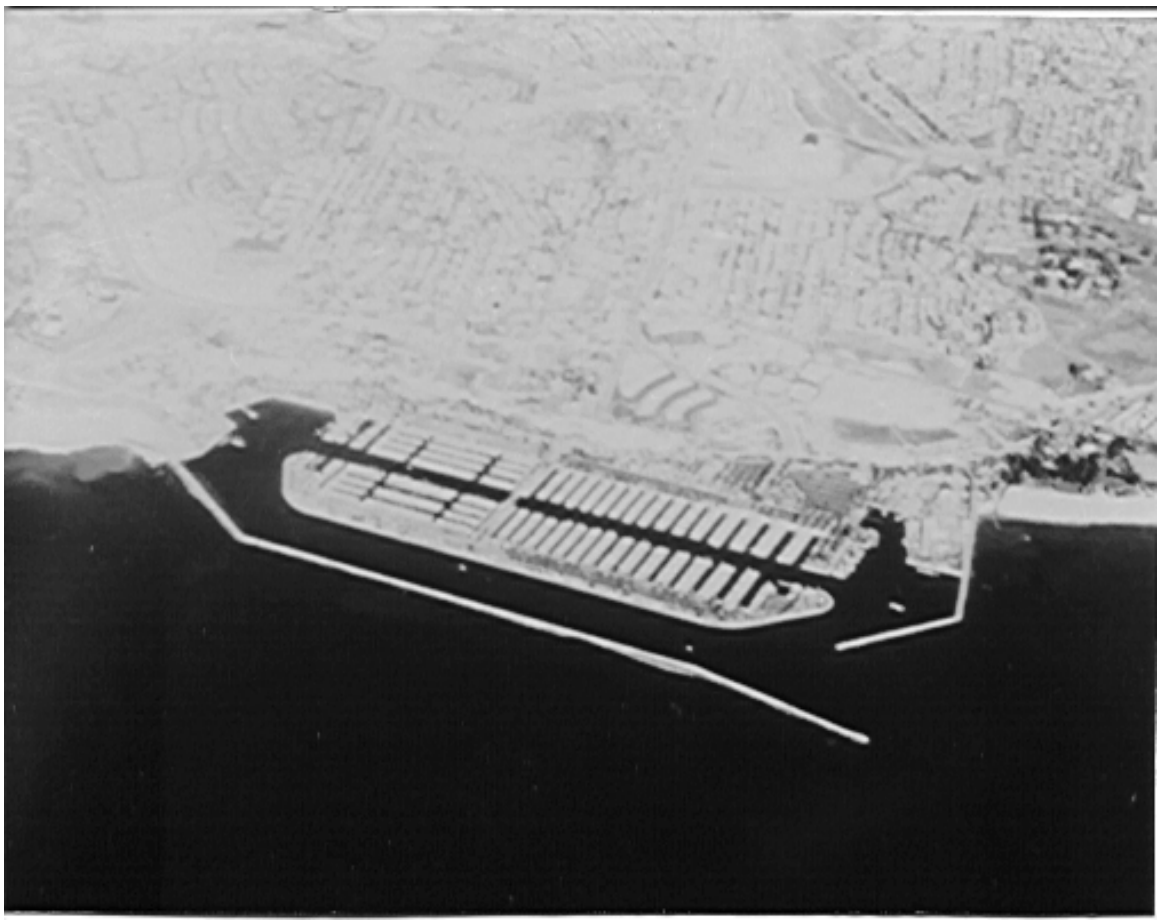

Figure V-5-45. Dana Point Harbor, California (May 1969)

(a) The area is exposed to storm waves from directions ranging from southwest counterclockwise to south-southeast and to ocean swells from the south. Damaging wave energy may reach the berthing areas by passing through the outer navigation entrance and by overtopping and/or passing through the rubble-mound breakwaters.

(b) As part of the original design effort, a 1:100-scale hydraulic model investigation was conducted to determine the optimum breakwater plan and location and size of the navigation opening that would provide adequate protection for mooring areas during storms (Wilson 1966). Waves with periods ranging from 9 to 18 sec and heights ranging from 2.4 to 5.5 m (8 to 18 ft) were generated from eight deepwater directions using an swl of +2.0 m (+6.7 ft) mllw. A wave height acceptance criterion of 0.46 m (1.5 ft) was established in the harbor berthing areas by the sponsor and waves in the fairway were not to exceed 1.2 to 1.5 m (4 to 5 ft).

(c) Experiments were conducted for existing conditions and 13 plans. Results for existing conditions indicated rough and turbulent conditions in the area even for low-magnitude storm waves. The proposed improvement plan involved construction of outer breakwaters and inner-harbor development consisting of east and west basin berthing areas partially enclosed by the shoreline on the north and a mole section on the south, southeast, and southwest (Figure V-5-46).

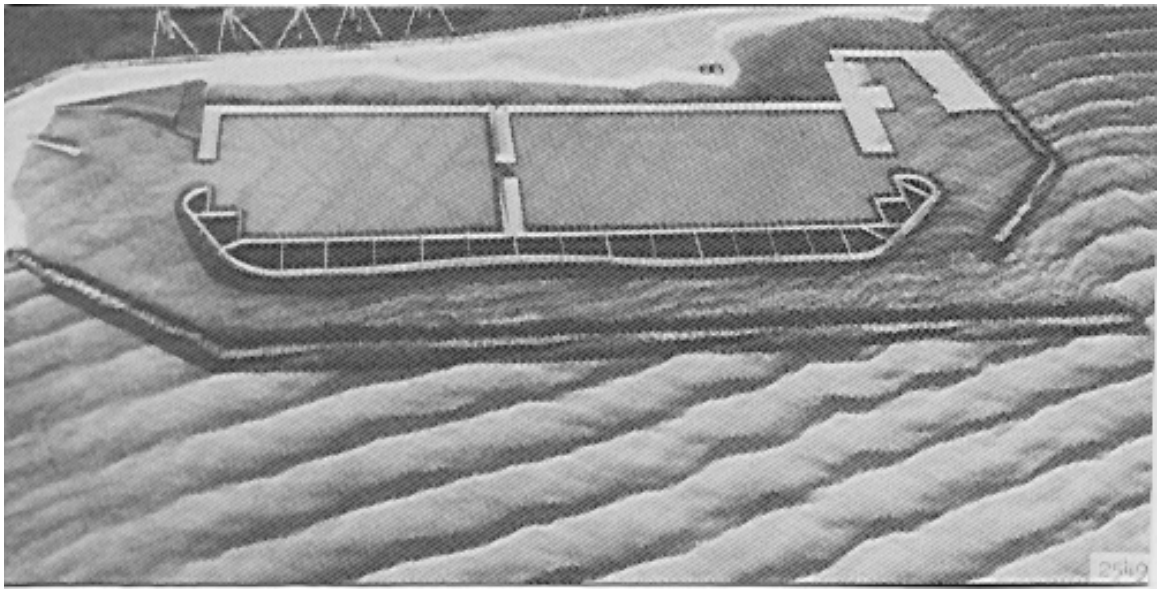

Figure V-5-46. Physical model view of Dana Point Harbor, California, under storm wave attack

(d) Experimental results indicated that wave conditions in the berthing areas were acceptable; however, wave heights in the fairway were about 2.0 m (6.5 ft) for severe storm wave conditions. It was noted that these conditions were due to a standing wave system caused by reflected waves from the mole slopes. Experimental results revealed that modifying the mole slope flanking the fairway, to include a berm, would reduce wave action considerably in the fairway.

(e) The harbor was constructed in accordance with recommendations from the physical model investigation. Post-construction monitoring has shown the harbor is performing as predicted. Mooring areas have experienced no wave problems. The outer west breakwater is overtopped by storm waves, which propagate across the interior channel to the outer revetted mole slope. Vessels in mooring areas behind the moles remain protected. The harbor has successfully endured intense storms, when other southern California small- craft harbor facilities have been severely damaged.

(3) Numerical modeling as a design tool. Numerical modeling requires computerized solution of equations that approximate harbor response to imposed natural forces. Numerical models and computer technology have evolved to the point where useful modeling of actual harbors can often be conveniently done on microcomputers. Numerical models are helpful in harbor studies, even for relatively simple harbor shapes. A combination of physical and numerical modeling is usually preferred for investigating the full range of conditions in a harbor. Numerical modeling related to harbors is best discussed in terms of the natural phenomenon to be modeled, such as waves, circulation, and shore response. Each model's equations and input/output forms are developed for application to particular phenomena. Model systems are now available that provide convenient access to a variety of modeling options under a single user-friendly interface (e.g. SMS 1994).

(a) Wind waves, swell, and harbor oscillations. Numerical wave models can be effectively applied to wave periods ranging from wind waves to long-period harbor oscillations. Numerical models have been useful for: Very long-period wave studies; initial evaluations of harbor conditions; comparative studies of harbor alternatives; and revisiting harbors documented previously with field and/or physical model data.

- For example, numerical models have been used effectively to select locations for field wave gauges (to achieve adequate exposure and avoid oscillation nodes) and to identify from many alternatives a few promising harbor modification plans for fine-tuning in physical model tests. Lillycrop et al. (1993) suggested that numerical modeling is preferable to physical modeling for oscillation periods longer than 400 sec. Both modeling tools can be used effectively for shorter period oscillations.

- Numerical wave modeling concerns are discussed in the following paragraphs, followed by an illustrative example. Additional information on numerical modeling of waves in harbors is available from a number of sources (e.g., Panchang, Xu, and Demirbilek (1998)).

- An initial step in modeling a harbor is to define the area to be covered and required horizontal resolution in the model grid. The coverage area should include the harbor and an area seaward encompassing bathymetry important for waves approaching the harbor. The seaward boundary should be a minimum of several wavelengths away from the harbor entrance, based on the longest wave periods to be modeled. Horizontal resolution is determined by the wavelength of the shortest wave period to be modeled. Typical resolution requirements are between $L/6$ and $L/15$ as the maximum grid element width. If grid elements are uniform in size over the entire grid, L should be based on the shallowest depths of interest. Depending on the particular study and grid-building software available, it may be preferable to build a grid with element sizes varying according to water depth, but still satisfying the wavelength-based maximum size criterion. Computer demands (memory, processing time, storage) in running a harbor model are directly linked to the total number of grid elements. Most harbor studies require a trade-off between coverage area and grid resolution to achieve a workable grid.

- Numerical models applied to harbors are usually based on a form of either the mild slope equation (MSE) or Boussinesq equations. Development of the equations is given by Dingemans (1997), Mei (1983), and others. MSE models are typically steady-state. The MSE model calculates an amplification factor (ratio of local wave height to incident wave height) and phase (relative to the incident wave) for every node in the grid. The MSE does not incorporate spectral processes. Typically, MSE models are run with a representative set of wave height, period, and direction combinations, based on knowledge of incident wave climate. If the MSE is linear, a single wave height for each period/direction combination will suffice. For wind wave and swell applications, regular wave results from the MSE model may be linearly combined, with appropriate weightings, to simulate harbor response to directional wave spectra.

- Boussinesq models are nonlinear and time-dependent. They are forced with an incident wave time series on the seaward boundary and produce a time series of wave response at each node in the grid. The time series may represent regular or irregular wave conditions. Boussinesq models are capable of more accurate representation of harbor wave response than MSE models, at the price of considerably greater computational demands. They are warranted in some practical studies and, with continuing intensive research and development, are likely to become a more workable option in the near future.

- Results from numerical harbor models are in the form of information at selected points or over the entire grid. Point information from Boussinesq models is comparable to time series from field or physical model wave gauges and may be analyzed in similar ways. Spatial information from Boussinesq models can provide animated displays of waves approaching, entering, and interacting with the harbor. Snapshots of waveforms over the harbor at selected times can easily be extracted for still displays. Spatial information from MSE models is in the form of snapshots of amplification factor and phase over the harbor area. Animated displays can be created by expanding amplification factor and phase information into sinusoidal wave time series, if desired.

(b) *Example: Kikiaola Harbor, Kauai, Hawaii*. Kikiaola Harbor is a small, shallow-draft harbor, located along the western part of the Kauai's south shore (Figure V-5-47). The original harbor consisted of west and east breakwaters. The harbor experienced excessive waves, resulting in the addition of inner and outer stub extensions to the east breakwater and a short inner breakwater. A wharf and boat ramp are located along the north boundary of the harbor, east of the inner breakwater.

- Prevailing northeast tradewinds result in a strong predominance of winds from the northeast, east, and southeast at the harbor. Typical wind speeds are 5 to 10 m/sec (10 to 20 mph). Winter storms can generate strong winds from the south. The harbor is exposed to waves approaching from a sector between the 134- and 278-deg azimuths, though the small island of Niihau creates some sheltering in the western exposure. Southern swell, generated by storms in the southern Pacific and Indian Oceans, is a significant part of the wave climate. Also, waves generated by storms in the North Pacific can wrap around the western side of Kauai and affect Kikiaola Harbor. Hurricanes can attack the harbor, which is important for structure design; but they are rare and do not impact operational concerns.

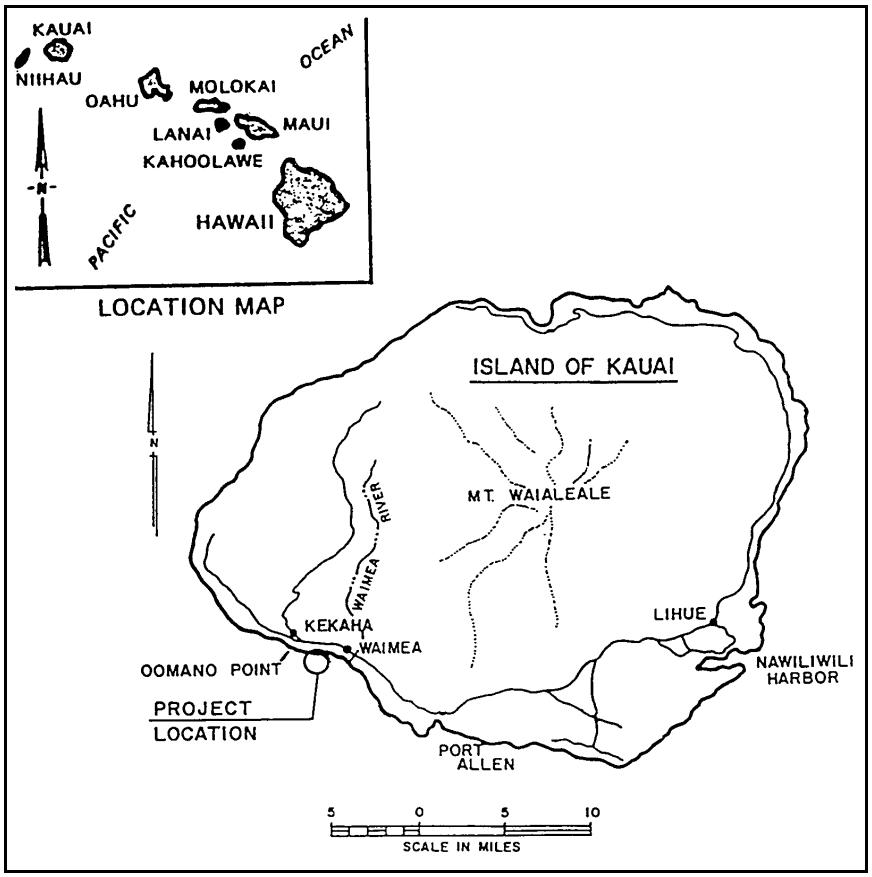
- Use of the existing harbor is limited by two primary factors. First, the harbor is quite shallow. Sediment movement along the local coast, predominantly from east to west, has resulted in shoaling of the entrance and inner harbor. Second, the existing entrance experiences breaking wave conditions that are hazardous to navigation. These two factors are interrelated. Breaking waves are more likely in the existing, shoaled entrance than they would be in a deeper, maintained entrance channel.

- Two plans for modifying the breakwater structures and navigation channels were defined, as follows (Figure V-5-48):

- *Plan 1*. Remove outer stub of east breakwater; remove and reconstruct inner stub of east breakwater a small distance further east; raise crest elevation of exposed portions of east breakwater by 1 m (3-4 ft) and flatten seaward slope to 1:2; widen outer 67 m (220 ft) of west breakwater; dredge 221-m- (725-ft-) long entrance channel with width varying from 32 to 62 m (105 to 205 ft) and maneuvering area to facilitate a 90-deg turn into access channel; dredge 98-m- (320-ft-) long access channel varying in width from 21 to 32 m (70 to 105 ft).

- *Plan 6*. Remove outer and inner stubs of east breakwater; raise crest elevation of exposed portions of east breakwater by 1 m (3-4 ft) and flatten seaward slope to 1:2; extend east breakwater further west to a distance of 33 m (100 ft) past the existing west breakwater location; shorten west breakwater to allow space for access channel; dredge entrance and access channels comparable to those in Plan 1.

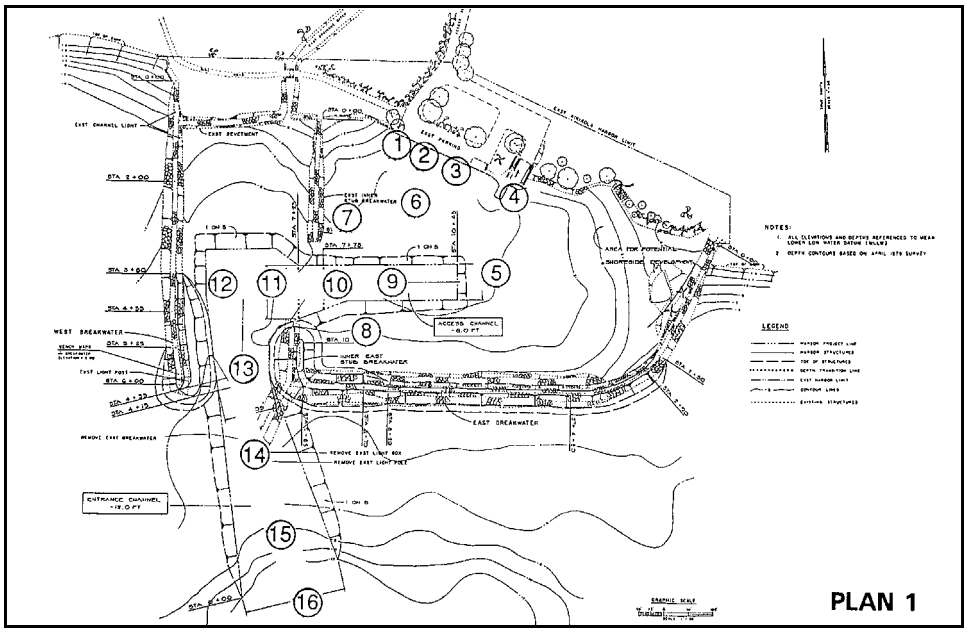
- A numerical model study was initiated to investigate wave conditions in the proposed plans relative to the existing harbor and to USACE criteria for channels and berthing areas (Thompson et al. 1998b). An MSE-based numerical model was used to analyze the harbor area (Chen and Houston 1987). Because water depths are shallow (on the order of 1 m in the existing harbor) and the shortest wave period to be modeled was 6 sec, a dense grid was required. To maintain a workable grid size for the model being used, the offshore extent of the grid was significantly limited and could not reach deep water.



(a) Location map

(b) Photograph (1998)

Figure V-5-47. Kikiaola Harbor, Kauai, Hawaii



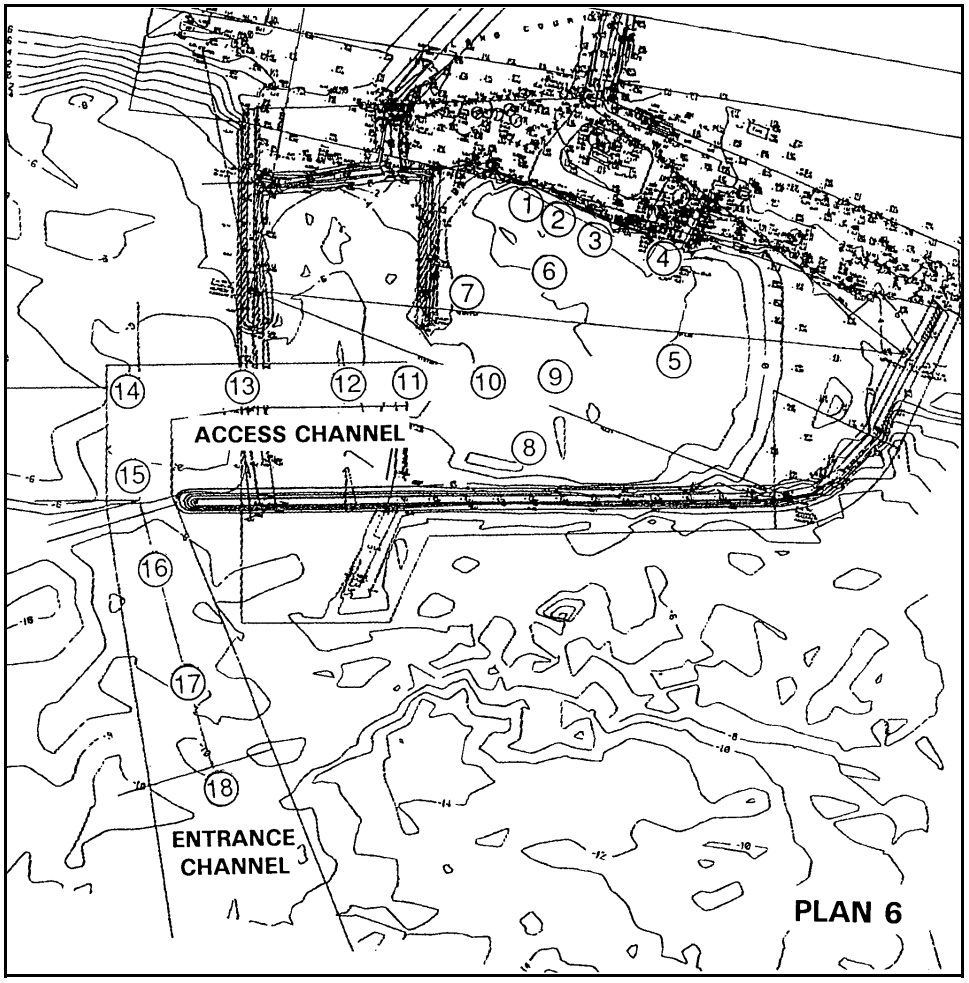


Figure V-5-48. Kikiaola Harbor alternative plans and model stations

- Wave climate at the seaward boundary of the harbor model grid was developed from updated WIS hindcasts in the Pacific OceanAugust 7, 2000. An additional modeling step accounted for sheltering by the islands of Kauai and Niihau as waves approach the harbor. Deepwater wave information was estimated at a point 1.6 km (1 mile) offshore from Kikiaola Harbor. Then, a shallow water transformation model was used to provide wave estimates at the seaward harbor model boundary, at about the 4-m (13-ft) water depth.

- The harbor model grid for the existing harbor consisted of 24,227 elements and 12,461 nodes. Model parameters, including boundary reflection coefficients and bottom friction, were set appropriate to the harbor configuration and model requirements. The tide range at Kikiaola Harbor is about 0.3 m (1 ft). Since harbor response is unlikely to vary much with water level over this small range, a water level of +0.3 m (+1 ft) mllw was used in all runs, representing a high tide condition.

- Wind wave and swell cases were periods ranging from 6 to 22 sec, in 1-sec increments, and approach directions of 164-, 184-, and 204-deg azimuths, representing the range of incident wave directions and entrance exposures. A linear form of the model was used (bottom friction set to zero), so a nominal 0.3-m (1-ft) wave height with each period/direction combination was sufficient. Thus, a total of (17 periods)x(3 directions) = 51 cases was run in the harbor model. Spectral results for each T_p and θ_p needed to represent the incident wave climate were simulated by linearly combining the 51 cases with appropriate weightings based on a JONSWAP spectrum with cos^{2s} directional spreading.

- Snapshots of amplification factor and phase for one incident wave condition illustrate harbor response (Figure V-5-49). A nonspectral condition is shown so that phases can be presented. The amplification factor increases over shoal areas just west of the entrance channel and then steadily decreases as the waves progress through the entrance and into the inner harbor. Plans 1 and 6 provide more shelter to the inner harbor than does the existing plan. Phase lines in the figure show the alignment of wave crests. They give a visual representation of diffraction and shoaling effects on wave direction and length as the 12-sec waves interact with harbor structures and bathymetry.

- Standard operational criteria used by USACE for wind waves and swell in small-craft harbors are:

- H_s in berthing areas will not exceed 0.3 m (1 ft) more than 10 percent of the time.

- H_s in access channels and turning basins will not exceed 0.6 m (2 ft) more than 10 percent of the time.

- To compare with USACE wave criteria, between 15 and 18 stations were selected in each plan, to include the wharf area, berthing area, access channel, and entrance channel (Figure V-5-48). Stations in the existing plan are identical to those shown for Plan 1 except the entrance channel stations are shifted appropriately. Spectral amplification factors were computed and applied to each incident H_s to give a wave climate at each station. The value of H_s exceeded 10 percent of the time was computed at each station. Results for Stations 1-9 are compared to the USACE berthing area criterion and the remaining stations to the USACE access channel criterion (Figure V-5-50). All plans, including the existing, satisfied the berthing criterion at all stations. The inner channel satisfies the channel criterion in all plans. The existing entrance channel does not meet the criterion; and the seaward portions of the Plan 1 and Plan 6 entrance channels slightly exceed the criterion. In conjunction with the increased width of the outer part of the plan entrance channels, the small exceedance of the USACE channel criterion is unlikely to interfere with safe navigation.

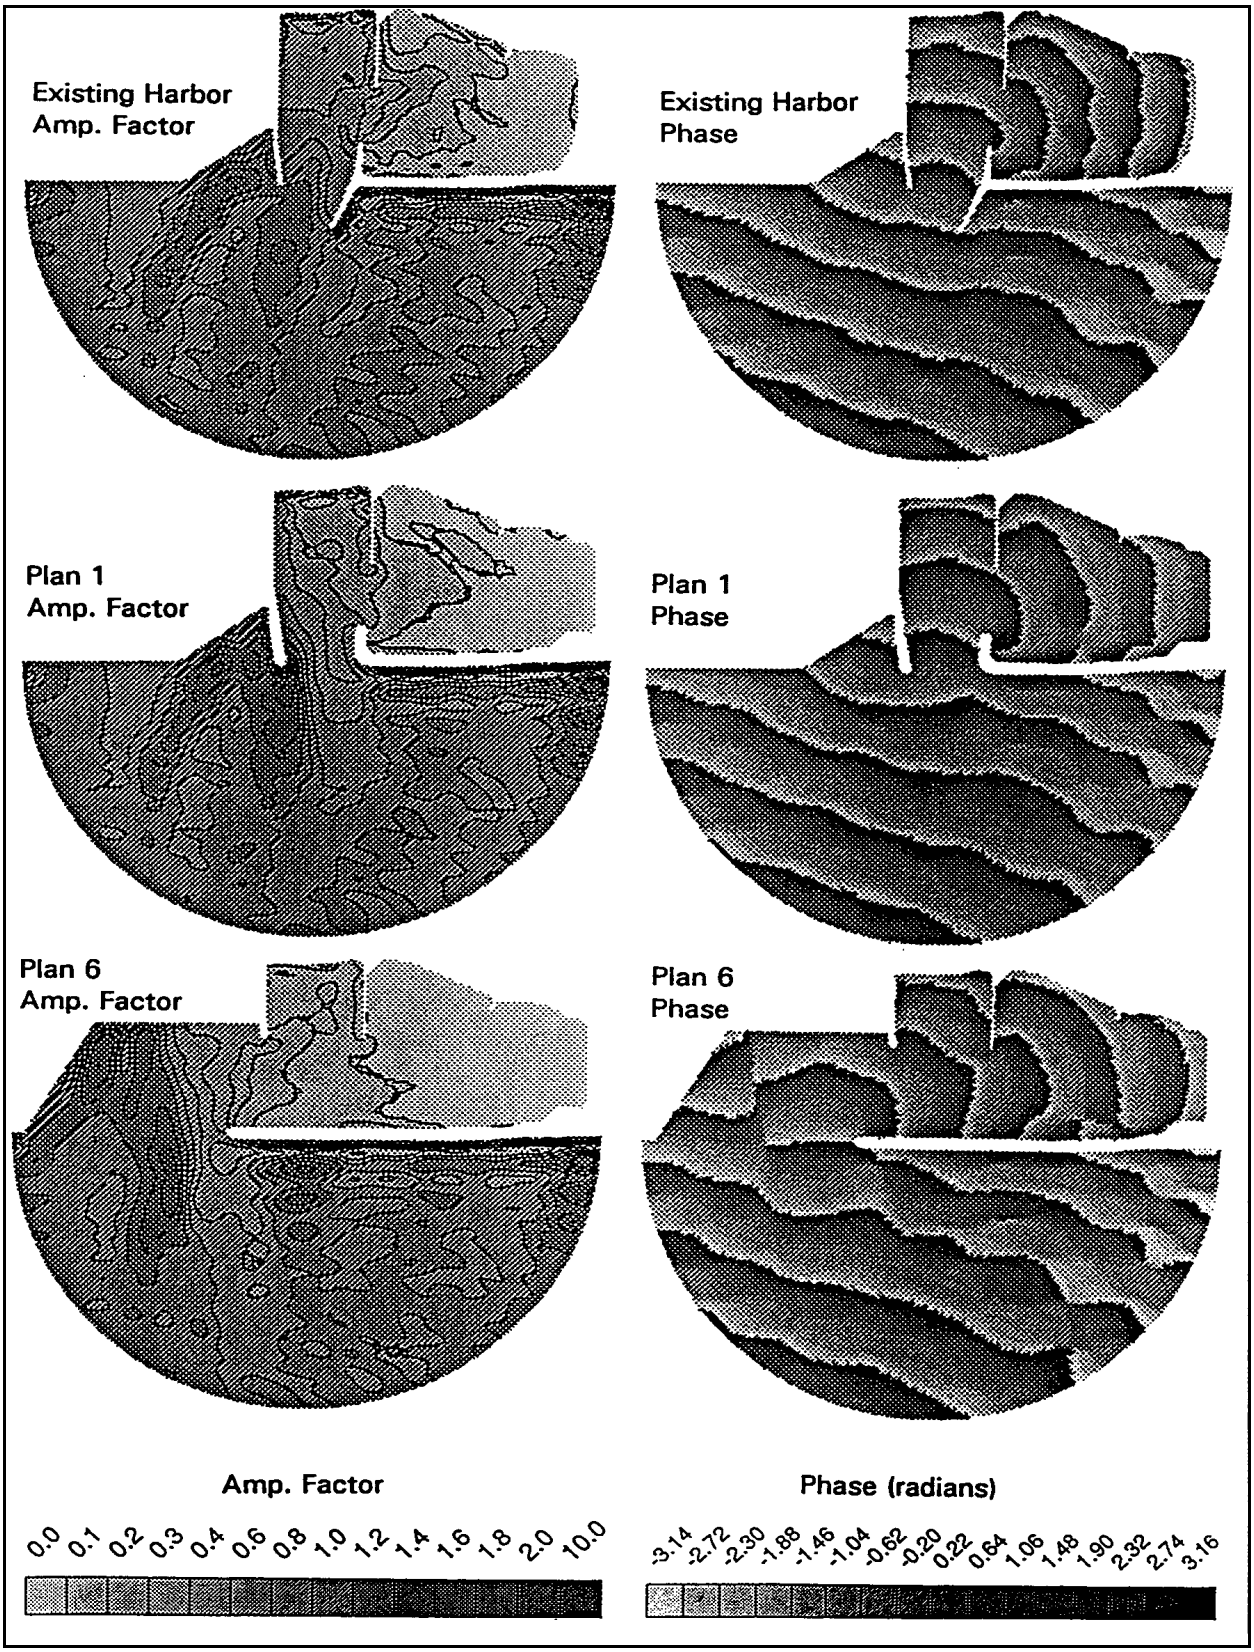

Figure V-5-49. Amplification factor and phase contours, 12-sec wave period, 200-deg azimuth approach direction, Kikiaola Harbor

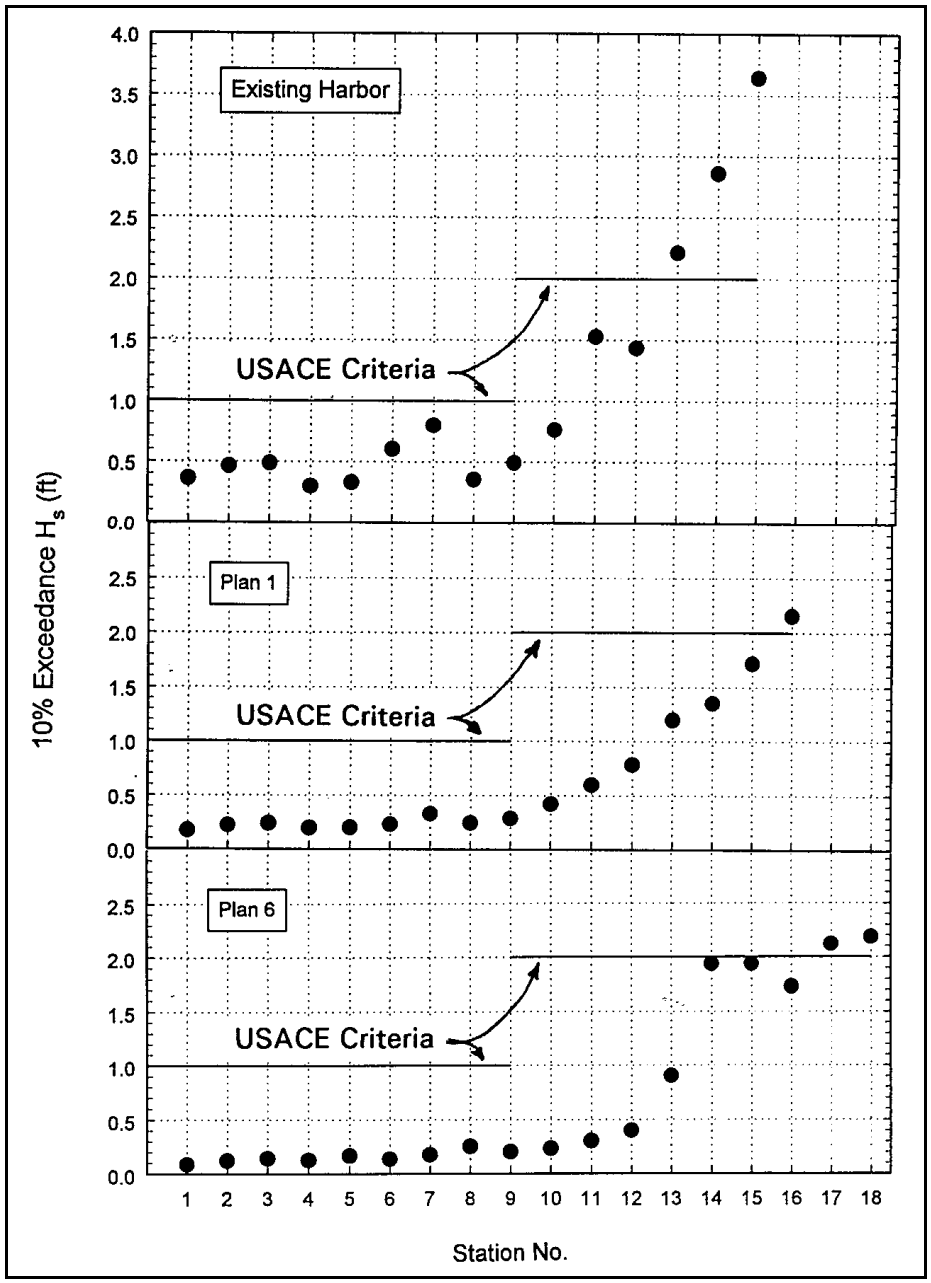

Figure V-5-50. Comparison of H_s exceeded 10 percent of the time, Kikiaola Harbor

- Harbor oscillation characteristics of the existing and plan harbors were also investigated to ensure the plans would not have operational problems due to oscillations. Model parameters were changed to give constant, nonzero bottom friction and full reflection from harbor boundaries. A total of 451 long-wave periods were run, ranging from 25 to 500 sec. The frequency increment between periods was 0.0001 Hz up to a period of 80 sec and 0.00006 Hz for longer periods. Fine resolution in frequency is needed to ensure that resonant peaks are captured. One long wave height is used, representing a moderately energetic long wave case, based on measurements at another Hawaiian harbor. One long wave direction, directly approaching the harbor entrance, is used, since past studies have indicated that harbor response is relatively insensitive to incident long wave direction.

- A snapshot of amplification factors in the existing harbor for a long-period resonance at a period of 150.6 sec represents a simple oscillation between the outer harbor and the east part of the inner harbor (Figure V-5-51). A node (indicated by very low amplification factor) is located a little east of the inner harbor entrance. Considering the most active areas of operational concern, amplification factors at the boat ramp (sta 4) and in the outer harbor (sta 12) were 2 and 3, respectively. A simple basis for judging the operational importance of harbor oscillation amplification factors is given in Table V-5-14 (Thompson, Boc, and Nunes 1998). Thus, the 150.6-sec resonance is not expected to be a problem in operational areas for boats. All amplification factors in all plans across the full range of long-wave periods were significantly less than 5, indicating that harbor oscillations are not a problem in the plan harbors. Additional information on numerical modeling of harbor oscillations is presented in Part II-7-5-f.

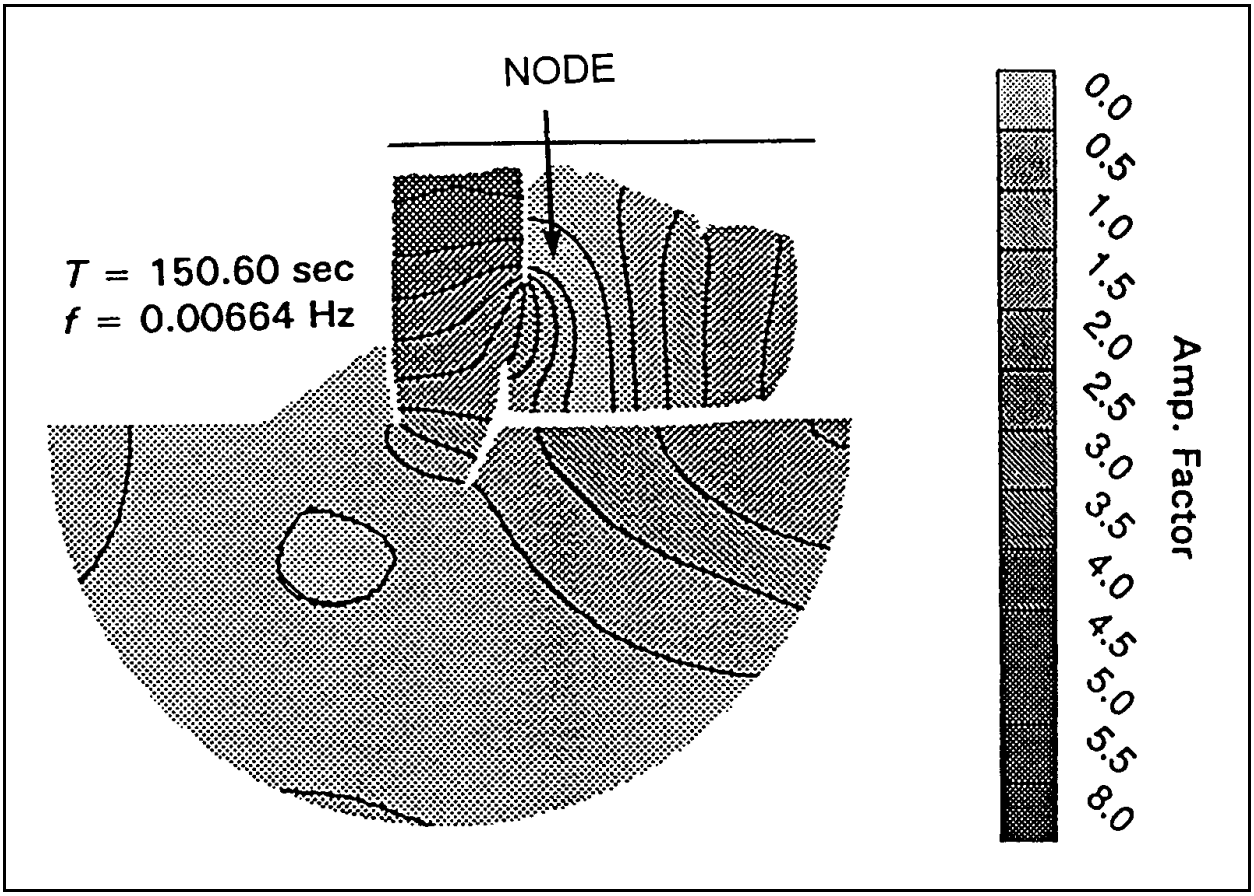

Figure V-5-51. Resonant long wave amplification factor contours, existing Kikiaola Harbor

Table V-5-14
Simple Criteria for Assessing Operational Impact of Harbor Oscillations

Amplification Factor	Operational Impact
> 5	Some problems
> 10	Major problems

(c) Flushing and circulation. Numerical models are effective for evaluating flushing and circulation in harbors and entrances due to forces such as tides and wind. This application is discussed in Part II-7. Numerical models also provide detailed currents along navigation channels needed in ship simulations.

(d) *Example: Maalaea Harbor, Maui, Hawaii.* Maalaea Harbor is a south-facing small-craft harbor located on the southwest coast of the Island of Maui (Figure V-5-52). The harbor facility consists of a 27-m- (90-ft-) wide, 3.7-m- (12-ft-) deep entrance channel and a 0.05-sq-km (11.3-acre) dredged basin. The harbor is protected by a 30-m- (100-ft-) long, 27-m- (90-ft-) wide breakwater on the south side and a 265-m- (870-ft-) long breakwater on the east side. A 91-m- (300-ft-) long paved wharf is located at the shore opposite the entrance. The west and central parts of the harbor are small-craft berthing areas.

Figure V-5-52. Maalaea Harbor, Maui, Harbor (from Air Survey Hawaii, March 1984)

- In response to needs for increased berthing space and better protection during severe wave conditions, the U.S. Army Engineer Division, Pacific Ocean, conducted studies to develop and evaluate harbor modification plans. To evaluate potential impacts on water quality in the harbor, a numerical model circulation and flushing study was conducted for the existing harbor and two proposed plans (Wang and Cialone 1995).

- Circulation in Maalaea Harbor is forced by tide and persistent, often strong winds from the north and northeast. Prototype data were collected over a 9-day period, including currents at two locations and tide. Concurrent wind measurements were available from a nearby airport.

- The numerical model used a curvilinear boundary-fitted coordinate system to generate a computational grid with two vertical layers. It provides current vectors over the harbor and a larger area outside the harbor (Figure V-5-53). The average horizontal grid cell size is 15 m (50 ft). The model is time-dependent, driven with time series of surface elevation along the seaward boundary and wind over the grid surface. Prototype data were used to calibrate the model. Parameters adjusted during calibration include friction, drag, and mixing coefficients.

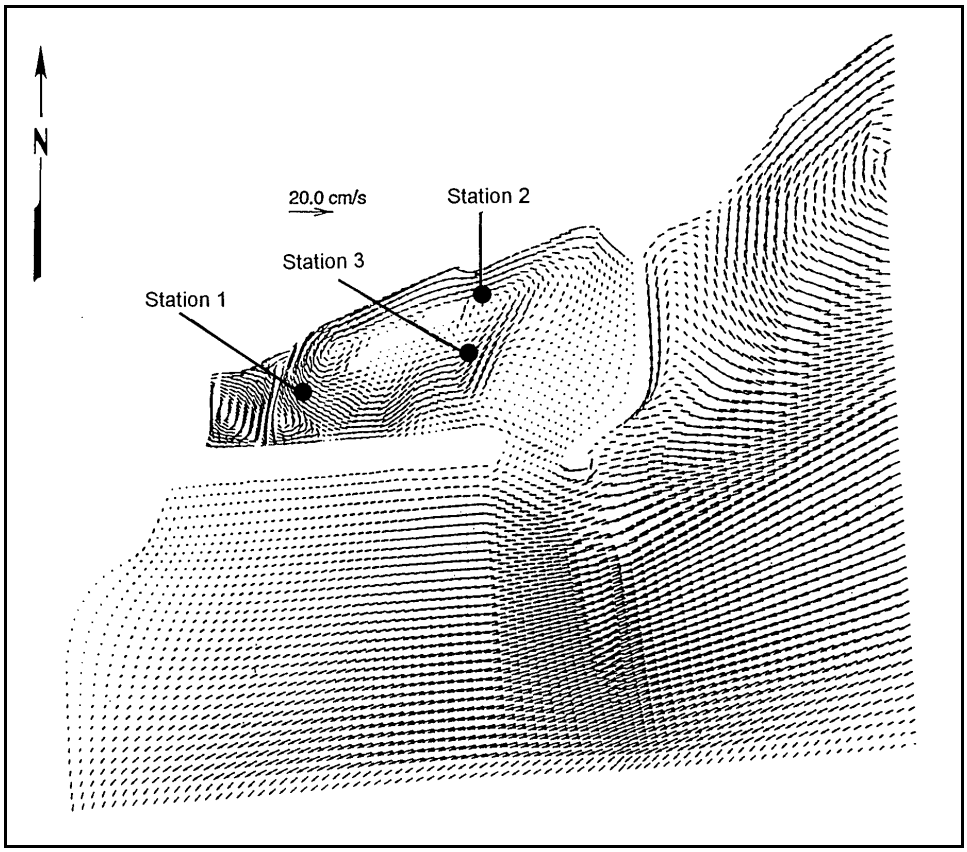

Figure V-5-53. Station locations and surface layer circulation snapshot at Day 3, Maalaea Harbor, existing plan

- Flushing time was defined as the time required for a conservative tracer to decrease to 36.8 percent ($1/e$, $e = 2.71828$) of its initial concentration. This time was evaluated in each plan by beginning a simulation with constant concentration of 100 ppt (parts per thousand) in the harbor and 0 ppt outside the harbor, running the simulation for multiple days, and extracting a concentration time series at three interior harbor stations (Figure V-5-53). Flushing time in the existing harbor was longest at sta 1, in the west part of the harbor and most distant from the entrance (Figure V-5-54). The 2.9-day flushing time was considered acceptable, based on flushing times of 2-4 days as acceptable for design, 4-10 days as marginal, and greater than 10 days as unacceptable (Clark 1983).

(e) Shore response. Possible changes in adjacent shoreline configuration and nearshore bathymetry in response to navigation structures and channel dredging are often a significant concern in navigation projects. Shoreline evolution with and without the project in place can be predicted and analyzed with numerical modeling tools. Guidance on sediment processes at inlets and harbors and numerical modeling options is given in Parts III-2 and V-6.

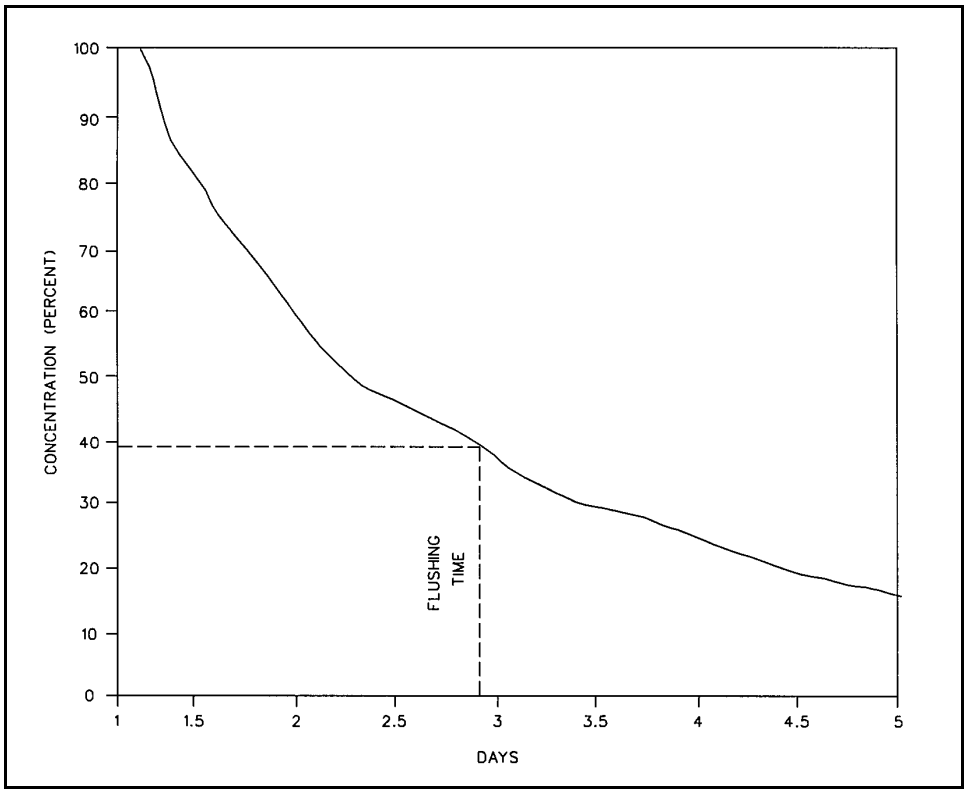

Figure V-5-54. Time series of conservative tracer concentration at sta 1, Maalaea Harbor, existing plan

b. Navigation modeling.

(1) Physical models. Physical models have been used for a variety of navigation studies, with vessel controls such as autopilot, human pilot steering, and free-running vessels with remote control. Physical models are particularly useful for evaluating the behavior of a vessel in the presence of intense, interacting forces, typically involving an entrance channel with ocean waves and possibly harbor or alongshore cross-currents. Waves and human control decisions are statistical processes. Free-running vessel motions in response to many samplings of those processes provide valuable design information about channel depth, width, layout, etc. Vessel position is tracked with high precision relative to channel boundaries in the model. The use of physical models for designing navigation projects is illustrated in the following example.

(a) *Example: Barbers Point Harbor, Oahu, Hawaii*. Barbers Point Harbor is a deep-draft commercial harbor located near the southwest corner of the Island of Oahu, Hawaii (Figures V-5-55 and V-5-56). The harbor was constructed along a previously uninterrupted coastline in 1982. The harbor complex includes a barge basin and small craft marina in addition to the deep-draft basin. The design ship was a general cargo vessel 219 m (720 ft) long with a beam of 29 m (95 ft) and a loaded draft of 10.4 m (34 ft). The entrance channel, designed for one-way traffic, is a constant 137 m (450 ft) in width and 12.8 m (42 ft) mllw in depth over its full length. Just past the coastline, channel depth transitions to 11.6 m (38 ft) mllw, the design depth of the inner channel and deep-draft harbor. The deep-draft basin is approximately 671 m x 610 m (2,200 ft x 2,000 ft) in size, covering an area of 0.37 sq km (92 acres).

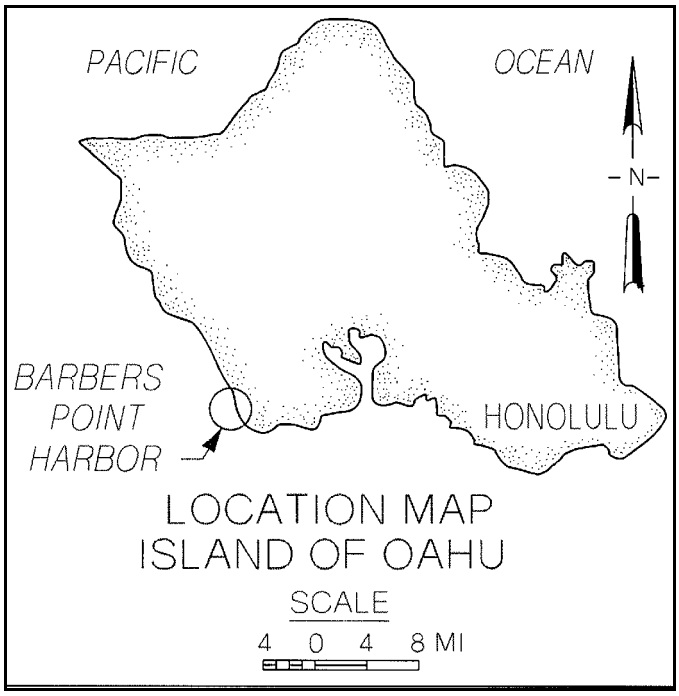

Figure V-5-55. Barbers Point Harbor, Oahu, Hawaii, location map

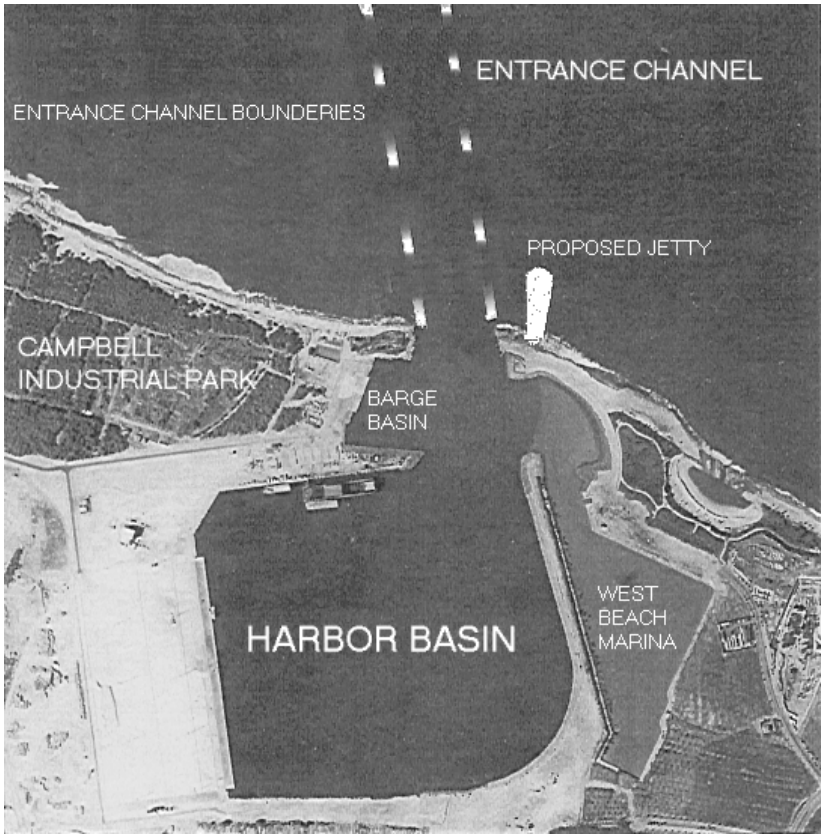

Figure V-5-56. Barbers Point Harbor, Oahu, Hawaii (August 1994)

- Changing economic conditions have created a need for the harbor to serve larger ships. In response to this need, the State of Hawaii and the U.S. Army Engineer Division, Pacific Ocean, sponsored physical and numerical model studies to assist in designing harbor modifications (Briggs et al. 1994, Harkins and Dorrell 1998). The primary study task was to evaluate the navigability of proposed channel and harbor configurations for a larger design ship unaided by tugs.

- A physical model of the harbor complex and adjacent coastal areas was constructed (Figure V-5-57). The model scale, 1:75 undistorted, was selected for proper reproduction of important harbor features, storm waves and longshore currents, and the design ship. Model bathymetry extended to the 30-m (100-ft) mllw bottom contour and a distance of about 1,067 m (3,500 ft) along the coast on either side of the entrance channel. Total area covered by the model was over 1,000 sq m (3,500 sq ft). A directional spectral wave maker was placed seaward of the modeled bathymetry. Longshore currents, which affect navigation in the existing harbor, were created in the model with a system of PVC pipe extending along each lateral boundary (with diffuser ports) and meeting at a pump station located behind the model, landward of the coastline. Pump controls allowed generation of longshore currents in either direction. Diffuser ports were open or plugged as needed to achieve desired current patterns.

Figure V-5-57. Physical model of Barbers Point Harbor

- Two design ships were identified, based on anticipated use of the harbor for container and bulk coal traffic. Existing ships were selected as representative of future harbor traffic, the *President Lincoln*, a C9 container ship with capacity of 2,900 TEU operated by American President Lines, and the *Bunga Saga Empat*, a bulk carrier (Figure V-5-58). The design bulk carrier was a modified version of the *Bunga Saga Empat*, with length increased by 30 m (100 ft). Design ship dimensions are summarized in Table V-5-15.

Figure V-5-58. Bulk carrier *Bunga Saga Empat*

Table V-5-15
Design Ship Dimensions for Barbers Point Harbor Studies

	Prototype Ship Dimensions	
	Container Ship	**Bulk Carrier**
Length Overall	262 m (860 ft)	259 m (850 ft)
Beam	32 m (106 ft)	32 m (106 ft)
Fully Loaded Draft	11.9 m (39 ft)	13.7 m (45 ft)

- Model ships were constructed to match the harbor model scale, 1:75 (Figures V-5-59 and V-5-60). Model ships were self-powered by onboard batteries. Forward and reverse speeds, rudder angle, and, for the container ship, bow thruster direction and speed were remote-controlled.

- A set of design transit conditions was selected for simulation. Prototype measurements of waves and currents near the harbor entrance were available. Wave data were collected over a period of approximately 4 years; currents were collected over a 65-day period. For harbor plan evaluation, the following conditions were used. The highest measured H_s values and a representative range of T_p and θ_p were selected, a total of eight wave conditions. The range of H_s and T_p values was 2.1 to 3.0 m (7.0 to 10.0 ft) and 6 to 18 sec, respectively. Longshore currents were selected to represent average, normal, and extreme conditions from both directions. Extreme currents were 0.41 m/sec (0.80 knot) from the north and 0.33 m/sec (0.65 knot) from the south. Based on data from a nearby airport, severe wind speeds of 10.3, 12.9, and 20.6 m/sec (20, 25, and 40 knots) were selected.

Figure V-5-59. Model bulk carrier

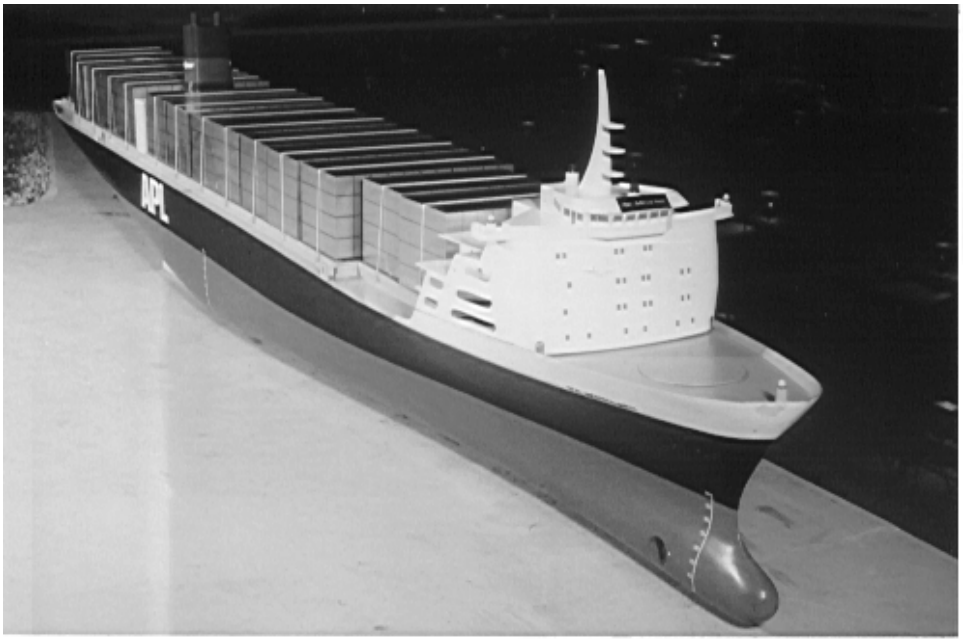

Figure V-5-60. Model container ship

- Six harbor plans were studied with varying combinations of the waves, current, and wind, as selected for design transit conditions. Wind forces were simulated with a ship-mounted fan. Model ships were guided by remote control between deep water and the protected harbor. Both inbound and outbound runs were made. Two experienced local pilots assisted in verifying the model setup and conducting some of the runs. Inbound runs were significantly more difficult than outbound runs. The ship must slow in approaching the entrance and it becomes more difficult to control. Typical inbound ship speeds are 13.0 km/hr (7 knots) at the seaward end of the entrance channel, 7.4-9.3 km/hr (4-5 knots) in the vicinity of the coastline, and 3.7-5.6 km/hr (2-3 knots) in the harbor. After a recommended harbor plan was identified, a number of channel/harbor depth variations were studied to optimize design depths. A total of nearly 2,000 runs were made, of which the majority were inbound.

- Navigability was evaluated by several methods during the course of the model studies. Ship operators recorded their observations after each run, with particular attention to any difficulties during the run. An overhead video camera recorded each run. A commercial motion analysis system was used to collect and analyze model ship motions. The system uses digital cameras and strobes to track reflecting balls. Six balls were mounted on the model ship (e.g., Figure V-5-59) and four were placed at fixed locations around the channel. After processing, the system provides a time series of clearance between ship hull and bottom.

- Physical model data on ship horizontal and vertical clearance in the channel were evaluated in a probabilistic assessment of channel design. The design then includes a consideration of the natural variability of wave, current, wind, ship track, and ship response, which is crucial in realistically assessing the probability of a momentary grounding event during ship transit. Thus risk of design ship contact with channel sides or bottom can be incorporated into the design process. The expected time interval between C9 container ship grounding events as a function of number of transits per year illustrates risk information available for design (Figure V-5-61). Since several different methods for estimating probabilities were applied to the physical model tests, the average from all methods is shown, bracketed by best and worst expected performance based on variability in the methods. Additional details are given by Briggs, Bratteland, and Borgman (2000).

- The recommended plan differs from the existing harbor in the following ways:

- Entrance channel is deepened and flares out at the seaward end to allow ships more maneuvering space during initial approach.

- Transition from entrance channel depth to harbor depth is moved from the coastline to the inner harbor basin opening. This change moves the transition to a lower wave energy environment and gives pilots more space to correct when vessel shear occurs at the depth discontinuity.

- Harbor is deepened and expanded in size by excavation in the east part of the harbor.

(b) Additional information, based on numerical model studies of Barbers Point Harbor oscillation characteristics, is available in Part II-7.

(2) Ship simulations. Increasingly, deep-draft channels are being designed using ship simulators. For example, the USAERDC ship simulator is schematized in Figure V-5-62. Ship simulations typically have pilots operate the steering wheel and ship controls and navigate a realistic course in real time. Pilots give verbal commands for tug assistance as needed, and an assistant operates tug controls. Pilots are drawn from professional pilot associations serving the project area. Their experience and intuition aids in evaluating existing projects as well as refining and studying new alternatives for safe and optimum channels and/or

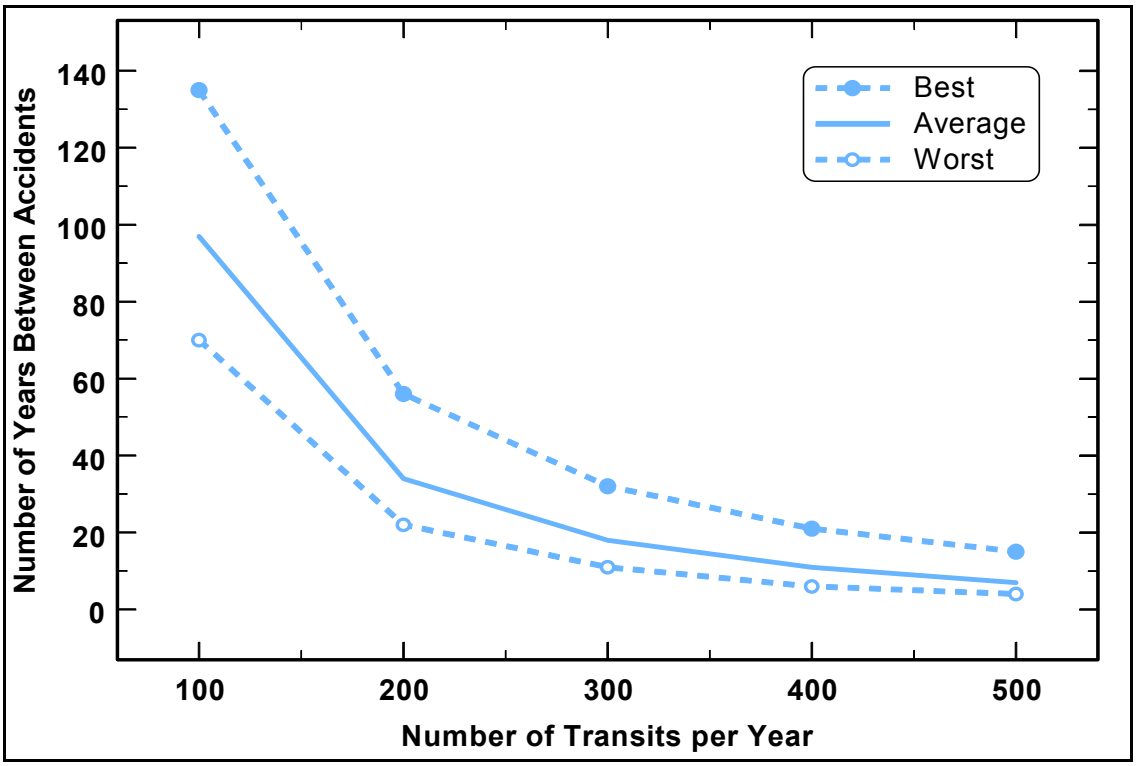

Figure V-5-61. Probability assessment for C9 container ship navigating recommended entrance channel, Barbers Point Harbor

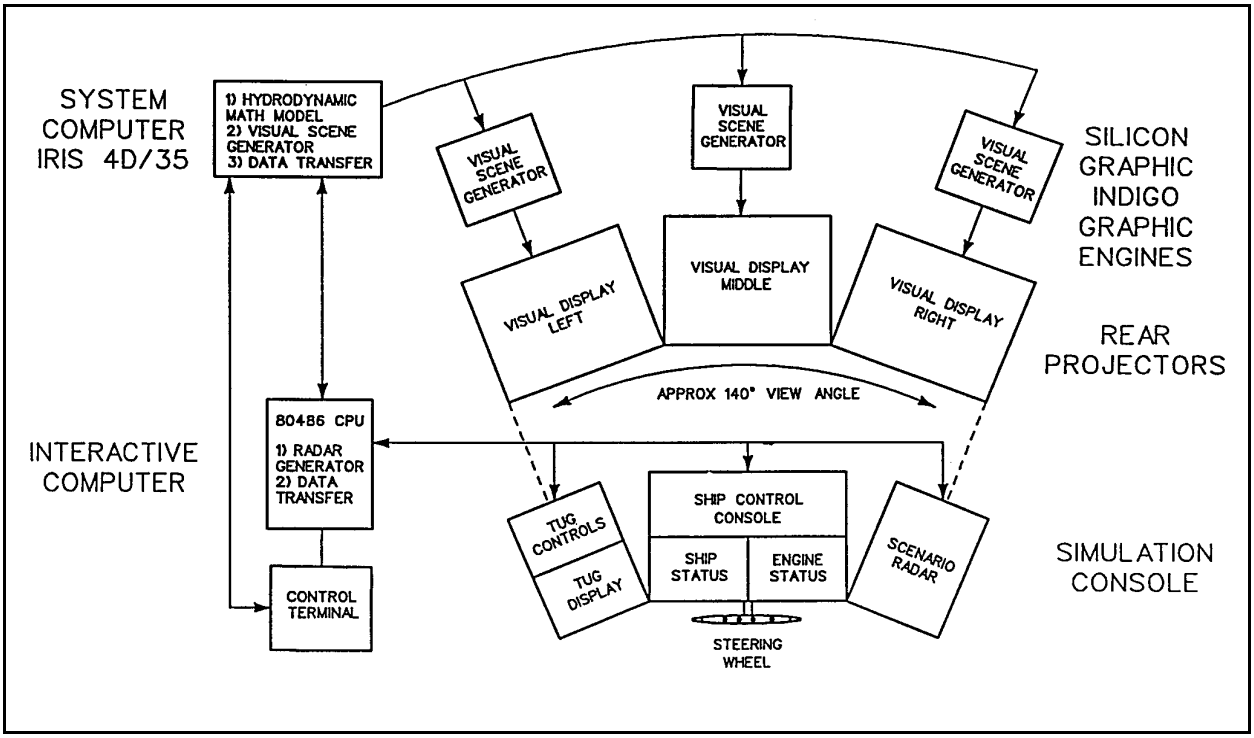

Figure V-5-62. USAERDC ship simulator system

turning basins. At some levels of project design, simulators may be used advantageously for fast-time runs with either autopilot or human control instead of a more comprehensive and costly real-time pilot evaluation program.

- Simulators are special numerical models involving representations of a ship, navigation channel, currents, wind, visual scene (including view over the ship, aids to navigation, bridges, docks, and other visual features needed for piloting cues and adequate realism), radar image, tugs and thrusters, ship bridge controls, and typical bridge instruments. Simulated forces and effects are depicted in Figure V-5-63. The ship model(s) experiences these forces and effects in ways similar to the prototype ship(s).

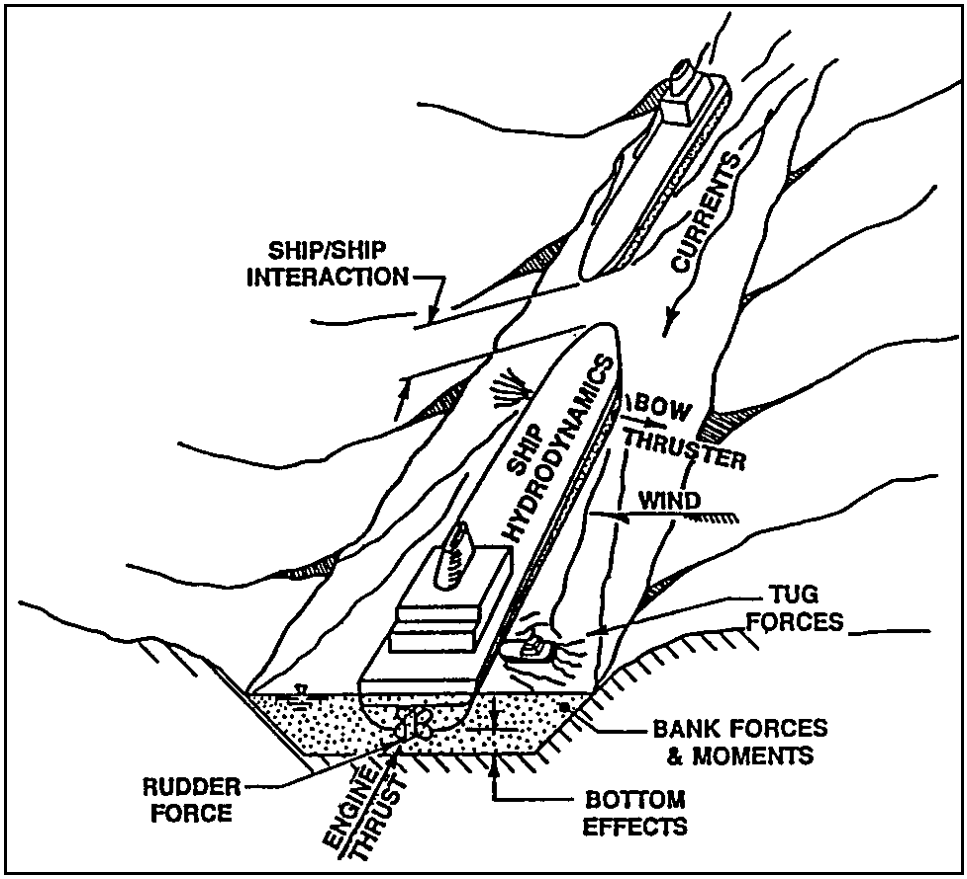

Figure V-5-63. Ship simulator forces and effects

- The key steps in a real-time simulation are shown in Figure V-5-64. Output information saved at selected short time intervals during a simulation includes ship position, engine and rudder settings, ship movement information (speed, heading, rate of turn, drift angle), and minimum clearance relative to channel boundaries. If tugs are used, information on tug forces imposed on the ship may also be saved.

- Two example ship simulator studies are discussed in the following paragraphs. More information on ship simulators is available from USACE (1998), Webb (1994), and PIANC (1997a).

(a) *Example: Alafia River Harbor, Florida*. The Alafia River Harbor is located along the eastern shore of Hillsborough Bay, about 13 km (8 miles) southeast of Tampa, Florida (Figure V-5-65). The

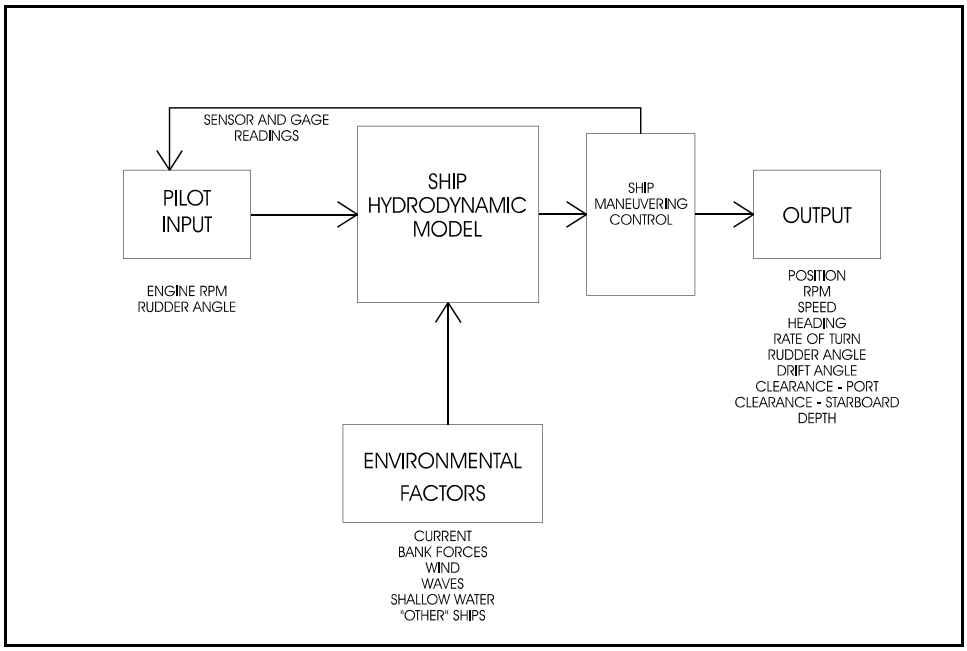

Figure V-5-64. Real-time simulation

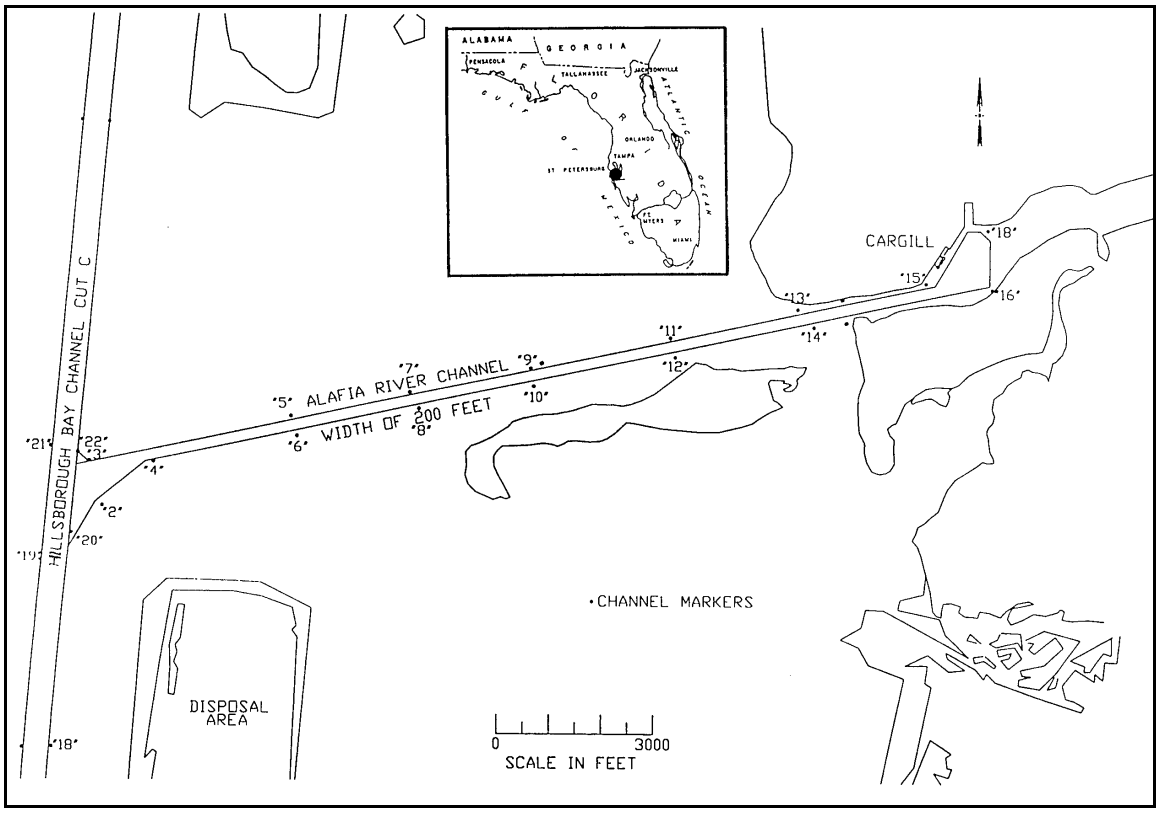

Figure V-5-65. Existing Alafia River Channel and turning basin

existing federally maintained project consists of a turning basin adjacent to the dock facilities and a channel connecting the turning basin to Hillsborough Bay Channel Cut C, the primary north-south shipping channel in Hillsborough Bay. Total length of the federal project is 5.8 km (3.6 miles). Channel depth is 9.1 m (30 ft) mllw. Channel width is 61 m (200 ft). The turning basin is 213 m (700 ft) wide and 366 m (1,200 ft) long.

- Alafia River Harbor is used mainly to ship phosphate rock and bulk phosphate products. Ships typically enter the harbor in ballast and load bulk materials until the ship draft reaches the limit allowed in Alafia River Channel or until the ship is fully loaded. Ships turn in the turning basin at the start of the outbound run, in a loaded condition.

- The U.S. Army Engineer District, Jacksonville, funded ERDC to conduct a ship navigation simulation study to investigate performance of two proposed plans for upgrading the Alafia River Channel and turning basin to accommodate larger ships. A notable part of the study is the detailed visual scene developed to provide pilots with realistic visual cues. The cues are a crucial part of slowing the ship on approach to the turning basin, approaching the dock, and turning the ship for the outbound run. Figure V-5-66 shows two pilots operating a bulk carrier. One pilot is guiding the ship, the other is operating tug controls on command. The ship has just entered the turning basin and turned toward the dock. The view direction (which is easily selected by the pilot) is to starboard, with the ship bow visible at the right side of the scene. The Alafia Channel heading out to Hillsborough Bay is visible at the left side, including a channel marker in the foreground. The dock and dock-side loading facilities are just to the left of the ship bow. Further left are numerous small trees and a line of rail cars. This scene adjusts continuously as ship position or pilot view direction change. Additional details of the study are given by Thompson et al. (1998a).

Figure V-5-66. Visual scene of Alfia River Harbor ship simulation study, inbound bulk carrier approaching dock

(b) *Example: San Juan Harbor, Commonwealth of Puerto Rico*. San Juan Harbor is located on the north coast of Puerto Rico, with open exposure to the Atlantic Ocean (Figure V-5-67). It is the largest port in Puerto Rico and a major container port. Noncontainerized cargo, such as petroleum products, lumber, grain, automobiles, and steel, is also imported to the island by sea. Rum, Puerto Rico's principal export, is shipped in containers. Cruise vessels frequently call on San Juan Harbor.

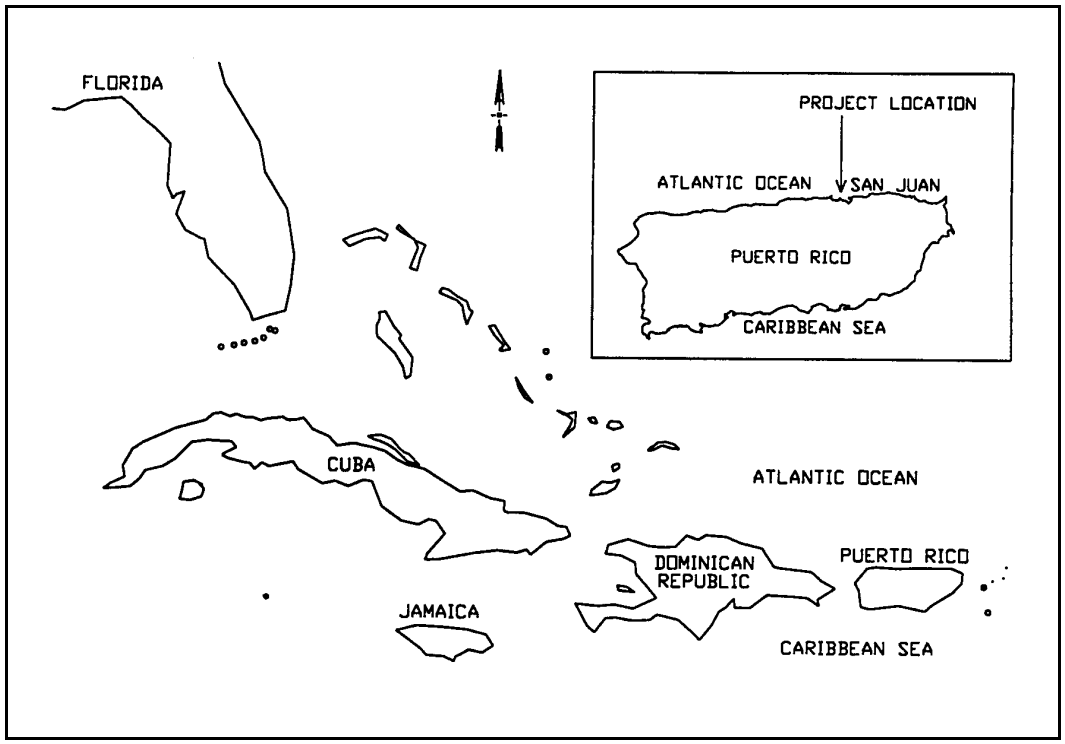

Figure V-5-67. San Juan Harbor, Commonwealth of Puerto Rico, location map

- Federally maintained channels include an entrance channel (Bar Channel), a main interior approach channel to the harbor complex (Anegado Channel), and three interior channels forming a triangular path accessing the principal dock areas (Army Terminal, Puerto Nuevo, and Graving Dock Channels) (Figure V-5-68). Design depth of the outer Bar Channel is 13.7 m (45 ft). The deepest approach to the harbor is the S-shaped path along Bar, Anegado, and Army Terminal Channels, with a controlling depth of 11.0 m (36 ft). Puerto Nuevo and Graving Dock Channels have design depths of 9.8 and 9.1 m (32 and 30 ft), respectively. Bar and Anegado Channel widths are 152 and 305-366 m (500 and 1,000-1,200 ft), respectively. The other three channels have design widths of between 91 and 122 m (300 and 400 ft).

- Wind and waves strongly affect the harbor entrance. Winds are usually steady and are described as being between 8 and 10 m/sec (15 and 20 knots) predominantly from the east and northeast. Waves typically approach the entrance from the north, northeast, and east, with significant heights up to 6-7 m (20-22 ft) during severe events.

- Pilots typically board inbound ships when they are 4.8 km (3 miles) from the harbor entrance. The entrance channel can be difficult to navigate in the presence of wind and wave conditions. Ships must maintain speed in the entrance channel for control, yet they must slow to make the relatively sharp turn into Anegado Channel. All documented accidents in recent years are groundings that have occurred on the south side of this turn. The turn is difficult for outbound ships, too, because of the

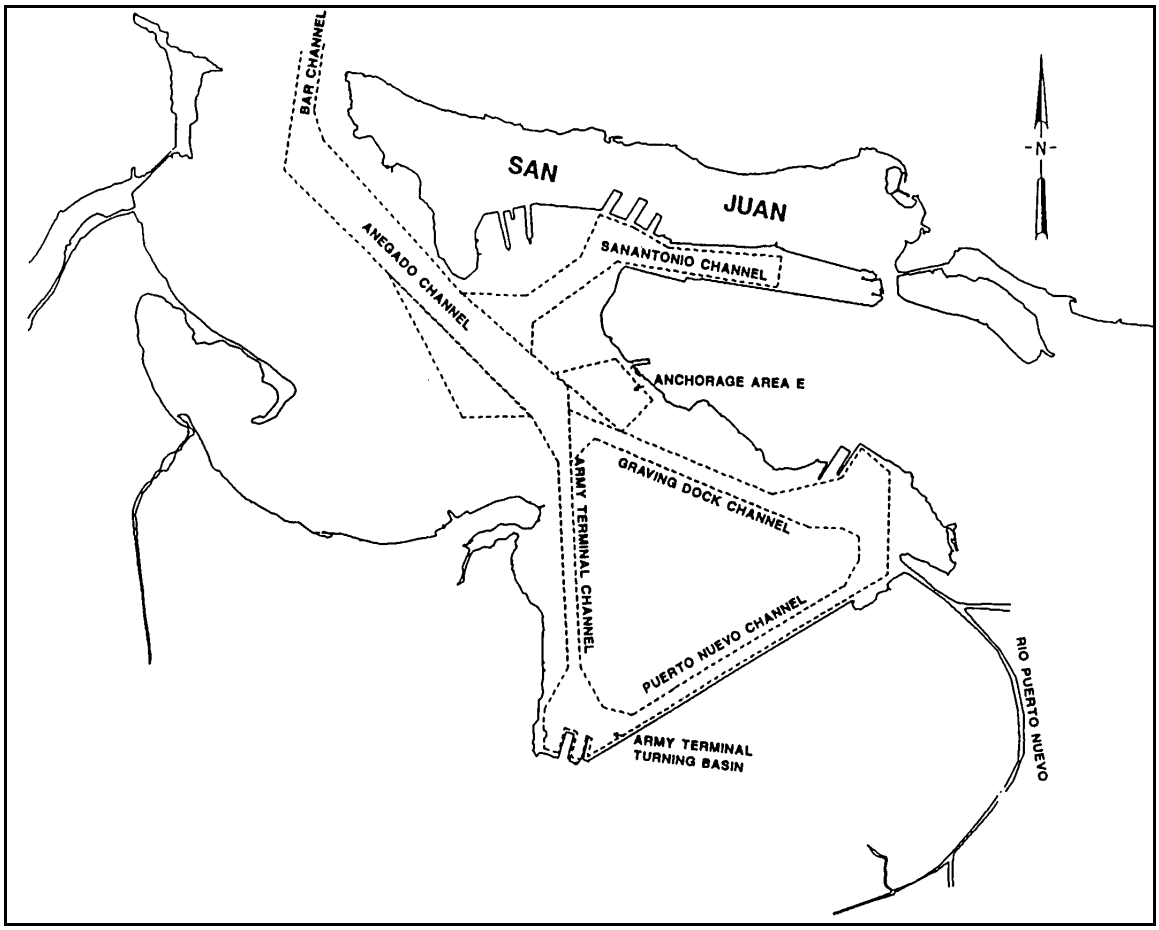

Figure V-5-68. San Juan Harbor channels

relatively narrow entrance channel. Sharp turns associated with the relatively narrow interior channels can also be difficult to navigate.

- The U.S. Army Engineer District, Jacksonville, funded a real-time ship simulator study of existing and two proposed alternative plans to address navigation concerns in San Juan Harbor channels and to allow access to deeper draft ships (Webb 1993). Controlling depth in the proposed plans is 11.9 m (39 ft) in Anegado, Army Terminal, and Puerto Nuevo Channels and 11.0 m (36 ft) in Graving Dock Channel. The purposes of the simulator study were to determine effects of the proposed improvements on navigation, to optimize channel width and alignment for safe and efficient navigation, and to determine necessary depths in Bar and Anegado Channel sections affected by waves.

- Design transit conditions were developed. A wind from the northeast was used with a speed of 10.3 m/sec (20 knots) in the outer entrance. Wind speed was decreased to between 0 and 7.7 m/sec (15 knots) in interior areas sheltered by bluffs and/or tall buildings. Wave information from a 20-year hindcast was used to define incident wave conditions for moderate and heavy seas. A numerical model transformed the selected incident wave conditions to the harbor and through the entrance, giving wave estimates along the channel. For simulation, incident H_s was 4.6 m (15 ft), coming from the northeast. This H_s is about the practical upper limit for ships to enter the harbor. The H_s progressively decreased along Bar Channel to 1.2 m (4 ft) and then to 0 after the turn into Anegado Channel. Tidal currents in the channels were determined with a numerical model of the

harbor embayment. Currents are very small. Since flood tide tends to reduce control of ships entering the harbor, flood tide currents were used with all simulations. A wave-driven cross-current of 0.3 m/sec was added in the more exposed section of the Bar Channel, based on pilot comments.

- Two design ships were used, a tanker 232.6 m (763 ft) in length (LBP) with a 38.1-m (125-ft) beam and a container ship 246.9 m in length (LBP) with a 32.3-m (106-ft) beam. The inbound tanker draft (loaded) was 9.8 m (32 ft) for the existing channels and 11.0 m (36 ft) for proposed channels. The outbound tanker draft (in ballast) was 7.9 m (26 ft). For both inbound and outbound runs, the container ship draft was the same as the inbound loaded tanker draft.

- The simulation was validated with the assistance of two pilots from the San Juan Harbor Pilots Association. Simulations were conducted in three 1-week periods. A total of six licensed San Juan Harbor pilots conducted the simulations (two per week), giving a representative range of experience and piloting strategies. Pilots completed a written questionnaire immediately after each run, including a rating scale of key project features. Some desirable modifications to the proposed plans emerged after the first week of simulations. The plans were adjusted to improve navigation in localized areas with difficult clearance and/or to reduce dredging in areas not needed for navigation.

- Design depths for the wave-influenced Bar and outer Anegado Channels were developed in a separate study component. A range of wave conditions and ship speeds were considered. The sum of vertical ship motion and squat was used to define the required underkeel clearance to be added to the 11.0-m (36-ft) ship draft. Because wave height decreases along the Bar Channel, a stepped design depth was recommended, with depth of 16.8 m (55 ft) at the seaward end of Bar Channel progressively decreasing in three steps to 13.7 m (45 ft) through the turn into Anegado Channel.

- Results from the simulations were summarized to evaluate proposed plans. For example, average pilot ratings for inbound container ship runs indicate the plans will significantly improve harbor access, especially in Puerto Nuevo Channel and at the turn separating it from Army Terminal Channel (Figure V-5-69). The wider entrance channel in the plans gives a significant improvement. Ship track plots from all runs show how the increased width and gentler turn would be used in navigation (Figure V-5-70). An unused area on the outside of the proposed turn is defined by the envelope of ship tracks. Simulations indicated that a ship could not enter this area and still turn safely. Therefore, one study recommendation was that the unused area be deleted from the plan, reducing dredging requirements. Complete results, conclusions, and recommendations are given by Webb (1993).

c. Specialized field studies.

(1) Harbors. As field measurement and data collection techniques have advanced, field studies have become powerful and reliable for documenting the behavior of existing harbors. However, the cost for comprehensive field studies is significant, and such studies are generally practical only for large projects with high economic impact. Typically, field data are used for calibration and validation in physical and numerical model studies. Field data helpful for harbor studies include incident directional waves, water levels, waves and currents at several interior locations, and winds. The data provide valuable information about harbor response to wind waves and swell, entrance channel wave conditions, harbor oscillations, and circulation and flushing. A representative, but extensive, field data collection program in the massive Los Angeles and Long Beach, California, harbor complex is described by Seabergh, Vemulakonda, and Rosati (1992). The program was aimed at enhancing physical and numerical models used in harbor planning.

(a) *Example: Kahului Harbor, Maui, Hawaii*. Kahului Harbor, located on the north shore of the Island of Maui, is the island's only deep-draft harbor and the busiest port in Hawaii outside of the Island of Oahu

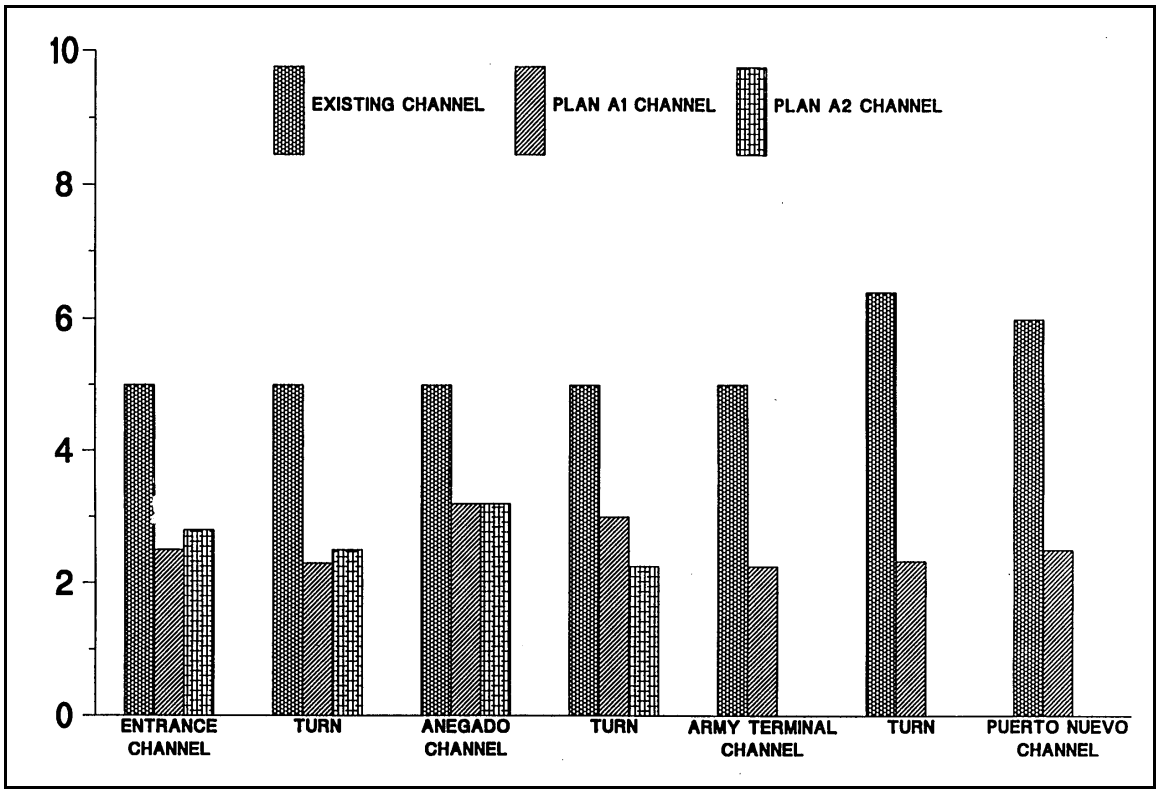

Figure V-5-69. Pilot degree of difficulty ratings, inbound container ship, San Juan Harbor

(Figure V-5-71). Commercial piers are presently on the east side of the harbor. In conjunction with long-term planning for expanded harbor usage, a field wave data collection program was established in the harbor. The program included an offshore directional array to measure incident waves and four pressure gauges in the harbor interior (Figure V-5-72). Interior gauge locations were determined with the assistance of a preliminary numerical model study of harbor wave response (Okihiro et al. 1994).

(b) Data from more than 1 year were collected and proved to be very helpful in subsequent harbor wave response, modeling, and planning studies (Thompson et al. 1996, Okihiro and Guza 1996).

(2) Ship tracking. The optimum depth and width of proposed navigation channel improvements may be determined with increased accuracy by measuring actual ship motions. The measurement program should encompass a significant number of transits of the route during adverse conditions. Availability of differential Global Positioning System (DGPS) apparatus for recording accurate ship fixes (±3 m) at a rapid rate (0.2 Hz or faster) makes this an affordable component of feasibility studies. Commercial software is available for data recording and display in formats applicable to channel design. These systems use standard DGPS receivers compatible with the U.S. Coast Guard network of DGPS radio beacons, as illustrated in Figure V-5-73. A time series of fixes is recorded with concurrent gyrocompass headings and other data, such as engine rpm, rudder angle, and relative wind speed and direction.

(a) Commercial gyrocompasses aboard seagoing cargo vessels usually provide heading accuracy of ±0.3 deg or better. Concurrent time series of position and heading define the swept path of the vessel. Comparison of ship tracks with tidal currents, winds, waves, water levels, visibility conditions, and other environmental conditions present at the time of recording, provide channel designers with realistic parameters for width computations.

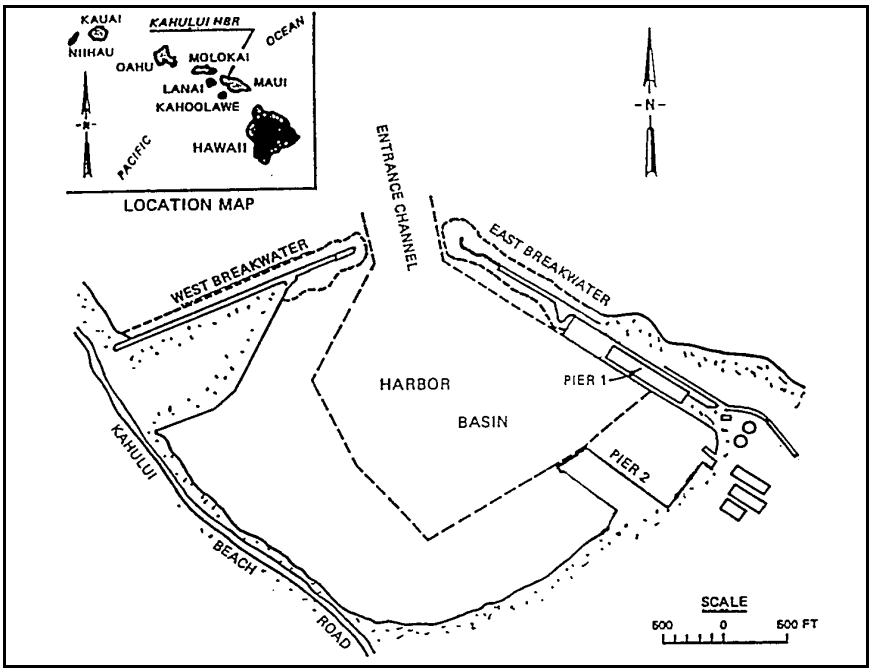

Figure V-5-71. Kahului Harbor, Maui, Hawaii, location map

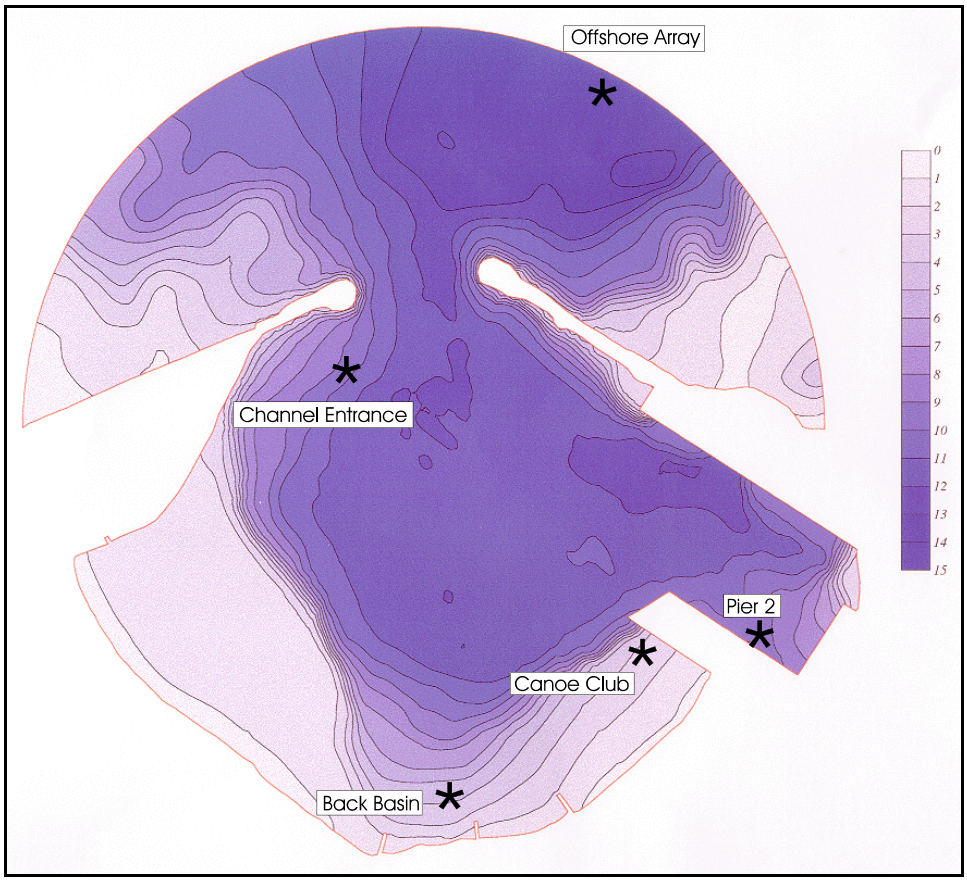

Figure V-5-72. Field gauge locations and bathymetry, Kahului Harbor

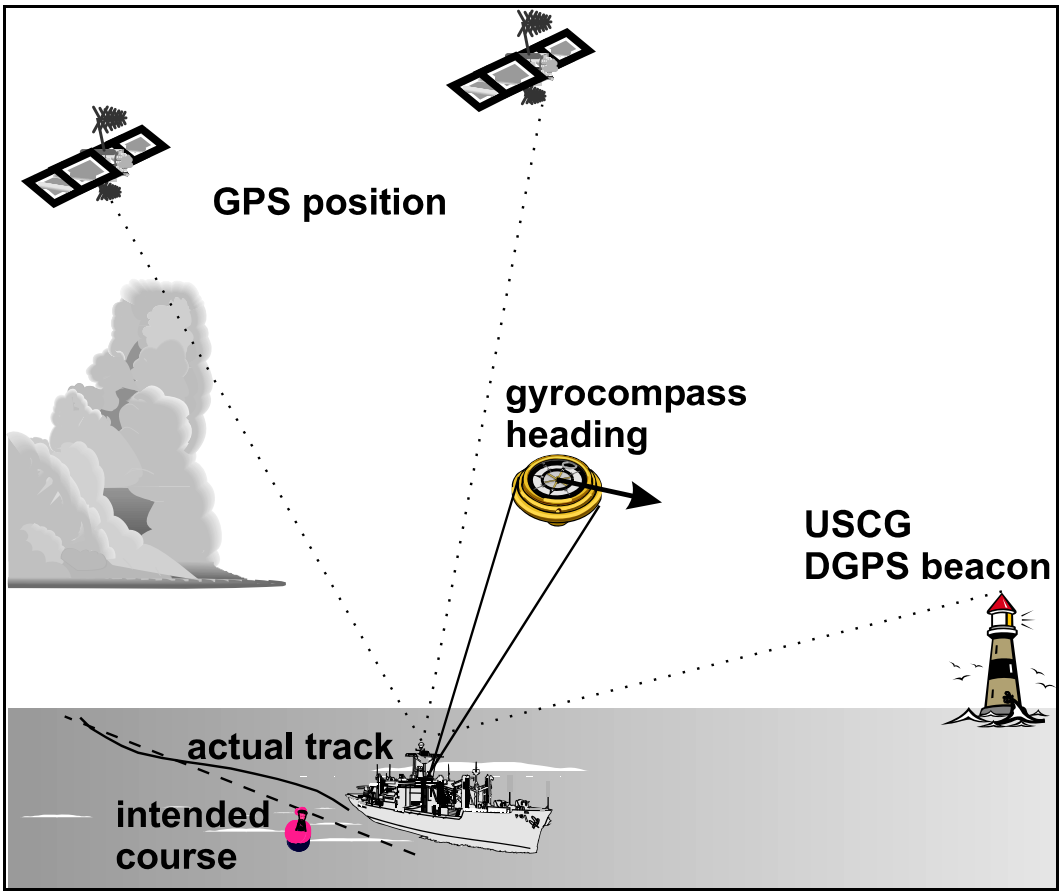

Figure V-5-73. Components of ship track measurements

(b) A dual-frequency DGPS system that measured horizontal and vertical location of ship bow and stern with 1 cm accuracy is described by Webb and Wooley (1998). The data, along with concurrent measurements of current and water level, provided direct calculation of ship squat. The data are useful for evaluating existing navigation conditions, designing modifications, and/or validating ship simulation models to study proposed conditions.

V-5-12. Definitions of Symbols

α_b	Breaking wave angle [deg]
A_C	Channel cross-section area [length^2]
B	Vessel beam at midships [length]
C_B	Block coefficient (Figure V-5-4) [dimensionless]
F_h	Channel depth Froude number [dimensionless]
F_L	Schijf limiting Froude number (Equation V-5-7) [dimensionless]
g	Gravitational acceleration [length/time^2]
h	Depth of channel [length]
h_1, h_2	Overbank depths [length]
L	Ship length [length]
N_B	Number of boats using the project
T	Vessel draft [length]
V	Vessel speed [length/time]
V_L	Schijf limiting ship speed in squat analysis [length/time]
W	Width of channel [length]
Z	Maximum ship squat [length]
Z_L	Maximum ship squat at Schijf limiting Froud number (Equation V-5-8) [length]
Z_T	Maximum squat in a trench channel (Equation V-5-9) [length]

Chapter V-6
Sediment Management at Inlets

V-6-1. Introduction

a. Overview. The U.S. Army Corps of Engineers (USACE) has a mission to provide military and civil works engineering to the nation. Congress authorized the navigation part of this mission in 1824, when USACE was directed to remove sandbars and snags from major navigable rivers. Today, USACE's dredging program involves the planning, design, construction, operation, and maintenance of riverine, estuarine, and coastal passages to meet navigation needs. The most dynamic of these waterways are inlets, entrances, and harbors on oceans, bays, and lakefronts, at which wind waves and tides or seiching of water may combine to transport sediment. The foremost navigation goal is to provide safe passage in these channels for vessels of a given design draft at the least cost. In fiscal year (FY) 1999, USACE dredged approximately 360 million cu m from Federal channels. Maintenance dredging accounted for an average of 85 percent of this volume while new work and emergency dredging made up the remainder. The most efficient means of managing sediment that enters these navigable waterways is the subject of this chapter.

b. Definitions.

(1) For convenience, the term "inlets" will be used herein to encompass all these navigation passages. Inlet generally refers to a short, narrow waterway that connects a lagoon or bay with a larger parent body of water (i.e., ocean or lake), and experiences the inflow and outflow of water due to tidal or seiching. Inlets may be stabilized with shore-perpendicular structures at the mouth, called jetties. Waves and currents at an inlet combine to form ebb- and flood-tidal shoals (Figures V-6-1a, b, and c).

(2) An entrance is the opening to a navigation channel (Figure V-6-1d). A harbor refers to any protected body of water that affords a place of safety for vessels (Figure V-6-1e). Well-situated harbors do not experience significant currents due to tides or seiching and therefore do not have notable ebb- or flood-tidal shoals.

(3) The term "sediment" includes all types of minerals or organic materials that have been deposited by water, wind, or ice. Many navigation channels shoal because of the inflow of sand and finer-grained sediments. If this material impedes navigation, it may be dredged to provide safe passage through the inlet. Littoral pertains to a lake, sea, or ocean. As applied herein, the term "littoral material" refers to sediments (sand, silt, clay, gravel, etc.) that are transported by waves and currents along or near the coast. Note that wind-blown, or eolian, sediment may also contribute to shoaling in navigable waterways. Beach-quality sediment generally refers to sand that is of a sufficient size, color, and composition to be placed on the beach or nearshore. Nonbeach-quality materials can be used in other ways to benefit the coastal zone, e.g., creating wetlands and environmental habitat.

c. Background.

(1) The need to create navigable passage is a direct consequence of the dynamic nature of inlets. As an illustration, imagine a new inlet that is breached from the ocean side of a barrier island during a storm. Waves, an elevated ocean water level, and tidal currents scour sediments from the barrier to form the new inlet. The material is carried landward and seaward to form incipient flood- and ebb-tidal shoals. As tidal cycles pass, a channel is incised into the former barrier bed, thereby establishing the inlet as a coastal feature. Sand and other sediments moving alongshore are entrained by inlet ebb and flood currents, and

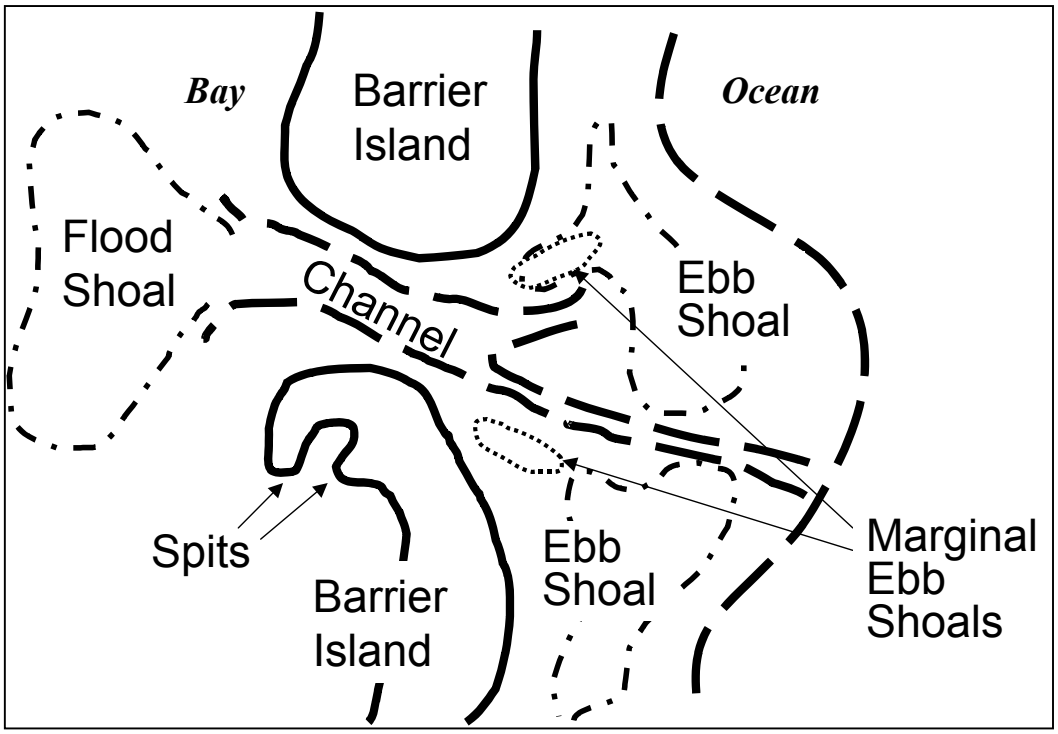

Figure V-6-1a. Conceptual illustration of unstabilized inlet

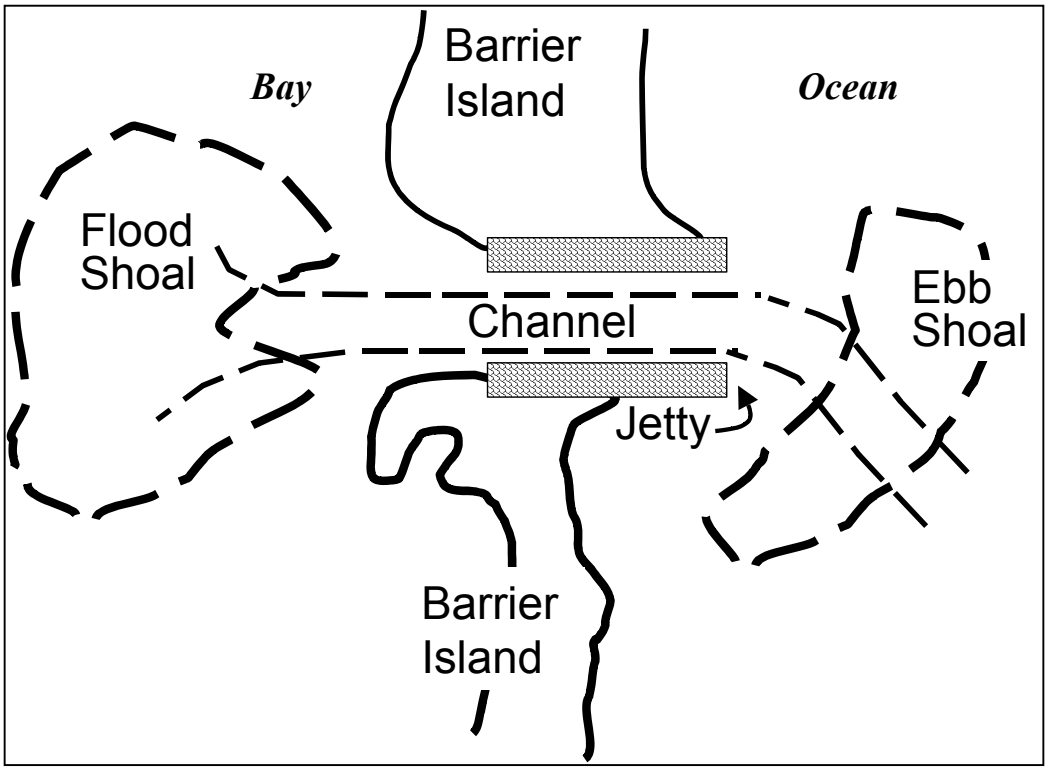

Figure V-6-1b. Conceptual illustration of stabilized inlet

Figure V-6-1c. Example of stabilized inlet: Shinnecock Inlet, Long Island, New York (22 April 1997)

Figure V-6-1d. Example of entrance: Port Canaveral, Forida, (date unknown)

Figure V-6-1e. Example of harbor: Oceanside, California, (12 February 1999, photograph by Eagle Aerial)

may be deposited in the inlet channels. The sediment may remain in the channels or may be jetted to the ebb- and flood-tidal shoals. As the inlet matures, the adjacent beaches may advance and retreat due to the changing waves, currents, and bathymetry in the vicinity of the opening. Volumetrically, the effect of this new inlet is a net loss to the adjacent beach system. Navigability of this new inlet is typically treacherous. Channels may meander and their depths may vary rapidly. Waves may break due to shoaling and due to current-induced wave steepening during ebb flows. Depending on the coastal processes and geologic constrictions, the inlet may migrate alongshore.

(2) The construction of jetties and dredging of channels are navigation controls that seek to promote safe passage through the inlet while minimizing construction and maintenance costs. Jetties stabilize the inlet's location and confine the tidal currents within the channel. In addition, the constricted currents help to clean the channel of shoaled sediment. Dredging improves channel navigability by increasing the depth as required to meet the needs of the design vessel, and straightening channel meanders that make passage through the inlet dangerous. However, the effective removal and disposal of sediment that is removed from the channel and the ebb- and flood-tidal shoals present an ongoing challenge.

(3) The goals of inlet sediment management are multifaceted:

(a) Through design of inlet structures, channels, and other controls (e.g., bypassing plants), to minimize the volume of sediment that accumulates within the navigable waterway.

(b) To remove shoaled sediment and morphologic features that inhibit safety at least cost.

(c) To optimize channel depth such that dredging frequency is reduced while the stability of inlet structures and adjacent beaches are not compromised.

(d) To keep the beach-quality dredged material within the nearshore beach system, effectively bypassing sand around the inlet.

(e) To place beach-quality material within the nearshore system and on adjacent beaches such that it does not cycle back into the inlet.

(f) To assist with other missions of USACE as appropriate, such as using dredged material to enhance environmental habitat, provide flood and storm damage protection, and establish or restore wetlands.

d. Summary. The purpose of this chapter is to discuss engineering works directed towards effective inlet sediment management and review analytical methods that can be applied in the design and evaluation of these projects. Experiences at several sites are reviewed to illustrate approaches to evaluating sediment management problems, the solutions that were implemented, and their performance.

V-6-2. Regional Sediment Management and Coastal Inlet Processes

a. Overview. This section discusses the effects that sediment management activities at inlets have both in the vicinity of the inlet and regionally (on the scale of tens of kilometers along the coast). First, regional sediment management is defined. The relationship between local, inlet-specific activities, and the response of other features within the region is discussed. Next, sediment transport processes at natural and engineered inlets are reviewed, with reference to material contained in Parts II-6 and IV-3.

b. Regional sediment management.

(1) Overview. Regional sediment management refers to the use of littoral, estuarine, and riverine sediment resources in an environmentally beneficial and economical manner. Regional sediment management strives to maintain or enhance the natural exchange of sediment within the boundaries of the physical system. A region may include a variety of geologic features, uplands, beaches, inlets, rivers, estuaries, and bays, and is defined by the sediment transport paths within this physical system (Figure V-6-2). Implementation of regional sediment management recognizes that the physical system and embedded ecosystems are modified and may respond to natural forcing and engineering activities beyond the formal dimensions and time frames of individual projects.

(a) USACE has a central role in the implementation of regional sediment management. The mission areas of USACE include navigation, environmental restoration, storm-damage reduction, and flood reduction. In particular, the mission area ensuring the navigability of our nation's waterways involves removing, transporting, and placing sediment. Some of this material can be used to achieve goals in other mission areas. As opposed to individual homeowners, county and state governments, and other Federal agencies, USACE's role spans both political and geographic boundaries. Although the term "regional sediment management" is new, recognition of the regional nature of coastal processes and the regional

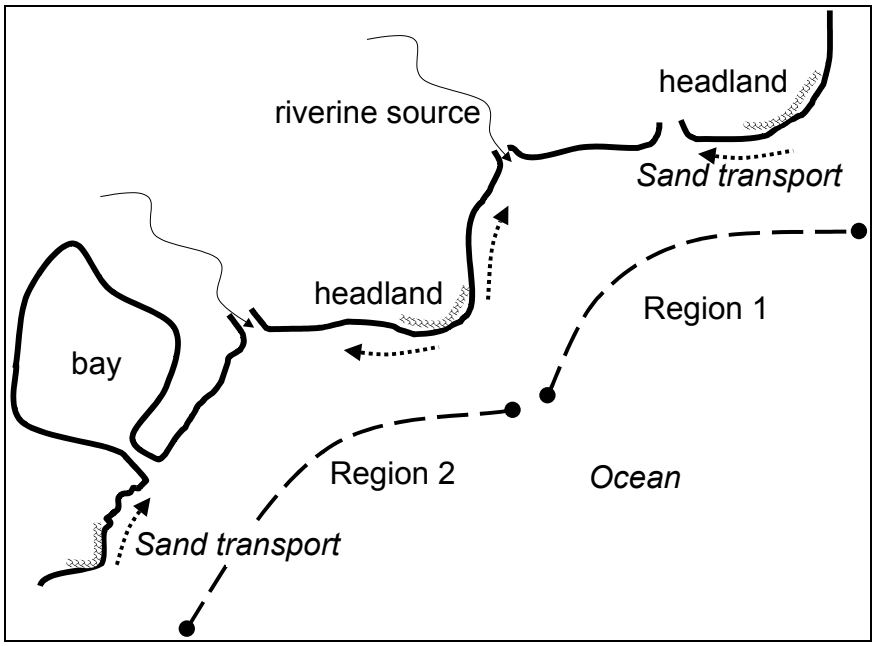

Figure V-6-2. Conceptual illustration of regions

influence of engineering works is not. The interrelationship between coastal navigation projects and contiguous beaches became a Federal interest at least as early as the 1930s (Brooke 1934). The first sand bypassing systems at navigation projects, designed to reinstate net longshore sand transport to downdrift beaches, were put into operation in the mid-1930s at Santa Barbara, California (mobile plant) (Penfield 1960) and South Lake Worth Inlet, Florida (fixed plant) (Caldwell 1951).

(b) Today, USACE is pursuing regional sediment management by collaborating with local and state governments to manage sediments over regions encompassing multiple projects. Schmidt and Schwichtenberg (2000) describe the Jacksonville District's application of regional sediment management principles for proposed improvements to Port Everglades, a deep-draft port on the east coast of Florida. These improvements include widening and deepening existing channels and turning basins, and creating a new turning basin to accommodate larger container ships. Federal shore protection projects along the adjacent three counties will require almost 59 million cu m of beach-quality sand. The District is working with county and state agencies to satisfy the navigational goals at Port Everglades while using the dredged sediments to nourish the adjacent beaches and restore environmental habitat. It is envisioned that beach-quality dredged material can be identified prior to dredging and placed directly on the beach. For mixed sediments, a temporary deposition site on an adjacent beach has been considered. After the dredged slurry has been deposited on the beach, hydrocyclones could separate fine sediments from beach quality sand. The beach-quality sand would be trucked to adjacent beaches, and the silt could be placed and vegetated to build natural berms and dunes.

(2) Critical role of inlets. Inlets are significant elements in controlling sediment movement and its distribution within local and regional domains. They may serve as a source if they funnel riverine, estuarine, and bay sediments to the open coastline. They may also act as a sink by diverting littoral material into the inlet and its bay, harbor, and estuaries. In a manner analogous to water flow through a tidal inlet (see Part II- 6), littoral material may be transported into the inlet on the flood (rising) tide and out of the inlet on the ebb (falling) tide. Flood or ebb dominance of water flow through an inlet, however, does not necessarily determine the net sediment transport direction through the inlet (Stauble et al. 1988; see also Part IV-3-4, or along the adjacent beaches. An inlet in a state of "dynamic equilibrium" indicates

that there is a net long-term (years to decades and longer) balance between water flow through the inlet and sediment transport to and from the inlet. The net, long-term effect is a hydrodynamic field that is sufficient to maintain flow through the inlet and maintain an approximate balance of sediment volume on the beaches to either side of the inlet. In the short term (days to years), cyclical events such as seasonal changes in waves and currents or storms may temporarily disturb the balance. Therefore, although an inlet may be in a state of dynamic equilibrium, it may require dredging to maintain navigability. Inlets that are not in a state of dynamic equilibrium include those that: migrate alongshore, are closing because of shoaling of the channels (either from an upland or ocean source of sediment), and are widening or scouring due to an increasing tidal prism or unstable geologic substrate. For an inlet to remain open, sediment entering the inlet must be diverted from the inlet's principal channels, or the channels must move. If sediment is not bypassed across the inlet, it must be transported by waves or currents away from the inlet throat and into interior shoals, exterior shoals, or beach impoundments; or, it must be removed by dredging. The following section describes hydrodynamic and sediment transport processes at inlets.

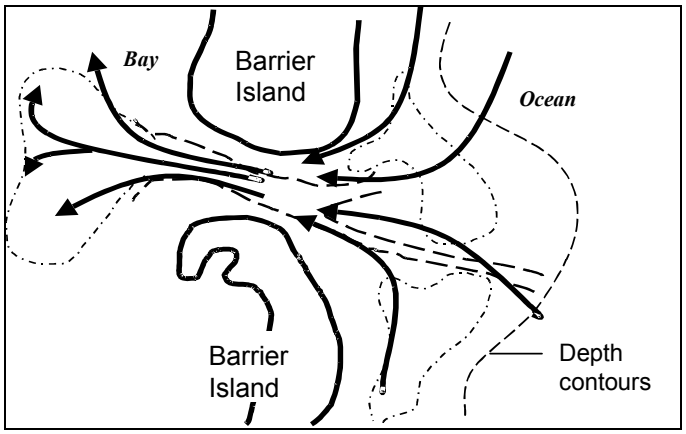
(3) Coastal inlet processes.

(a) Inlet features. The following is an overview of principal inlet flow fields and sedimentary features. Parts II-6-1 and IV-3-4 present more detailed descriptions of inlet hydrodynamics and sediment transport/morphology.

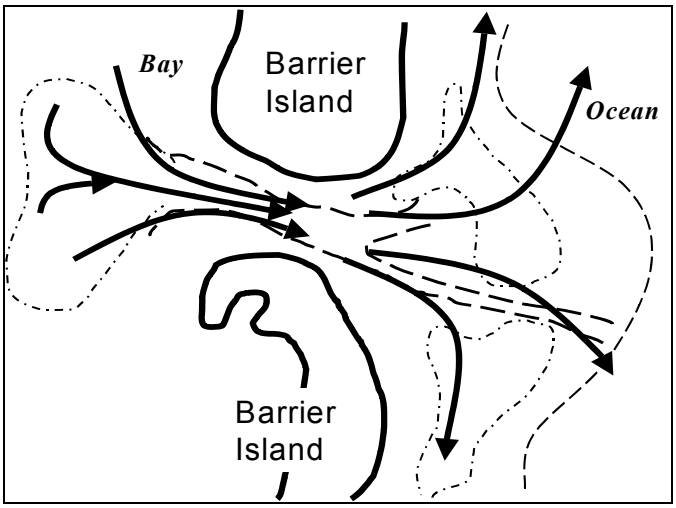
Typical elements of nonstabilized and stabilized tidal inlets are illustrated in Figures V-6-1a and b, respectively. An inlet connects a larger, open-water body (the ocean, sea, lake, etc.) with a generally smaller, protected water body (a bay, lagoon, estuary, or river) through a land body such as a barrier spit. The inlet technically includes the entire seabed between the banks of the adjacent barrier shores, measured from the seaward edge of the ebb shoal to the landward edge of the flood shoal (discussed in the following paragraph). The inlet throat is the region with the smallest cross-sectional flow area and highest velocities. The channel (geologically known as a gorge or thalweg) defines the deepest parts of the inlet. There may be several channels in a natural inlet, which may migrate, vanish, or alternate in dominance. The navigable channel is the one that is deepest at a given time or is maintained for navigation by dredging.

A tidal inlet (also known as a lagoonal inlet) connects a tidal water body with the bay, and features significant flow directed both into and out of the inlet throat as a function of water level fluctuations in the ocean and bay. (Riverine mouths or fluvial inlets are dominated by river discharge and minimally affected by flood tide flow). During flood tide, currents are funneled toward the inlet mouth from the ocean (Figures V-6-3a and V-6-4a). In the absence of high, impermeable jetties (Figure V-6-3a), the flood flow is typically most dominant along the ocean shorelines of the adjacent barrier islands, sometimes creating and/or following marginal flood channels. The flood flow converges and accelerates in the throat. Upon its discharge, the flood flow diverges and decelerates beyond the inlet's bayside mouth, depositing sediment in a flood shoal. The flow reverses during ebb current, although rarely symmetrically (Figures V-6-3b and V-6-4b). The ebb flow sweeps sediment from the flood shoal and inlet channels and carries it through the inlet throat. The ebb flow discharges from the inlet's ocean mouth similarly to a free jet, depositing its sediment load in an ebb shoal. The ebb shoal may protrude significantly into the deeper ocean, forming the ebb shoal plateau or terminal lobe.

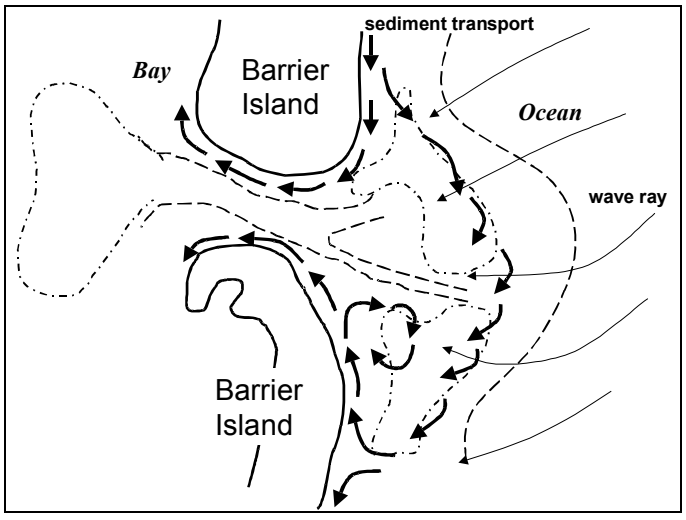
The coast in the direction from which the majority of offshore wave energy arrives is termed the updrift shoreline (top barrier island in Figures V-6-3c and V-6-4c). The opposite coast is the



(a) Flood flow

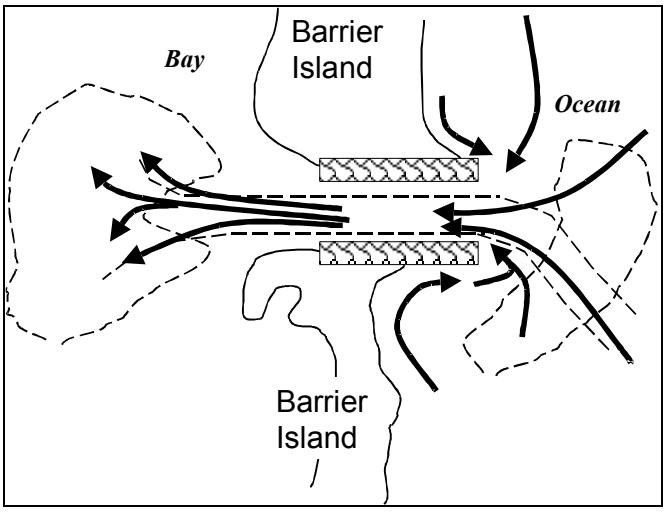


(b) Ebb flow

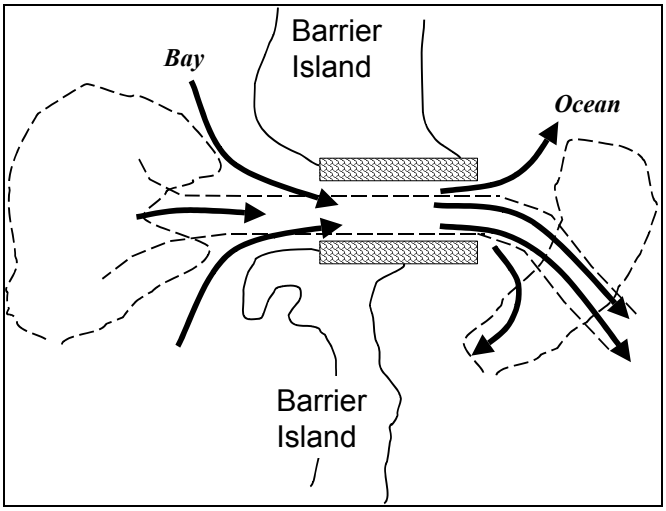


(c) Waves

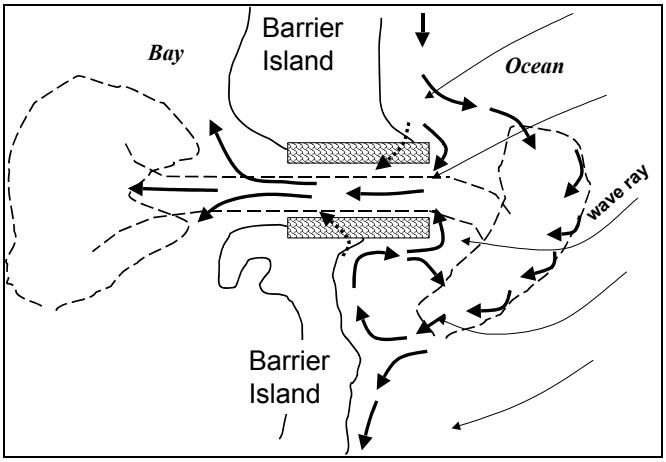
Figure V-6-3. Idealized sediment transport pathways for unstabilized inlet



(a) Flood flow



(b) Ebb flow



(c) Waves

Figure V-6-4. Idealized sediment transport pathways for stabilized inlet

downdrift shoreline. Along the updrift shoreline, obliquely incident waves transport sediment alongshore and directed toward the inlet. Across the inlet mouth, the waves breaking upon the ebb shoal transport sediment both toward (into) the inlet and toward the downdrift shoreline. The ebb shoal may, in turn, be skewed toward or elongated beyond the downdrift shoreline. Downdrift of the inlet (a distance of anywhere between one-half and 10 km), wave refraction across the ebb plateau decreases the obliquity of the wave's angle and the associated magnitude of the downdrift-directed transport. Closest to the inlet, transport along the shoreline (leeward of the ebb shoal) may even be reversed, so that transport is directed toward the inlet from the downdrift shoreline. This transport is augmented by diffraction currents (resulting from decreased wave energy and water level setup) directed toward the inlet along the immediate downdrift shoreline. The sediment transported toward the inlet from the downdrift shore may be carried into the inlet and/or diverted toward the ebb shoal by gyres or eddies (circular currents) associated with the inlet's tidal currents. If the jetties are not sand-tight, sediment may be transported over or through these structures (dotted lines in Figure V-6-4c).

As illustrated in Figure V-6-5a, inlets where longshore currents dominate are more likely to form an ebb shoal with a shallow, arcuate form across the mouth. If tidal currents dominate littoral transport processes (Figure V-6-5b), marginal ebb shoals (also known as linear bars) are likely, aligned with and bordering the inlet channels. Mixtures of both types of shoals are not uncommon. These characteristics are typically observed at unstabilized inlets.

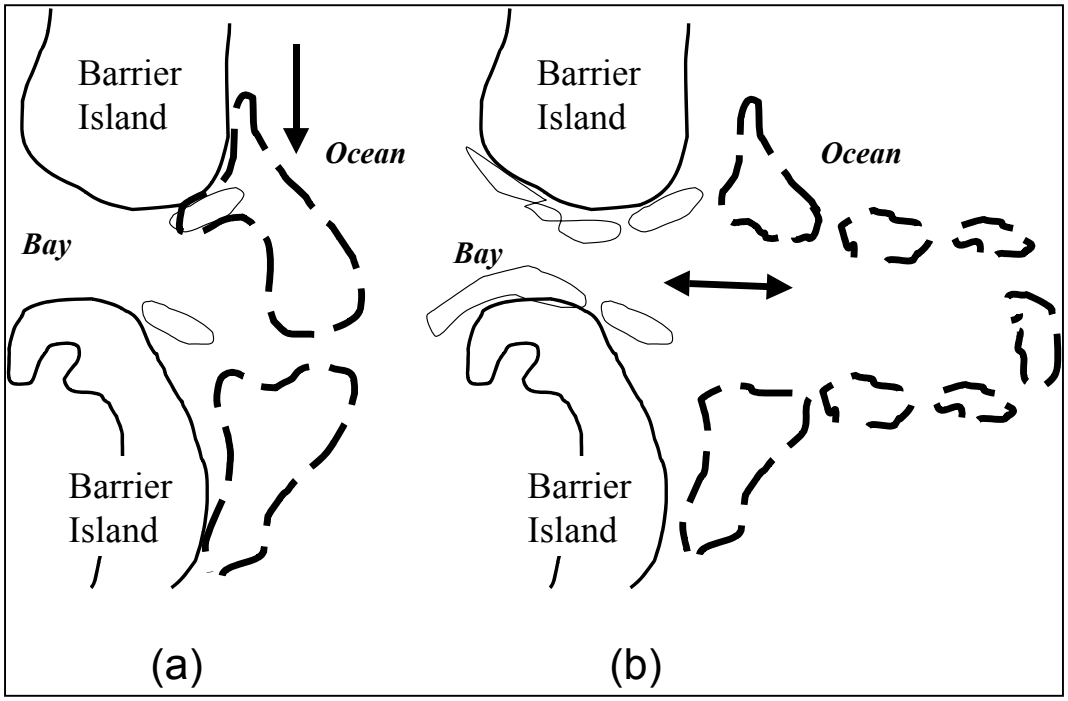


Figure V-6-5. Unstabilized tidal inlets for which (a) longshore current effects dominate, and (b) tidal current effects dominate (adapted from Oertel 1988)

Other sedimentary features include interior spits and channel shoals (see Figure V-6-1a). Spits are emergent landforms that result from the deposition of littoral drift from the adjacent shores. Channel shoals are submerged deposits that encroach upon or cover parts of the inlet seafloor. Spits and channel shoals are usually attached to the barrier island at, or just landward of, the point at which the transport spills from the shoreline into the inlet.

Processes other than just tidal-induced currents and waves can heavily influence inlet dynamics and morphology. These include wind, salinity differences between the ocean and bay waters, wave-current interactions, river discharge, underlying geology, and inlet orientation. These concepts are outlined in Parts II-6 and IV-3.

(b) Bypassing processes. Sediment may be trapped at an inlet or it may also be bypassed by a variety of natural forces. Bruun and Gerritsen (1959) described three principal mechanisms of bypassing for unstabilized inlets: Wave-induced transport along the ebb tidal shoal (bypass bar). Transport into and out of the inlet by tidal currents. Migration and welding of sandbars.

Figure V-6-6 illustrates wave-induced transport along the ebb tidal shoal (termed, in this case, a bypassing bar). Waves transport sand (littoral drift) from the updrift shoreline toward the inlet. Some of the sand is transported (ramped) directly to the ebb shoal (or bar). This sand is temporarily or permanently stored in the shoal, or is transported downdrift by waves. Once outside the principal influence of the inlet's ebb flow, waves transport the sand both landward and further downdrift, where it can rejoin the downdrift shoreline and littoral stream.

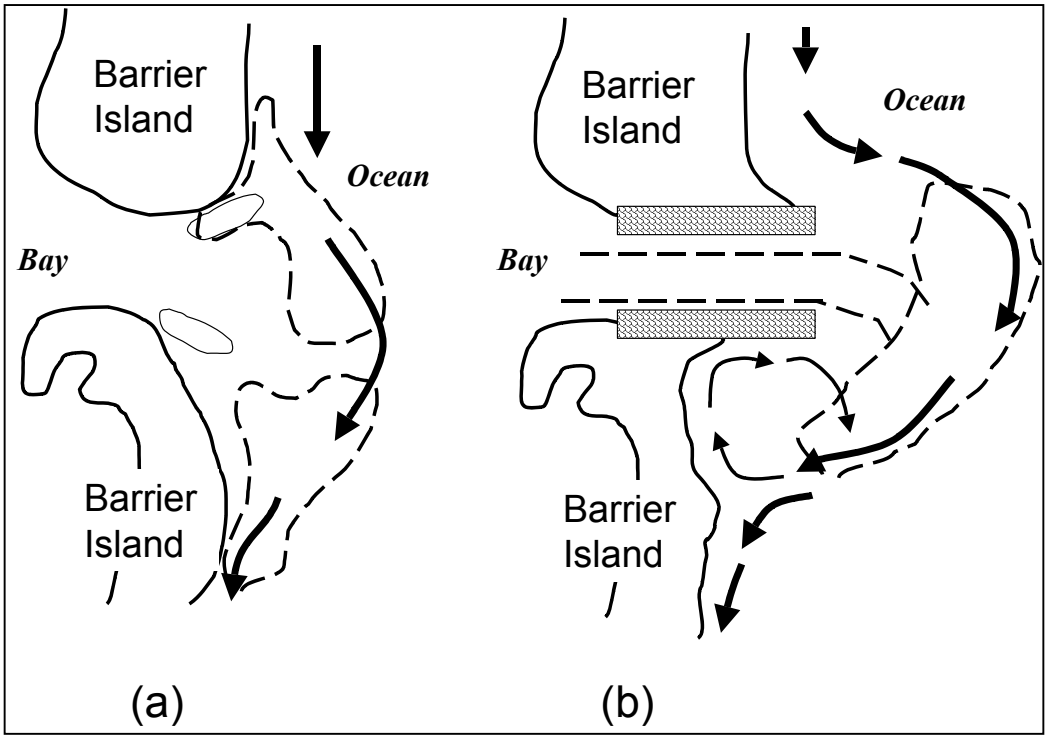

Figure V-6-6. Idealized wave-induced bypassing along the ebb tidal shoal ("bypass bar") for (a) unstabilized and (b) stabilized inlets

Figure V-6-7 illustrates idealized wave and current bypassing. A portion of the littoral drift from the updrift shore may be transported toward the inlet mouth. There, it may be temporarily or permanently stored as part of the updrift beach, creating a bulbous shoreline shape or a shallow plateau at the shoreline's toe, or it may be impounded at the updrift jetty. Or, waves and marginal flood currents may transport the sediment directly into the inlet. Flood currents sweep sand bayward from the inlet's ebb shoals, channels, and interior shoals, and deposit the sand on the flood shoal and along shoals and spits which line the inlet's interior shoreline. Ebb currents, in turn, sweep sand seaward from the flood shoal (and the channels and interior shoals) and deposit it in the ebb shoal. There, the sand may be again swept bayward by flood currents and returned by ebb currents, or may be transported along the ebb shoal by waves, where it can eventually rejoin the downdrift shoreline as previously described.

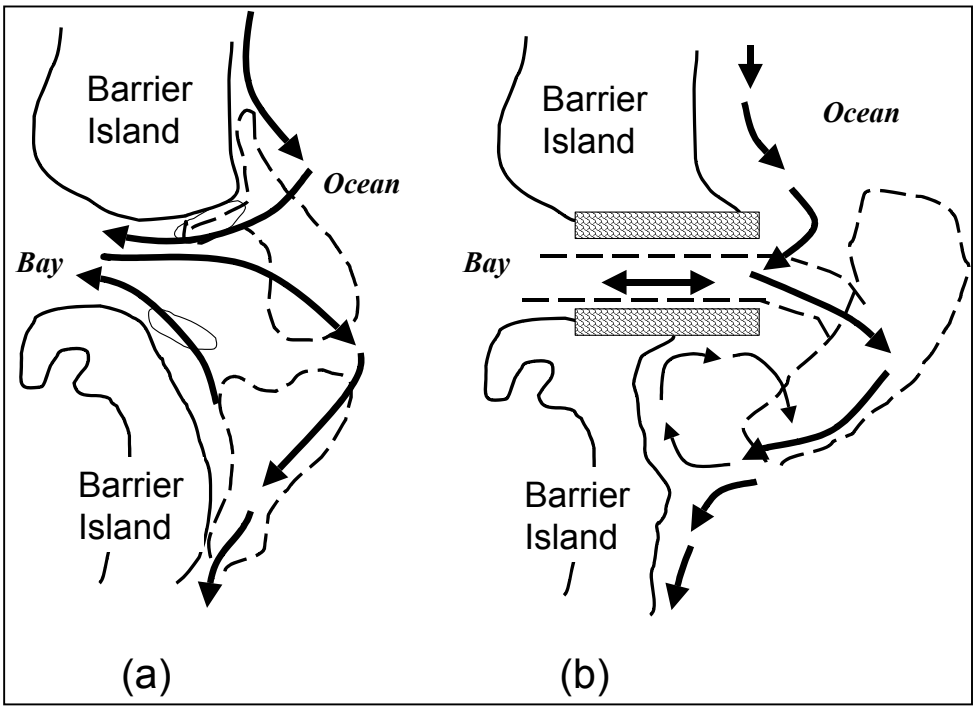

Figure V-6-7. Idealized wave and tidal current bypassing for (a) unstabilized and (b) stabilized inlets

Sand can also be bypassed directly across the ebb shoal in a zig-zag pattern by the combined action of waves and tidal currents. During transport reversals (when the waves approach from the opposite direction), the bypassing pattern can reverse; however, the methods and efficiency of the bypassing are rarely identical, particularly if the inlet and ebb shoal morphology is not symmetrical about the inlet center line. (Lack of symmetry is frequently encountered when one direction of transport dominates). These bypassing mechanisms are generally considered to be a more-or-less steady process, modulated in intensity by periods of increased littoral transport (storms, high waves, etc.).

In Figure V-6-8, increasing numbers indicate the time sequence of bypassing through migration and welding of bars. This process may occur to some degree at stabilized inlets, but it is more common for unstabilized inlets. Waves again transport sand from the updrift shore toward the inlet. Large shoals then form at the edge of the shoreline and the inlet, and/or a spit may develop

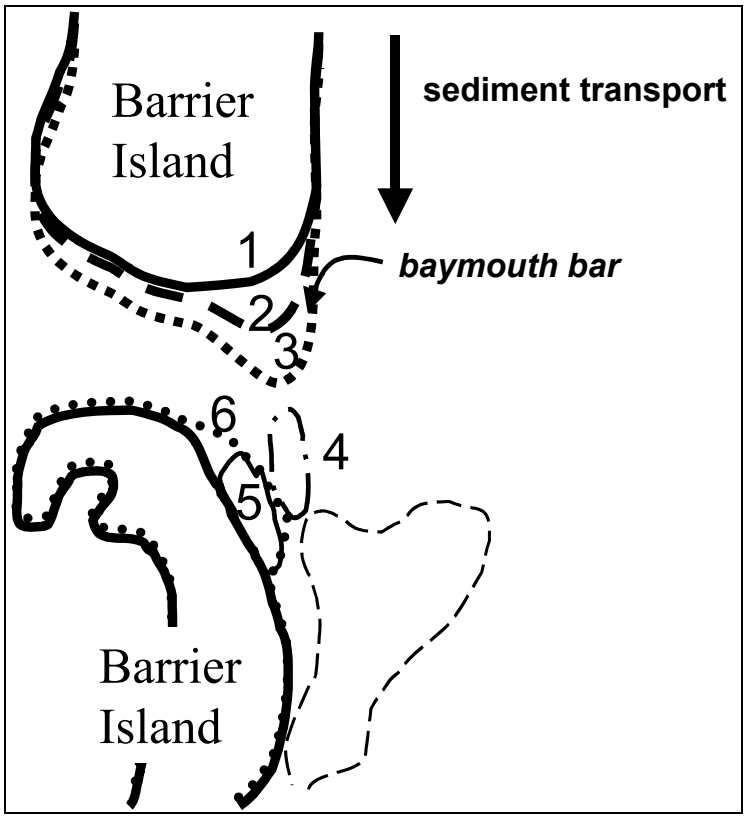

Figure V-6-8. Idealized bypassing through migration and welding of bars for an unstabilized inlet (increasing numbers indicate time sequence)

across the inlet throat (a baymouth bar). Growth of the shoals and spit force the inlet channel to, migrate downdrift. This, in turn leads to channel encroachment upon the downdrift shoreline and conesquent beach erosion. Eventually, the channel's hydraulic efficiency becomes sufficiently poor such that the inlet will close, or the channel will breach the shoals or spit (usually during a storm or flood) near the channel's original location. The shoals or spit, now severed from their direct updrift sediment source, become subject to downdrift-directed transport by waves. These sand bodies, thus, migrate downdrift and shoreward where they eventually weld onto the downdrift shoreline, nourishing the beach which was previously eroded by the inlet channel's earlier migration.

In this way, sand can be naturally bypassed in a cyclical manner, by which the updrift and downdrift shorelines retreat and advance in periodic cycles. The channel shoals and spits are the means of the bypassing mechanism. Their creation, severance, and downdrift attachment can be gradual (quasisteady) or episodic. Time scales of the cycle may range anywhere from 3 to 50 years (FitzGerald 1984, 1988; Fenster and Dolan 1996; Gaudiano and Kana 2001).

In a variation of this pattern for unstabilized inlets (not shown in Figures V-6-6 through V-6-8), waves transport sand from both adjacent shorelines toward the inlet mouth. Strong ebb and flood currents transport the sand into and out of the mouth. The sand is deposited in the ebb tidal plateau as well as large marginal ebb shoals that line the inlet channel. The emerging marginal shoals are ultimately subject to the landward-directed transport of wave action, and eventually migrate toward shore and weld to the beach. The result is a pattern of erosion and deposition along barrier islands marked by the formation of large intertidal bars along the inlet channel, and

apparently little (or at least, uncertain) net sediment bypassing. FitzGerald (1984) and Gaudiano and Kana (2001) described this process as controlling South Carolina's barrier island/inlet shorelines, noting cycles of ebb-tide delta growth and decay (15 to 20 percent changes in volume) which last from 4 to 8 years. Further elaboration of these processes is presented by FitzGerald (1988) and in Part IV-3 and Part IV-4.

Inlets, particularly unstabilized ones, can bypass sand through a combination of the bypassing mechanisms. As part of the bypassing process, unstabilized inlets may migrate, usually in the net downdrift direction, but they can also migrate updrift (see Aubrey and Speer (1984) and Douglass (1991), among others).

Inlets' natural bypassing processes also serve to illustrate the dynamic nature of the shorelines adjacent to an inlet. Roughly, the scale of the bypassing features (and therefore of the directly affected shoreline lengths) can range from 1/2 km updrift and 1-2 km downdrift for a small inlet (for example, 200 m wide), to several kilometers updrift and tens of kilometers downdrift for a large inlet (for example, >1,000 m wide) (The alongshore extent of inlets' influence is discussed in Part V-6) Beach erosion is often manifest if upland development is sited within an inlet's zone of migration or cyclical accretion/erosion associated with natural bypassing and ebb delta fluctuation. This inopportune timing of oceanfront development refers to the platting of land or establishment of construction setback lines, along the oceanfront or the inlet's interior shorefront, at times when the shoreline is at an anomalously advanced location associated with the inlet's cycle.

c. Inlet operation and maintenance activities. To maintain navigable waterways, USACE as well as state and local agencies construct jetties and dredged channels. These activities may change inlet processes (see also Part IV-4).

(1) Dredging of shoals or channels within an inlet, whether with or without structural (jetty) improvements, can increase the inlet's potential to act as a sediment sink. Most simply, the response is analogous to the natural tendency for a depression in the seabed to fill with sediment from the surrounding seabed and the active littoral system. If sand dredged from the inlet during the initial work or its subsequent maintenance is not placed upon the adjacent beaches or otherwise within the active littoral system, then the net long-term effect is expected to be erosion of the adjacent beach on one or both sides of the inlet.

(a) Inlet dredging may also increase the inlet's flow velocities or its tidal prism (the volume of water that flows into or out of the inlet in one-half tide cycle). (See Part II-6.) This may result in enlargement of the inlet shoals, and seaward displacement of the ebb shoal. Enlargement of shoals will remove sediment from the open coast to the inlet channels and on to the flood and ebb shoals. Seaward displacement of the ebb shoal is expected to reduce bypassing capacity of the inlet.

(b) An example of this effect is the 1892 creation of St. Lucie Inlet, Florida, by local residents, who, desiring a convenient channel between Indian River and the Atlantic Ocean, dredged through the sandy barrier island (Sargent 1988). Beach sand was rapidly diverted from the adjacent shores to form large ebb and flood tidal shoals. Within 37 years after the initial cut, the updrift shoreline (Hutchinson Island to the north) retreated up to 540 m from its preinlet location, and the downdrift beach (Jupiter Island) retreated over 650 m (USAED, Jacksonville, 1973). The construction of a 1,010 m-long north jetty in 1929 partially restored the north shoreline's location over the next 30 years by impounding littoral drift, but not before millions of cubic meters of sand had been (mostly irretrievably) diverted from the littoral system (Olsen Associates, Inc. 1995). A 490-m jetty was constructed at the south side in 1980, but does not nearly extend to that shoreline's preinlet location.

(2) Dredging a channel through the ebb tidal platform can also change bypassing mechanisms via the ebb shoal. Initially, portions of the shoal adjacent to the channel are subject to shoreward-directed transport by waves and can simultaneously be deflated by wave- and current-induced erosion. These portions of the shoal may migrate landward and weld to the up- or downdrift shore, resulting in significant accretion of the beach. The welded shoal and its seaward plateau, severed from its bypassing-related sand source, eventually erode and cause the beach to recede from its artificially advanced position. An example of this process may include Bald Head Island, North Carolina, located directly east of the Cape Fear River entrance. The initial stabilization and deepening of the Cape Fear River entrance channel beginning in the 1870s, by dredging, is thought to have severed the inlet's large outer bypassing plateau. The eastern lobe of the ebb shoal (totaling about 4.6 million cu m) migrated shoreward and resulted in a 370- to 600-m advance of the Bald Head Island shoreline directly east of the inlet between 1890 and 1920. The shoreline position then remained relatively stable for about 50 years. At the same time, however, the submerged toe of the severed shoal, which had welded to the shoreline, steadily eroded. Resort and residential development along the accreted, quasi-stable shoreline began in the early 1970s. But by 1974, the shoreline began to rapidly erode toward its earlier location, receding at an average rate of 20 to 30 m/year (Cleary and Hosier 1988; Olsen Associates, Inc. 1989; Jarrett 1990). Similar examples of deflation and landward migration of severed ebb tidal deltas are described for inlet improvement projects at Murrell's Inlet, South Carolina, and Little River Inlet on the North Carolina/ South Carolina border (Douglass 1987; Hansen and Knowles 1988; Chasten 1992).

(3) Structural stabilization of an inlet channel by jetties can have numerous consequences to the sediment-sharing system and adjacent shorelines. Sand-tight jetties may perform much like groins and impound littoral material. Sand may accrete the beach on the updrift shore and, during reversals in longshore transport direction, to a lesser degree on the downdrift beach. If the ebb shoal connects to the beach, construction of the jetty may extend through the bypassing platform, thereby interrupting this bypassing mechanism. Or, jetties may block the formation of bypassing spits and shoals that would otherwise cyclically grow from the updrift shoreline and migrate to the downdrift shoreline.

(a) Jetties can also transport littoral material seaward via offshore-directed (rip) currents that can develop along their updrift face. In some cases, the diverted sand may deposit in the ebb shoal, and it may or may not ever return to the downdrift beach through natural mechanisms.

(b) Jetties displace an ebb shoal seaward as a function of their length and the degree to which they increase the inlet's tidal prism and velocity. For example, the construction of the 3.2-km-long jetties at St. Mary's entrance in the late 1800s is estimated to have caused the net deposition of 92 million cu m of sand across an ebb tidal platform. This platform has been displaced about 4,000 m seaward of the original shoal (Olsen 1977; USAEWES 1995).

(c) Weir jetties, or structures that are low or porous, may increase the degree to which sand is diverted from the adjacent shores. Weir jetties constrict flood currents toward the shoreline, increasing the flow velocity and sediment transport directed into the inlet (Figure V-6-9). The subsequent ebb flow is minimally reduced by the weir's presence and transports the sediment seaward beyond the limit of the weir and jetty structure. (This process can be minimized if the sand falls into a sediment trap and is regularly bypassed by mechanical means to the adjacent shores.) Similarly, low or porous jetties allow flood flow to transport sediment into the inlet from the adjacent seabed, but then act to transport the sediment further seaward during ebb flow by their jetting action upon the ebb current. Dean (1988) has described the latter phenomenon at St. Mary's entrance.

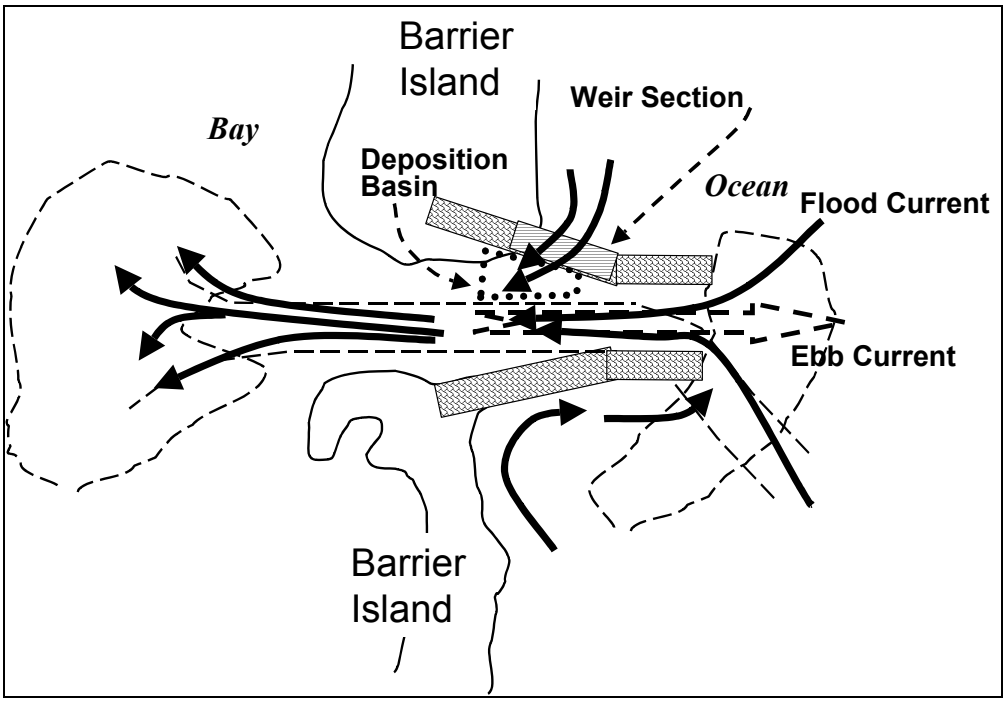

Figure V-6-9. Flood and ebb tidal flow in a weir jetty system

(d) Jetties also influence the littoral transport pattern along adjacent shorelines by developing shadow zones in which the refracted wave field is modified (see Figure V-6-4c). On the downdrift side of a jetty (or in the downdrift lee of an ebb shoal modified by the jetty's presence), sand transport is generally directed into the shadow (i.e., toward the jetty) from the adjacent shoreline by:

Refraction and diffraction of waves about the structure's seaward end.

Diffraction currents associated with a decrease in wave energy within the shadow zone.

The processes can cause a leeward impoundment fillet against the jetty.

d. Inlet modifications of longshore transport.

(1) As discussed in Part III-2, coastal engineering analyses often involve two types of longshore transport rates. (Note that the discussion herein defines rates as positive quantities; the presentation in Part III-2-2(a) applies an alternate definition.) The net longshore transport rate is defined as the difference between the right-directed and left-directed longshore transport over a specified time interval for a seaward-facing observer:

$$Q_{net} = Q_R - Q_L \tag{V-6-1}$$

where the leftward-directed transport rate Q_L and rightward-directed rate Q_R are taken as positive.

(2) The gross longshore transport rate is defined as the sum of the right-directed and left-directed transport rates over a specified time interval for a seaward-facing observer:

$$Q_{gross} = Q_R + Q_L \quad \text{(V-6-2)}$$

Inlets can trap longshore sediment transport from both directions, resulting in a greater amount of transport interruption than simply the net transport rate. That is, inlets are a potential sink to the gross longshore sediment transport in the region. Additionally, tidal currents, ebb-shoal bathymetry, and shoreline morphology can each increase the gross transport directed toward the inlet, increasing the inlet's diversion of littoral drift from the adjacent system. Examples are described in the following paragraphs.

(3) Figure V-6-10(a) depicts a fully-bypassing, equilibrated inlet in which 100 units and 40 units of longshore transport, respectively, are directed toward the inlet from the updrift and downdrift coastlines. The net and gross transport quantities are thus 60 units and 140 units, respectively. As the inlet is assumed to be fully bypassing, there is no net change to the adjacent shorelines.

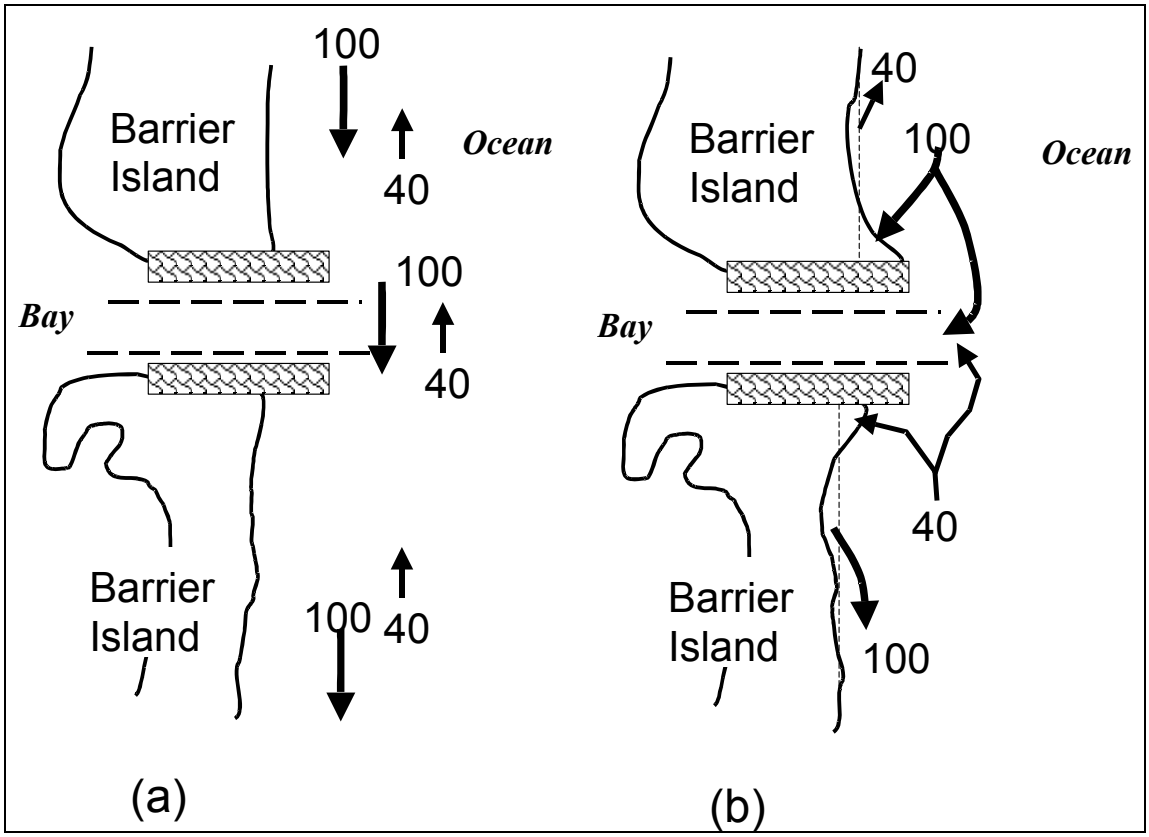

Figure V-6-10. Example of inlet-adjacent shore erosion associated with (a) a fully-bypassing inlet, and (b) an inlet that is a complete littoral sink

(4) Figure V-6-10(b) depicts an inlet which is a complete littoral sink under the same transport conditions as previously described. An inlet may be a complete littoral sink immediately after formation; as it matures, bypassing via the shoal system increases. In Figure V-6-10(b), the incident, updrift transport (100 units) is assumed to be diverted to an updrift impoundment fillet, the inlet channel, and/or shoals. The downdrift shoreline, beyond the jetty's wave shadow and deprived of the 100 units of incident transport, must yield 100 units of beach material in response to the longshore transport potential. During transport reversals, the incident transport (40 units) is likewise assumed to be diverted to a minor impoundment fillet on the other side of the inlet, the

inlet channel, and shoals. If the updrift impoundment fillet is wholly located in the jetty shadow of the reversal waves, or otherwise removed from the littoral stream by refraction effects, then the updrift shoreline, beyond the shadow, must yield 40 units of beach material in response to the longshore transport potential. If impoundment fillets form, the inlet will not shoal and the net effect is the same as the net longshore transport rate: 60 units of accretion (updrift) and erosion (downdrift). However, if no impoundment fillets form, or if the impoundments are already at capacity, the inlet channel and/or shoals may capture the gross transport (140 units), with 40 units of erosion (updrift) and 100 units of erosion (downdrift).

(5) In Figure V-6-10(b), the potential for net updrift erosion associated with the inlet is counterintuitive. Its ultimate manifestation depends upon the degree to which the updrift impoundment fillet is capable of yielding sand to the adjacent shore during transport reversals. In the limit, when there is no impoundment at the updrift jetty and when all of the updrift transport directed toward the inlet is lost therein (and there is no bypassing from the downdrift shoreline), the potential for updrift inlet-related erosion is totally realized.

(6) Wave refraction across the ebb shoal plateau may locally increase the rate of longshore transport directed toward the inlet mouth. Inlet-directed transport may likewise be induced from diffraction currents that result from gradients in breaking wave energy within the wave-shadow of the ebb shoal plateau. Additionally, a shoreline that is curved toward the inlet's mouth, such as that which results from local beach erosion, further exaggerates the local rate of inlet-directed longshore transport. The latter is a result of the increased angle with which waves break along the shoreline. Each of these phenomena can potentially increase the rate at which sand is transported toward the inlet and mouth.

(7) Figure V-6-11 illustrates potential alteration of the pattern of longshore transport by an ebb shoal. Waves 1.0 m in height and 8 sec in period were refracted from deep water across the bathymetry illustrated in the bottom graphic. The incident wave conditions were: From the left (+23 deg), 40 percent annually; from shore-normal (0 deg), 35 percent annually; from the right (-23 deg), 25 percent annually.

(8) The bathymetry is idealized, but is representative of an inlet for which littoral drift dominates tidal flow and for which the net longshore transport direction is from left to right. The upper graphic depicts the potential longshore transport rate computed from each of the three refracted wave cases. The middle graphic depicts the total right-directed, left-directed, and net transport rates that result from the weighted superposition of the individual transport curves. The component transport rates (upper graphic) are normalized by the maximum transport value among the three cases. In the middle graphic, the transport values are normalized by the maximum value of the net transport rate. Only the effect of obliquely incident waves is considered, and transport induced by alongshore gradients in wave height (diffraction currents) and tidal currents are omitted. The methods employed to compute these transport rates are described in Part III-2-2, and, later in this chapter.

(9) In this example, waves from each of the three offshore directions result in transport directed toward the inlet mouth within the alongshore reach of the ebb shoal's refractive influence. Within this region (indicated by asterisks in the middle graphic), no transport is directed away from the inlet. Additionally, the transport magnitude increases significantly beyond that of the ambient transport (i.e., the transport associated with obliquely incident waves outside of the shoal's refractive influence). The result is an increase in transport toward the inlet mouth – with

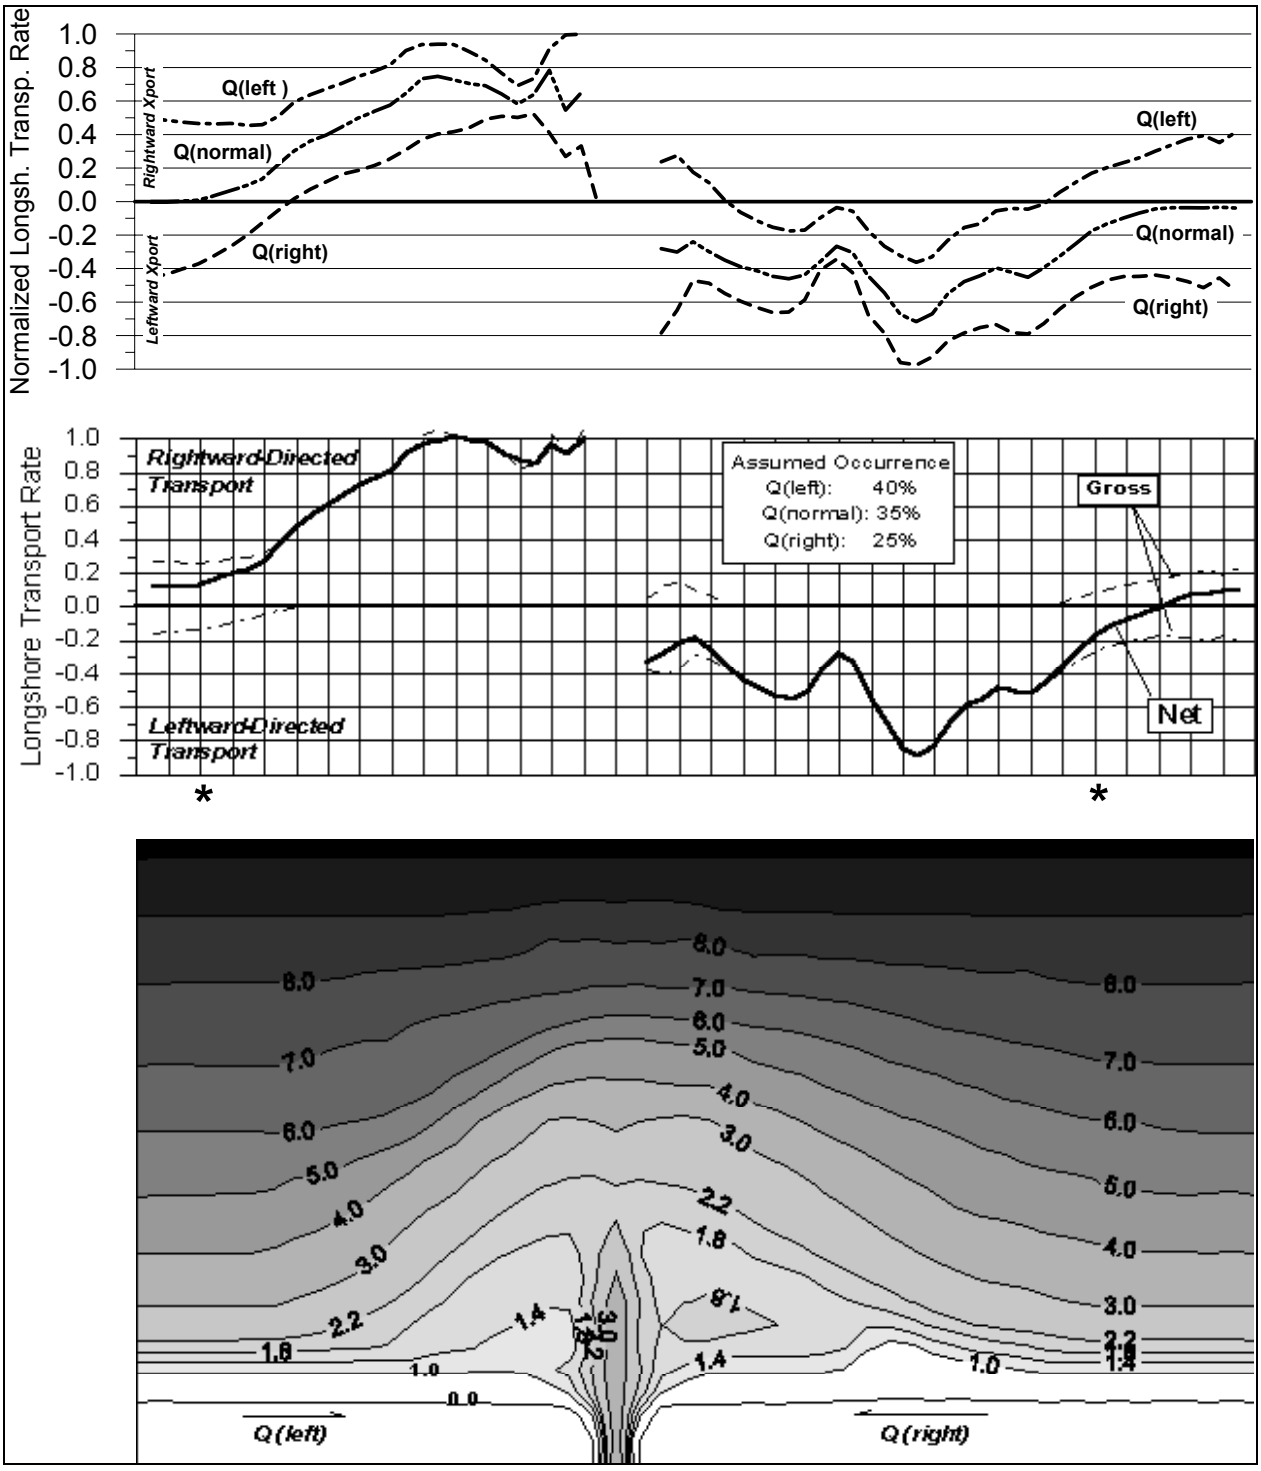

Figure V-6-11. Illustration of longshore sediment transport potential computed for three wave conditions incident to inlet's ebb shoal plateau (depths in meters)

EXAMPLE PROBLEM V-6-1

GIVEN:

The right- and left-directed volume transport rates (volume per unit of time) entering and leaving sections of shoreline upcoast and downcoast of an inlet induced by obliquely incident waves and currents are shown in the following tabulation for each section and for the inlet. Assume the inlet is a total littoral barrier (i.e., no bypassing; material can move into the inlet, but material cannot move out of the inlet).

A	B	C	D	Inlet	E	F	G	H	I
100 → 100	120 →	125 →	125 →	0 →	0 →	0 →	30 →	80 →	100 →
30 ←	30 ←	10 ←	0 ←	0 ←	60 ←	40 ←	50 ←	40 ←	30 ← 30

FIND:

The potential volume rate of change at shoreline sections A through I associated with these transport rates, and the total net volume rate of change on the left (updrift) and right (downdrift) sides of the inlet. Material transported into a section is positive (accretion = +) and material transported out of a section is negative (erosion = -).

SOLUTION:

The volume rate of change at each section A through I is equal to the algebraic sum of all volume transport rates entering and leaving each section. For example, at section C, the volume rate of change is the difference between what goes into section C (+120 + 0 = +120) and what comes out of section C (-125 + (-10) = -135). The algebraic sum of these two numbers (+120 + (-135) = -15) is the volume change per unit of time at section C.

Table V-6-1
Updrift Volume Change

Updrift	Vol. Change
A	0
B	-40
C	-15
D	0
Subtotal	-55
Inlet	+125
Total	+70

Table V-6-2
Downdrift Volume Change

Downdrift	Vol. Change
E	-20
F	+10
G	-40
H	-60
I	-20
Subtotal	-130
Inlet	+60
Total	-70

The total volume rate of transport on the left (updrift) side of the inlet (sections A through D) is equal to the volume rate of material transport entering and leaving through the left face of section A (+100 + (-30) = + 70) plus the volume rate of material transport entering and leaving through the right face of section D (-125 + 0 = -125). The algebraic sum of these two values (+70 + (-125) = -55) is the subtotal of all the changes occurring on the updrift side of the inlet (stations A through D). Thus, the left side of the inlet is eroding at a rate of -55 per unit of time.

(Continued)

EXAMPLE PROBEM V-6-1 (Concluded)

The total volume rate of transport on the right (downdrift) side of the inlet (sections E through I) is equal to the volume rate of material transport entering and leaving through the left face of section E (+0 + (-60) = -60) plus the volume rate of material transport entering and leaving through the right face of section I (-100 + (+30) = -70). The algebraic sum of these two values (-60 + (-70) = -130) is the subtotal of all the changes occurring on the downdrift side of the inlet (sections E through I). Thus, the right side of the inlet is also eroding, but at a rate of -130 per unit of time.

The total volumetric rate of change across the shoreline from sections A through I equals that material entering and leaving the left face of section A (+100 + (-30) = +70) plus that material entering and leaving the right face of section I (-100 + (+30) = -70. Thus, the total volumetric rate of change across sections A through I equals zero since the net amount of material entering the left face of section A is equal to the net amount of material leaving the right face of section I. However, the left (updrift) side of the inlet is eroding at a rate of -55 per unit of time, and the right (downdrift) side of the inlet is eroding at a rate of -130 per unit of time. Since the total erosion rate across sections A through I equals (-55 + (-130) = -185 per unit of time), and the net material rate entering the left face of section A is equal to the net material rate leaving the right face of section I, the material being eroded from the sections to the left and right of the inlet must be accumulating in the inlet. And, indeed, this is the amount of material rate passing through the right face of section D (+125) into the inlet (no material leaves the inlet), plus the amount of material rate passing through the left face of section E (+60) into the inlet (again, no material leaves the inlet), for a total of +185 per unit of time accumulating in the inlet.

no mechanism for reversal. The larger transport gradient erodes sand from the beach and transports it toward the inlet. An inlet's total potential effect is therefore equal to the sum of the ambient gross transport plus additional transport locally directed toward the inlet that is induced by the perturbation caused by the inlet on the local geometry.

e. Alongshore extent of inlet influence.

(1) The length of coastline directly influenced by an inlet is manifest, in large part, by alongshore changes in the nearshore bathymetry (and associated wave field), and alongshore changes in the beach profile shape and magnitudes of historical shoreline fluctuation. The ultimate degree to which an inlet modifies adjacent shores is a function of the volume of sand contained in its other features (Fitzgerald 1988; Bodge 1994b; Fenster and Dolan 1996); that is: impounded by jetties and other structures; captured in the flood and ebb tidal shoals; dredged; placed on adjacent beaches (e.g., dredged material or other source of fill).

(2) Absolute distances of inlet influence remain a subject of study, but may extend further than were previously thought. Shoreline response immediately adjacent to an inlet is typically obvious and erroneously led earlier investigators to conclude that the extent of inlet improvements' influence was limited to short reaches downdrift; usually some multiple (about 3 to 10) of the jetty length away from the inlet. Many, if not most, estimates in the literature of the length of inlet influence were truncated by the limited extent of coast that the investigators examined (Bruun 1995).

(3) Based upon analysis of shoreline change rates, Fenster and Dolan (1996) report the spatial influence for natural inlets along the wave-dominated North Carolina coast as up to 13.0 km, and up to 6.1 km along the mixed-energy, tide-dominated Virginia barrier islands. Dean and Work (1993) report downdrift inlet influence for inlets along Florida's central and southern Atlantic coastlines as at least 2 km

to more than 6 km; however, their analysis was limited to 6 km or less. The erosive effect of the entrance to Lagos, Nigeria, may extend at least 40 to 50 km downdrift (Bruun 1995). Migniot and Granbaulan (1985) report inlet-influenced erosion reaching 50 to 80 km downdrift of river entrances on the southwest coast of France. Bruun (1995) describes inlet-attributable erosion occurring 30 to 35 km downdrift of the Hirtshals navigation works on the North Sea coast of Denmark, 20 to 25 years after the construction of entrance breakwaters and dredging increases. Inlet-adjacent erosion may be particularly severe when the beaches are restricted by geological features, such as pocket beaches on the United States Pacific coast, but this hypothesis needs further research. Terich and Komar (1974) and Komar (1976) describe this effect at the entrance to Tillamook Bay, Oregon.

(4) Outside of the direct influence area (i.e., within the shadow of bypassing bars, jetties, etc.), an inlet's influence appears to decrease exponentially away from the inlet. One example is Port Canaveral Entrance (Bodge 1994a). This effect is also predicted by analytic shoreline-change models, including, for example, the one-line model of Pelnard-Considére (1956) described in Part III-2-2. According to Pelnard-Considére's solution for shoreline change adjacent to a sediment-trapping structure, the shoreline recession y at a distance x downdrift of the structure, at the time t_f at which the structure becomes filled to capacity and begins to bypass sand, is:

$$\frac{y}{Y} = \left[\exp\left(-u^2\right) - \sqrt{\pi} u \; erfc\left(u\right) \right] \tag{V-6-3}$$

where

$$u = \frac{x}{y} \frac{1}{\sqrt{\pi}} \tan \alpha_b \tag{V-6-4}$$

and

$$t_f = \pi \, Y^2 / 4g \, \tan^2(\alpha_b) \tag{V-6-5}$$

(5) The parameter Y is the structure length, *erfc*( ) the error function complement, and α_b is the angle of the breaking wave crests relative to the shoreline (assumed to be quasi-steady). Both y and Y are measured relative to the no-structure shoreline. The longshore diffusivity, ε,

$$\varepsilon = \frac{K H_b^{25} \sqrt{g / \kappa}}{8(s-1)(1-n)(h_* \quad B)} \tag{V-6-6}$$

is a measure of the tendency of wave action to spread out a shoreline perturbation, where K is an empirical coefficient from the longshore transport Equation III-2-5 (of order 1), H_b is the breaking wave height, g is the acceleration of gravity, κ is the ratio of local breaking wave height to local depth (about 0.8), s is the ratio of sediment to water specific gravity (about 2.65), and n is sediment porosity (about 0.4). The value h_* is the depth of active sediment transport (depth of closure) and B is the beach berm height, where B and h_* are positive values above and below the water level, respectively.

(6) Figure V-6-12 presents solutions to Equation V-6-3 for various wave breaking angles. For typical angles on the order of 2 to 8 deg, shoreline recession on the order of 5 percent of the structure's length is predicted between 15 and 50 jetty lengths downdrift. In the case of a 200-m-long jetty, this corresponds to 10 m of recession at locations between 3 and 12 km downdrift of the jetty.

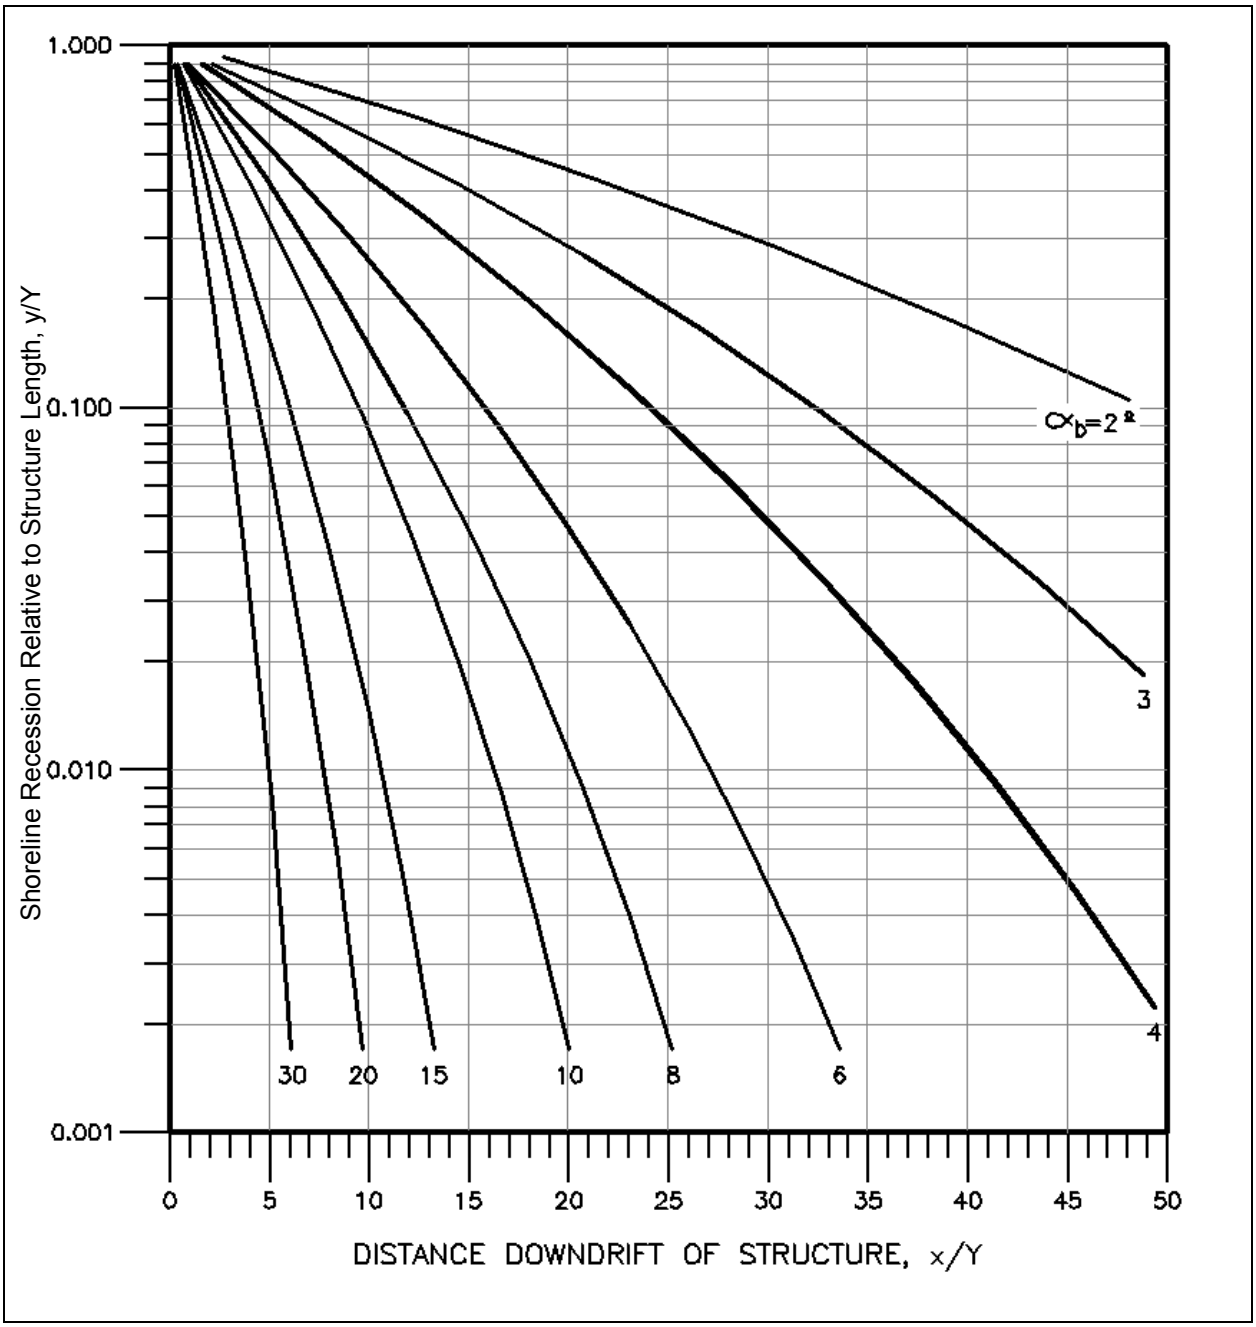

Figure V-6-12. Solutions of Equation V-6-3 (from Bodge 1994b)

(7) Dean and Work (1993) present a solution for Pelnard-Considère's equation for the case where sand is removed from the system at a rate Q_I at the inlet location x = 0:

$$y(x,t) = \frac{2p\,Q_I\sqrt{t}}{(h_* + B)\sqrt{\pi\,\varepsilon}}\,y' \tag{V-6-7}$$

where p describes the degree to which the inlet's sand removal alters each of the inlet's two adjacent shorelines; i.e.,

$$p = \frac{\left(\text{sand lost to inlet from shoreline of interest}\right)}{\left(\text{sand lost to inlet from both shorelines}\right)} \tag{V-6-8}$$

$$y' = \left[\sqrt{\pi}\, v\, erfc\left(v\right) - \exp\left(-\left(v^2\right)\right)\right] \tag{V-6-9}$$

$$v = \frac{|x|}{\sqrt{4gt}} \quad ; \quad |x| = v\sqrt{4gt} \tag{V-6-10}$$

(8) In Equation V-6-8, a value of p = 0.5 implies that the inlet's sink effect (Q_I) is evenly distributed between the two adjacent shorelines; whereas a value of p = 1.0 implies that all of the inlet's sink effect occurs from the shoreline of interest. As another example, p = 0.3 implies that 30 percent of the inlet's sink effect occurs from the shoreline of interest (whereas the other 70 percent occurs as sand losses from the other shoreline).

(9) Figure V-6-13 shows nondimensional solutions of Equation V-6-9. Additional examples and applications of Pelnard-Considère's shoreline change solution are presented in Part III-2-2. As described in that chapter, solutions for $y(x,t)$ can also be linearly added to yield the combined response of shoreline perturbations.

(10) Although Equations V-6-3 and V-6-7 provide useful theoretical insight to the potential response of a shoreline near an inlet, they are generally of limited practical value in assessing real world response. The equations do not readily account for alongshore variabilities in breaking wave angle nor sand impoundment adjacent to inlet jetties. Likewise, cross-shore transport and seasonal reversals in longshore transport direction are not taken into account. Nonetheless, these equations can be examined for order-of-magnitude effects which might be expected for a given inlet situation.

(11) From the Pelnard-Considère equations, Dean (1993) likewise presents solutions of shoreline change adjacent to an inlet for the case where sand is directed toward a dredged inlet by transport induced by ambient oblique waves and by the inlet's perturbative effect to the local shoreline. Dean observes that in the absence of effective jetties, the rate of sand that enters the inlet decreases with the reciprocal square root of time (i.e., $1/T_d^{1/2}$); however, the cumulative amount of sand entering the inlet over time from the adjacent shorelines is infinite. Dean also notes that the equations predict that the location of maximum shore erosion migrates with time away from the inlet. That is, measurements taken at one fixed point along the shoreline would first demonstrate no inlet erosion effect, then a rapid rate of erosion, then a decreasing rate as the shoreline asymptotically approaches an equilibrium, eroded position. Alternately stated, the peak erosion zone would migrate like a wave away from the inlet, and the magnitude of this peak rate would decrease with time.

(12) Bruun (1995) describes numerous examples where erosion downdrift of an inlet appears as an obvious near field effect and as a less obvious, but faster-migrating, far field effect. Bruun concluded that the downdrift shoreline development at a littoral drift barrier may in general, but not always, be described by a short (near field) effect as well as a long distance (far field) effect, both of which move downdrift at various rates. The short distance influence occurs first. After it develops to a certain extent, the long distance effect may appear, gradually moving downdrift faster than the short distance but fading out with distance. The short distance peak of the erosion occurs close to the littoral drift barrier, and moves down-drift at a rate of about 0.3 to 0.5 km/year compared to a rate of 1 to 1.5 km/year for the long distance ero-sional front. Bruun suggests that the short-distance effect is a coastal geomorphological feature, whereas the long-distance effect is a materials-deficit feature.

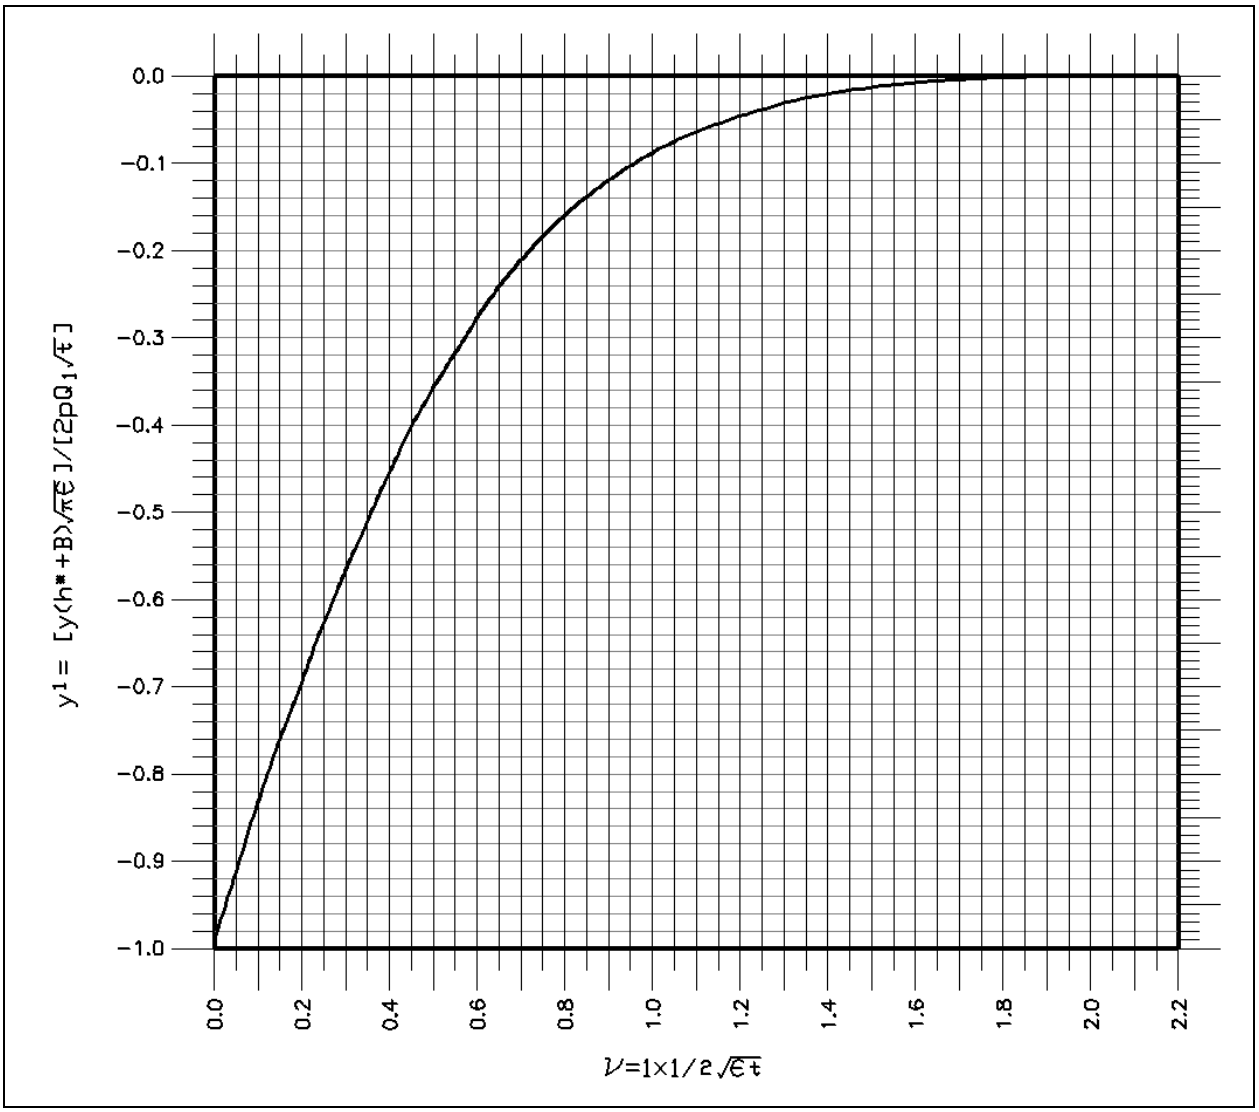

Figure V-6-13. Solution of Equation V-6-9

f. Estimating alongshore extent of inlet influence. Five methods to estimate the alongshore extent of inlet influence are as follows: Examination of historical shoreline changes; even-odd analysis; alongshore variations in beach morphology; wave refraction analysis; examination of inlet's net sink effect.

(1) Of these, Methods 1 and 2 (and to a lesser extent, 5) rely principally upon shoreline change data. Methods 3 and 4 (and, principally 5) rely upon data that are mostly distinct from shoreline change or location data. Methods 2, 3, and 4 typically yield only estimates of direct inlet effect; whereas Methods 1 and 5 potentially yield estimates of both direct and indirect (near field and far field) inlet effects. Method 5 may be the most powerful approach because it first assesses the inlet's littoral impact within the inlet, and then attempts to identify the adjacent shoreline length along which the inlet's volumetric impact is manifest. In practice, some combination of all five methods is typically necessary to assess the volumetric and lineal extent of an inlet's effect upon the adjacent shores.

EXAMPLE PROBLEM V-6-2

GIVEN: An inlet's north jetty is 240 m long (Y). It is estimated that 90 percent (p) of the inlet's net shoaling rate of 55,000 m^3/year (Q_I) is attributable to sand losses from the nonjettied downdrift shoreline. The inlet was created at time t = 0 year, at which time the shoreline was initially straight and in equuilibrium. Assume a beach of typical quartz sand of specific gravity S = 2.65, and with berm elevation B = +2 m and a depth of closure h_* = 6 m, both relative to the same datum. The average breaking wave height H_b = 0.8 m. Assume the ratio of local breaking wave height to local depth to be κ = 0.8, and the constant from the longshore transport Equation III-2-5 is K = 0.5. Assume also that the breaking wave crests typically approach with an angle of breaking $\propto_b$ = 4 deg relative to the shoreline, directed to the south.

FIND: The theoretical shoreline response downdrift of this inlet at the time the updrift jetty initially begins to bypass sand. This response consists of two parts: the impoundment effect, and the sand loss effect. These two components are computed separately and added to determine the total shore recession.

SOLUTION: The maximum recession downdrift of the inlet which is stabilized only by one jetty on the updrift side of the inlet will exist at the time t_f when bypassing begins to occur around the jetty. To determine t_f , the diffusity, ε , must first be obtained from Equation V-6-6:

$$\varepsilon = \frac{KH_b^{2.5}(g/\kappa)^{0.5}}{(8)(S-1)(1-n)(h_* \quad B)}$$

where the gravitational constant g = 9.81 m/sec^{-2} and the sediment porosity n = 0.4 (a typically representataive value).

$$\varepsilon = \frac{(0.5)(0.8m)^{2.5}(9.81m\,\sec^{-2}/0.8)^{0.5}}{(8)(2.65-1)(1-0.4)(6m+2m)}$$

$$\varepsilon = 0.0158m^2/\sec = 498{,}600m^2/year$$

The time at which bypassing is expected to begin can now be determined by Equation V-6-5:

$$t_f = \pi Y^2/4\varepsilon(\tan\alpha_b)^2$$

$$t_f = \frac{(3.1416)(240m)^2}{(4)(0.0158m^2/\sec)(\tan 4.0)^2}$$

$$t_f = 5.85 \text{ x } 10^8 \sec = 18.5 \text{ years}$$

First, compute the erosion due to the impoundment effect. Erosion downcoast of the inlet will be a maximum at the inlet and occur at the time that sand begins to pass around the jetty of length Y = 240 m. This erosion will become asymptotic to the original downcoast shoreline. For convenience, arbitrary multiples of the jetty length in a downcoast x-direction are considered (i.e., x/Y = 1, 2.5, 5, 10, ….., 40 times the jetty length, Y). These computations are tabulated in column 1 of Table V-6-3.

(Continued)

EXAMPLE PROBLEM V-6-2

Table V-6-3
Calculations for Impoundment and Sand Loss Effects at Inlet

Impoundment Effect					Sand Loss Effect		
1	2	3	4	5	6	7	8
x/Y (select)	*y/Y* (Figure V-6-12 for α_b=4°)	*x* (m) (= col. 1 x 240 m)	*y* (m) (= col. 2 x 240 m)	$\nu = \lvert x\rvert/(4\varepsilon t)^{1/2}$	*y'*(from Fig. V-6-13)	*y* (m) (Equation V-6-7)	y_{tot} (m) (Cols. #4 + #7)
1	0.95	240	-228	0.040	-0.93	-40	-268
2.5	0.85	600	-204	0.099	-0.83	-35	-239
5	0.70	1200	-168	0.197	-0.70	-30	-198
10	0.45	2400	-108	0.395	-0.45	-19	-127
15	0.29	3600	-70	0.592	-0.28	-12	-82
20	0.18	4800	-43	0.789	-0.16	-7	-50
25	0.092	6000	-22	0.987	-0.09	-4	-26
30	0.05	7200	-12	1.184	-0.06	-3	-15
35	0.024	8400	-6	1.381	-0.04	-2	-8
40	0.011	9600	-3	1.579	-0.02	-1	-4

For the arbitrary values of x/Y of column 1, the corresponding values of y/Y for α_b = 4 deg are determined from Figure V-6-8. Here y is the impoundment effect component of the total recession. The appropriate y/Y values for the arbitrary x/Y values with α_b = 4 deg are shown in column 2. Column 3 shows the x-distances downcoast for the arbitrary x/Y values of column 1. Next, the Impoundment Effect, y, is obtained by multiplying the y/Y values of column 2 by Y = 240 m, and these results are shown in column 4.

It is now necessary to compute the erosion recession distance associated with the sand loss effect from the downdrift shoreline into the inlet over the 18.5-year period during which the updrift impoundment fillet formed. This erosion distance is a function of two additional parameters (ν and y') which must first be determined.

The parameter ν is defined by Equation V-6-8 as:

$$\nu = \frac{|x|}{(4\varepsilon t_f)^{0.5}}$$

$$\nu = \frac{|x|\, m}{\left[(4)(0.0158 m^2/\sec)(5.85 \times 10^8 \sec)\right]^{0.5}}$$

$$\nu = \frac{|x|}{6080}$$

(Continued)

EXAMPLE PROBLEM V-6-2 (Concluded)

For each of the values of x in column 3, and for the time t_f = 18.5 years (5.85 x 10^8 sec), the corresponding dimensionless value of υ is computed, and displayed in column 5.

The parameter y' can be determined from Equation V-6-7 or from Figure V-6-9, for each of the values of υ from column 5. These values of y' are shown in column 6.

For each of the y' values shown in column 6, the corresponding value of y due to the sand loss effect can be determined from Equation V-6-7:

$$y(x,t) = \frac{2p\,Q_I(t)^{0.5}\,y'}{(h_* + B)(\pi\varepsilon)^{0.5}}$$

At t = t_f = 18.5 years, and for each y' value which is also a function of distance x,

$$y = \frac{(2)(0.9)(55{,}000m^3/year)(18.5years)^{0.5}\,y'}{(6m+2m)\left[(3.1416)(498{,}600m^2/year)\right]^{0.5}}$$

$$y = 42.5y'(m)$$

Thus, for each y' value computed at the alongshore distances x of column 3, the corrresponding recession due to the sand loss effect has been determined, and is shown in column 7.

The total recession at an alongshore location from the inlet, x, is the sum of the recession due to the impoundment effect (column 4) plus the recession due to the sand loss effect (column 7). These total recession values are shown in column 8. For example, at location x = 1,200 m downdrift of the inlet (here x/Y = 5, since Y = 240 m), the shoreline recession is predicted to be -168 m + (-30 m) = -198 m.

(2) The practical utility of the methods that rely upon shoreline change data can be significantly degraded by the limitations of historical shoreline data. Shoreline change data contain temporal and/or survey noise; or, may be biased by artificial manipulation; or, may not adequately characterize the beach profile's behavior as a whole. Three precautions are thus warranted when using adjacent shoreline change data to ensure the best quality conclusions:

(a) *Identify the season and/or storm events that characterize the survey data*. Shoreline locations developed from surveys, charts, or photographs that contain the record of a particular wave event (such as a storm or a period of reversed transport) may not represent the net long-term behavior of the local coastline. If a time series of shoreline positions is available, this problem is often obvious as an anomalous advance of the shoreline followed immediately by a more or less equivalent retreat (or vice versa). Remediation of this problem often requires deleting of the suspect data set.

(b) *Identify the effect of seawalls, beach nourishment, and other artificial manipulations upon the data.* Seawalls or other structures bias data by maintaining the shoreline at more or less constant location. This is often evidenced by an anomalously low (or zero) rate of shoreline change amidst an otherwise erosional coastline. The placement of beach fill by nourishment or bypassing obviously results in a large

initial advance of the shoreline. Less obvious, however, is the fact that shoreline change rates measured within 1 or 2 years after such activity will be anomalously high because of profile equilibration. Failure to recognize the effects of seawalls and beach-fill placement will result in gross overestimation of shoreline stability. Also, failure to recognize the accelerated rate of profile adjustment after beach-fill placement will result in gross overestimation of erosion. Remediation of this problem generally requires deleting (or adjusting) those data that are artificially biased. In the case of beach fill, the estimated effect of the fill's presence can be subtracted from the data; or better, if profile data are available, changes in total beach volume should be considered instead of shoreline location (see the following paragraph).

(c) *Determine the degree to which the elevation selected as the shoreline characterizes the profile behavior as a whole.* The translation of a discrete elevation at which the shoreline is identified may not accurately represent the overall profile's behavior. For example, lower elevations (such as the mean low water line) typically exhibit seaward advance if a profile erodes because of profile flattening. The flatter slopes of lower elevations are highly sensitive to profile change when computing the horizontal location at a given elevation. The mean high water line (mhwl) is typically selected to represent shoreline changes. Particularly along coasts that feature high bluffs or dunes, however, mhwl changes may not reflect beach erosion manifest by dune retreat. For example, 36 percent of the State of Florida's historical beach profiles examined along two of that state's east coast counties exhibited retreat of the dune face and concurrent advancement of the mhwl. For another 36 percent of the profiles, both the dune face and the mhwl exhibited retreat, but in two-thirds of those cases, the rate of dune face recession was over twice as great as that of the mhwl (Savage 1990).

(3) If local shoreline change is not representative of the profile change as a whole, net changes in beach volume should be considered instead of shoreline location. Here, volume changes above the depth of closure (or other sufficiently deep elevation) should be considered; i.e., the volume change per unit alongshore length of shoreline (cu m/m or cu yd/ft, etc.). Alternately, where shoreline change must be specified, as in the case of one-line analytic or numerical models, the local volume change can be converted to an equivalent, artificial shoreline change. This is computed by dividing the volume change (volume/alongshore length) by a specified profile depth (height), where the latter is usually taken as the vertical distance between the berm elevation, B, and the depth of closure, h_*. Precautions regarding the transformation of shoreline changes to volume changes are discussed in the following paragraphs (see Methods 3 and 5).

(a) *Method 1: Examination of historical shoreline changes*. In this method, temporal fluctuations in shoreline location adjacent to an inlet are quantified by comparing (overlaying) historical charts, aerial photographs, profile surveys, etc. Specifically, the cross-shore location of a specific beach elevation (mean high water, etc.) is identified at constant locations along the coast for each time at which data are available. The rates of shoreline change at each location, and between consecutive data sets, are then computed. (Alternately, the change in beach volume above a certain elevation can be quantified at each location for each data set.) Using these methods, Fenster and Dolan (1996) describe three criteria to identify the spatial extent of inlet processes on adjacent shorelines:

> The cessation of abrupt changes in the rates of change alongshore, and/or the reduction in variability of these rates alongshore. Rate-of-change values are deemed no longer abrupt if:

- The difference in rate values between adjacent transects over an X-meter-long reach does not increase or decrease by more than x meters per year (where X and x may be on the order of about 100- to 500 m and 0.2- to 0.3 m, respectively, depending upon the general coastline of interest).

- The standard deviation of a subset of along-the-shore values (neglecting the transects nearest the inlet) is minimized.

The slope of a regression line drawn through a subset of along-the-shore values (neglecting transects nearest the inlet) most closely equals zero.

Changes in the sign of the rate value from erosion to accretion (or vice versa).

A change from less erosional to more erosional (or vice versa); or, from less accretionary to more accretionary (or vice versa).

A change in slope of the cumulative shoreline change or volume change computer along the shoreline.

- For natural inlets located on the wave-dominated North Carolina coast and the mixed-energy, tide-dominated Virginia barrier coast, Fenster and Dolan (1996) found that the first criterion revealed the greatest lineal extent of inlet-related shoreline impact (≤6.1 km). The second criterion generally yielded the next greatest degree of impact (≤5.2 km), and third criterion yielded the most conservative estimate (≤4.3 km). Paraphrasing their results, Fenster and Dolan concluded that there are zones in which inlet-related processes dominate shoreline trends (estimated from the third criterion), and where inlet-related processes influence shoreline trends (estimated from the first criterion). The second criterion yields estimates between the two zones.

- The fourth criterion is a potentially useful synthesis of the first three, particularly where shoreline change data are noisy. In this approach, the shoreline change (or more meaningfully, the local volume change (volume per unit alongshore beach width)), is integrated along the shoreline, starting at the inlet ($x = 0$). The process of integration smoothes fluctuations between adjacent profiles. This allows improved visualization of large-scale trends and easier discrimination of the data points that are dominating the data set. Integrating away from the inlet (and for a positive-valued shoreline axis), positive slopes in the cumulative curve represent shoreline accretion while negative slopes represent erosion.

(b) *Method 2: Even-odd analysis*. Dean and Work (1993) describe the application of the so-called "even-odd" analysis of profile change data (Berek and Dean 1982) for shoreline changes adjacent to inlets in Florida. The total shoreline (or volume) change y at an alongshore distance x from the inlet is considered to be composed of an even (symmetric) component, $y_E(x)$, and an odd (antisymmetric) component, $y_O(x)$:

$$y(x) = y_E(x) + y_O(x) \tag{V-6-11}$$

where $y_E(x) = y_E(-x)$, and $y_O(x) = -y_O(-x)$. The even and odd components are extracted from the total (measured) shoreline (or volume) change signal by

$$y_E(x) = [\, y(x) + y(-x) \,] / 2 \tag{V-6-12a}$$

$$y_O(x) = [\, y(x) - y(-x) \,] / 2 \tag{V-6-12b}$$

The even component is a change that is symmetric about the inlet center line ($x = 0$). Physically, it is interpreted as an ambient, or background change that is common to both shorelines adjacent to the inlet (e.g., storm erosion, relative sea level change), equal placement of fill on both sides of the inlet, or equal transport from the two shorelines into the inlet.

EXAMPLE PROBLEM V-6-3

GIVEN:

Historical charts from 1927 and 1956, sampled at 250-m intervals (x), were used to develop mean high water shoreline changes (y) both north and south of an inlet. These data are shown in columns 1 and 2, respectively, in the following table for directions both north and south of the inlet. Positive values reflect shoreline seaward advance (accretion = +), and negative values reflect shoreline retreat (erosion = -). North of the inlet, the profile's active vertical height $h_* + B = 8.0$ m. Within 1,500 m south of the inlet, $h_* + B = 6.5$ m. Further south, $h_* + B = 7.5$ m. These data are shown in column 3. Here h_* is the depth of profile closure, and B is the berm thickness. The sum of $h_* + B$ is the thickness of sand movement.

EXAMPLE PROBLEM V-6-3 (Continued)

FIND:

The updrift and downdrift limits of inlet influence upon the adjacent shoreline based upon these historical shoreline change data. Identify the total net volume gained or lost from each adjacent shoreline.

SOLUTION:

The updrift and downdrift inlet effects on the adjacent shorelines are apparent from the data of columns 1 and 2. Here are shown distances alongshore from the inlet, and the corresponding mean high water shoreline changes.

The volume of material V either gained or lost per beach cross section taken at 250-m intervals can be estimated by approximating the cross-sectional area A at each interval and multiplying by the interval distance alongshore x. The cross-sectional area A at a beach section can be approximated as the product of the mean horizontal high water change (y, from column 2) and the section profile's active vertical height ($h_* + B$, from column 3), such that $A = y(h_* + B)$, shown in the Figure V-6-14. When multiplied by x = 1 m alongshore, the resulting volume ΔV is the amount of material being gained or lost per meter of shoreline in the vicinity of that particular beach cross section, and is shown in column 4. When the cross-sectional A is multiplied by the interval distance alongshore (x, from column 1), the resulting volume V is the amount of material being gained or lost between the adjacent cross sections, and is shown in column 5. The summation of the volume of material on both the north and south sides of the inlet are shown in column 6, and these volumes are in Figure V-6-14.

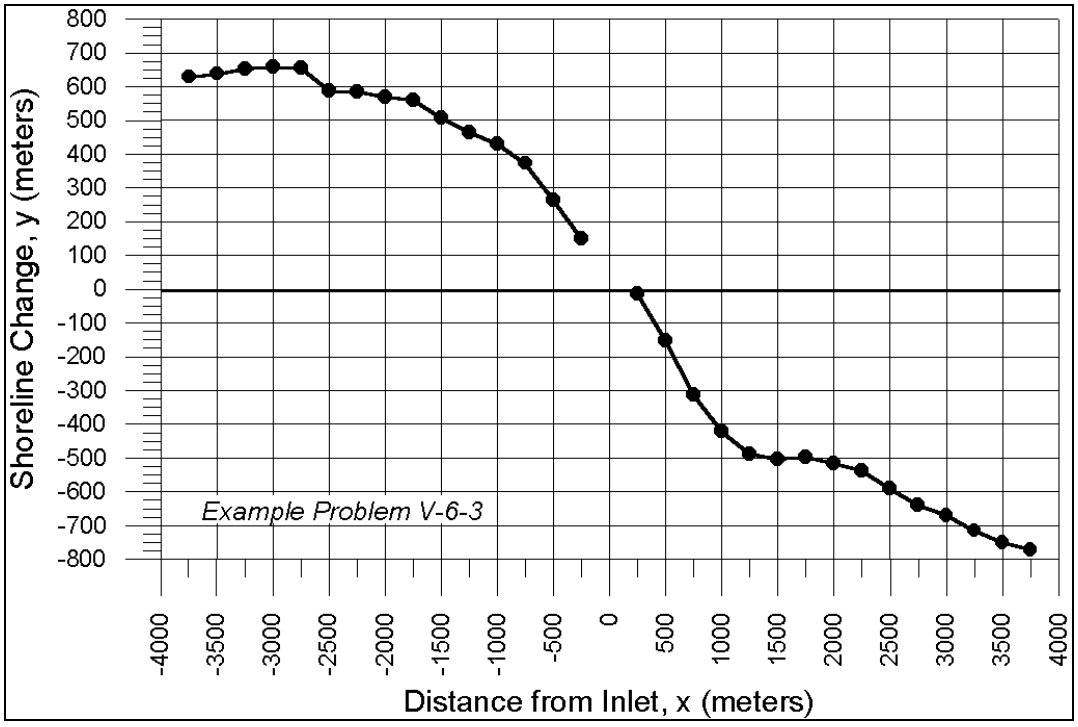

Figure V-6-14. Shoreline change as a function of distance from inlet (Example Problem V-6-3)

EXAMPLE PROBLEM V-6-3 (Concluded)

From this graph, it can be seen that the limit of direct inlet influence is about 2,500 to 2,700 m north of the inlet, and totals about 660,000 cu m of impoundment. Over the period of record, this equates to 660,000 cu m/29 years = 22,800 cu m/year, on average. There is a primary (near field) inlet effect within about 1,500 to 1,700 m south of the inlet, totaling about 500,000 cu m of erosion. There is an apparent far field inlet effect beginning about 2,000 m south of the inlet and extending beyond the 3,750-m limit of data. Within the limit of data, the net volume change downdrift of the inlet is 774,000 cu m of erosion, or about 26,700 cu m/year, on average. The actual downdrift deficit may be greater, as the inlet's influence apparently extends beyond the data limit (indicated by the continuing downward slope of the cumulative-volume curve at the right end of the graph). The fact that the downdrift erosion is greater than the updrift accretion (-774,000 cu m vs. +660,000 cu m) suggests that sand is being lost from the downdrift side by both interruption of the net southerly-directed transport and losses of northerly-directed transport from the south shoreline into the inlet.

The odd component is antisymmetric about the inlet center line. It can be interpreted as the inlet's interruption effect upon the net littoral drift (e.g., impoundment along the updrift shoreline and erosion along the downdrift shoreline), placement of fill on one side of the inlet, accretion of the shoreline due to an attachment of the ebb tidal shoal, etc. Again, volume change (instead of shoreline change) is as aptly used in these equations. Likewise, the difference in shoreline or volume changes before and after a given event in time can be considered by this approach. In this case, the given event may be the creation of, or some modification of, the inlet.

By its nature, the even-odd analysis assumes that shoreline changes (and transport processes) are symmetric/antisymmetric across the inlet center line. Accordingly, the degree to which results from the even-odd analysis accurately reflect actual inlet processes depends upon the degree to which the inlet-adjacent processes are, indeed, symmetric. Imbalances of volume change across the inlet are inherently spread across the inlet (i.e., split between the two shorelines) by the even-odd analysis. In Example ProblemV-6-4, the impoundment effect of both sides of the inlet is equal, while in Example Problem V-6-5, erosion of the downdrift shoreline greatly exceeds the accretion (impoundment) of the updrift shoreline. The result is a significant net deficit of sand in the system.

In Example Problem V-6-5, the total, net value of the inlet's effect is correct for the shoreline lengths considered (at least for the assumed background erosion rate); however, the distribution of the inlet's computed effect may not be correct. That is, the computed distribution assumes that the net inlet-induced loss from the littoral system (-995,000 cu m) is evenly divided between the updrift and downdrift shores. In reality, the net inlet-induced loss from the system may be much greater for one shore than for the other.

The fact that neither the odd- nor even-components tend to zero at the limits of the measurements reveals the net volume deficit in the system. The non-zero values at the analysis' limits also illustrate that the inlet's sediment influence extends beyond the ±4,000-m distance considered in the analysis.

The odd-component is often (incorrectly) assumed to solely represent the inlet's effect. Note, however, that even if the odd-component vanished to zero at the limits of the analysis, the fact that the even-component does not tend to zero indicates that the inlet effect may extend beyond the limits of the analysis. (This is easily demonstrated in this example by setting the measured shoreline change at +4,000 m equal to the shoreline change value at –4,000 m.)

(c) *Method 3: Alongshore variations in beach morphology.* Changes in the beach profile shape and sediment texture may provide evidence of the extent of the inlet's direct effect. For example, in order that adjacent beach profiles close at a common depth across a littoral barrier, accretional shorelines updrift of the barrier must be steeper than erosional shorelines downdrift. The limit of inlet's direct effect may be marked by the point at which variations in the profile shape (steepness) decrease, or when the profile reaches a shape or steepness similar to the remainder of the shore far from the inlet. In practice, profile steepness can be simply expressed as the horizontal length between two fixed elevations on the profile (usually measured from the berm to a depth between the beachface and closure), relative to the fixed elevation difference.

A useful way to compare profile similarity is to compute, for each profile station, the relationship between the change in profile volume and the change in shoreline locations (for some fixed elevation):

$$G_p = \frac{\Delta V}{\Delta y} = \frac{\text{volume change per unit shoreline length}}{\text{change of shoreline location}} \tag{V-6-13}$$

The S.I. units of G_p are cu m/m of shoreline change per meter along the shore; cu m/m/m = m. If the profile shape remains identical as the shoreline advances or retreats, G_p is equal to the height of the active profile; i.e., the vertical height between the top of the berm and the depth of profile closure, $(B + h_*)$. As previously noted, however, profiles steepen as sand is impounded updrift of a barrier (such as a jetty), and flatten as the shoreline recedes due to sediment deficits or the inlet's sink effect. The value of G_p is typically greater for impoundment-type shorelines, and lesser for receding-type shorelines.

The overall practical value of this method is limited because it identifies only the inlet's direct influence. It therefore yields a conservative (short) estimate of inlet effect. Moreover, natural changes in beach morphology, wave climate, or sediment type may obscure those variations that are attributable to the inlet.

(d) *Method 4: Wave refraction analysis.* An inlet's perturbative effect upon nearshore bathymetry strongly influences the transformation (refraction, shoaling, diffraction, etc.) of waves as they approach and break along the shoreline. This, in turn, influences the littoral drift patterns. (See, for example, Figure V-6-11.) Wave refraction analysis is a useful means by which to investigate this effect.

Chapter II-3-2 describes methods to compute wave transformation. Of central importance in the current application is the computation, along the shore, of the wave height and angle at the point of incipient breaking (i.e., immediately at the breakpoint), and the associated longshore sediment transport potential. Use of a grid-based wave refraction model (such as RCPWAVE) is assumed. In order to capture the effect of the inlet's ebb shoals, it is important that the wave transformation be computed all the way to the shoreline or final wave breaking point. That is, computation of breaking wave conditions at the shoreline from the wave conditions at some nearshore reference depth that is along the seaward edge of the ebb shoal plateau will greatly underestimate the inlet's perturbative effect on the wave field (Bodge, Creed, and Raichle 1996).

EXAMPLE PROBLEM V-6-4

GIVEN:

Shoreline surveys spaced 500 m apart both north (+x) and south (-x) of a small inlet were used to identify changes in the location of the mean high water shoreline between 1976 and 1980. These data are shown in columns 1 and 2, respectively, of the table below. Background erosion (i.e., outside the inlet's influence) is thought to be about 0.33 m (1 ft) over this period.

(Continued)

EXAMPLE PROBLEM V-6-4 (Continued)

FIND:

The even- and odd-components of the shoreline change signals adjacent to this inlet, and the net effect of the inlet along the shoreline beyond ambient (background) changes.

SOLUTION:

In this example, the even-odd analysis is applied under the assumption that shoreline changes (and transport processes) are symmetric across the inlet center line (i.e., it assumes the shoreline on one side of the inlet is a reverse mirror image of the other side). Therefore, shoreline change data should be obtained at the same corresponding distances on both sides of the inlet to apply the even-odd analysis (i.e., data should be compiled at distance +x on one side of the inlet and -x on the other side of the inlet).

The even and odd components of the shoreline change can be determined by Equations V-6-12a and V-6-12b, respectively, and from the data of columns 1 and 2.

$$y_E(x) = \frac{y(x) + y(-x)}{2}$$

$$y_O(x) = \frac{y(x) - y(-x)}{2}$$

For example, at x = 2,000 m:

$$y_E(2{,}000) = \frac{(-9) + (5)}{2} = -2$$

$$y_O(2{,}000) = \frac{(-9) - (5)}{2} = -7$$

At x = -2,000 m:

$$y_E(-2{,}000) = \frac{(5) + (-9)}{2} = -2$$

$$y_O(-2{,}000) = \frac{(5) - (-9)}{2} = 7$$

The even and odd components for all the x-stations are shown in columns 3 and 4, plotted in Figure V-6-15.

(Continued)

EXAMPLE PROBLEM V-6-4 (Continued)

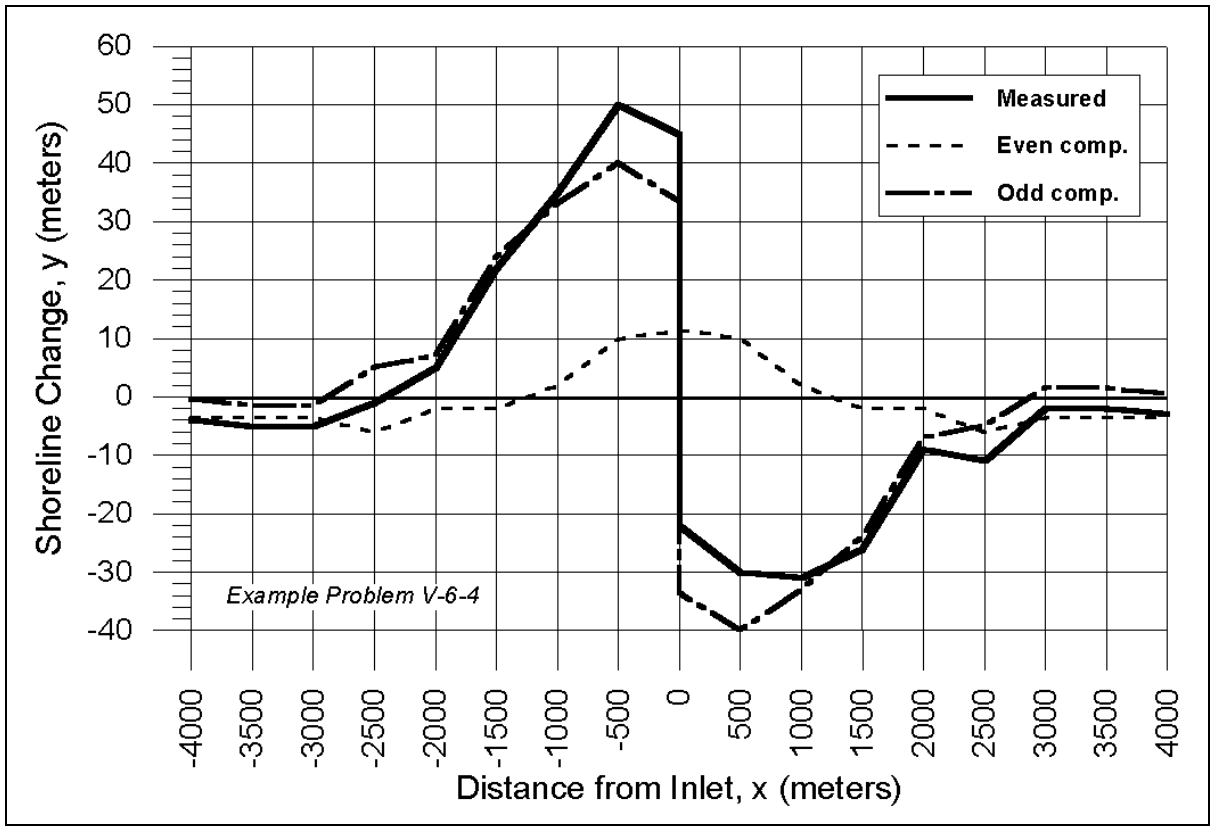

Figure V-6-15. Even-odd analysis for Example Problem V-6-4

From this graph, the positive portion of the even components suggests that there is transport directed towards the inlet within –1,250 to +1,250 m. The odd component reveals the presence of an impoundmnet fillet north of the inlet and a corresponding sediment deficit south of the inlet.

(Continued)

EXAMPLE PROBLEM V-6-4 (Concluded)

The estimated effect of sand transport direct toward the inlet along both shorelines (column 6) is computed as the even component (column 3) minus the estimated background signal of -0.33 m (column 5). For example, at x = +2,000 m, this effect is -2.0 - (-0.33) = - 1.67 m. Values for all the stations are listed in column 6. The estimated impoundment effect of the inlet is simply equal to the odd component (column 4), and is listed again in column 7.

The total net inlet effect relative to the estimated background signal (column 8) is computed as the measured shoreline change (column 2) minus the background signal of -0.33 m (column 5). For example, at x = +2,000 m, the total net inlet-induced effect is -9 - (-0.33) = -8.67 m. Values for all the stations are listed in column 8.

The volume changes associated with the shoreline change data are computed as the shoreline change value multiplied by the active profile depth (6.0 m) multiplied by the alongshore length of beach represented by each station. For example, the measured volume change estimated for the -x stations is:

$$[(-4 - 5 - 5 - 1 + 5 + 22 + 35 + 50)(500) + (45)(250)](6) = 358{,}500 \text{ cu m}$$

The net volume changes are listed at the bottom of each column for the updrift (-x) and downdrift (+x) shorelines, and for the sum of both.

In this example, the total net measured change across both shorelines (-17,000 cu m) is attributed to the area's background erosion rate (column 5). No net erosional effect is computed from transport toward the inlet (column 6), although there is a redistribution of 55,700 cu m of sand from the zone further than 1,000 m away from the inlet to the area within 1,000 m of the inlet. (This volume is computed as the sum of the changes in column 6 within +/-1,000 m of the inlet.) The net volume of the inlet's impoundment effect is computed to be 367,000 cu m (column 7). Neglecting the re-distribution of sand caused by inlet-induced transport (column 6), and neglecting any net accumulation of sand within the inlet's shoals which is not manifest as shoreline erosion within the +/-4-km study area, the inlet's net downdrift deficit beyond background erosion is therefore 367,000 cu m. This effect appears to extend about 3,000 m south of the inlet.

EXAMPLE PROBLEM V-6-5

GIVEN:

Shoreline surveys spaced 500 m apart both north (+x) and south (-x) of a small inlet document changes in the location of the mean high water shoreline between July 1956 and December 1968 (12.5 years). These data are shown in columns 1 and 2 of Table V-6-6. Background retreat (outside of the inlet's influence) is assumed to be 0.8 m/year over this time period, for a total retreat of 10 m.

(Continued)

EXAMPLE PROBLEM V-6-5 (Continued)

FIND:

The even- and odd-components of the shoreline change signals adjacent to the inlet, and the net effect of the inlet beyond ambient (background) shoreline change.

SOLUTION:

As stated earlier, the degree to which results from the even-odd analysis accurately reflect actual inlet processes depends upon the degree to which inlet and adjacent processes are, indeed, symmetric. In this example, retreat of the downdrift shoreline greatly exceeds the advance due to impoundment of the updrift shoreline. The result is a significant deficit of sand in the system.

The even and odd components of the shoreline change are again determined by Equations V-6-12a and V-6-12b, respectively, and from the data of columns 1 and 2.

$$y_E(x) = \frac{y(x) + y(-x)}{2}$$

$$y_O(x) = \frac{y(x) - y(-x)}{2}$$

For example, at x = 2,000 m:

$$y_E(2{,}000) = \frac{(-75) + (-2)}{2} = -38.5$$

$$y_O(2{,}000) = \frac{(-75) - (-2)}{2} = -36.5$$

At x = -2,000 m:

$$y_E(-2{,}000) = \frac{(-2) + (-75)}{2} = -38.5$$

$$y_O(-2{,}000) = \frac{(-2) - (-75)}{2} = 36.5$$

(Continued)

EXAMPLE PROBLEM V-6-5 (Concluded)

The even and odd components for all the x-stations are shown in columns 3 and 4, and plotted in Figure V-6-15.

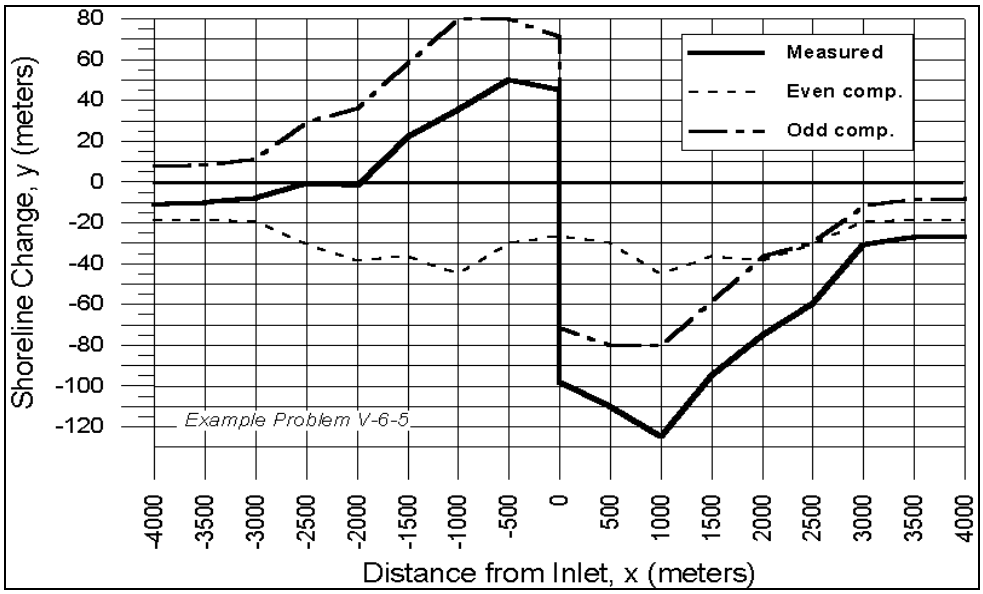

Figure V-6-16. Even-odd analysis for Example Problem V-6-5

The background erosion rate is 0.8 m/year x 12.5 years = 10 m. This value (column 5) is subtracted from the even component (column 3) since this component represents the common (symmetric) signal across both shorelines. The result is listed in column 6.

The even component, adjusted for background erosion effects, suggests that there is transport directed toward the inlet and lost therein. The net effect of this loss is computed as -497,000 cu m from each shoreline, for a total of -995,000 cu m (column 6). The odd component reflects the inlet's gross impoundment effect and the associated downdrift deficit associated with the impoundment's interruption of net littoral drift. This value is computed as -1,045,000 cu m (column 7).

Of the total net volume change estimated from the measured shoreline change data, -1,505,000 cu m (column 2), the -10 m background change accounts for -510,000 cu m (column 5). The balance is the inlet's net effect, -995,000 cu m (column 8). The even-odd analysis distributes this net deficit even across the inlet (i.e., -497,000 cu m for each shoreline, column 6). When added to the impoundment effect, the computed net result is 548,000 cu m of net accretion along the updrift shoreline and -1,542,000 cu m of net erosion along the downdrift shoreline (column 8).

For each alongshore column of the refraction grid, and for each case of interest, the shoreward-most occurrence of a nonbroken wave is identified; i.e., where the wave height H is less than κ times the water depth, h. The breaking index κ is typically equal to about 0.8, or as otherwise specified in the refraction model. Assuming shallow water wave conditions, the breaking wave height H_b and α_b can be estimated from:

$$H_b \sim \frac{A_1}{1 - \frac{1}{5} A_1 A_2} \tag{V-6-14}$$

$$\alpha_b = \sin^{-1}\left[\frac{\sin\hat{\alpha}}{C}\sqrt{g H_b / \kappa}\right] \tag{V-6-15}$$

where

$$A_1 = (\kappa / g)^{1/5} H^{4/5} (C_g \cos\hat{\alpha})^{2/5} \tag{V-6-16a}$$

$$A_2 = g (\sin\hat{\alpha})^2 / C^2 \tag{V-6-16b}$$

The values C and C_g are the wave celerity and group celerity, respectively, at the reference (non-broken wave) location. The value $\hat{\alpha}$ is the wave angle at the reference location measured relative to the local shoreline orientation:

$$\hat{\alpha} = \alpha - \beta \tag{V-6-17}$$

where α is the wave angle relative to the grid at the reference location (i.e., the value output by the wave refraction analysis) and β is the shoreline angle relative to the grid at the alongshore column of interest.

From Part III-2-2, the potential longshore transport rate is computed for each column, and for each wave case, from

$$Q = \mathrm{K}' H_b^{5/2} \sin(2\alpha_b) \tag{V-6-18}$$

where Q has units of volume per time; and where

$$\mathrm{K}' = \frac{K\sqrt{g}}{16(s-1)(1-n)} \tag{V-6-19}$$

and K is the dimensionless coefficient from the CERC Formula (Equation III-2-5).

EXAMPLE PROBLEM V-6-6

GIVEN:

Local water depths, wave heights, and angles were computed by a numerical wave transformation model for five grid elements of one column of a numerical computational grid. The wave period T is 9.0-sec, and the shoreline angle (β) at this column is +2.0 deg relative to the grid. The numerical model's breaking index is $\kappa = H_b/h_b = 0.8$, where H_b is the wave height at breaking and h_b is the water depth where the 9.0 sec wave breaks. Assume the sand specific gravity S = 2.65, the in-place sediment porosity n = 0.4, and the imprecise dimensionless coefficient from the CERC Formula (Equation III-2-18) is taken to be K = 0.5.

Table V-6-7
Numerical Model Results for Longshore Transport Potential Calculations

GIVEN: Numerical Model Results				Compute
Grid Row #	Depth *h* (m)	Wave Ht *H* (m)	Angle α (deg)	κ = *H*/*h*
1	0	0	0	--
2	0.3	0.24	3.5	0.8
3	0.7	0.56	5.4	0.8
4	1.7	0.57	5.6	0.34
5	2.9	0.52	5.8	0.18

FIND:

The incipient breaking wave height and angle, and the longshore transport potential from nearshore wave conditions computed across this numerical wave transformation grid.

(Continued)

EXAMPLE PROBLEM V-6-6 (Continued)

SOLUTION:

The incipient breaking wave height and angle occur in the grid row closest to the shoreline where the breaking index $\kappa = H/h$ is less than 0.8. Here H is the wave height and h is the water depth at a particular cell of the grid. Hence, it is necessary to compute κ for each row of this column of cells, starting at the shoreline and working seaward. At grid row 1, the water depth is 0.0, and H/h is undefined. At grid row 2, H/h = 0.24/0.3 = 0.8 (a broken wave). At grid row 3, H/h = 0.56/0.7 = 0.8 (also a broken wave). At grid row 4, H/h = 0.57/1.7 = 0.34 (a non-broken wave). Thus, the shoreward-most occurrence of a non-breaking wave is at grid row 4 where the water depth is 1.7 m. (Note: The wave height and angle in the above table for grid row 4 are not breaking wave characteristics. Breaking, however, does occur somewhere within grid row 4. Grid row 4 becomes the reference location from which breaking conditions, H_b and α_b, will be computed.) Here this 9.0 sec wave has a non-broken wave height H = 0.57 m and a non-broken wave angle $\alpha = 5.6$ deg relative to the grid. A definition sketch of the layout of the grid relative to the shoreline and approaching wave crests is presented in Figure V-6-17.

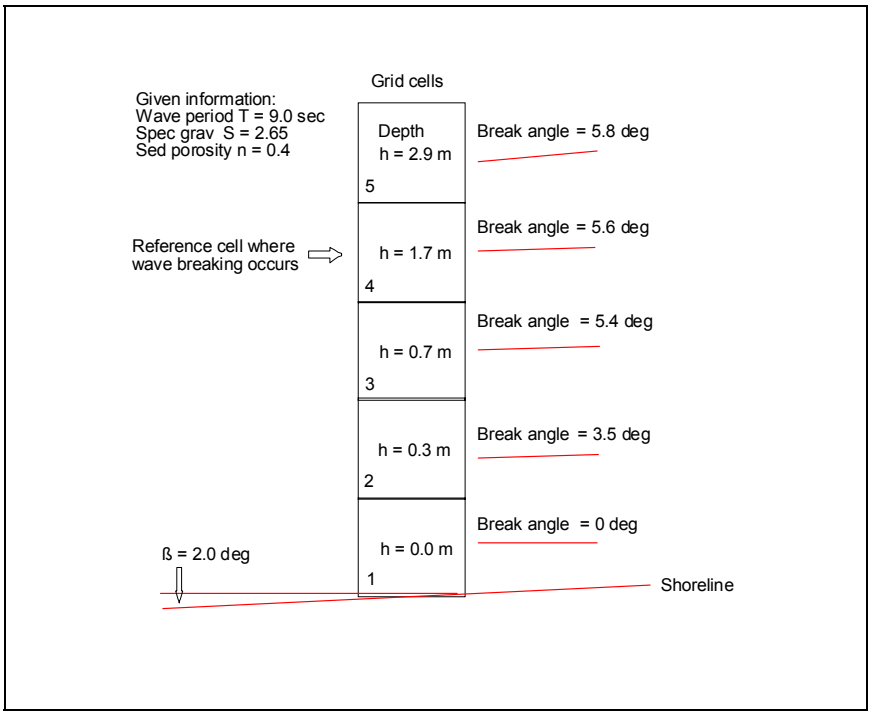

Figure V-6-17. Sketch of numerical model results for Example Problem V-6-6

(Continued)

EXAMPLE PROBLEM V-6-6 (Continued)

The value $\hat{\alpha}$ is the wave angle at the reference location measured relative to the local shoreline orientation. From Equation V-6-17:

$$\hat{\alpha} = \alpha - \beta$$

where α is the wave angle relative to the grid at the reference location (i.e., the output value from the numerical wave transformation model), and β is the shoreline angle relative to the grid at the grid column of interest.

Assuming shallow-water wave conditions, the breaking wave height (H_b) and breaking wave angle α_b can be estimated from Equations V-6-14 and V-6-15, respectively:

$$H_b = \frac{A_1}{1 - \frac{A_1 A_2}{5}}$$

$$\alpha_b = \sin^{-1}\left[\frac{\sin\hat{\alpha}}{C}(gH_b/\kappa)^{0.5}\right]$$

A_1 and A_2 are defined by Equations V-6-16a and V-6-16b, respectively.

where $$A_1 = (\kappa/g)^{0.2} H^{0.8} (C_g \cos\hat{\alpha})^{0.4}$$

and $$A_2 = \frac{g(\sin\hat{\alpha})^2}{C^2}$$

The acceleration due to gravity is g = 9.81 m/sec^2. The values C and C_g are the wave celerity and group celerity, respectively, at the reference (nonbreaking) location where the wave period T = 9.0 sec and the water depth h = 1.7 m. From Equation II-1-7:

$$C = L/T$$

where L is the local wavelength. Hence, it becomes necessary to determine the local wavelength L at this location. From Equation II-1-10:

$$L = \frac{gT^2}{2\pi}\tanh\left(\frac{2\pi h}{L}\right)$$

(Continued)

EXAMPLE PROBLEM V-6-6 (Continued)

The solution of this expression for the local wavelength L involves some difficulty because L occurs on both sides of the equation. There are, however, a number of ways to solve this equation. It can be solved by iteration, or from tabulated values of L and C by Goda (1985), or from tabulated values of h/L_0 and h/L by Wiegel (1954), or by the procedure of Fenton and McKee (1990), or by use of Figure II-1-5 (Part II). From either of these methods, with T = 9 sec and h = 1.7 m, it can be determined that L = 36.27 m. Applying the CEM method (for example), $L_0 = gT^2/2\pi = 9.81(9)^2/2\pi$ = 126.46 m. Thus, h/L_0 = 1.7/126.46 = 0.01344. From Figure II-1-5 at h/L_0 = 0.01344, it can be determined that $\sinh(2\pi d/L)$ = 0.2988, from which $2\pi d/L$ = 0.2945, and from which L = 36.27. Because $C = L/T$, C = 36.27 m/9 sec = 4.03 m/sec.

By Equation II-1-49:

$$C_g = \frac{1}{2}\frac{L}{T}\left[1 + \frac{\frac{4\pi h}{L}}{\sinh\frac{4\pi h}{L}}\right]$$

$$C_g = \frac{1}{2}\frac{36.27m}{9\,\sec}\left[1 + \frac{\frac{(4)(\pi)(1.7m}{36.27m}}{\sinh\frac{(4)(\pi)(1.7m)}{36.27m}}\right]$$

$$C_g = 3.91\,m/\sec$$

Angle α = 5.6 deg (the wave angle relative to the grid), and was determined by the numerical model output at grid row 4. Angle β = 2.0 deg (the shoreline angle relative to the gird) was given. Hence:

$$\hat{\alpha} = \alpha - \beta = 5.6\,\text{deg} - 2.0\,\text{deg} = 3.6\,\text{deg}$$

$$A_1 = (\kappa/g)^{0.2} H^{0.8} (C_g \cos\hat{\alpha})^{0.4}$$

Here κ is the model's breaking wave index, $\kappa = H_b/h_b = 0.8$.

$$A_1 = (0.8/9.81m\sec^{-2})^{0.2}(0.57m)^{0.8}(3.91m\sec^{-1}\cos 3.6\,\text{deg})^{0.4}$$

$$A_1 = 0.677m$$

$$A_2 = g(\sin\hat{\alpha})^2 / C^2$$

(Continued)

EXAMPLE PROBLEM V-6-6 (Concluded)

$$A_2 = 9.81 m \sec^{-2} (\sin 3.6 \deg)^2 / (4.03 m \sec^{-1})^2$$

$$A_2 = 0.00238\ m^{-1}$$

$$H_b = \frac{A_1}{1 - \frac{A_1 A_2}{5}} = \frac{0.0667m}{1 - \frac{(0.667m)(0.00238m^{-1})}{5}}$$

$$H_b = 0.067\ m$$

$$\alpha_b = \sin^{-1}\left[\frac{\sin\hat{\alpha}}{C}(gH_b / \kappa)^{0.5}\right]$$

$$\alpha_b = \sin^{-1}\left(\sin 3.6 \deg / 4.03 m \sec^{-1}\right)\left[(9.81 m \sec^{-2})(0.67m)/0.8\right]^{0.5}$$

$$\alpha_b = 2.56\ deg$$

The potential longshore sediment transport rate can now be determined by Eq. V-6-16:

$$Q = K' H_b^{2.5} \sin(2\alpha_b)$$

where

$$K' = \frac{Kg^{0.5}}{16(S-1)(1-n)}$$

$$K' = \frac{(0.5)(9.81 m \sec^{-2})^{0.5}}{(16)(2.65 - 1)(1 - 0.4)}$$

$$K' = 0.099 m^{0.5} \sec^{-1}$$

from which

$$Q = (0.099 m^{0.5} \sec^{-1})(0.67m)^{2.5}[\sin(2)(2.56 \deg)]$$

$$Q = 0.0033 m^3 \sec^{-1}$$

EXAMPLE PROBLEM V-6-7

GIVEN:

The potential longshore transport rate (Q, in units of volume per time) for each of five alongshore columns of a refraction grid, and for three different wave conditions each during the time period of interest, are presented as lines 1-3 in the Table V-6-8. The percentages of occurrence (P) of the three wave conditions are 22, 25, and 16 percent. There were no waves (calm) during 37 percent of the time period of interest. These percentages of occurrence are shown as lines 4-6 in the table.

Table V-6-8
Potential Longshore Transport Rate Information for Fire Grid Columns

		Grid Column				
Line	Parameter	1	2	3	4	5
1	Q_1 (cu m/hr)	2.9	3.3	5.2	6.4	6.2
2	Q_2 (cu m/hr)	-0.7	-0.4	1.6	1.8	2.1
3	Q_3 (cu m/hr)	-6.8	-6.5	-1.5	0.8	0.2
4	P_1 (%)	0.22	0.22	0.22	0.22	0.22
5	P_2 (%)	0.25	0.25	0.25	0.25	0.25
6	P_3 (%)	0.16	0.16	0.16	0.16	0.16
7	P_1Q_1 (cu m/hr)	0.64	0.73	1.14	1.41	1.36
8	P_2Q_2 (cu m/hr)	-0.18	-0.10	0.40	0.45	0.53
9	P_3Q_3 (cu m/hr)	-1.09	-1.04	-0.24	0.13	0.03
10	Q_R (cu m/hr)	0.64	0.73	1.54	1.99	1.92
11	Q_L (cu m/hr)	-1.27	-1.14	-0.2	0	0
12	$Q_{(NET)}$ (cu m/hr)	-0.63	-0.41	1.30	1.99	1.92
13	Q_{RN} (cu m/hr)	0.32	0.37	0.77	1.00	0.96
14	Q_{LN} (cu m/hr)	-0.64	-0.57	-0.12	0	0
15	$Q_{(NET)N}$ (cu m/hr)	-0.32	-0.21	0.65	1.00	0.96

FIND:

The total rates of right-directed (+), left-directed (-), and net transport potential for the five grid columns along this shoreline. Normalize the results by the net transport maxima.

SOLUTION:

The potential longshore transport rate (Q) can be expressed as some function of the breaking wave height (H_b) and the breaking wave angle (α_b), as given by Equation V-6-18,

$$Q = K' H_b^{2.5} \sin(2\alpha_b)$$

with units of volume per time (e.g., cu m/hr).

(Continued)

EXAMPLE PROBLEM V-6-7 (Concluded)

A numerical simulation wave refraction model was used to determine the breaking wave height (H_b) and breaking wave angle (α_b) for each of the five columns of the refraction grid. Equations V-6-14 through V-6-19 were then used to determine the potential longshore transport rate Q (cu m/hr) for these conditions, and these are GIVEN values shown as lines 1-3. The expression for the potential longshore transport rate Q (cu m/hr) (Equation V-6-18) inherently assumes there is an unlimited supply of sand available for movement. The total amount of sand moved during the time interval of interest is, therefore, the product of the rate of movement Q (cu m/hr) multiplied by the time interval (which may be more or less than 1 hr). The three wave conditions under consideration here existed for P_1 = 22 percent, P_2 = 25 percent, and P_3 = 16 percent of an hour, respectively. These percentages of occurrence are presented as lines 4-6.

The rate of actual material movement per hour by a particular wave climate is determined as the product of the potential longshore transport Q (cu m/hr) and the percentage of occurrence of that particular wave. Hence, the rates of actual material movement are shown as P_1Q_1, P_2Q_2, and P_3Q_3 on lines 7-9, respectively. These are the weighted values of actual (potential) transport rate, weighted based on the percent of time (hour) that a particular wave climate actually existed.

The weighted sum of the actual (potential) transport rates for each column is the sum of all components of transport moving to the right (+), and to the left (-). These values are shown as lines 10 and 11, respectively. For example, for column 1, the weighted sum of the three transports produced by the three different wave climates are 0.64, -0.18, and -1.09 cu m/hr (Lines 7-9 of column 1). The transport to the right Q_R (+) is the only positive value of the three (0.64 cu m/hr), shown as Line 7. The transport to the left Q_L (-) is the sum of the two negative transports (-0.18 and -1.09 cu m/hr), shown as lines 8 and 9. The weighted sum of the actual (potential) transport rates for the five columns of the numerical grid are shown as lines 10 and 11, for right transport Q_R and left transport Q_L, respectively. The weighted net transport $Q_{(NET)}$ is the algebraic sum of the right transport Q_R and the left transport Q_L , and is shown as line 12.

The weighted sums of the actual (potential) longshore transports are then normalized by the maximum value of $Q_{(NET)}$ for all columns as shown in line 12. This maximum value occurs at column 4 (1.99 cu m/hr). All values of lines 10-12 are normalized (divided) by this value, and these right normalized values Q_{RN}, left normalized values Q_{LN}, and net normalized values $Q_{(NET)N}$ are shown as lines 13-15, respectively. These values indicate the relative actual (potential) longshore transport quantities per column of the numerical grid with respect to the maximum value of these parameters occurring within the region of interest.

The total right-directed and left-directed potential transport rates at a given alongshore column are, respectively, the weighted sum of the positive-valued and negative-valued transport estimates for that column:

$$Q_R = \sum p_i Q_i \quad for \quad Q_i \geq 0 \tag{V-6-20}$$

$$Q_L = \sum p_i Q_i \quad for \quad Q_i \leq 0 \tag{V-6-21}$$

where p_i is the fractional occurrence of each wave case i. Likewise, the net transport potential is the weighted sum of all transport values at a given column:

$$Q_{NET} = \Sigma\left(p_i Q_i\right) = Q_R + Q_L \tag{V-6-22}$$

The net, right- and left-directed potential transport rates for each grid column along the shore can then be examined or plotted to assess the alongshore extent and nature of the inlet's influence upon the refracted wave field and the associated littoral transport patterns (see, as an example, Figure V-6-11). The results are also useful in elucidating the inlet's sand transport pathways and for subsequent development of the sediment budget.

This approach is limited in that it does not address transport induced by tidal currents or gradients in wave height. Likewise, it addresses only the inlet's direct effect upon the shoreline and does not reveal far field erosion caused by the inlet's sink effect upon the littoral transport.

(e) *Method 5: Examination of inlet's net sink effect.* Whereas methods 1, 2, and 3 discern an inlet's effect through examination of shoreline change, this method primarily relies upon changes measured at and within the inlet. This is potentially advantageous because shoreline position data are often ambiguous and may reflect engineering activities such as dredged material placement, while, in some cases, the inlet's impoundment of sand adjacent to and within the inlet is more readily discerned (usually with some level of quantifiable uncertainty). Additionally, the assessment of the inlet's impacts is not a priori biased (limited) by the length of shoreline selected for examination.

An inlet's net sink effect is defined as the quantity of material that the inlet has taken from the littoral system. In most cases, natural and stabilized inlets remove sand from the littoral system through accretion of adjacent shores, shoaling in channels, and accretion of ebb- and flood-tidal shoals. However, inlets with riverine input may be the source of littoral material for the coast (e.g., Columbia River, Washington/Oregon).

The net sink effect, or volumetric impact, is first computed by adding: The volume (or rate) of impoundment adjacent to the inlet entrance; the volume (or rate) of net sand accumulation within the inlet's channels and shoals; the volume (or rate) of sand removed from the littoral system by dredging and offshore (or out-of-system) disposal. (If dredged material is placed on the adjacent beaches, it remains within the adjacent littoral system and thus is not added to the total).

Then, the following is subtracted from this total: The volume (or rate) of riverine (or other upland) sedimentary input; the volume (or rate) of barrier removed due to creation (through dredging or breach) of the inlet (if this event is within the time period of consideration).

The resulting value is the volume (or rate) of sand which has been removed from the adjacent shores' littoral systems over the period of examination. Inlet-adjacent volume changes are then examined to discern the minimum distance away from the inlet along which this volumetric impact is manifest.

EXAMPLE PROBLEM V-6-8

GIVEN:

Measured shoreline changes adjacent to an inlet are presented in columns 1 and 2 of Table V-6-9 for the period 1975-1989. Surveys from 1980 and 1988 suggest that the inlet's ebb and interior shoals outside the limits of dredging accreted by 152,000 cu m ±48,000 cu m. The correlation G_p between profile volume change per unit of shoreline length (alongshore) and cross-shore beach width change is estimated to be:

a. Updrift (east) of the inlet: 7.5 cu m/m of shoreline length per meter of cross-shore beach width change (7.5 cu m/m/m).

b. Downdrift (west) of the inlet: 7.2 cu m/m of shoreline length per meter of cross-shore beach width change) (7.2 cu m/m/m).

Profile erosion between 1.5 and 3.5 km downdrift of the inlet is restricted by the presence of seawalls. An average of about 192,000 cu m is dredged from the inlet's entrance channel every 3 years, all of which is disposed in deep water offshore. In 1987, 360,000 cu m of beach fill were placed between 0 and 4.5 km downdrift (west) of the inlet from an offshore sand source. Neglect riverine input of sand. Assume that erosion induced by the inlet along the updrift shoreline is negligible. The total rate at which the inlet removes sand from the littoral system is the sum of:

a. The updrift impoundment rate.

b. The inlet's net shoaling rate (after dredging).

c. The rate at which maintenance-dredging sand is disposed outside the littoral system.

FIND:

The lineal and volumetric extent for which the inlet's net sink effect can be attributed to measured shoreline erosion.

SOLUTION:

The natural inlet and shoreline processes are assumed to be similar over the entire period of interest (1975-1989). The change in shoreline volume per unit of shoreline length (alongshore) ΔV (m^3/m), per unit of change of cross-shore beach width change Δy (m), is denoted by Equation V-6-11:

$$G_p = \frac{\Delta V \text{ (volume change per unit of shoreline length alongshore)}}{\Delta y \text{ (cross - shore beach width change)}}$$

This relationship G_p was previously estimated to be 7.5 m^3/m of shoreline length (alongshore) per meter of cross-shore beach width for the coastal segment immediately updrift of the inlet, and 7.2 m^3/m of shoreline length (alongshore) per meter of cross-shore beach width for the coastal segment immediately downdrift of the inlet. The average annual cross-shore shoreline change data of column 2 with units of m/year can be converted to average annual local volume change data with units of m^3/m/year by using Equation V-6-11.

(Continued)

EXAMPLE PROBLEM V-6-8 (Continued)

Since $$G_p = \frac{\Delta V}{\Delta y}\ m^3 / m / m$$

then $$\left(G_p\ m^3 / m / m\right)\left(\frac{\Delta y}{\Delta t}\ m / year\right) = m^3 / m / year$$

For example, at x = +7 km,

$$(7.5\ m^3/m/m)(-0.1\ m/year) = -0.75\ m^3/m/year$$

These equivalent average annual local volume change data are shown in column 3.

The effective shoreline reaches for each section updrift and downdrift of the inlet are shown in column 4. Next, the total rate of change along each reach of shoreline was determined by the simple trapezoidal rule (i.e., by multiplying the local volume change rate (column 3) by the local effective shoreline reach (column 4)). For example, the volume change at x = +7 km is

$$(-0.75\ m^3/m/yr)(1{,}000\ m) = -750\ m^3/year$$

These results are shown in column 5. Then the cumulative volume changes along the updrift (east) and downdrift (west) shorelines were determined, starting at the inlet for each direction. These results are shown in column 6. From examination of column 6, the updrift impoundment appears to extend about 4 km east of the inlet, and totals about 47,000 m^3/year (updrift impoundment rate).

The inlet's net shoaling rate between 1980 and 1988 was transformed to an annual average rate as (152,000 m^3 ±48,000 m^3)/8 year = 19,000 ±6,000 m^3/year (inlet net shoaling rate).

The rate of dredging and out-of-system disposal is annualized as 192,000 m^3/3 year = 64,000 m^3/year (maintenance dredging).

Again, the total rate at which the inlet removes sand from the littoral system is the sum of: the updrift impoundment rate; the inlet's net shoaling rate (after dredging); and the rate at which maintenance-dredging sand is disposed outside the littoral system.

Hence, the total rate at which the inlet removes sand from the littoral system is:

47,000 cu m/year + (19,000 ± 6,000) cu m/year + 64,000 cu m/year = 124,000 to 130,000 cu m/year

Hence, in the absence of the beach nourishment project, the downdrift beach is expected to exhibit a loss of between 124,000 and 136,000 cu m/year. Instead, primarily due to the 360,000-cu m-fill, the downdrift beach exhibited a net measured loss of only 49,925 cu m/year along the 13-km reach for which data are given.

To more carefully assess the inlet's actual impact, the beach fill must be included in the analysis. This fill, which was placed on the shore between 0 and 4.5 km downdrift of the inlet, was also removed (eroded) from the beach; therefore, it must be included in the total amount of material removed from the beach. This analysis is performed in the following table. Only the downdrift (west) shoreline is listed in the table since it is only this shoreline that is affected by the beach fill.

(Continued)

EXAMPLE PROBLEM V-6-8 (Continued)

The average annual cumulative volume change downdrift of the inlet (column 6) has been converted to the equivalent total cumulative volume change over the 14-year period between the 1975 and 1989 survey period by multiplying column 6 by 14 years. These data are shown in column 7.

The placed beach fill was also removed (eroded) from the beach. We assume that the 360,000 cu m of beach fill was uniformly distributed over the 4.5-km placement area (i.e., 80 cu m/m of shoreline. Column 8 shows the corresponding fill volume placed within each reach (between each station). From these results, the cumulative alongshore fill volume was computed, and is shown in column 9 as the cumulative placed fill volume along the beach downdrift of the inlet.

The cumulative alongshore volume change over the 14-year survey period, with the beach fill considered, was computed by adding the cumulative placed beach fill volume (column 9) to the cumulative measured beach fill volume change (column 7). These sums are shown in column 10 as the cumulative total volume change. The equivalent average annual cumulative total volume change is computed by dividing these values (column 10) by the survey interval (14 years). These results are shown in column 11. The cumulative updrift and downdrift volume changes, with and without consideration of the fill, are shown in Figure V-6-18.

Table V-6-10
Calculations for Cumulative Volume Change West of Inlet

From previous table			Downdrift volume change with beach fill considered (included)

(Continued)

EXAMPLE PROBLEM V-6-8 (Concluded)

With the effect of the fill included (column 11), the downdrift volume change within the 13-km limit of data equals -75,640 cu m/year. This value is only about 56 to 61 percent of the total net impact (124,000 to 136,000 cu m/year) estimated from the inlet's diversion of sand from the littoral system (i.e., via updrift impoundment, net shoal growth, and out-of-system maintenance dredging disposal). Neglecting any inlet-induced erosion updrift of the inlet, the remaining 39 to 44 percent of the inlet's impact (48,360 to 60,360 cu m/year) must therefore occur further downdrift than 13 km.

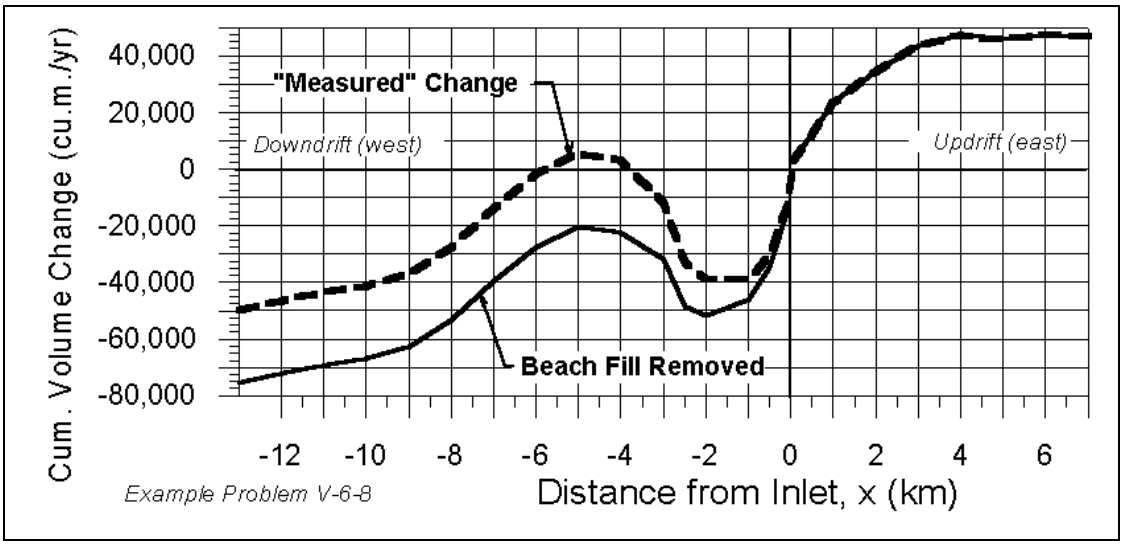

Figure V-6-18. Cumulative volume change with and without beach fill (Example Problem V-6-8)

In summary, the inlet's volumetric impact to the adjacent shorelines is estimated to range from 124,000 to 136,000 cu m/year. About 56 to 61 percent of this quantity (about 75,640 cu m/year) is manifest as erosion within 13 km downdrift (west) of the inlet. The total littoral impact, therefore, extends beyond 13 km from this inlet.

In applying this method, it must be realized that both natural and stabilized inlets have a net volumetric impact. The tendency is to assume that the volumetric impact of a stabilized inlet is entirely due to its stabilization and engineering activities. However, the same inlet in its natural state would also have an impact. The equivalent value for a natural inlet can be estimated by examining volumetric changes at a natural inlet with similar longshore transport rates, tidal range, and wave climate. Then, the volumetric change due to stabilization and engineering activities of the study site can be estimated by subtracting the two volumes.

In practice, the volume of sand impounded at the inlet's entrance (usually by jetties) can be estimated from profile surveys or shoreline-change data using the along-the-shore cumulative approach described above in method 1, criterion No. 4. (See Example Problem V-6-3.) The net volume of sand retained within the inlet shoals is estimated through comparison of bathymetric survey data; or at worse, through comparison of aerial photography with an assumed rate of vertical shoal thickness or accumulation. The volume of sand removed by dredging is estimated from records. Care should be taken to: Avoid double-counting of shoaling volumes and dredging volumes; exclude dredging quantities for new work associated with first-time construction or harbor deepening; exclude nonlittoral fractions (i.e., silt, clay, rock) from the dredging quantities.

Account for dredging quantities placed upon the adjacent shorelines from inlet/harbor maintenance and new work, or offshore sources.

In this fairly typical example, the downdrift shoreline changes, by themselves, do not reveal a clear picture of the inlet's signature. Methods 1 and 2 would therefore be of little value in this example, and methods 3 and 4 would not likely reveal the complete extent of the inlet's influence.

g. Inlet interactions with adjacent beaches.

(1) General.

Sediment may accumulate outside and inside an inlet. Sand storage exterior to the inlet is observed in the form of impoundment fillets along the shorelines adjacent to the inlet entrance. Also, a mature inlet with a well-developed ebb tidal shoal may bypass sand via the ebb shoal, resulting in an attachment zone, or bulge, on the downdrift beach. Interior sand storage occurs in the form of shoals, spits, and shoaling in channels. Mechanisms for this interior storage include (a) leakage of sand over, through, and around the inlet's terminal structures (jetties), and (b) wave- and current-driven transport to the inlet shoals. The effect of inlet-related bathymetry upon the wave field and sediment transport patterns can be observed through examination of wave refraction (discussed in the previous section), and by bathymetric and shoreline influences upon tidal currents.

Understanding the interaction of the inlet with its adjacent beaches is based upon:

(a) The degree to which the inlet's jetties impound, leak, or bypass sand.

(b) The direction, distribution and relative strength of the inlet's tidal currents.

(c) The effect of the inlet's ebb shoal plateau and adjacent bathymetry upon wave transformation (refraction) and littoral transport potential.

(d) The pattern in which shoals form within the inlet.

(e) The location and frequency of maintenance dredging of littoral sediments, and the placement history (location and frequency) and quality (e.g., sediment type and size) of this material.

Methods by which these factors may be examined are outlined in the following paragraphs.

Site observations and data.

There is no substitute for site visits and hours spent observing, walking, and wading along the inlet and its adjacent beaches. Observations should be preferably made during both strong ebb flow and flood flow, and at least once during energetic wave conditions from each of the principal directions of offshore incidence. Site visits should be initiated before commencing detailed studies to better identify those processes and data sources that bear examination. During or after the office analysis, additional site visits are necessary to assess the applicability of the analysis' results and to identify processes that require further study.

Important sources of historical data include:

- Aerial photography.
- Bathymetric surveys and charts.

- Beach profiles and historical shoreline maps.
- Dredging records.
- Discussions with dredging contractors experienced with the inlet's shoaling patterns.
- History of man's improvements and alterations.
- History of storm events.
- Existing reports and anecdotal histories of the inlet and adjacent shores.

If adequate data are not already available, researchers should consider the following new data:

- Controlled, rectified aerial photography.

- Shoreline location survey.

- Bank-to-bank bathymetric survey of the inlet throat, entire flood and ebb shoals, marginal shoals, and nearshore seabed.

- Beach profiles for characterizing the shape of the existing beach as a function of distance from the inlet, and direct comparison to previously collected beach profile data.

- Physical surveys of existing inlet structures (topography, elevations, permeability, etc.).

- Tidal current data focusing upon the horizontal distribution of principal flows and gyres on both the ebb flow and flood flow (dye injections into the water with concomitant aerial photography can be useful in this regard).

- Dye studies to discern jetty leakage (if not otherwise obvious).

- Directional wave data for a meaningful time period (includes hindcast data).

- Jet-probing, vibracore, core-boring, surface grab samples, periodic samples from the dredge plant, and other geotechnical means by which to discern those portions of the inlet's shoals and channels which contain littoral sediments derived from the adjacent shorelines.

- Environmental studies necessary to determine possible effects of disturbing portions of the inlet system for sand management (not discussed herein).

To the greatest extent practical, bathymetric surveys and beach profile surveys should be planned so as to facilitate comparison with existing, historical data. EM 1110-2-1810, "Coastal Geology," lists sources of geographic data in the United States. Other summaries of inlet-related data sources include Barwis (1975, 1976), Weishar and Fields (1985), and Chu, Lund, and Camfield (1987). The local sponsor (in the case of a Federal navigation project) or local interest(s) responsible for managing an inlet, and their private-sector contractors often hold the greatest repository of data specific to a given inlet, most of which is otherwise unavailable.

(2) Detection.

Approaches by which to discern how an inlet interacts with the adjacent beaches are described in the following paragraphs.

(a) Impoundment fillets and attachments. The degree to which sand is stored at an inlet's jetties can be detected by the shoreline signature (anomalous accretion) or the profile shape (anomalous steepness). Identification of these signals is described in Part V-6-2, methods 1, 2, and 3. Impoundment can occur on

either or both sides of a stabilized inlet. Sand may also be stored in the attachment zone, the region in which the inlet bypasses sand via the ebb-tidal shoal. This can be observed through a bulge in the shoreline and an extension of the ebb shoal towards the downdrift beach.

(b) Jetty leakage. Three elements demonstrate a jetty's permeability: its elevation relative to the adjacent beach and seabed; its length relative to the adjacent beach planform; and its porosity.

Elevation. The elevation of most old jetties is typically less than a meter above high water. Jetty crests below the elevation of the berm on the adjacent beach (usually more than 1 to 2 m above high water) allow wave runup to transport sand over the structure and into the inlet. This is typically shown by a high-water shoreline, berm shoreline, or dune line that curves landward immediately adjacent to the inlet (see Figure V-6-19). This local curvature is the result of a sluice that forms between the beach and the jetty. Because the jetty is lower than the beach, a downhill gradient exists from the beach toward the jetty. This promotes return flow of wave runup from the beach toward the jetty, which, in turn, accelerates sand transport from the beach into the inlet beyond that which would be normally transported by tidal currents and oblique incident waves.

Length. In the limit, beach profiles for which the closure depth (the limiting depth of sediment transport) falls seaward of the jetty's end will experience transport from the beach, around the jetty, and into the inlet. Field observation suggests that this effect becomes particularly significant when the beach profile adjacent to the jetty has accreted to the point where the average-annual, low-tide breaking depth (i.e., $h = H_{avg}/\kappa$, low-water datum) is at or seaward of the end of the jetty. In such a condition, it is likely that most, if not all, of the littoral drift that reaches the jetty passes around it. In this instance, the jetty is considered to be saturated.

At the same time, even in the saturated-jetty case, some fraction of the incident littoral drift may still be impounded further updrift of the jetty by the existing impoundment fillet. In this instance, the impoundment fillet continues to grow in a planform shape that may be similar to a backwater curve in classical hydraulics. This signature is sometimes evident in the shoreline's planform, and is predicted by analytic models such as Pelnard-Considère (1956) (see Part III- 2).

(c) Porosity. Jetty porosity is defined by sand transport through the structure. For bulkhead-type jetties, porosity results from cracks, corrosion, nonsealed joints, deterioration of backing (filter) cloth, or other sources of seepage. For rock or other armor-and-core structures, porosity results from insufficient chinking of stable, small rock within the voids between the large rocks or armor units. While this effect may be present within the structure's core, it is most commonly encountered near the top (waterline) of the structure. Here, there is generally minimal or no core, and small stones may have been washed out of the structure. Jetty porosity should be suspected for all rock structures that are low in elevation and/or narrow in profile (i.e., less than three or four armor units' width at the high waterline).

Jetty porosity is also demonstrated by the transmission of waves or current, however small, through the structure. Where transmission is uncertain, dye can be injected on the upwave or upcurrent side of the structure and observed. Porosity may also be evidenced by the occurrence of shoals immediately adjacent to the downwave / downcurrent side of the structure. Similarity between the shoal sediment and that of the adjacent beach is additional evidence of porosity.

In addition to the three factors previously listed, the appearance and growth rate of shoals and spits within the inlet is additional evidence of jetty permeability. This is discussed in item (e) in the following paragraphs.

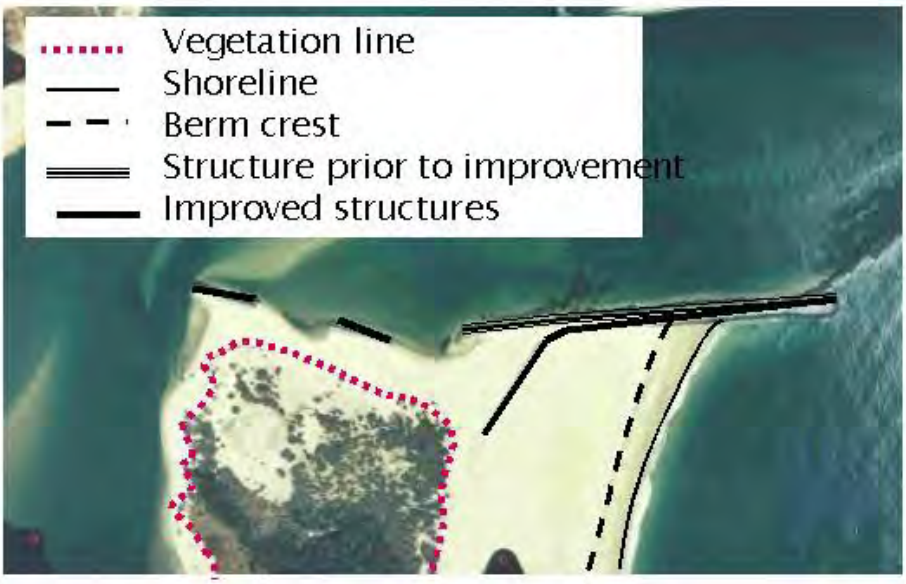

Figure V-6-19. Aerial photograph of Ocean City Inlet, MD, showing high-water shoreline, berm shoreline, and duneline

(d) Jetty rips. Offshore-directed rip currents can form along the upwave side of shore-perpendicular structures (such as jetties). These rip currents divert sand from the beach offshore, where the sand may or may not be transported to or along the inlet's ebb shoal. Rips are visually evident by a seaward-directed flow of water and the steepening of waves that encounter the rip. A modest sluice within 5 to 50 m adjacent to the structure may be visible at low tide. Lifeguards and surfers familiar with the area can be useful sources of data regarding local current and wave patterns.

(e) Inlet bathymetry and shoaling patterns. The location, rate of growth, and direction of movement of inlet shoals and spits, as well as the inlet's overall bathymetry, are excellent indicators of an inlet's sediment transport pathways. Use of bathymetry and shoaling patterns as a diagnostic tool requires, at a minimum, a bank-to-bank bathymetric survey of the inlet throat, flood shoal(s), and entire ebb shoal plateau. The latter should ideally extend outward and alongshore from the inlet entrance to capture the apparent point at which the ebb shoal attaches to the adjacent shorelines (if at all). Diagnostic ability is greatly improved when multiple, comparative surveys collected over time are available. Whenever possible, navigation channel condition surveys should be expanded to include bank-to-bank coverage of the inlet and as much of the inlet's shoals as possible. Pre-dredging, condition surveys are ideal because the shoals have had maximum opportunity to form prior to their removal by dredging. Reliance upon condition surveys that only include the navigation channel risks missing critical elements of the system's sediment transport pathways.

Charts and surveys of the inlet should be contoured at frequent depth intervals in order to illuminate shoaling patterns. Even using traditional, coarse-resolution nautical charts (for which only limited contours are routinely plotted), this technique can offer an enlightening view of the inlet's transport patterns. In the United States, the original National Ocean Service "T-sheets," upon which the printed nautical charts are based, provide additional data. The location and shape of shoals can reveal the potential source of the shoals' sand and the apparent direction of transport. The location of deep areas (outside of dredged areas) indicates apparent, preferred orientation of flow; and, in turn, areas where current-induced erosional stress may be exercised upon the adjacent shore. Figure V-6-20 illustrates an example of an off-the-shelf nautical chart of an inlet, before and after the addition of higher-resolution depth contours.

A particularly effective approach is to digitize, contour, and color-enhance the bathymetric data to more clearly reveal shoaling patterns. Pertinent upland features (jetties, shoreline, channel markers, etc.) should be added to the graphic to allow better visual correlation between the shoals, channels, and the inlet improvements. A prototype example is shown in Figure V-6-21, where lighter shading corresponds to shoals. Shading-enhanced depth contours readily show the leakage of sand through and around both jetties, the subsequent transport of the sand toward the flood shoal, and transport from the flood shoal toward the inlet entrance.

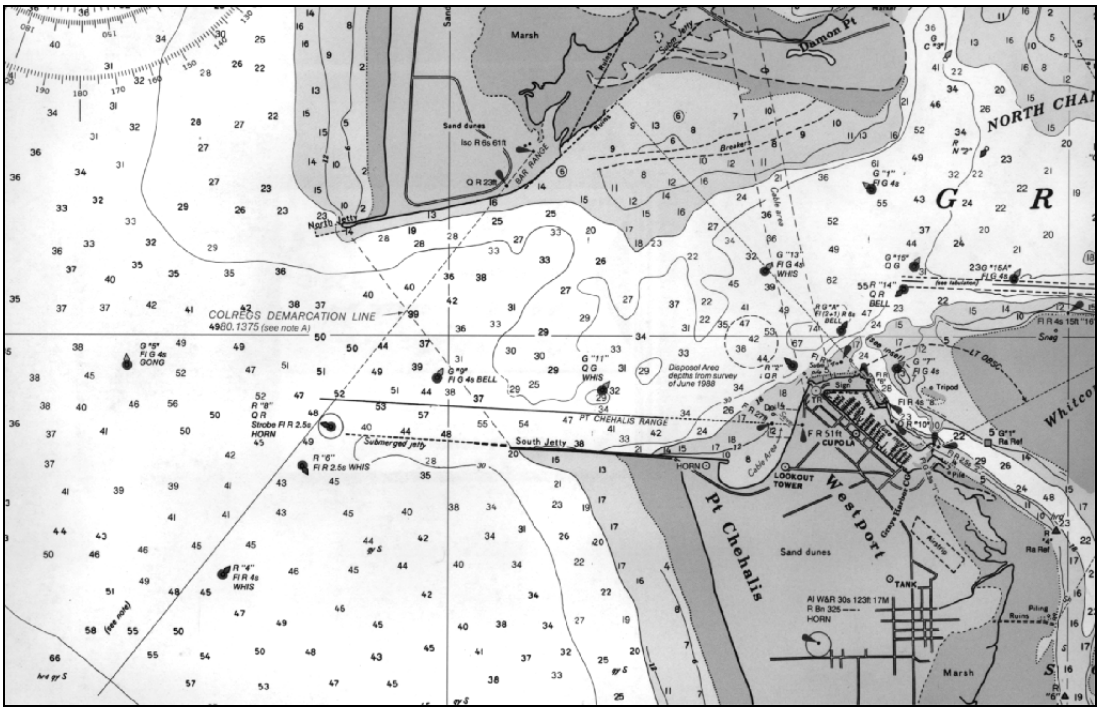
The location, growth, and chronic reappearance of shoals can highlight the paths by which sand enters an inlet. Shoals located near a jetty's seaward end indicate a saturated jetty or jetty rip currents. Shoals near a jetty's landward end suggest a structure that is porous or too low. Shoals and spits that form by sand transport through and over the jetty's landward section are most generally displaced well landward of the adjacent shoreline. These shoals are subject to landward-directed transported by incident waves that sweep along the inlet's interior shorelines. An emergent, sandy shoreline along the inlet's interior, connecting the jetty to the interior shoals, is further evidence of transport through or over the landward section of the jetty, or around the end of a short, saturated jetty. The possibility should also be considered that interior shoals may have been created (or enhanced) by riverine sand that enters the inlet and settles in quiescent water.

Figure V-6-22 illustrates an example in which the chronic reappearance of four distinct shoals along the inlet channel clearly reflects jetty leakage. The seaward two shoals correspond to known transport around the ends of the jetties. The landward two shoals correspond to transport through and over the jetties along the adjacent beaches' shorelines. Diving inspection, core boring, and dredging confirmed that the sediment from all four shoals is distinct from the silts and clays of the channel, but closely matches the adjacent beach sand.

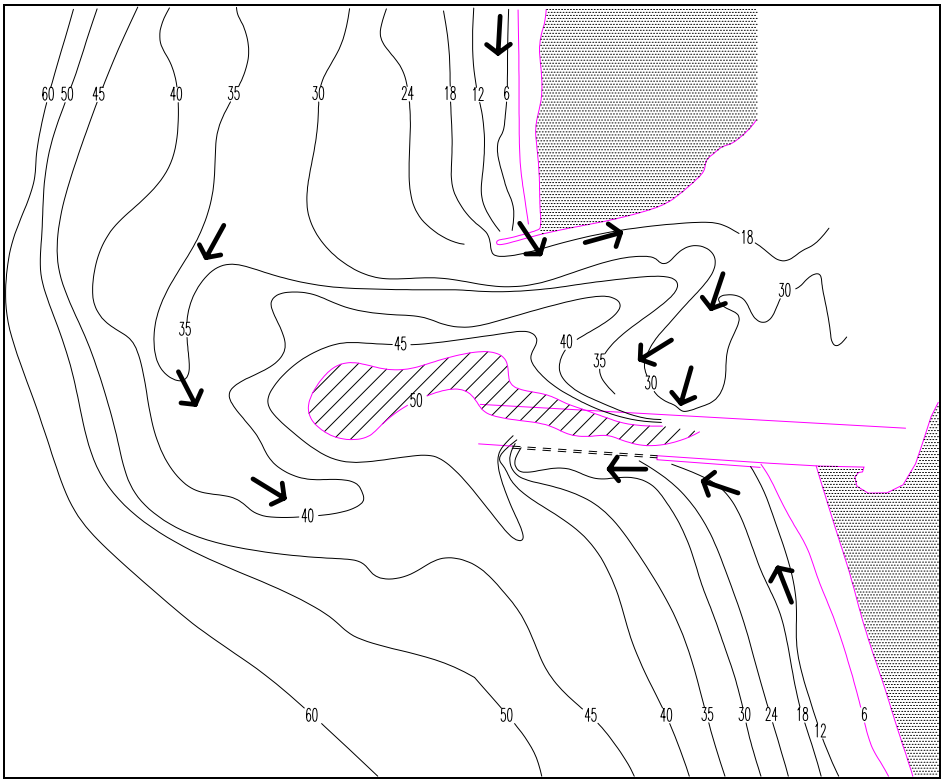
Comparisons of ebb and flood shoal surveys are necessary to estimate the net growth rate of these features. The degree to which these shoals contain nonlittoral material (e.g., silts and clays from rivers) should be considered so that the contributions from the riverine and coastal sources can be properly attributed. Identifying material type is typically based on examining samples from core-boring, dredged material, box-cores, or recovery methods. If only surface samples are available, care should be taken to consider whether silts and clays overlay sandy shoals that originated from the adjacent beaches.

In some locations, sand from shoals (particularly interior shoals) has historically been dredged for upland use. This practice, infrequently recorded or quantified – may have removed significant quantities of sand from many inlet systems (sand which originated from adjacent beaches). Evidence of interior shoal dredging may be offered by the increase of adjacent landfills (readily noted in historical aerial photography) and anecdotal information.

(f) Dredging records. Dredging records may be available from the inlet's managing agency or local sponsor, USACE district offices, and dredging contractors. The date(s), locations of dredging and disposal, purpose (maintenance or new work), and quantity are of central importance. The quantity of dredged littoral (sand) material vs. nonlittoral (silt-clay) material must be identified to differentiate coastal versus upland or riverine origin. Shoaling records (condition surveys) combined with geotechnical data (USAEWES 1995) and/or discussions with dredging contractors and contract managers can be employed for this purpose. Additionally, the location of, and cross-sectional shape of, the shoaling pattern are strong indicators of the source. Shoals that form near shallow, sandy portions of the ambient seabed (such as the ebb shoal) are more likely to be of littoral origin. Shoals that form against one side of the channel, as opposed to those that form uniformly across the channel bottom, are also more likely to be of littoral (beach) origin.



(a)



(b)

Figure V-6-20. Nautical chart with and without addition of higher-resolution contours. Arrows indicate sediment transport paths suggested by bathymetry

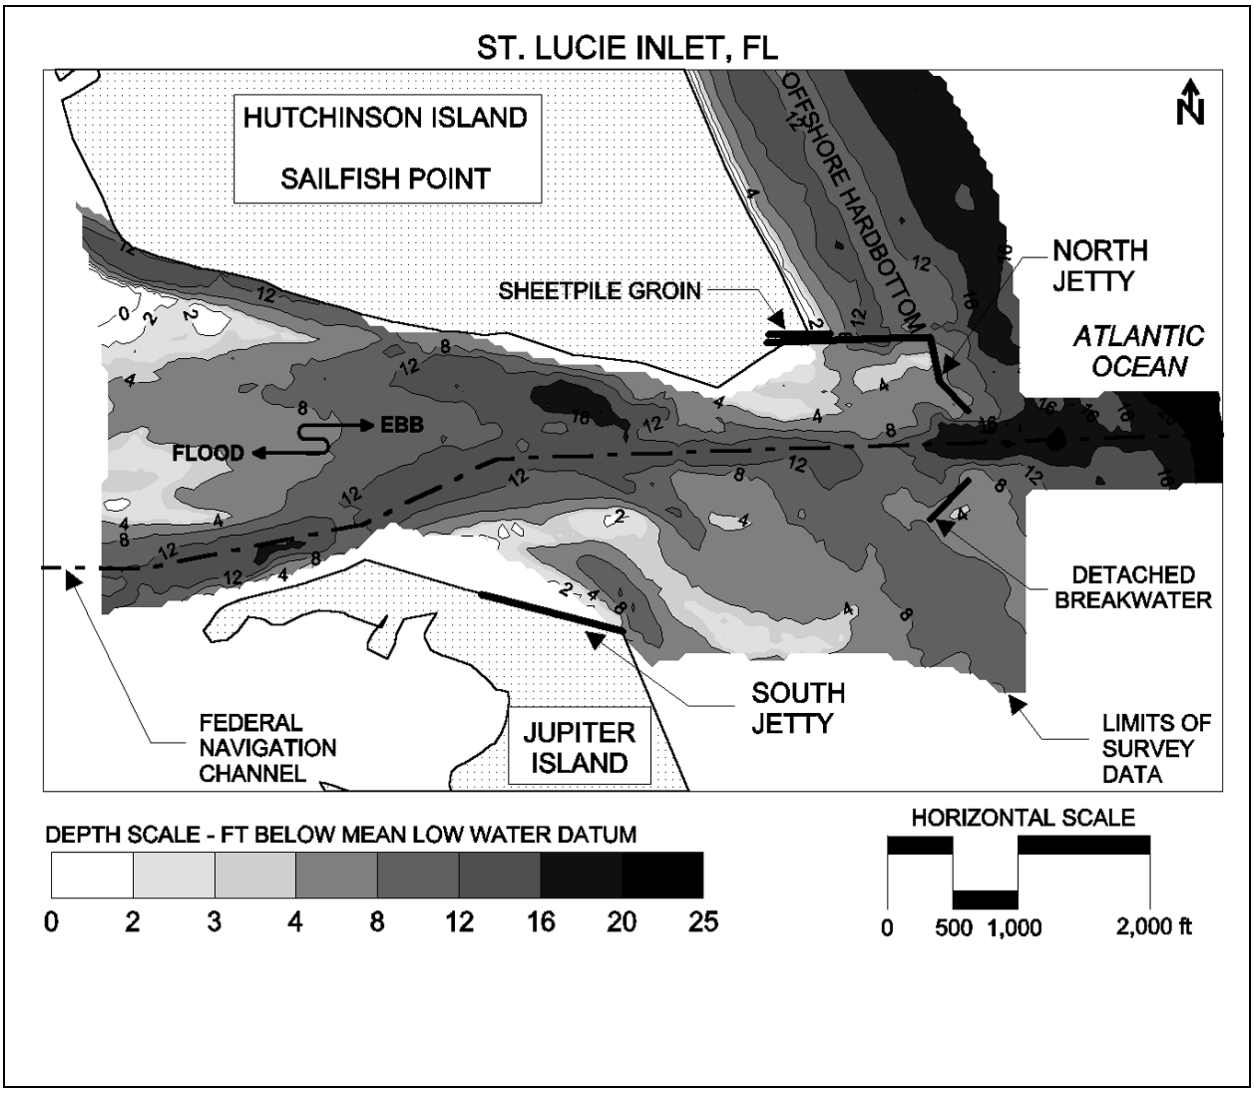


Figure V-6-21. Bathymetric chart of St. Lucie Inlet, Florida (c. 1995), digitized and gray-scale enhanced to better define the presence of shoals and channels

Figure V-6-23 illustrates a classic example of such shoaling signatures. The bar cut of the Brunswick Harbor Federal navigation channel is maintained at a depth of about 10 m (mlw) through an ambient seabed that was historically only 1 to 5 m deep. Material dredged from along the north bank and channel center line in the vicinity of Section A is typically beach-quality sand originating from the area's net southerly littoral drift. Material from the vicinity of Section B is typically silt and clay that settles into the deep channel from the surrounding seabed (slumping), riverine transport (terrigenous source), and oceanic deposition (pelagic settling).

We should note that not all of the littorally-supplied material at an inlet is necessarily sand. Some fraction of the dredged material may consist of silt, clay, gravel or organics of littoral origin. If this material is deposited offshore, it still represents removal of littoral material from the system, and must be included in computations of the inlet's littoral impact.

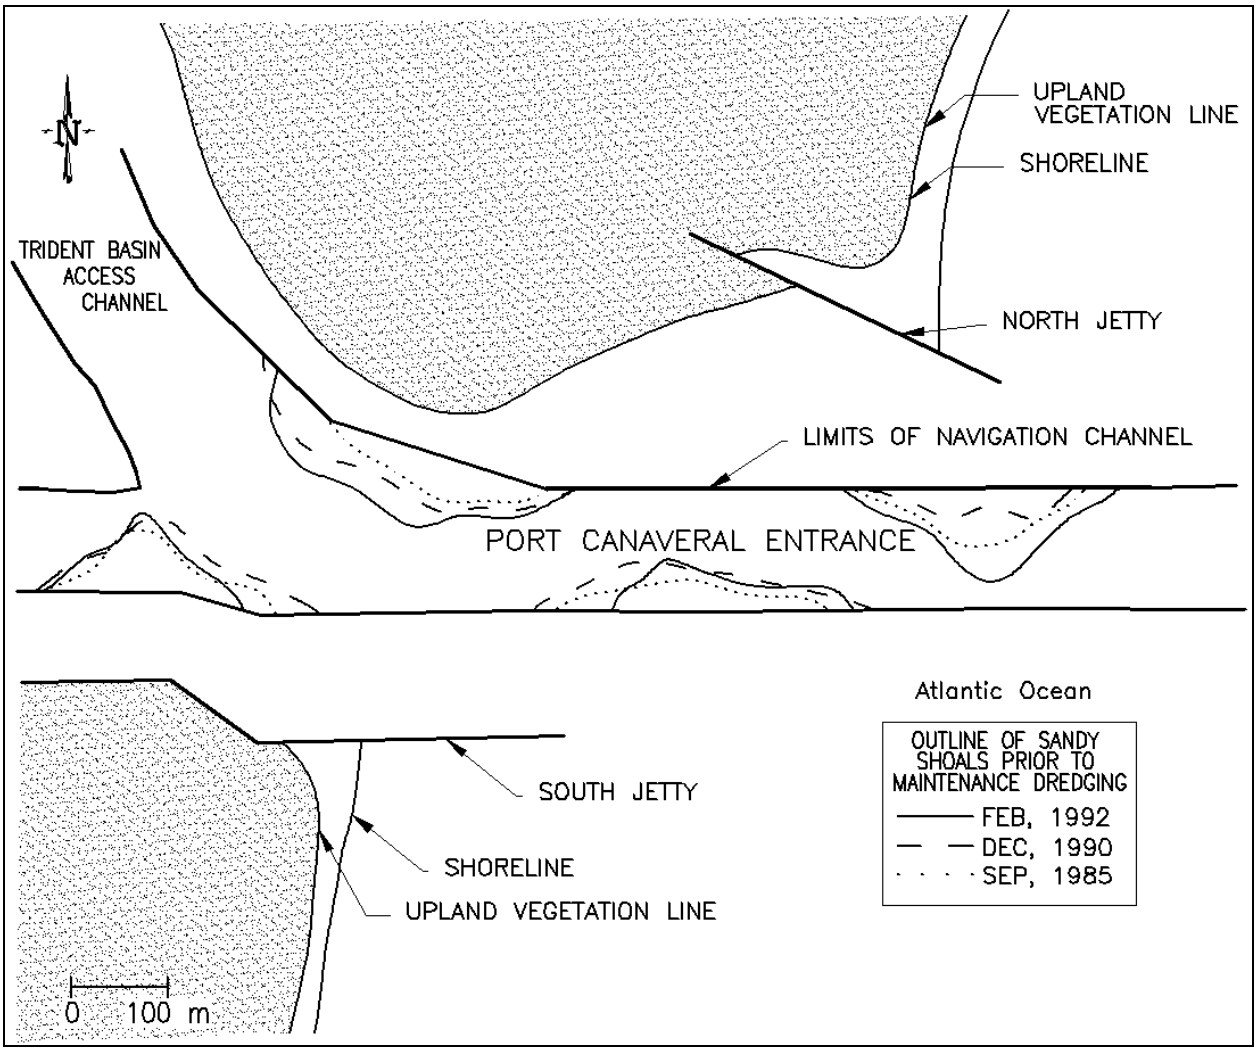

Figure V-6-22. Historical locations of sandy shoals within Port Canaveral Entrance, Florida prior to implementation of jetty/inlet improvements (Adapted from Bodge 1994a)

Dredging for new work (increased channel or harbor dimensions) is typically not included in inlet impact analysis because the material that is dredged is considered to have been a static part of the littoral system. In reality, this exclusion underestimates inlet impacts because some portion of the requisite dredging usually involves removal of beach sand that sloughs into the new channel during initial construction. However, the portion of advance maintenance dredging which features littoral material is included in the inlet impact analysis.

The degree to which increased channel dimensions or other inlet modifications alter dredging requirements can also reveal the degree to which the inlet diverts sand from the littoral system. This, again, requires discrimination of that part of the dredging quantity that was of littoral (beach sand) origin and undertaken for maintenance. Plotting the average-annual or cumulative quantity of maintenance-dredged littoral material as a function of time, and noting those times at which inlet modifications were undertaken, is a potentially useful technique to examine this effect (see Figure V-6-24).

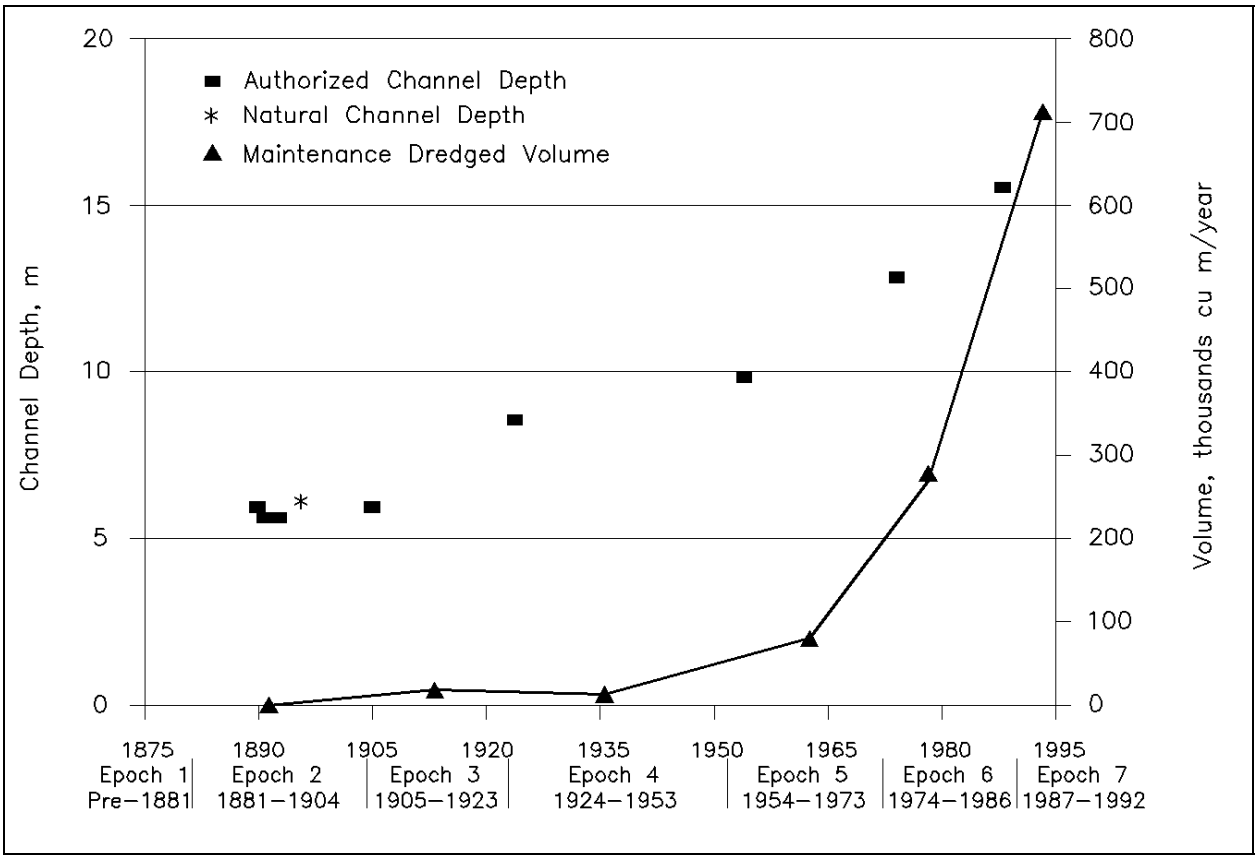

Figure V-6-24. Average annual volume of maintenance dredging at St. Mary's Entrance Channel and authorized channel depths; 1870 to 1992 (from USAEWES 1995)

h. Conclusion. This part of Chapter V-6 has discussed inlet processes and engineering activities at inlets. Inlets and associated engineering activities not only interact with local beaches and morphology, but also have the potential to alter sediment transport patterns and rates over the regional scale, especially over periods of many years. Methods discussed herein allow the coastal researcher to evaluate the impacts of these processes on the inlet morphology and adjacent beaches. These evaluations, together with inlet and adjacent beach sediment budgets (discussed in Chapter V-6-3), will improve the general understanding of the specific inlet's operation, and allow the engineer to optimize the timing and scope of engineering activities at the inlet and along the adjacent beaches.

V-6-3. Inlet and Adjacent Beach Sediment Budgets

a. Overview. This chapter discusses sediment budgets at inlets and their adjacent beaches. First, a history of sediment budgets is provided, followed by the theory of sediment budgets and required data sets to develop an inlet and adjacent beach sediment budget. Examples of previous sediment budgets are presented, and a series of example problems are given. The chapter concludes with a description of recent sediment budget methodologies.

b. Introduction.

(1) A sediment budget is an accounting or tabulation of the inflows and outflows of sediment together with the change in sediment volume within specified boundaries and for the time interval covered by the data. It is similar to a home budget that balances income (source of money), expenses (sinks of money), savings (positive amount), and debts (negative amount). Formulation of a realistic inlet and adjacent beach sediment budget is an essential prerequisite to the development of a successful inlet sand management strategy. Because an inlet's effect upon the adjacent shorelines is a function of the gross transport rates (not just the net rate), it is important to include both right- and left-directed transport in the sediment budget, as well as local, inlet-induced transport. In those cases where transport reversals occur at some time during the period of consideration (i.e., the majority of practical cases), inclusion of only the net transport rate will result in a potentially serious misinterpretation of the inlet's sediment transport pathways and associated volumetric rates of change.

(2) Development of the sediment budget requires that the rates and directions of sand transport adjacent to, within, and through the inlet be "deconvolved" from measured rates of volumetric change within the inlet system; specifically, the updrift and downdrift shorelines, the inlet shoals, and the channels. Allowances for the effects of dredging, beach fill, and other engineering of the inlet features must also be made. Development of the sediment budget is complicated by uncertainties in alongshore sand transport rates, typically incomplete or "noisy" volume-change data, and the fact that the number of transport rates for which values are unknown is greater than the number of equations which define the transport paths. The latter point means that the equations for an inlet sediment budget are almost always underconstrained. Accordingly, a unique solution is rarely possible. The goal, instead, is to develop a suite of possible solutions that is based upon reasonable assumptions of the inlet's processes. In this way, estimates of the practical ranges (or limiting values) of the rates at which sand is transported into or across the inlet from each shoreline can be made for various assumptions of the incident, alongshore transport rate or other physical parameters.

c. Theory.

(1) Since the 1950s, sediment budgets have been created to define the magnitudes and direction of sediment transport within a defined region and to understand, for example, inlet channel sedimentation and patterns of erosion and accretion along the coast. A balanced sediment budget yields an integrated picture of sediment (typically sand) motion, associated beach change, dredging and infilling of navigation channels at inlets, and other engineering activities within the reach covered by the analysis. Typically, the more reliable data form the foundation for the sediment budget, and lesser-known or more uncertain parameters are calculated to balance the budget by applying the principle of conservation of mass of sand (converted to volume or volumetric rate). A balanced sediment budget is a valuable tool for investigating observed coastal change and for forecasting the overall future state of the coast and consequences of management alternatives. Examination of an unbalanced sediment budget provides basic and useful information about the coastal system. An unbalanced budget may indicate a deficiency in the data set forming the budget (Dolan et al. 1987), reveal a misunderstanding in certain physical processes and assumptions (Inman 1991), or give bounds on the uncertainty range for the data sets. Whether or not formally developed, the sediment budget concept is fundamental to coastal engineering and science, usually providing the backdrop by which processes and projects are evaluated and alternatives considered. For additional background discussion, see Komar (1996, 1998).

(2) A sediment budget is a tallying of sediment gains and losses, or sources and sinks, within a specified control volume (or cell), or series of connecting cells, over a given time. There are numerous ways of formulating a sediment budget (e.g., Jarrett 1991; Bodge 1999). The difference between the sediment sources and the sinks in each cell, hence, for the entire sediment budget, must equal the rate of

change in sediment volume occurring within that region, accounting for pertinent engineering activities. The sediment budget equation can be expressed as,

$$\sum Q_{source} - \sum Q_{sink} - \Delta V + P - = R \quad \text{Residual} \tag{V-6-23}$$

in which all terms are expressed consistently as a volume or as a volumetric change rate, Q_{source} and Q_{sink} are the sources and sinks to the control volume (expressed as positive values), respectively, ΔV is the net measured change in volume within the cell, P and R are the amounts of material placed in and removed from the cell, respectively, and Residual represents the degree to which the cell is balanced. For a balanced cell, the residual is zero. Note that the notation for Q_{source} and Q_{sink} due to Longshore Sand Transport (LST) may differ, depending on the application. In Equation V-6-23, Q_{source} and Q_{sink} are expressed as positive values (this differs from that specified in Longshore Sand Transport discussion of Part III-2-2).

(3) Figure V-6-25 schematically illustrates the parameters appearing in Equation V-6-23. For a reach of coast consisting of many contiguous cells, the budget for each cell must balance in achieving a balanced budget for the entire reach.

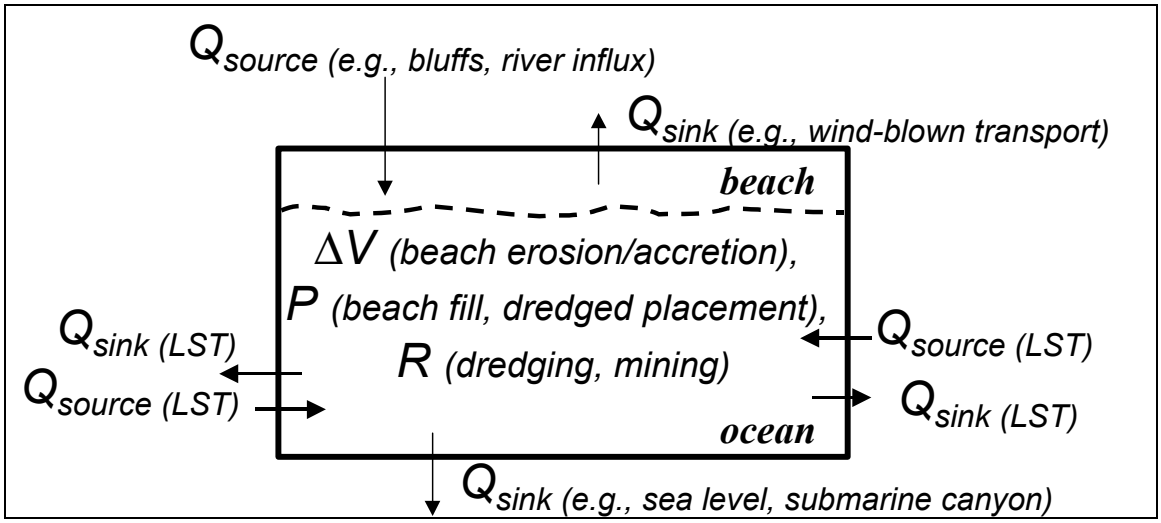

Figure V-6-25. Sediment budget parameters as may enter Equation V-6-23

(4) As noted in Figure V-6-25, sources to the sediment budget include longshore sediment transport, erosion of bluffs, transport of sediment to the coast by rivers, erosion of the beach, beach fill and dredged material placement, and a decrease in relative sea level. Examples of sediment budget sinks are longshore sediment transport, accretion of the beach, dredging and mining of the beach or nearshore, relative sea level rise, and losses to a submarine canyon. If inlets are located within the domain of a coastal sediment budget, they present significant challenges because inlets and the adjacent beaches are connected. Inlets increase the complexity of sediment budgets for several reasons. First, sediment-transport magnitudes and pathways are difficult to define at inlets even in a relative sense. Flood and ebb currents, combined waves and currents, wave refraction and diffraction over complex bathymetry, and engineering activities complicate transport rate directions and may increase or decrease their magnitudes. Because the pathways of sediment movement in the vicinity of an inlet can be circuitous, equations describing the sediment budget of regions directly adjacent to the inlet are not unique (that is, different formulations are possible).

(5) An inlet channel has the potential to capture the left- and right-directed components of the gross longshore transport of sediment, and the inlet system may bypass left- and right-directed longshore transport. Thus, knowledge of the net and gross transport rates, as well as the potential behavior of the inlet with respect to the transport pathways, may be required to correctly represent transport conditions within the vicinity of inlets, as emphasized by Bodge (1993).

d. Project applications.

(1) Sediment budgets can enter at any of four stages in project development:

(a) Existing condition. A sediment budget for the existing condition is the most common type considered. This budget forms the basis for evaluating the impacts of future engineering activities and the natural evolution of the inlet or coast.

(b) Historical (pre-engineering activity) condition. This budget is typically constructed for comparison with the existing-condition budget. A common application using the two budgets is to estimate shore erosion on adjacent beaches attributable to the impacts of inlet-related engineering activities that may warrant mitigation.

(c) Forecast future condition. Adapting and extrapolating the existing-condition sediment budget can assess the potential response to future projects or modifications.

(d) Intermediate condition. Sediment budgets representing other periods create a model of inlet or coastal evolution through time, which may lend insight to interpreting present or future evolution. As examples, intermediate-condition sediment budgets may document evolution of the inlet from initial formation to a quasi-equilibrium state, or may provide a picture of long-term natural bypassing through a cycle of channel migration and welding of a portion of the ebb-tidal shoal to the adjacent beach.

e. History of and procedure for sediment budget formulation.

(1) Consider a regional approach.

(a) For accurate representation of a local project area, especially in the vicinity of inlets, a sediment budget is formulated with its lateral boundaries located well beyond the apparent (expected) local project boundaries. A regional sediment budget might include multiple barrier islands, several inlets or several headlands and pocket beaches to fully capture the past and potential future changes in the sediment transport rate magnitude and direction.

(b) Inlets that have been stabilized by jetties for periods ranging from decades to centuries have the potential to influence the transport of sediment on the adjacent beaches for many kilometers, a distance that may extend well beyond what is considered the direct area of the inlet. Thus, a regional sediment budget that incorporates adjacent barrier islands, bay regions, underlying geology, estuarine and riverine impacts, and perhaps several inlets, may be required to assess the impacts of past and future projects. Engineering activities at navigable inlets and other data required for an inlet sediment budget have a high degree of uncertainty. Examples of these data include dredging quantity, location, and littoral quality; adjacent beach-fill volumes, initial cross-shore and longshore adjustment, and littoral quality; limited ebb-and (more commonly) flood-tidal shoal bathymetric coverage; and assessing the degree to which structures block, reduce, and modify the sediment transport pathways and magnitudes (Kraus and Rosati 1998a, 1999).

EXAMPLE PROBLEM V-6-9

Given:

Referring to figure V-6-26, balance the sediment budget equation given that $Q_{1\ source} = 250$, $Q_{1\ sink} = 100$, $Q_{2\ source} = 100$, $Q_{2\ sink} = 200$, $Q_{4\ source} = Q_{4\ sink} = 0$, $\Delta V = -70$, $P = 130$, and $R = 250$ (all units are thousands of cu m/year).

Find:

Find the value of $Q_{3\ sink}$ that balances the sediment budget (see Equation V-6-23 and Figure V-6-26).

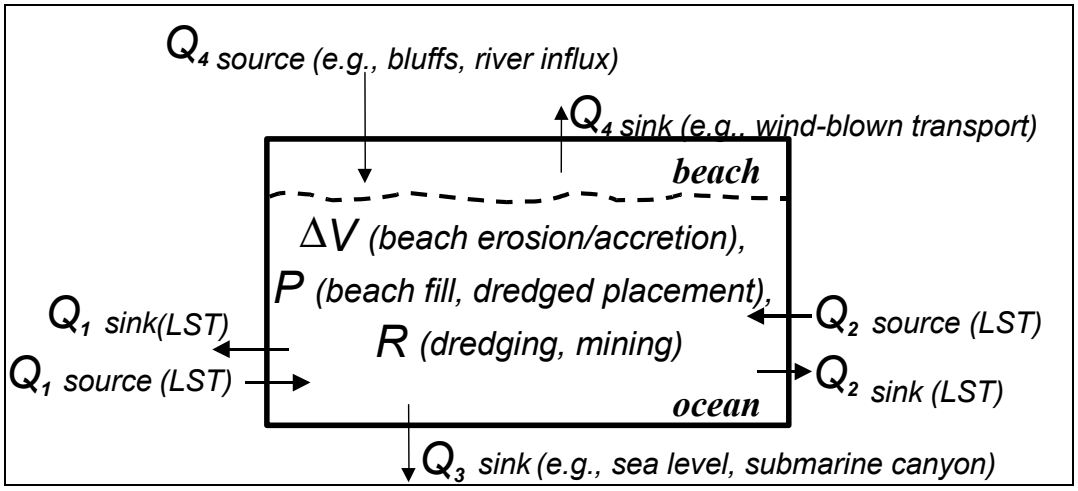

Figure V-6-26. Sediment budget for Example V-6-9

Substituting into Equation V-6-23 gives

$$\sum Q_{source} - \sum Q_{sink} - \Delta V + P - R = Residual$$

$$(250 + 100) - (100 + 200 + Q_{3\ sink}) - (-70) + (130) - 250 = 0$$

$$Q_{3\ sink} = 30$$

The value of $Q_{3\ sink}$ indicates that 30,000 cu m/year are transported out of the littoral cell, in the offshore direction.

(c) In one of the earliest works that may be considered a regional sediment budget, Caldwell (1966) summarizes a study performed in the 1950s by the U.S. Army Engineer District, New York, for the north New Jersey coast (USACE, 1957, 1958). The budget, formulated by examining changes in shoreline position, served as a field laboratory of shore processes with the objective of examining alternatives to mitigate for erosion. This celebrated study deduced a regional divergent nodal point in net longshore transport direction at Mantoloking, located just north of Dover Township. Net longshore transport to the north increased with distance north from Mantoloking because of the sheltering by Long

Island, New York. The budget considered net and gross longshore sand transport for this 190-km reach including 10 inlets over time intervals of 50 to 115 years.

(d) Another example of a regional sediment budget is that of Jarrett (1977, 1991) for the North Carolina shoreline, including three barrier islands and two inlets. Mann (1993) discussed use of a near field versus regional sediment budget. The near field sediment budget represents local (project area) sediment sources, sinks, and pathways. The regional sediment budget combines the near field budget with the sediment-transport processes occurring on the adjacent shorelines. For development of inlet sand management strategies (and estimating the inlet's littoral impacts), Mann recommends consideration of a regional sediment budget so that interactions of the inlet (and any proposed modifications) on the adjacent shorelines can be assessed. Although it may be difficult to define and balance all sources, sinks, and sediment transport pathways within a regional context, this comprehensive approach may allow the practitioner to recognize a source or sink of sediment hundreds of kilometers away that has a potential significance to the project area (Komar 1998).

(2) Develop a conceptual budget. Kana and Stevens (1992) introduced a conceptual sediment budget, which they recommend developing in the planning stage prior to making detailed calculations of individual sources and sinks. The conceptual sediment budget is a qualitative model giving a regional perspective of the inlet interaction with beach processes, containing the effects of offshore bathymetry (particularly shoals and, therefore, wave-driven sources and sinks), and incorporating natural morphologic indicators of net (and gross) sand transport. The conceptual model may be put together in part by adopting sediment budgets developed for other sites in similar settings, and incorporates all sediment sinks, sources, and pathways. The conceptual model should be developed initially, perhaps based upon a reconnaissance study at the site as part of the initial data set. Once the conceptual sediment budget has been completed, data are assimilated to validate the model rather than to develop the model.

(3) Ensure compatibility of temporal and spatial scales. In a discussion of the planning process for coastal projects, Kraus (1989) advocated the concept that the temporal and spatial scales of data used to develop and drive a model (whether a numerical, analytical, physical, or conceptual model) must be commensurate with these scales of the model itself. For example, a sediment budget developed based on pre- and post-storm data representing a day-to-month-length temporal scale within the immediate vicinity of the inlet should not be extrapolated to forecast to temporal scales of years and decades for a region extending over several barrier islands. Similarly, a sediment budget developed based on a 50-year period cannot adequately bracket the seasonal fluctuation observed locally at the project site. Sediment budgets are commonly required to represent periods of engineering and geomorphic significance, from 3-5 years (dredging cycle at inlets) to 30-50 years (project life span; time scale for cyclic ebb shoal welding). Data sets reflecting the longer durations are required to develop the sediment budget for spatial scales reflecting a regional approach. However, seasonal and year-to-year variability should be considered and can contribute to the uncertainty in a sediment budget, or form the basis for a sensitivity analysis.

(4) Delineate littoral cells. A littoral cell (or control volume) defines the boundaries for each sediment budget calculation, and denotes the existence of a complete self-contained sediment budget within its boundaries (Dolan et al. 1987). Bowen and Inman (1966) introduced the concept of littoral cells (Inman and Frautschy 1966) within a sediment budget. The southern California coast lends itself to this concept, with evident sources (river influx, sea cliff erosion), sinks (submarine canyons), and coastal geology (rocky headlands) defining semicontained littoral cells and subcells (Komar 1996, 1998). A littoral cell can also be defined to represent a region bounded by assumed or better-known transport conditions, or natural and engineered features such as the average location of a nodal region (zone in which $Q_{net} \sim 0$) in net longshore transport direction or a long jetty.

(5) Consider net and gross transport rates. For cells of the regional budget that may capture a portion of the left- or right-directed transport, both of these components must enter in the formulation. Examples include submarine canyons and inlet channels that capture both left- and right-directed transport; inlet weirs which may trap a portion of the left- or right-transport rate; and initial beach response at a long groin or headland feature, which may indicate accretion associated with left- and right-directed transport. Caldwell (1966) considered the gross transport rate as a potential indicator of shoaling for inlets in the vicinity of Cape May, New Jersey. Jarrett (1977, 1991) balanced potential longshore energy flux calculations with measured beach and tidal inlet change to solve for net and gross rates of longshore sand transport. Bodge (1993) focussed on the inlet and its adjacent beaches, and emphasized the importance of considering the gross components of longshore sediment transport, especially for inlets that act as sediment sinks. The gross transport rate can also provide an upper limit for the net, left-, and right-directed rates.

(6) Assign values and uncertainties.

(a) Known, estimated, or easily-obtained values and their associated uncertainties are assigned to source, sinks, and engineering activities within the sediment budget. This step should represent a low level of effort to quickly assess the integrity of the macrobudget (discussed in the following paragraphs) and to flush out any problems before detailed analysis begins.

(b) Every measurement has limitations in accuracy and contains a certain error. For coastal and inlet processes, typically direct measurement of many quantities cannot be made, such as the long-term longshore sand transport rate or the amount of material bypassing a jetty. Values of such quantities are obtained with predictive formulas or through estimates based on experience and judgement, which integrate over the system. Therefore, measured or estimated values entering a sediment budget can be considered as consisting of two terms, expressed schematically as

$$\textit{Reported Value} = \textit{Best Estimate} \pm \textit{Uncertainty} \tag{V-6-24}$$

Uncertainty, in turn, consists of error and true uncertainty. A general source of error is limitation in the measurement process or instrument. True uncertainty is the error contributed by unknowns that may not be directly related to the measurement process. Significant contributors to true uncertainty enter through natural variability and unknowns in the measurement process. These include temporal variability (daily, seasonal, and annual beach change); spatial variability (longshore and across shore); definitions (e.g., shoreline orientation, direction of random seas); and inability to quantify a process, such as the volume of material pumped to a beach, or the sediment pathways at an inlet. Other unknowns can enter, such as grain size and porosity of the sediment (especially true in placement of dredged material).

(c) As an example, suppose the variable X is a sum or difference of several independent parameters as $X = x + y - z + \ldots$, then the two common estimates for the uncertainty are:

$$\delta X_{\max} = \delta x + \delta y + \delta z + \ldots \tag{V-6-25a}$$

and

$$\delta X_{\text{best}} = \sqrt{(\delta x)^2 + (\delta y)^2 + (\delta z)^2 + \ldots} \tag{V-6-25b}$$

In both expressions, the errors add, whether or not the variables enter the quantity being reported as a sum or difference. Equation V-6-25a represents an extreme bound for the plausible error. Equation V-6-25b is the root-mean-square (rms) error, and the validity of this expression rests on the assumptions that the

individual uncertainties are independent and random. The rms error accounts for the uncertainty in uncertainty by giving a value that is not an extreme, such as δX_{max}.

(d) Suppose the quantity entering the budget is expressed as a product or quotient of independent variables as $X = xyz$ or as xy/z. In either case, the uncertainty in X is:

$$\left(\frac{\delta X}{X}\right)_{max} = \frac{\delta x}{x} + \frac{\delta y}{y} + \frac{\delta z}{z} \tag{V-6-26a}$$

and

$$\left(\frac{\delta X}{X}\right)_{best} = \sqrt{\left(\frac{\delta x}{x}\right)^2 + \left(\frac{\delta y}{y}\right)^2 + \left(\frac{\delta z}{z}\right)^2} \tag{V-6-26b}$$

and it is seen that the errors are additive whether a variable enters as a product or quotient. These equations state that the relative uncertainty of a product or quotient is equal to the sum of relative uncertainties of each term forming the product or quotient. Kraus and Rosati (1998a, 1999) further discuss uncertainty in coastal-sediment budgets.

(7) Formulate a macrobudget. A macro-budget is a quantitative balance of sediment inflows, outflows, volume changes, and engineering activities within the regional conceptual budget. Essentially, the macrobudget solves the budget with one large cell (perhaps by temporarily combining many interior cells) that encompass the entire longshore and cross-shore extents of interest. Balancing the macro-budget reduces the possibility of inadvertently including potential inconsistencies in a detailed or full budget (Kraus and Rosati 1999).

(8) Refine estimated values and uncertainties. Once the macrobudget has been balanced, detailed analysis for all inflows, outflows, volume changes, and engineering activities pertaining to each individual cell may commence. Originally estimated values used in formulating the macrobudget are used to provide reasonable ranges for each quantity.

(9) Use residuals to balance individual cells. As presented in Equation V-6-23, both a balanced sediment budget cell and the macrobudget have the sum of all sources, sinks, and engineering activities equal to zero. Inman (1991) discussed recording an unbalanced sediment budget cell (a cell with a non-zero residual in Equation V-6-23) as a region requiring more definition and investigation of the unknown processes. Knowledge of the residual may also be useful to bracket the uncertainty range for the data sets (Kraus and Rosati 1999).

(10) Conduct sensitivity testing. Once a sediment budget has been formulated, it can be copied and modified to evaluate the impact of any assumptions on the final sediment budget. Different data sets for the same project site can be applied to evaluate seasonal variations in beach change and transport rate direction and magnitude. A balanced budget representing a historical time period can be copied and altered to represent a potential future with-project condition.

f. Data required. The types of data sets that are available for refining sediment budget quantities are discussed in the following paragraphs. This section supplements the data required for inlet analysis described in Section V-6-2(f).

(1) Aerial photography. Interpretation of aerial photographs offers the best means of obtaining broad qualitative understanding of the site. As examples, photographs of sites with relatively clear water can identify the planform shape of the flood-tidal shoal to estimate its volume if more quantitative data are unavailable. The pattern of wave breaking over the ebb-tidal shoal indicates the planform shape of this feature, which might lend qualitative understanding of its interaction with adjacent beaches and of sediment pathways. Overwash fans on adjacent barrier islands indicate pathways for loss of sediment to the coastal littoral system, from which quantification of volumes might proceed. Shoals adjacent to jetties might indicate sediment-transport over and through the structure as a potential sediment transport pathway. In a more quantitative analysis, controlled and rectified aerial photographs are commonly interpreted to identify the berm or high-water line (HWL) shoreline position (Kraus and Rosati 1998b).

(2) Beach-profile surveys. Volume change, ΔV, in the beach can be obtained accurately through repetitive surveys of the beach profile. The volume change for a given profile is typically assumed to represent the region of beach of length Δx between adjacent profile lines. Both the elevations B of the berm and of the profile closure depth D_C can be estimated from beach-profile surveys if the profile data are sufficiently accurate and well controlled. The active berm crest is a discernible morphologic feature on the profile representing the upward limit reached by the water under normal tide and water-level conditions. The profile may have two berm crests if the beach has recently accreted, and the elevation of the seaward-most feature should be noted. The depth of closure is located where no significant depth changes occur over times of engineering significance (typically, 10 to 50 years) (see Hallermeier 1978; Birkemeier 1985; Wise 1998). Kraus, Larson, and Wise (1999) discuss the depth of closure in detail and extend its definition to cover varied conditions as encountered in engineering practice. Profile surveys performed near structures may indicate their condition. For example, a jetty that allows sediment transport over and through it might be indicated by a berm-crest elevation adjacent to the structure that is comparatively lower than the berm crest further away from the structure. Similarly, surveys close to structures reveal whether the profile deviates from the average shape far from the structures, improving estimates of sand volume. The investigator should be cautious in interpreting beach-profile data near the inlet because of migrating shoal features that may affect the profile shape.

(3) Shoreline-position data. Shoreline-position data may be obtained from analysis of topographic and HWL surveys, aerial photographs, beach-profile surveys, and bathymetric data (Anders and Byrnes 1991; Byrnes and Hiland 1995). In a qualitative manner, beach morphology indicated by shoreline position may imply sediment-transport pathways or controls. As examples, a salient or bulge-type feature in the shoreline downdrift of an inlet may represent the location for ebb shoal bypassing to the adjacent beach. Rocky headlands and outcroppings indicate geologic controls on sediment-transport pathways.

(a) As quantified in a sediment budget, the change in shoreline position Δy averaged over a given longshore distance Δx can be converted to a volume change by assuming that the shoreline translates parallel to itself over an active depth D_A, given by

$$D_A = B + D_C \tag{V-6-27}$$

in which B is the elevation of the seaward-most active berm relative to a datum, and D_C is the depth of closure measured from the same datum. The volume change[1] ΔV over a time interval Δt is given by

$$\Delta V = \frac{\Delta y \Delta x D_A}{\Delta t} \tag{V-6-28}$$

(b) If available, the impoundment rate at a shore-perpendicular structure such as a groin or jetty that is sand tight gives an estimate of the longshore sediment-transport rate.

(4) Bathymetry. Historical and recent bathymetric data sets are a valuable resource for determining the rate of volume change in the inlet channel and on the ebb and flood-tidal shoals. If coverage is sufficient, differences in bathymetric surfaces give the subaqueous volume change on the adjacent beaches and channel and ebb- and flood-tidal shoals. It is noted that, in the past, typical bathymetric coverage has been limited to the inlet channel. However, the benefits of increasing the survey area to include the ebb- and flood-tidal shoals far outweigh the additional costs, particularly in view of reductions in the cost of bathymetric surveys (e.g., SHOALS bathymetric survey system, Parson and Lillycrop 1998). Bathymetric data can also indicate sediment-transport pathways. As examples, a finger shoal extending from the tip of a jetty likely indicates a dominant sediment transport pathway, and the morphologic form of an ebb-tidal shoal that connects to the adjacent beaches may indicate inlet bypassing. Aerial photography of flood-tidal shoals at different, but known tidal elevations can be referenced to create a contour map of the shoals, and thereby to estimate a shoal volume.

(5) Engineering history.

(a) Engineering activities of significance to a sediment budget fall into two categories – those that are of a descriptive nature and must be quantified within the sediment budget; and those that are a priori quantified. Rehabilitation of a jetty is an example of a descriptive activity that requires quantification. The morphology of the inlet and adjacent beach before and after structure rehabilitation, as well as the type of rehabilitation (e.g., raising the jetty crest elevation, inserting a sand-tight core, adding armor stone), and other pertinent data sets indicate the effectiveness of the structure. Consideration should be given as to the degree of sediment transport through, over, and around the structure before and after rehabilitation. Another example of descriptive data is the grain size of dredged material placed on the adjacent beaches. From this information, the engineer must estimate percentage of material that would remain in the active littoral zone.
