FIFTH EDITION, THOROUGHLY REVISED AND ENLARGED

TOTAL ISSUE, FIFTY-FIVE THOUSAND

NEW YORK
JOHN WILEY & SONS, INC.
LONDON: CHAPMAN & HALL, LIMITED
1930

The Publishers and the Editor-in-Chief will be grateful to readers of this volume who will kindly call attention to any errors of omission or of commission therein. It is intended to make our publications standard works of study and reference, and, to that end, the greatest accuracy is sought. It rarely happens that the early editions of books are free from errors; but it is the endeavor of the Publishers to have them removed, and it is therefore desired that the Editor-in-Chief may be aided in his task of revision, from time to time, by the kindly criticism of readers.

JOHN WILEY & SONS, Inc.
440 Fourth Avenue, New York

First Edition printed in December, 1910; reprinted March, 1911
Second Edition printed August, 1912; reprinted October, 1913
Third Edition printed March, 1916; reprinted January, 1918
Fourth Edition printed January, 1920; reprinted March, 1921,
March, 1924, July, 1925
Fifth Edition printed February, 1930

Printed in U. S. A.

Composition, Electrotyping, Printing, and Binding
by Braunworth & Company, Brooklyn, N. Y.

PREFACE TO FIFTH EDITION

THIS edition closely follows the plan and the scope of the first four editions of which the late Mansfield Merriman was Editor-in-Chief. The present edition has been thoroughly revised and brought up to date. Much new matter has been added, many new cuts have been included and the entire work has been reset. Compared with the Fourth Edition the number of pages has been increased from 1995 to 2263. The large size of the book has suggested offering this edition both under one cover and under two. In two volumes it will serve the convenience of engineers who travel and those engaged in field work. The order of the sections has been changed to provide a more logical arrangement; the first eleven sections present general principles and materials, the second eleven sections treat of principles, design and applications in the several fields comprised under civil engineering. This order facilitates the use of the two-volume set. The complete index is included in each of the two separate parts.

Thos. H. Wiggin as Associate Editor-in-Chief has supervised the bringing out of this edition. His generalship during three years of continuous effort is reflected in the completed work. The editorial staff has been changed by the withdrawal of Ira O. Baker (deceased), Louis Fischer (deceased), Arthur H. Blanchard and Frederick E. Turneaure, whose places have been filled by Walter J. Douglas, Wilmer Souder, John S. Crandell and Arthur G. Hayden, respectively, and by the addition of Harrison P. Eddy and Charles J. McCarthy. George A. Goodenough died in 1929, after his section had been completed by him. The index has been prepared by Arthur R. Holbrook, a designing and constructing engineer of long experience on large engineering works. The Publisher and the Printer have spared no effort toward keeping the book up to its former high quality.

The Fifth Edition is believed to contain the latest accepted thought in the field of civil engineering theory and practice and to be, as heretofore, an authoritative work of reference.

THADDEUS MERRIMAN

NEW YORK, March, 1930.

PREFACE TO FIRST EDITION

IN November of 1908 the undersigned laid out a rough plan for the contents of a new Civil Engineers' Pocket Book and invited several highly qualified men to act as Associate Editors. In January of 1909 preliminary outlines of each of the sections were arranged by correspondence. In April of 1909 these outlines were perfected, and a preliminary table of contents of the entire book was sent to each editor together with instructions relating to the plan of treatment, the details of arrangement and typography, and the preparation of manuscript and drawings. In September of 1909 the first copy was sent to the engraver and printer. Now, after more than two years of arduous work in corresponding, compiling, writing, editing, proof reading, and indexing, the plates are about to be put on the press.

The Editor-in-Chief is responsible for the division of the book into sections and, in most cases, for the arrangement of chapters and articles. To every sheet of manuscript, every drawing, every galley proof and every page of type and plate proof he has given careful attention. He and the printer are responsible for the typography of the volume.

Each Associate Editor is responsible for the subject-matter of his section and has read and corrected the page proofs of it. Thanks are due to each and all for hearty cooperation and cheerful compliance with the instructions and wishes of the Editor-in-Chief.

From the instructions issued to Associate Editors in April of 1909 the following sentences are cited as explanatory of the plan of this volume:

> Pocket books are consulted by engineers because facts, formulas, tables, and methods can be found more quickly than by referring to textbooks or treatises. A pocket book must be prepared from this point of view. It should cover the ground with great conciseness and clearness, and be thoroughly up to date.
>
> The work is to be on a higher plane than former American Pocket Books. While Taschenbuch Hütte may generally be taken as a model regarding the presentation of mathematical matter, it is certain that this new Pocket Book should be very much better in respect to practical subjects. The reader is supposed to have a good knowledge of elementary mathematics, so that it is unnecessary to express formulas in words.
>
> Demonstrations are not required, but methods which cannot be expressed by formulas should be clearly explained and usually be illustrated by numerical examples. Logical order is not so important as in textbooks, and there should be no hesitation in deviating from it when deemed desirable. This is a reference book only.
>
> The fundamental principles to be kept in mind in preparing the copy are these: (1) Select those topics to which civil engineers desire to refer. (2) Condense the matter so that the greatest amount may be put in the assigned space and at the same time be clearly presented. (3) This Civil Engineers' Pocket Book must be better and fuller than any heretofore published in the English language.

The thirteen sections of the book contain 75 chapters, 620 articles, 495 tables, and 944 numbered figures which are equivalent to about 1200 ordinary cuts, since in many cases several similar figures are grouped together. The number of tables is so large that it is impracticable to mention them in the table of contents, for the mere list of their titles would occupy over eight pages of fine type, but references to all will be found in the index. Sections 2 to 11 inclusive deal with civil engineering proper, while Section 1 gives tables for approximate mathematical computations and Sections 12 and 13 treat of mathematics, mechanics, physics, meteorology, and weights and measures. These thirteen sections fill 1314 pages, and they are followed by a detailed alphabetic index which occupies 66 pages.

Regarding typography it has been the aim to render this Pocket Book more legible and artistic than any heretofore published. The page is longer and wider than usual, all type is leaded, there are no tables reading lengthwise of the page, and there are no short pages except at the beginning and end of a section. The effort has been made to economize space at every step where this did not conflict with the rules of good typography.

It is not claimed that this first edition is perfect. There are some duplications in minor topics and a few have been overlooked, while full unity of treatment has not been secured. Completeness, unity, and perfect accuracy are difficult of attainment in a first edition, and it can only here be affirmed that earnest efforts have been made to secure these desirable qualities. It is believed, moreover, that all whose names appear on the title-page have a pride in their connection with the volume and feel that it is a contribution to engineering literature which will promote sound engineering practise.

In conclusion it seems advisable to call the attention of readers of this book to the words of caution written by John B. Henck in 1854: "It may be remarked that it was no part of the purpose of this volume to furnish a collection of mere rules, professing to require only an ability to read for their successful application. Rules can seldom be safely applied without a clear understanding of the principles on which they rest."

20. Multipliers for Transferring Logarithms

	Common to Napierian	Example	
1	2.302585093	Example.	
2	4.605170186	Find Nap log of 105	
3	6.907755279		
4	9.210340372	Com log 105 =	2.02119
5	11.512925465	2	4.605170
6	13.815510558	.02	46052
		1	2303
7	16.118095651	1	230
8	18.420680744	9	207
9	20.723265837	Nap log 105 =	4.65396

	Napierian to Common	Example	
1	0.434294482	Example.	
2	0.868588964	Find number corresponding to Nap log $\bar{1}.6078$	
3	1.302883446		
		.6	0.26058
4	1.737177928	07	304
5	2.171472410	8	35
6	2.605766891		+0.26397
7	3.040061373	$\bar{1}$	−0.43429
8	3.474355855	Com log =	$\bar{1}.8297$
9	3.908650337	Number =	0.6756

21. Multipliers for Finding Lengths of Circular Arcs

	Degrees	Minutes	Seconds
1	0.017453293	0.000290888	0.000004848
2	0.034906585	0.000581776	0.000009696
3	0.052359878	0.000872665	0.000014544
4	0.069813170	0.001163553	0.000019393
5	0.087266463	0.001454441	0.000024241
6	0.104719755	0.001745329	0.000029089
7	0.122173048	0.002036217	0.000033937
8	0.139626340	0.002327106	0.000038785
9	0.157079633	0.002617994	0.000043633

Example.

Find length of arc for a central angle of 48° 45′ in circle of 12 ft. radius.

40°	0.698132
8°	.139626
40′	.011636
5′	.001454
	0.85085
	12
Length =	10.210 ft.

22. Mathematical Constants

Symbol	Number	Logarithm
π	3.1415927	0.4971499
2π	6.2831853	0.7981799
3π	9.4247780	0.9742711
4π	12.5663706	1.0992099
5π	15.7079633	1.1961200
6π	18.8495559	1.2753011
7π	21.9911486	1.3422479
8π	25.1327412	0.4002399
9π	28.2743339	1.4513924
$4\pi/3$	4.1887902	0.6220886
$\pi/2$	1.5707963	0.1961199
$\pi/4$	0.7853982	$\bar{1}.8950899$
$\pi/6$	0.5235988	$\bar{1}.7189986$
$\pi/30$	0.1047198	$\bar{1}.0200286$
$\pi/180$	0.0174533	$\bar{2}.2418774$

24. Explanation and Use of the Mathematical Tables

Arguments and Functions are the two kinds of numbers that appear in a table, the former being the numbers for which the values of the functions have been computed; thus, in sin θ, values of θ are arguments and those of sin θ are functions. In this book arguments are generally in bold-face type and functions in common type. An argument is placed at the side of the table and sometimes part of it is placed at the side and part at the top or foot; thus, when the reciprocal of 0.192 is sought, 0.19 is found at left-hand side and .002 at top, then 5.208 is found at the intersection of the horizontal row and the vertical column. **Interpolation** is the process of finding the function for an argument that falls between two tabular arguments. This is generally done by regarding the function as varying uniformly between the two adjacent tabular values. Hence if the given argument a is half-way between two tabular arguments a_1 and a_2, the required function f is the mean of the two corresponding tabular functions f_1 and f_2. In general when $a_2 > a_1$ and $f_2 > f_1$, the value of f for an argument a which lies between a_1 and a_2 is

$$\mathbf{f} = \mathbf{f}_1 + \frac{\mathbf{a} - \mathbf{a}_1}{\mathbf{a}_2 - \mathbf{a}_1}(\mathbf{f}_2 - \mathbf{f}_1) \qquad \text{or} \qquad \mathbf{f} = \mathbf{f}_2 - \frac{\mathbf{a}_2 - \mathbf{a}}{\mathbf{a}_2 - \mathbf{a}_1}(\mathbf{f}_2 - \mathbf{f}_1)$$

the first formula being preferable when $a < 1/2\,(a_1 + a_2)$, although both are applicable for any a. Thus by Table 14 the area of a circle for diameter 2.533 is found to be 5.039. When the functions decrease as the arguments increase, $f_2 - f_1$ is negative; thus log cot 42° 17′ is found from Table 2 to be 0.0413.

When a function is given and it is required to find the argument, the same process applies if a_1, a, a_2 are regarded as the functions and f_1, f, f_2 as the arguments. For example, when a cotangent is given as 1.8501 and the angle is required, the function is seen from Table 3 to fall between 1.8807 and 1.8040 which correspond to the arguments 28° and 29°; here the difference of the tabular functions is .0767 for a difference of 60′ in the arguments, while the difference 1.8807 − 1.8501 is 0.0306; then 306/767 = .4 and .4 × 60 = 24, whence the required angle is 28° 24′, closely.

An error of one or two units usually occurs in the last figure of a function obtained by interpolation, since the tabular values do not really vary in the manner supposed. An interpolated argument is liable to a similar error, hence care should be taken not to extend the figures too far; in the last numerical example, however, it happens that the last figures should be 231.

Logarithms of Numbers (Tables 1 and 26). The word logarithm and its abbreviation log, when used without qualification, refer to a common logarithm which is defined by the equation $10^{\log n} = n$. Table 1 gives the decimal part, or mantissa of a logarithm, while the integral part or characteristic is to be supplied according to the following rules. When the number is greater that 1, the characteristic of its log is positive and is one less than the number of figures preceding the decimal point; thus,

$$\log 6.54 = 0.81558 \quad \log 65.4 = 1.81558 \quad \log 654 = 2.81558 \quad \log 6540 = 3.81558$$

When the number is less than 1, the characteristic of its log is negative and is numerically one greater than the number of ciphers immediately following the decimal point, thus the four-place log of 6 is 0.7782, and

$$\log 0.6 = \bar{1}.7782 \qquad \log 0.06 = \bar{2}.7782 \qquad \log 0.006 = \bar{3}.7782 \qquad \log 0.0006 = \bar{4}.7782$$

Here the mantissa is positive, so that $\bar{2}.7782$ is the same as $-2 + 0.7782$. When the given number is an integral power of 10, the mantissa is zero, so that log 1000 = 3, log 100 = 2, log 10 = 1, log 1 = 0, log 0.1 = −1, log 0.01 = − 2, log 0.001 = − 3, or in general $\log 10^m = m$.

Multiplication and Division of numbers may be performed by the help of logarithms and the use of the following rules:

To multiply *a* by *b*,	$\log a + \log b = \log ab$
To divide *a* by *b*,	$\log a - \log b = \log a/b$

Here log *a* and log *b* are obtained from Table 1 or 26 and the above rules for the characteristic; then the numbers corresponding to log *ab* and log *a/b* are found from the Table. For example, to multiply 68.31 by 0.2754, the sum of the logs is 1.27444 and its corresponding number is 18.812, the last decimal being one unit in error.

Powers and Roots of numbers are most conveniently computed by logarithms and the use of the following rules:

To raise *a* to the *n*th power,	$n \log a = \log a^n$
To extract the *n*th root of *a*,	$\frac{1}{n} \log a = \log a^{1/n}$

For example to raise 0.6831 to the 1.53 power: $1.53 \times \bar{1}.83448 = -1.53 + 1.27675 = \bar{2}.47 + 1.27675 = \bar{1}.74675$ which is log of 0.55815. To find the fifth root of 0.6831: one-fifth of $\bar{1}.83448$ is $1/5\,(-5 + 4.83448) = \bar{1}.96690$ which is log of 0.9262; or it is perhaps better to multiply by 0.2 instead of dividing by 5, thus $0.2\,(\bar{1}.83448) = 0.2\,(-1 + 0.83448) = -0.2 + 0.16690 = -1 + 0.8 + 0.16690 = \bar{1}.96690$.

Table 2 contains logarithms of trigonometric functions to four decimal places at intervals of 1°, the characteristics being given. When the angle is less than 45° look for it on the left side and for the name of the function at the top; when greater than 45° look for it on the right side and for the function at the foot. In many books these functions are called logarithmic sines, logarithmic tangents, etc., while the characteristics are written 8 and 9 instead of $\bar{2}$ and $\bar{1}$, thus requiring some multiple of 10 to be subtracted later. Here the final logarithm of a computation is correct without such subtraction; thus to compute $(\cos 18°)^3$ write $\log (\cos 18°)^3 = 3 \log \cos 18° = \bar{1}.9346$, which is log of 0.8601. If any one wishes to use the old but illogical method, he can, in taking a log from a table, write 9. instead of $\bar{1}$. and 8. instead of $\bar{2}$. as in Table 27.

Table 2 gives four-place logs of trigonometric functions. The columns for log arc refer to the angles expressed in radians or to the arc of the circle expressed in terms of radius unity. Thus for 10°, the arc is 0.1745 and log arc to 10° is $\bar{1}.2419$; the arc of 57°.3 is 1.0000 and log arc 57°.3 is 0.0000. The above remarks regarding characteristics should be noted.

Natural Trigonometric Functions (Arts. 3 and 28–29). Table 3 gives four-place functions for every degree and Tables 28–29 give five-place for functions for intervals of 1′ in angle. For explanation of the term arc, see preceding paragraph. For rules regarding the signs of functions greater than 90° see Sect. 2. The secant of an angle is the reciprocal of its cosine and cosecant is the reciprocal of sine. The logarithms of the functions in Table 3 are given in Table 2, and those of the functions in Tables 28 and 29 are in Table 27. Log sec = − log cos and log cosec = − log sin.

Reciprocals, Powers, and Roots (Arts. 4–10, pp. 14–26). The arrangement of most of these is like that of a logarithmic table, the last figure of the argument being given at the top and foot. By properly moving the decimal point in both argument and function, Tables 4–8 may be used for other numbers than those given. For example, reciprocals of 0.0504, 0.504, 5.04, 50.4 are 19.84, 1.984, 0.1984, 0.01984 to four significant figures; square roots of 3.04 and 304 are 1.744 and 17.44, while those of 30.4 and 3040 are 5.514 and 55.14. When the decimal point is moved one place in a number it is moved two places in the square and three places in the cube.

The Three-halves Powers in Table 9 have been taken from Horton's Weir Experiments, Coefficients and Formulas (Water Supply and Irrigation Paper 200 of U. S. Geological Survey, 1907) and are here given to four decimal places only. All those which end in 5 in Horton's table have been recomputed.

Table 10 has been computed for this Handbook, the work being done in duplicate. To find $(10\,n)^5$, $(10\,n)^{1/5}$, $(10\,n)^{5/2}$, and $(10\,n)^{2/5}$ multiply the tabular values by 100000, 1.5849, 316.23, and 2.5119. To find $(0.1\,n)^5$, $(0.1\,n)^{1/5}$, $(0.1\,n)^{5/2}$ and $(0.1\,n)^{2/5}$ multiply the tabular values by 0.00001, 0.63096, 0.0031623, and 0.39811.

Circles and Spheres (Arts. 11–17, pp. 27–33). Tables 11, 14, 16 give circumferences of circles, areas of circles, and volumes of spheres for diameters in units and tenths. When the decimal point is moved one place in a diameter, it is to be moved one place in a circumference, two places in an area, and three places in a volume. Thus, for diameters 1.53 and 15.3 ft., the areas of the circles are 1.839 and 183.9 sq. ft., and the volumes of the spheres are 1.875 and 1875 cu. ft When the diameters are given in units and eighths, Tables 12, 15, 17 are to be used.

Table 13, which gives properties of circular segments, has been taken from Taschenbuch Verein Hütte, 1905. Lengths of the arc of the segment are given in Table 3 up to 90° and for larger angles may be found from Table 21. Example: for central angles of 35° and 105° and a radius r, the arcs are $0.6109\,r$ and $1.8326\,r$, the chords are $0.6014\,r$ and $1.5867\,r$, the rises are $0.0463 =$ and $0.3912\,r$, and the areas are $0.01864\,r^2$ and $0.4\,3333\,r^2$.

Areas of Spheres may be found by multiplying the circular areas in Tables 14 and 15 by 4, since the area of a sphere is equal to that of four great circles. Thus, area of a sphere for diameter 1.53 is 7.356, the last figure being one unit in error.

Miscellaneous Tables (Arts. 18–23, pp. 34–36). Table 18 gives hyperbolic sines, cosines and tangents for arguments up to 4.9. The hyperbolic cotangent, coth u, may be found by taking the reciprocal of tanh u. Powers of the Napierian base, $\epsilon = 2.71828$, may be obtained by taking the sum of cosh u and sinh u when u is positive and their difference when u is negative; thus, $\epsilon^{2.5} = 12.1825$ and $\epsilon^{-2.5} = 0.0821$.

Napierian Logarithms, often called hyperbolic logs or natural logs, are given in Table 19 for numbers from 1 to 119. The abbreviation Nap log designates these, and they are defined by the equation $\epsilon^{\text{Nap log } n} = n$, where ϵ is the Napierian base 2.71828. Extended tables of Napierian logs are unnecessary since they may be easily computed from common logs as shown by the example in Table 20.

Table 21 gives multiples for computing lengths of circular arcs for any given central angle. In Table 22, the symbol π represents the ratio of the circumference of a circle to its diameter, ϵ the base of the Napierian system of logarithms, and μ the modulus of the common system of logarithms; $1/\mu$ is the Nap log of 10.

Circumferences and areas of circles may be computed with accuracy to six or seven significant figures by the help of the multiples of π given in Table 22 using circumference $= \pi d$ and area $= \pi r^2$ where d is the diameter and r the radius.

25. Precision of Results Computed from Tables

Numbers in Tables are not generally precise in the last figure, and hence a lack of precision occurs in the final result of a computation. It is important that a computor should use the tables so as to obtain the most precise result and also that he should not attribute to the result a precision that does not exist. In general no more than four reliable significant figures can be obtained from a four-place table; indeed the fourth significant figure is liable to an error of one-quarter of one unit. Hence the Tables 28 29 cannot be used for cases where six or more significant figures are required to be accurately determined, but their use is limited to cases where only four or five are needed. The greater part of the computations in engineering require only three or four significant figures to be determined with accuracy.

The values given in tables may have a maximum error of one-half a unit in the last figure. Thus in Table 3 the value of sin 18° is given as 0.3090, this meaning that the true value lies between 0.30895 and 0.30905; in Table 28 it is given as 0.30902, this meaning that the true value lies between 0.309015 and 0.309025. When a quantity, like 576.48 sin 18° is to be computed by the four-place natural sine, the multiplication gives 178.13232, but the last four figures have no precision, since all that can be concluded by the use of the number 0.3090 is that the result lies between 178.103498 and 178.161142. Hence the result of this multiplication should be written 178.1, and it should be recognized that the last figure may have an error of one-half a unit. When a five-place sine is used the numerical value of $a \sin \theta$ is liable to an error of half a unit in the fifth significant figure when $\sin \theta$ is taken from Table 28 without interpolation.

An interpolated value may have double the error of a tabular value, since it is obtained by using the difference of two tabular values one of which may have a positive error while the other may have a negative error. Thus sin 8° 18′.5 is found from Table 28 to be 0.14450, this meaning that the true value lies between 0.14449 and 0.14451. Hence the quantity $a \sin \theta$ when obtained by the multiplication of a by a sine interpolated from a five-place table may have an error of one unit in the fifth significant figure. All figures beyond the fifth have no precision whatever and are entirely misleading.

The Probable Error of a number taken from a table is that error which is as likely as not to be exceeded. When the number is directly taken from the table its probable error is one-fourth of a unit in the last figure; when it is obtained by interpolation its probable error is one-half of a unit in the last place. An interpolated value has really a probable error slightly greater than that just stated, since the function does not vary uniformly between two tabular values as the method of interpolation implies.

When the product of two quantities f_1 and f_2 is to be obtained by using tabular values, the product $f_1 f_2$ may have a maximum error $(f_1 + f_2)\, r$ and its probable error is $1/2\ (f_1 + f_2)\, r$ where r is half a unit in the last place when the numbers are directly taken from the table and one unit when interpolation is made. Thus, the four-place product of 4.12^2 and 7.43^2, when obtained by multiplying the four-place squares given in Table 5, is 936.7, the probable error of which is 0.18; the last figure is here really three units in error but an error so large will occur only about one time in a hundred. For cases of this kind logarithms give more precise results; thus by four-place logs the product of 4.12^2 and 7.43^2 is 937.2 where the last figure is only one unit in error.

The quotient f_1/f_2 also has the probable error $1/2\ (f_1 + f_2)\, r$. When several quantities taken from tables are combined either by direct multiplication or division, the probable error of the result is $1/2\ (f_1 + f_2 + f_3 + \ldots)\, r$ and its maximum error may be twice as great. When logarithms are used, the probable and maximum errors are much smaller.

Inexperienced computors sometimes, in making interpolations, use all the figures obtained in the multiplication of differences, and thus carry the work several places further than the tabular values warrant. This procedure not only entails additional work and gives extra figures which are wholly inaccurate, but it leads the computor to suppose that his results have a far higher degree of precision than is actually the case, hence vitiating his judgment and perhaps leading to the deceit of others as well as of himself. The above indicates that no more significant figures should appear in intermediate work or final results than are given in the tables which are used.

In this discussion the data of the computation are regarded as free from error. When the data are obtained by measurement, these are affected by the errors and uncertainties of the measurements and hence the probable errors of the computed results are greater than those noted above. See Sect. 2, Art. 14.

SECTION 2

MATHEMATICS AND MECHANICS

BY

EDWARD R. MAURER

PROFESSOR OF MECHANICS IN UNIVERSITY OF WISCONSIN

ELEMENTARY MATHEMATICS

1. Algebra

Notation. Known or constant quantities are usually represented by the first letters of the English alphabet and unknown or variable quantities by the last letters. The Greek letter π is universally used for 3.14159 . . . In this book ϵ is used for 2.71828 . . .. and other Greek letters are rarely used except for angles. Names of Greek letters are

α Alpha	η Eta	ν Nu	τ Tau
β Beta	θ Theta	ξ Xi	υ Upsilon
γ Gamma	ι Iota	o Omicron	ϕ Phi
Δ, δ Delta	κ Kappa	π Pi	χ Chi
ϵ Epsilon	λ Lambda	ρ Rho	ψ Psi
ζ Zeta	μ Mu	Σ, σ Sigma	ω Omega

In this volume the sign / is often used to indicate division; thus, 3/8 is the same as $\frac{3}{8}$ and a/b is the same as $a \div b$. For the product of the first n natural numbers $n!$ is used.

Powers and Roots. The notation a^n denotes the nth power of a, even when n is negative or fractional. Rules for powers are: $(+a)^n = +a^n$, $(-a)^n = +a^n$ if n is an even integer and $-a^n$ if n is odd; also $(a^m)^n = a^{mn}$, $a^{-n} = 1/a^n$, $a^0 = 1$. For multiplication and division of powers, $a^m \times a^n = a^{m+n}$ and $a^m/a^n = a^{m-n}$.

The notation $a^{1/n}$ or $\sqrt[n]{a}$ denotes the nth root of a. Replacing m and n in the last paragraph by $1/m$ and $1/n$, the rules there given for powers apply also to roots. An even root of a positive number is positive or negative and an odd root is positive; an odd root of a negative number is negative and an even root is impossible or imaginary.

The symbol i denotes $\sqrt{-1}$, which is the simplest imaginary quantity. If a is positive and n even, then $(-a)^{1/n} = a^{1/n}i$. Powers of i are $i^2 = -1$, $i^3 = -\sqrt{-1}$, $i^4 = +1$. A complex quantity is one partly real and partly imaginary, as $a + bi$; The complex numbers $-1/2\,(1 + 3^{1/2}i)$ and $-1/2\,(1 - 3^{1/2}i)$ are two of the cube roots of unity.

Factors of some algebraic expressions are

$$a^2 - b^2 = (a - b)(a + b) \qquad a^2 + b^2 = (a - bi)(a + bi)$$
$$a^3 + b^3 = (a + b)(a^2 - ab + b^2) \qquad a^3 - b^3 = (a - b)(a^2 + ab + b^2)$$
$$a^n - b^n = (a - b)(a^{n-1} + a^{n-2}b + a^{n-3}b^2 + \ldots + b^{n-1})$$
$$a^n - b^n = (a + b)(a^{n-1} - a^{n-2}b + a^{n-3}b^2 - \ldots - b^{n-1}) \text{ if } n \text{ is even}$$
$$a^n + b^n = (a + b)(a^{n-1} - a^{n-2}b + a^{n-3}b^2 - \ldots + b^{n-1}) \text{ if } n \text{ is odd}$$

When a and b are small compared to 1, then approximately,

$$(1 + a)(1 + b) = 1 + a + b \qquad (1 + a)^m(1 + b)^n = 1 + ma + nb$$
$$1/(1 + a) = 1 - a \qquad 1/(1 - a) = 1 + a \qquad \sqrt{ab} = 1/2(a + b)$$

Logarithms. When $y = b^x$ and b is a fixed number, x is the logarithm of y to the base b, or $\log_b y = x$. When $b = 10$ the logarithms are in the common system; thus since $100 = 10^2$, and $0.1 = 10^{-1}$, the common logs of 100 and 0.1 are $+2$ and -1. When $x = 0$, $y = 1$, and hence for all systems the log of 1 is 0. Numbers greater than 1 have positive logs and those less than 1 negative logs. When $b = 2.71828$ . . . the logs are in the Napierian system.

Proportion. All rules are included in this, where m, n, p, and q have any values:

$$\text{if} \quad \frac{a}{b} = \frac{c}{d}, \qquad \text{then} \quad \frac{ma + nb}{pa + qb} = \frac{mc + nd}{pc + qd}.$$

A Permutation is any arrangement that can be made of several things; thus, for three letters there are six arrangements: abc, acb, bac, bca, cab, cba. The number of permutations of n things taken r at a time is $n(n - 1)$ . . .

$(n - r + 1)$. For example the number of permutations of seven things taken three at a time is $7 \times 6 \times 5 = 210$. A **combination** is a group made by taking things without reference to their order; thus for three letters there is only one combination abc. The number of combinations of n things taken in groups of r is $[n(n-1)\ldots(n-r+1)]/r!$. For example, when seven lines radiate from a point the number of combinations of these taken two at a time is $7 \times 6/2 = 21$, and hence there are 42 angles that can be measured.

The Binomial Theorem or formula is a means for writing out the power of a binomial in a series. It is

$$(a \pm b)^n = a^n \pm na^{n-1}b + \frac{n(n-1)}{1 \cdot 2}a^{n-2}b^2 \pm \frac{n(n-1)(n-2)}{1 \cdot 2 \cdot 3}a^{n-3}b^3 + \ldots$$

When n is a positive integer it holds in all cases; when n is a fraction or negative it holds only if a is greater than b. In the first case the expansion (right-hand member) has $n + 1$ terms; in the second the number of terms is infinite. The coefficients of the powers of a and b in the expansion are called binomial coefficients; the general formula for the rth coefficient is $Cr = [n(n-1)(n-2)\ldots(n-r+1)] \div [1 \times 2 \times 3 \times \ldots r]$. Thus when $n = 5$, the coefficients are 1, 5, 10, 10, 5, 1.

If x stands for b/a, then $(a \pm b)^n = a^n(1 \pm x)^n$, and the expansion of a binomial of the type $(a \pm b)$ can be expressed by that of a binomial of the type $(1 \pm x)$. When n is a positive integer the following hold in all cases, but when n is a fraction or negative they hold only if x is between 0 and 1.

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{1 \cdot 2}x^2 \pm \frac{n(n-1)(n-2)}{1 \cdot 2 \cdot 3}x^3 + \ldots$$

$$\frac{1}{1 \pm x} = (1 \pm x)^{-1} = 1 \mp x + x^2 \mp x^3 + x^4 \mp x^5 + \ldots$$

$$\sqrt{1 \pm x} = (1 \pm x)^{1/2} = 1 \pm \frac{1}{2}x - \frac{1 \cdot 1}{2 \cdot 4}x^2 \pm \frac{1 \cdot 1 \cdot 3}{2 \cdot 4 \cdot 6}x^3 - \ldots$$

$$\frac{1}{\sqrt{1 \pm x}} = (1 \pm x)^{-1/2} = 1 \mp \frac{1}{2}x + \frac{1 \cdot 3}{2 \cdot 4}x^2 \mp \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6}x^3 + \ldots$$

When x is small compared to 1, the first two or three terms in the four preceding expansions give generally a sufficient approximation in ordinary computations.

A Series is a succession of numbers which proceed according to some fixed law. A converging series is one whose sum, as the number of its terms is indefinitely increased, approaches some finite value as a limit; a diverging series is one whose sum, so taken, increases indefinitely. An **arithmetic series**, or arithmetic progression, is one in which the differences between successive terms are equal, as in a, $a + d$, $a + 2d$, $a + 3d$, . . . ; the nth term is $a + (n-1)d$, and the sum of the n terms is $1/2\, n\, [2a + (n-1)d]$. A **geometric series**, or geometric progression, is one in which the ratios of successive terms are equal, as in a, ar, ar^2, ar^3, ... ; the nth term is ar^{n-1}, and the sum of the n terms is $a(r^n - 1)/(r - 1)$.

Some special series (see also preceding paragraph for Binomial series):

$$1 + 2 + 3 + 4 + \ldots + (n-1) + n = 1/2\, n(n+1)$$
$$2 + 4 + 6 + 8 + \ldots + (2n-2) + 2n = n(n+1)$$
$$1 + 3 + 5 + 7 + \ldots + (2n-3) + (2n-1) = n^2$$
$$1 + 2^2 + 3^2 + 4^2 + \ldots + (n-1)^2 + n^2 = 1/6\, n(n+1)(2n+1)$$
$$1 + 2^3 + 3^3 + 4^3 + \ldots + (n-1)^3 + n^3 = 1/4\, n^2(n+1)^2$$

$$a^x = 1 + \frac{x}{1}\log_\epsilon a + \frac{x^2}{2!}\log_\epsilon^2 a + \frac{x^3}{3!}\log_\epsilon^3 a + \ldots \quad (1)$$

$$\epsilon^x = 1 + \frac{x}{1} + \frac{x^2}{2!} + \frac{x^3}{3!} + \ldots \text{ where } \epsilon = 2.71828 \ldots \quad (2)$$

$$1/2 \log_\epsilon x = \frac{x-1}{x+1} + 1/3 \frac{(x-1)^3}{(x+1)^3} + 1/5 \frac{(x-1)^5}{(x+1)^5} + \ldots$$

If $x^2 < 1$, $\log_\epsilon (1 \pm x) = \pm x - 1/2\, x^2 \pm 1/3\, x^3 - 1/4\, x^4 \pm \ldots$ (3)

$$1/2 \log_\epsilon \frac{1+x}{1-x} = x + \frac{x^3}{3} + \frac{x^5}{5} + \frac{x^7}{7} + \ldots \quad (4)$$

In right-hand members of the following, x is the angles in radians:

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} \ldots \quad (5) \qquad \cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} \ldots \quad (6)$$

$$\tan x = x + \frac{x^3}{3} + \frac{2\,x^5}{3 \cdot 5} + \frac{17\,x^7}{3^2 \cdot 5 \cdot 7} \ldots \quad (7)$$

Approximations when x is Small. In series (1) the first two terms, or at most three, are generally sufficient when x is small compared to a, and in (2), (3), (4) when x is small compared to 1. In (5), (6), (7), two terms, or even one, may be sufficient when x is less than the arc of 10°; thus, for 8° the value of x is $(8/180)\pi = 0.13963$, and $\sin x = x - 1/6\, x^3 = 0.13918$, which is one unit in error in the fifth decimal place. When the angle is less than 5°, the values of x and $\sin x$ do not differ more than one unit in the fourth decimal place. (See Sect. 1, Art. 5.)

2. Solution of Equations

Algebraic Equations, rational and integral, and of the first, second, third, or fourth degrees have been solved algebraically; that is, formulas have been found for the values of the unknown, the roots of the equation.

A Linear Equation, one of the first degree, as $ax + b = 0$, has only one root, namely $x = -b/a$.

A Quadratic Equation, one of the second degree, as $x^2 + 2\,ax + b = 0$ has two roots, namely $-a \pm (a^2 - b)^{1/2}$. If $a = 0$, the roots are equal and opposite in sign; if $b > a^2$ both roots are imaginary.

A Cubic Equation, or one of the third degree, can be written in the form $x^3 + 3\,ax^2 + 3\,bx + 2\,c = 0$; it has three roots, here called x_1, x_2, and x_3. To determine these compute B and C from $B = -a^2 + b$ and $C = a^3 - 3/2\,ab + c$, and s_1 and s_2 from $s_1 = \left(-C + \sqrt{B^3 + C^2}\right)^{1/3}$ and $s_2 = \left(-C - \sqrt{B^3 + C^2}\right)^{1/3}$

then
$$x_1 = -a + (s_1 + s_2)$$
$$x_2 = -a - 1/2\,(s_1 + s_2) + 1/2\sqrt{-3}\,(s^1 - s_2)$$
$$x^3 = -a - 1/2\,(s_1 + s_2) - 1/2\sqrt{-3}\,(s^1 - s_2)$$

When $B^3 + C^2$ is negative the numerical solution leads to irreducible imaginary forms although the three roots are real.

Equations of Degree Higher than the Second can generally be solved best by factoring, by trial, or graphically. In the following $f(x)$ is used to denote any expression containing x, and is read "a function of x," and so $f(x) = 0$ may denote any equation containing x; the value of $f(x)$ when $x = a$ is denoted by $f(a)$.

(1) Factoring Method: Factor $f(x)$ and equate each factor to zero; solve each of these new equations for x; these roots are also roots of $f(x) = 0$. Thus, to find the roots of $x^3 - 19\,x - 30 = 0$, note that $x^3 - 19\,x - 30 = (x + 3)(x^2 - 3\,x - 10)$; from $x + 3 = 0$, $x = -3$ and from $x^2 - 3\,x - 10 = 0$, $x = +5$ and -2; hence -3, $+5$, and -2 are the roots sought.

(2) Trial Method: Make guesses at the roots until a value is found which nearly satisfies the equation; such a value is an approximate root. In finding it, note that if $f(x) = 0$ designates the equation, and if x_1 and x_2 are numbers such that $f(x_1)$ and $f(x_2)$ are of opposite sign, then there is an odd number of roots of $f(x) = 0$ between x_1 and x_2. Thus, to find a root of $f(x) = x^3 + 4x^2 - 5x - 15 = 0$: trying $x = 1$ and $x = 3$ one gets $f(1) = -15$ and $f(3) = +33$; 1 and 3 are not close values of the root but there is a root between them; trying 2 one gets $f(2) = -1$, a closer value. Trying 2.1, one gets $f(2.1) = +1.4$; the root is between 2 and 2.1.

(3) Plotting Method: The equation to be solved being $f(x) = 0$, plot the graph of $y = f(x)$ (see Art. 3); the abscissas of the intersections of the graph with the x axis are roots of $f(x) = 0$. Or, break up $f(x)$ into the difference of two functions of x as $f_1(x)$ and $f_2(x)$ and plot the graphs of $y = f_1(x)$ and $y = f_2(x)$; then the abscissas of the intersections of the two graphs are roots of $f(x) = 0$. Thus, to solve $x^3 + 4x^2 - 5x - 15 = 0$: the graph of $y = x^3 + 4x^2 - 5x - 15$ is shown by the solid curve of Fig. 1, and the abscissas of its intersections with the x axis are about 2.1, -1.6, and -4.3, which are also the roots sought. Or, again, $x^3 + 4x^2 - 5x - 15$ can be broken up into $(x^3 + 4x^2) - (5x + 15)$; the dashed curve is the graph of $y = x^3 + 4x^2$ and the straight line is the graph of $y = 5x + 15$; the abscissas of the intersections of these two graphs are about 2.1, -1.6 and -4.3, and they are the roots sought.

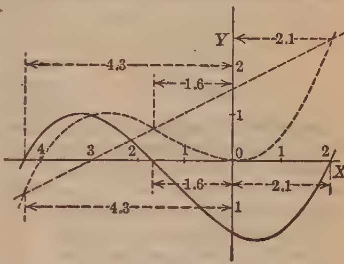

Fig. 1

Transcendental Equations are those involving trigonometry or logarithms; such equations with one unknown can be solved by one of the foregoing methods. For example, to find the roots of $\tan x - 2x = 0$ (x being in radians): plot the graphs of $y = \tan x$ and $y = 2x$, and determine the abscissas of the intersections of the graphs; the abscissas are the roots, one being $x = 1.16$.

To find the horizontal tension t in a catenary cable whose length is 22 ft., span 20 ft., and weight 10 lb. per lin. ft. The equation to be solved is $e^{10/t} - e^{-10/t} - 22 = 0$. By trial t is found to lie between 12 and 14; trying $t = 13$, the equation reduces to $+0.0298 = 0$; trying $t = 13.1$ it reduces to $-0.0012 = 0$, hence the root is a little less than $= 13.1$.

An equation which arises in the theory of a column round at one end and fixed at the other is $x - \tan x = 0$, where x is to be in radians. This equation has many roots, the smallest one being $x = 4.49341$.

3. Graphic Representations

Rectangular Coordinates. XX' and YY' (Fig. 2) are two rectangular coordinate axes or x and y axes; and XOY, YOX', $X'O'Y$, and $Y'OX$ are the first, second, third, and fourth quadrants respectively; O is the origin of coordinates. The position of any point in the drawing, as P, relative to the axes may be specified by two coordinates, the x coordinate, or abscissa of P, and the y coordinate, or ordinate of P. The abscissa, denoted by x, is the distance of P from the y axis, and the ordinate, denoted by y, is the distance of P from the x axis; the coordinates have signs as follows:

x is positive when P is to the right of the y axis,
x is negative when P is to the left of the y axis,
y is positive when P is above the x axis,
y is negative when P is below the x axis.

When P is actually plotted by means of its coordinates, the coordinates are also said to have been plotted. If the coordinates of P are x and y, say, P is referred to as the point (x, y).

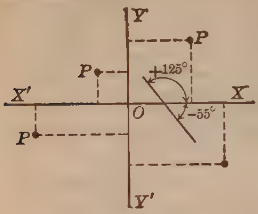

Fig. 2

Graphs. An equation between any two variables as x and y is sometimes written $y = f(x)$, for brevity; it is read "y equals a function of x." The graph of any equation as $y = f(x)$ is a graphical representation of the relation between y and x; to determine the graph compute values of y corresponding to assumed values of x, plot points whose coordinates are the corresponding values of x and y computed, and then draw a smooth curve through the points.

Logarithmic Plotting. The equation $y = f(x)$ may be represented by a graph obtained by plotting corresponding values of $\log x$ and $\log y$, instead of x and y, values of y having been obtained from $y = f(x)$ for assumed values of x; such a graph is a logarithmic graph. If values of x and $\log y$, or y and $\log x$ are plotted, the graphs are semi-logarithmic. These graphs are more advantageous than the ordinary one in some cases, and can be got as readily by using logarithmic or semi-logarithmic rulings, as in Figs. 4 and 6 in which the unequal divisions are like those on an ordinary slide rule, based on the logarithms of numbers, and the figures on the rulings are not logarithms but the corresponding numbers, also as on a slide rule. If $y = f(x)$ is graphed on such ruling by plotting corresponding values of x and y, the graphs are logarithmic or semi-logarithmic, exactly like those first described.

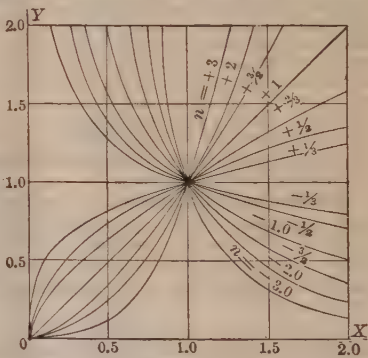

Fig. 3

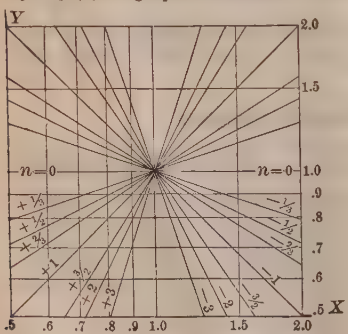

Fig. 4

The intercept of a graph on the x (or y) axis is the x (or y) coordinate of the intersection of the graph with x (or y) axis. The **slope angle** of a straight line is the angle between the line and the positive x axis; the slope angles of all lines may be expressed by angles between 0 and 180°, or $-90°$ and $+90°$ (see Fig. 2). The slope, or gradient, of a graph at any point is the tangent of the slope angle of its tangent line at that point.

The graph of $y = mx + c$, into the form of which any equation between two variables of the first degree can be put, is straight; m = the slope of the graph and c = its intercept on the y axis. Thus $y = -2x + 3$ has a graph sloping upwards to the left at an angle of 63-1/2° and cutting the y axis 3 units above the origin.

The graph of $y - b = m(x - a)^n + c$ is curved, its shape depending upon the numerical values of m and n; a, b, and c affect only the position of the graph with respect to the coordinate axes. Fig. 3 represents graphs of $y = x^n$ for the different values of n noted. The corresponding graphs of $y = mx^n$ are enlargements in the y direction if $m > 1$ and reductions if $1 > m > 0$ of those shown; if m is negative, the effect is enlargement or reduction as explained and a rotation of the graphs through 180° about the x axis. The logarithmic graph of $y = x^n$ is straight; Fig. 4 shows these graphs corresponding to those of Fig. 3. The logarithmic graphs of $y = mx^n$ are also straight, but they do not pass through the point (1, 1).

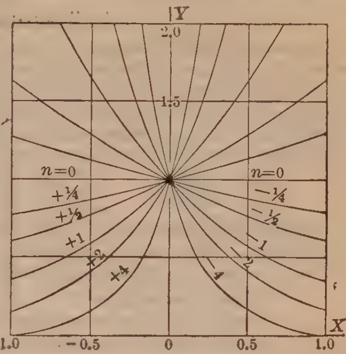

Fig. 5

The graph of $(y - a) = m\epsilon^{nx-b} + c$, a "logarithmic or compound interest" equation, is curved; its shape depends on the numerical values of m and n; a, b, and c affect only the position of the curve relative to the coordinate axes. Fig. 5 represents graphs of $y = \epsilon^{nx}$ for the several values of n noted. In $y = m\epsilon^{nx}$, m affects the graphs shown as explained in the preceding paragraph. The semi-logarithmic graph of $y = \epsilon^{nx}$ is straight; Fig. 6 shows these graphs corresponding to those of Fig. 5. The semi-logarithmic graph of $y = m\epsilon^{nx}$ is also straight, but it does not pass through the point (0, 1).

To Find an Equation for a Given Graph. If the graph, plotted on axes x and y, is straight, the equation is of the first degree; let (x_1, y_1) and (x_2, y_2) be the coordinates of any two points of the graph; the equation is $(y - y_1)(x_2 - x_1) = (x = x_1)(y_2 = y_1)$. If the intersection of the graph with either axis is available, that intersection may well be taken as one of the points; if it passes through the origin, that may be advantageously chosen. If the graph is curved, there may be no corresponding equation but an equation can usually be found which will approximately fit at least a limited portion of the graph.

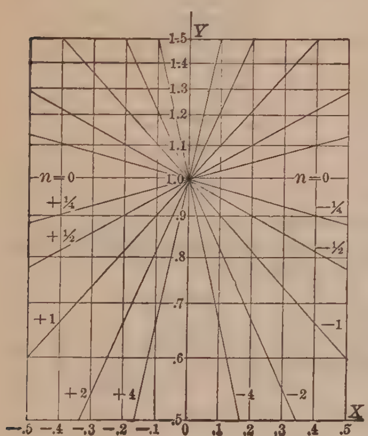

Fig. 6

(1) If the graph resembles a portion of one of the family represented in Fig. 3, plot its logarithmic graph; if this is practically straight, the original graph can be closely represented by $y = mx^n$. To determine m and n: $m = y$ when $x = 1$, and this value of y can be got from either graph, probably more accurately from the logarithmic; then in $\log (y/m) \doteq n \log x$ substitute the coordinates x and y of any point and solve for n.

(2) If the graph resembles a portion of one of the family represented in Fig. 5, plot semi-logarithmically (Fig. 6); if the resulting graph is practically straight, then the

original graph can be closely represented by $y = m\epsilon^{nx}$. To determine m and n, the value of m is found from $m = y$ when $x = 0$, and this value of y can be got from either graph, probably most accurately from the semi-logarithmic graph; then in $\log_\epsilon y = \log_\epsilon m + nx$ substitute the x and y coordinates of any point on either graph and solve for n.

4. Trigonometry

Functions of Acute Angles. If from a point in either line bounding an angle (Fig. 7) a perpendicular is drawn to the other line, then in the right triangle thus formed the leg adjacent to α is the base, and the leg opposite, the perpendicular; they are denoted by b and p respectively, and the hypotenuse by h. The sine, cosine, tangent, cotangent, secant, and cosecant of the angle are defined (and abbreviated) thus:

$$\sin\alpha = p/h \qquad \cos\alpha = b/h \qquad \tan\alpha = p/b$$
$$\csc\alpha = h/p \qquad \sec\alpha = h/b \qquad \cot\alpha = b/p$$

The versed sine, abbreviated vers, is unity minus the cosine; thus $\text{vers}\,\alpha = 1 - \cos\alpha$. The exsecant, abbreviated exsec, is secant minus unity, thus $\text{exsec}\,\alpha = \sec\alpha - 1$. From the foregoing it follows that

$$\sin\alpha/\cos\alpha = \tan\alpha \qquad \cos\alpha/\sin\alpha = \cot\alpha$$
$$\sin\alpha\csc\alpha = \cos\alpha\sec\alpha = \tan\alpha\cot\alpha = 1$$
$$\sin^2\alpha + \cos^2\alpha = \sec^2\alpha - \tan^2\alpha = \csc^2\alpha - \cot^2\alpha = 1$$

If $\alpha + \beta = 90°$, $\sin\alpha = \cos\beta$, $\tan\alpha = \cot\beta$, $\sec\alpha = \csc\beta$. If the arc $A''B'$ (Fig. 7) be struck from O with a radius unity, then in the triangle $OA'B'$ h is unity and in the triangle $OA''B''$ b is unity. Then also

$$\sin\alpha = A'B' \qquad \cos\alpha = OA' \qquad \tan\alpha = A''B''$$
$$\sec\alpha = OB'' \qquad \text{vers}\,\alpha = A'A'' \qquad \text{exsec}\,\alpha = B'B''$$

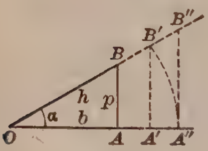

Fig. 7

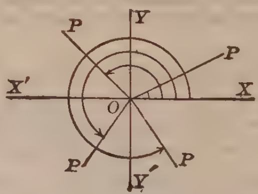

Fig. 8

Functions of any Angle. Let $\alpha = XOP$ (Fig. 8), x and y = the coordinates of P, and $h = OP$. Then whether α is in the first, second, third, or fourth quadrant, the functions of α are defined as follows:

$$\sin\alpha = y/h \qquad \cos\alpha = x/h \qquad \tan\alpha = y/x$$
$$\csc\alpha = h/y \qquad \sec\alpha = h/x \qquad \cot\alpha = x/y$$

Since x and y may be positive or negative, the functions may also be; the sign of a function depends on the quadrant of α, thus:

quad	sin	cos	tan	cot	sec	csc
1	+	+	+	+	+	+
2	+	−	−	−	−	+
3	−	−	+	+	−	−
4	−	+	−	−	+	−

The values of the functions for the four cardinal angles are:

angle	sin	cos	tan	cot	sec	csc
0°	0	+ 1	0	∞	+ 1	∞
90	+ 1	0	∞	0	∞	+ 1
180	0	− 1	0	∞	− 1	∞
270	− 1	0	∞	0	∞	− 1
360	0	+ 1	0	∞	+ 1	∞

Functions of angles greater than 90° are not given in trigonometric tables generally. These can be obtained from the functions of acute angles by means of the following in which a_2, a_3, and a_4 denote angles in the second, third, and fourth quadrants respectively.

a_2	$180° - a_2$	$a_2 - 90°$	a_3	$a_3 - 180°$	$270° - a_3$	a_4	$360° - a_4$	$a_4 - 270°$
sin =	+ sin =	+ cos	sin =	− sin =	− cos	sin =	− sin =	− cos
cos =	− cos =	− sin	cos =	− cos =	− sin	cos =	+ cos =	+ sin
tan =	− tan =	− cot	tan =	+ tan =	+ cot	tan =	− tan =	− cot

Negative Angles. Angles in the preceding figures and those referred to in the foregoing were regarded as measured from OX in the counterclockwise direction and considered positive; an angle regarded as measured clockwise is considered negative. OP (Fig. 8) may be specified by a positive or a negative angle, the arithmetic sum of the two being 360°. If α denotes merely the numerical value of any angle, then

$$\sin(-\alpha) = -\sin\alpha \qquad \cos(-\alpha) = \cos\alpha \qquad \tan(-\alpha) = -\tan\alpha$$
$$\csc(-\alpha) = -\csc\alpha \qquad \sec(-\alpha) = \sec\alpha \qquad \cot(-\alpha) = -\cot\alpha$$

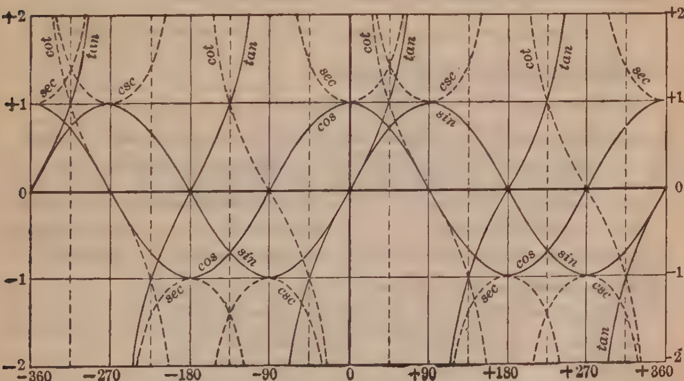

Fig. 9. Graphs of Trigonometric Functions

Graphs of sine, cosine, tangent, cotangent, secant, cosecant are given in Fig. 9 for values of angle from − 360° to + 360°. The graphs of the last four functions have infinite branches, asymptotic to the solid vertical lines adjacent at the upper and lower margins. The figure shows the sign and periodicity of any function of any angle between the limits named and roughly the relative values of the functions of any particular angle.

Inverse, or Anti-Functions. The symbol $\sin^{-1} x$ means the angle whose sine is x, and is read inverse sine of x and anti-sine of x (also arc sine x). Similarly $\cos^{-1} x$, $\tan^{-1} x$, $\cot^{-1} x$, $\sec^{-1} x$, $\csc^{-1} x$, $\text{vers}^{-1} x$, the last meaning an angle α such that $(1 - \cos\alpha) = x$. While the direct functions (sine, etc.) are single valued, the indirect are many valued; thus $\sin 30° = 0.5$, but $\sin^{-1} 0.5 = 30°$ or $150°$ . . .

Trigonometric Relations. For functions of an angle expressed in terms of each of the others, the following abbreviations are used:

$$A = \pm\sqrt{1 - \sin^2\alpha} \qquad B = \pm\sqrt{1 - \cos^2\alpha} \qquad C = \pm\sqrt{1 + \tan^2\alpha}$$

$$F = \pm\sqrt{\csc^2\alpha - 1} \qquad E = \pm\sqrt{\sec^2\alpha - 1} \qquad D = \pm\sqrt{1 + \cot^2\alpha}$$

$$\sin\alpha = B = \tan\alpha/C = 1/D = E/\sec\alpha = 1/\csc\alpha$$

$$\cos\alpha = A = 1/C = \cot\alpha/D = 1/\sec\alpha = F/\csc\alpha$$

$$\tan\alpha = \sin\alpha/A = B/\cos\alpha = 1/\cot\alpha = E = 1/F$$

$$\cot\alpha = A/\sin\alpha = \cos\alpha/B = 1/\tan\alpha = 1/E = F$$

$$\sec\alpha = 1/A = 1/\cos\alpha = C = D/\cot\alpha = \csc\alpha/F$$

$$\csc\alpha = 1/\sin\alpha = 1/B = C\tan\alpha = D = \sec\alpha/E$$

Functions of the sum and difference of two angles:

$$\sin(\alpha \pm \beta) = \sin\alpha\cos\beta \pm \cos\alpha\sin\beta$$

$$\cos(\alpha \pm \beta) = \cos\alpha\cos\beta \mp \sin\alpha\sin\beta$$

$$\tan(\alpha \pm \beta) = (\tan\alpha \pm \tan\beta)/(1 \mp \tan\alpha\tan\beta)$$

$$\cot(\alpha \pm \beta) = (\cot\beta\cot\alpha \mp 1)/(\cot\beta \pm \cot\alpha).$$

If x is small, say 3 or 4°, then the following are close approximations, in which the coefficients x must be expressed in radians (1° = 0.01745 radian).

$$\sin(\alpha \pm x) = \sin\alpha \pm x\cos\alpha, \qquad \cos(\alpha \pm x) = \cos\alpha \mp x\sin\alpha$$

Functions of half and double angles:

$$\sin 1/2\,\alpha = \sqrt{1/2\,(1 - \cos\alpha)} = 1/2\sqrt{1 + \sin\alpha} - 1/2\sqrt{1 - \sin\alpha}$$

$$\cos 1/2\,\alpha = \sqrt{1/2\,(1 + \cos\alpha)} = 1/2\sqrt{1 + \sin\alpha} + 1/2\sqrt{1 - \sin\alpha}$$

$$\tan 1/2\,\alpha = \sqrt{(1-\cos\alpha)/(1+\cos\alpha)} = (1-\cos\alpha)/\sin\alpha = \sin\alpha/(1+\cos\alpha)$$

$$\cot 1/2\,\alpha = \sqrt{(1+\cos\alpha)/(1-\cos\alpha)} = (1+\cos\alpha)/\sin\alpha = \sin\alpha/(1-\cos\alpha)$$

$$\sin 2\alpha = 2\sin\alpha\cos\alpha, \qquad \cos 2\alpha = 2\cos^2\alpha - 1 = 1 - 2\sin^2\alpha,$$

$$\tan 2\alpha = 2\tan\alpha/(1 - \tan^2\alpha) \qquad \cot 2\alpha = (\cot^2\alpha - 1)/2\cot\alpha.$$

Sums and products of functions:

$$\sin\alpha\cos\beta = 1/2\sin(\alpha + \beta) + 1/2\sin(\alpha - \beta)$$

$$\cos\alpha\sin\beta = 1/2\sin(\alpha + \beta) - 1/2\sin(\alpha - \beta)$$

$$\sin\alpha\sin\beta = 1/2\cos(\alpha - \beta) - 1/2\cos(\alpha + \beta)$$

$$\cos\alpha\cos\beta = 1/2\cos(\alpha - \beta) + 1/2\cos(\alpha + \beta)$$

$$\sin(\alpha + \beta)\sin(\alpha - \beta) = \sin^2\alpha - \sin^2\beta = \cos^2\beta - \cos^2\alpha$$

$$\sin\alpha + \sin\beta = 2\sin 1/2\,(\alpha + \beta)\cos 1/2\,(\alpha - \beta)$$

$$\sin\alpha - \sin\beta = 2\cos 1/2\,(\alpha + \beta)\sin 1/2\,(\alpha - \beta)$$

$$\cos\alpha + \cos\beta = 2\cos 1/2\,(\alpha + \beta)\cos 1/2\,(\alpha - \beta)$$

$$\cos\alpha - \cos\beta = -2\sin 1/2\,(\alpha + \beta)\sin 1/2\,(\alpha - \beta)$$

5. Plane and Spherical Triangles

Plane Triangles. The three angles are denoted by α, β, and γ, and the respective opposite sides by a, b, and c; also s denotes $1/2\ (a + b + c)$, r radius of inscribed circle, R radius of circumscribed circle, and A area of the triangle. Then, $\alpha + \beta + \gamma = 180°$

$$a/\sin\alpha = b/\sin\beta = c/\sin\gamma \text{ ("law of sines")}$$
$$c^2 = a^2 + b^2 - 2\,ab\cos\gamma, \qquad r = \sqrt{(s-a)(s-b)(s-c)/s}$$
$$A = sr = 1/2\ ab\sin\gamma, \qquad R = 1/2\ a\csc\alpha.$$

Solution of Right Triangles. If an acute angle and one side or if two sides of a right triangle are given the other elements can be determined. Let h = hypotenuse, α and β acute angles, and a and b the legs opposite them, respectively. The acute angles are complementary, that is, $\alpha + \beta = 90°$; the area is $1/2\ ab$ always. Five cases may be distinguished:

Given h and α; $\quad a = h\sin\alpha, \quad b = h\cos\alpha$
Given a and α; $\quad b = a\cot\alpha, \quad h = a\csc\alpha$
Given b and α; $\quad a = b\tan\alpha, \quad h = b\sec\alpha$
Given a and h; $\quad \alpha = \sin^{-1} a/h,\ b = \sqrt{(h+a)(h-a)}$
Given a and b; $\quad \alpha = \tan^{-1} a/b,\ h = \sqrt{a^2 + b^2}$

Solution of Oblique Triangles. If any three of the six elements (three angles and three sides) of a triangle are known, the remaining three can be determined provided one of the given three is a side. Any problem will fall under one of four cases.

Case 1. Given one side and two angles. Then the third angle equals 180° minus the sum of the two given. If the given side is a, then

$$b = a\sin\beta/\sin\alpha \quad \text{and} \quad c = a\sin\gamma/\sin\alpha.$$

Case 2. Given two sides and the included angle (a, b and γ). Then

$$1/2(\alpha + \beta) = 90° - 1/2\gamma,\ 1/2(\alpha - \beta) = \tan^{-1}[\tan 1/2(\alpha+\beta)\cdot(a-b)/(a+b)]$$
$$\alpha = 1/2\ (\alpha + \beta) + 1/2\ (\alpha - \beta) \qquad \beta = 1/2\ (\alpha + \beta) - 1/2\ (\alpha - \beta)$$
$$c = a\sin\gamma/\sin\alpha.$$

Case 3. Given two sides a and b and the angle α opposite one of them. Then $\sin\beta = (b/a)\sin\alpha$, giving two values of β, one acute and one obtuse unless $\sin\beta > 1$, in which case the data are impossible. Calling these two angles β_1 and β_2 respectively, then

corresponding to β_1, $\gamma_1 = 180 - (\alpha + \beta_1)$ and $c_1 = a\sin\gamma_1/\sin\alpha$
corresponding to β_2, $\gamma_2 = 180 - (\alpha + \beta_2)$ and $c_2 = a\sin\gamma_2/\sin\alpha$

That is, there are two solutions unless $\gamma_2 < 0$, when only the first holds. (The meanings of these exceptions, $\sin\beta > 1$ and $\gamma_2 < 0$, will become evident if a geometrical construction of the triangle is attempted.)

Case 4. Given the three sides. Let s denote $1/2\ (a + b + c)$. Then

$$\cos 1/2\,\alpha = \sqrt{s(s-a)/bc} \quad \cos 1/2\,\beta = \sqrt{s(s-b)/ca} \quad \cos 1/2\,\gamma = \sqrt{s(s-c)/ab}$$

Spherical Triangles. The intersection of the surface of a sphere with a plane through its center is a great circle of the sphere; an arc of the circle is measured by the angle between the radiuses of the sphere drawn to the ends of the arc. A spherical angle is the angle between two intersecting arcs of great circles; it is measured by the angle between their tangents at the intersection. A spherical triangle is a portion of the surface of a sphere bounded by arcs of three great circles. Spherical triangles are classified in the same way as plane triangles: isosceles, equilateral, right etc. The spherical excess of a triangle is the excess of the sum of its angles over 180°. Any spherical triangle can be solved if any three of its six elements (three sides and three angles) are given; from the following formulas a solution may be made in any given case. The notation is as follows: α, β, and γ represent the three angles, while a, b, and c designate the opposite sides respectively, and e = the spherical excess.

$$\sin a/\sin\alpha = \sin b/\sin\beta = \sin c/\sin\gamma$$

$$\cos c = \cos a \cos b + \sin a \sin b \cos\gamma$$

$$\cos\gamma = -\cos\alpha\cos\beta + \sin\alpha\sin\beta\cos c$$

$$\cot 1/2\, e = (\cot 1/2\, a \cot 1/2\, b + \cos\gamma)/\sin\gamma$$

A spherical right triangle can be solved if any two of its elements, not including the right angle, are given. In the following h is the hypotenuse, a and b the other two sides, and α and β the angles opposite a and b respectively.

$$\sin a = \sin h \sin\alpha = \tan b \cot\beta \qquad \cos\alpha = \cos a \sin\beta = \cot h \tan b$$

$$\cos h = \cos a \cos b = \cot\alpha\cot\beta$$

6. Geometry and Mensuration

Angles. The common unit of angle is the degree (one-ninetieth of a right angle); the degree is divided into 60 minutes and the minute into 60 seconds. Another unit is the *radian*, called also the unit in circular measure of angles; it is an angle equal to that between two radiuses of a circle which embrace an arc equal to the radius. Then

$$1 \text{ radian} = 180 \div \pi \text{ degrees} = 57.296°, \qquad 1 \text{ degree} = 0.0175 \text{ radian}$$

If an angle α subtends a circular arc whose length and radius are s and r respectively, then $\alpha = s/r$ or $s = r\alpha$ provided that s and r are expressed in the same unit and α in radians.

Triangles. Let a, b, and c = lengths of sides; α, β, and γ the opposite angles, h the altitude to the side b, s denote $1/2\,(a + b + c)$, and A = area.

$$A = 1/2\, bh = 1/2\, ba \sin\gamma = 1/2\, b^2 \sin\gamma \sin\alpha/\sin\beta = \sqrt{s(s-a)(s-b)(s-c)}$$

Quadrilaterals. Let D_1 and D_2 = lengths of the two diagonals and a the angle between them, then $A = 1/2 D_1 D_2 \sin a$. Parallelogram: let a = one side, b = base, a = angle between a and b, h = altitude; then $A = bh = ab \sin a$. Trapezoid: let b and B = parallel sides, and h = altitude; then $A = 1/2\,(b + B)h$.

Polygons. The area A equals the sum of the areas of the constituent triangles. For a regular polygon (equal sides and equal angles) let R = radius of circumscribed circle, r = radius of inscribed circle, a = length of a side, n = number of sides, 2α = central angle subtended by one side; then

$$A = 1/4\, na^2 \cot\alpha = 1/2\, nR^2 \sin 2\alpha = nr^2 \tan\alpha \quad a = 2R\sin\alpha = 2r\tan\alpha$$

Circle (Fig. 11). Circumference $L = 2\pi r = \pi d$. Area $A = \pi r^2 = 1/4\pi d^2$. Chord $C = 2r \sin 1/2\,\theta$. Rise of arc $h = r\,(1 - \cos 1/2\,\theta)$. Arc subtended by θ $a = \pi d \times (\theta \text{ in degrees})/360 = r\,(\theta \text{ in radians})$; when h is small compared to C, $a = 1/3(8c - C)$; this is approximate, but even when $h = r$, the error is less than 1-1/4 %. Sector $OMPN$: area = area of circle (θ in degrees)/360. Segment $MPNM$: area = area sector $- 1/2\, r^2 \sin\theta$; when h is small compared to C, area $= 2/3\, Ch$, also $h\,(8c + 6C)/15$, both approximate; when $h = 1/4\, r$, the first errs about 3-1/2 % and the second less than 1%.

To Find the Center of a Given Circle, draw a chord and then a perpendicular to the chord at its middle point; this line extended in both directions to the circumference is a diameter. To draw a circle through three points: join one of the points with the others, thus getting two chords; at the middle points of the chords erect perpendiculars; the intersection of these is the center of the circle. If, in the preceding problem, the center is inaccessible or the radius is too long for drawing instruments, proceed as follows, the three points being A, O, A', Fig. 10: draw arcs Aa' and $A'a$ with centers at A' and A respectively; extend AO to determine a and $A'O$ to determine a'; divide aA' into equal parts ab, bc, etc.; lay off $a'b'$, $b'c'$, etc., equal to ab; join A with any point as b and A' with the corresponding point b'; the intersection P of these joining lines is a point in the circle. If in the preceding problem it is desired to determine points in the circle by ordinates as NP, let r = radius of the circle, h = rise or center ordinate OQ, C = chord AA', y = any ordinate as NP, and $x = QN$ (distance of that ordinate from the center one), then $r = (4\,h^2 + C^2)/8\,h$, and

$$y = \sqrt{r^2 - x^2} - (r - h) = \sqrt{r^2 - x^2} - \sqrt{r^2 - C^2/4}$$

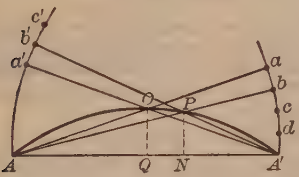

Fig. 10

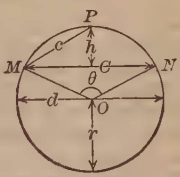

Fig. 11

Ellipse (see also Art. 11). The circumference of an ellipse whose semi-axes are a and b is $\pi(a + b)k$ where k is an abbreviation for $(1 + c^2/4 + c^4/64 + c^6/256 + \ldots)$ and $c = (a - b)/(a + b)$. The following table gives k for several values of c:

c	k	c	k	c	k	c	k	c	k
0.05	1.0006	0.25	1.0158	0.45	1.0516	0.65	1.1083	0.85	1.1903
.10	1.0025	.30	1.0215	.50	1.0635	.70	1.1267	.90	1.2154
.15	1.0054	.35	1.0311	.55	1.0768	.75	1.1466	.95	1.2430
.20	1.0100	.40	1.0404	.60	1.0922	.80	1.1677	1.00	1.2732

The area of an ellipse is given by πab; the area of any part as $ABQP$ (Fig. 12) is $xy + ab \sin^{-1} x/a$, in which x and y are the distances of P or Q from the axes.

Hyperbola (see also Art. 11). The area of any symmetrical segment like $PAQP$ (Fig. 13) is $xy - ab \log_\epsilon (x/a + y/b)$, where $2\,a$ and $2\,b$ are the lengths of the axes of the hyperbola and x and y the distances of P or Q from the axes.

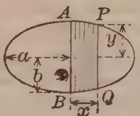

Fig. 12

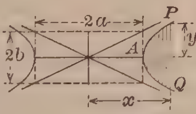

Fig. 13

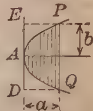

Fig. 14

Parabola (see also Art. 11). The length of any arc beginning at the vertex as AP (Fig. 14) is $(b^2/4\,a)\left[\sqrt{c(1 + c)} + \log_\epsilon\left(\sqrt{c} + \sqrt{1 + c}\right)\right]$, in which c is an abbreviation for $4\,a^2/b^2$, a and b being distances as marked. The area of a symmetrical segment like $PAQP$ is two-thirds that of the rectangle $PEDQ$.

Irregular Figure (Fig. 15). To find the area divide the figure into an even number of strips of equal width; the more numerous these strips the more accurate is the result given by the following formulas. The first of the ordinates bounding the strips is called y_0, the second y_1, etc., n the number of strips, w their common width and A the area. The following formulas give A approximately:

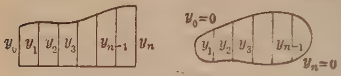

Fig. 15

$A = w(1/2\, y_0 + y_1 + y_2 + \ldots + y_{n-1} + 1/2\, y_n)$, Trapezoidal.

$A = 1/3\, w(y_0 + 4\,y_1 + 2\,y_2 + 4\,y_3 + \ldots + 2\,y_{n-2} + 4\,y_{n-1} + y_n)$, Simpson's.

$A = w(0.4\,y_0 + 1.1\,y_1 + y_2 + y_3 + \ldots + y_{n-2} + 1.1\,y_{n-1} + 0.4\,y_n)$, Durand's.

Simpson's rule applies only when n is odd; when n is even the area of $n - 3$ strips may be computed and then the area of the remaining 3 strips may be found by

$$A = 3/8\, w\, (y_0 + 3\,y_1 + 3\,y_3 + y_j), \text{ Cotes's.}$$

Prism. Let V = volume, h = altitude, A = base area; $V = Ah$. Truncated prism: V = the product of the length of line joining the centers of gravity of the bases and the area of section perpendicular to the line. Truncated triangular prism: V = product of one-third the sum of the parallel edges and the area of section perpendicular to edges.

Cylinder. Let V = volume, A = base area, h = altitude; $V = Ah$. Right circular cylinder: Let r = base radius, S = area cylindrical surface; $V = \pi r^2 h$, $S = 2\,\pi r h$, $A = \pi r^2$. Frustum right circular cylinder: H = greatest height, h = least height; $V = \pi r^2 (H + h)/2$, $S_{,} = \pi r(H + h)$. Wedge of right circular cylinder (Fig. 16); Let $2\,C$ = straight edge of base, p = altitude of the base (segment of circle), $2\,\phi$ = central angle of the arc of base in degrees, r = radius of base; $V = [C\,(3\,r^2 - C^2) + 3\,r^2\,(p - r)\,\phi\,\pi/180]\; h/3\,p$, $S = [C + (p - r)\phi\pi/180]\; 2\,rh/p$. Hollow right circular cylinder: R = outer radius of base, r = inner radius, t = thickness $= R - r$; $V = \pi(R^2 - r^2)h = \pi\,(2\,R - t)\,th = \pi\,(2\,r + t)\,th$.

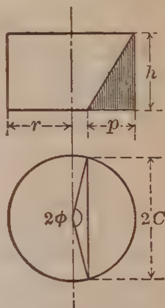

Fig. 16

Pyramid. Let V = volume, A = area base, h = altitude; $V = Ah/3$. Frustum of a pyramid: let A and a = areas of bases; $V = (A + a + \sqrt{Aa})\, h/3$.

Cone. Let V = volume, A = area of base, h = altitude; then $V = Ah/3$. Circular Cone: let r = radius of base; $V = \pi r^2 h/3$. Right circular cone: area of conical surface, $S = \pi r \sqrt{r^2 + h^2}$. Frustum of right circular cone: let R = radius larger and r = radius smaller base; $V = \pi\,(R^2 + Rr + r^2)h/3$; $S = \pi\,(R + r)\sqrt{(R - r)^2 + h^2}$.

Sphere. Let V = volume, A = area, r = radius, and d = diameter. Then $V = 4/3\,\pi r^3 = 1/6\,\pi d^3$; $A = 4\,\pi r^2 = \pi d^2$. Zone: let h = altitude, a = radius larger base, b = radius smaller base; $V = 1/2\,\pi h\,(a^2 + b^2 + h^2/3)$; convex $A = 2\,\pi r h$; $r^2 = a^2 + [(a^2 - b^2 - h^2)/2\,h]^2$. Segment (zone with one base): make $b = 0$ in formulas for zone. Sector with one conical surface (Fig. 17): $V = 2/3\,\pi r^2 h$, total $A = \pi r\,(2\,h + a)$.

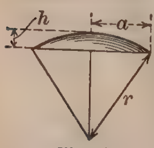

Fig. 17

Ellipsoid. Every section is a circle or an ellipse. Let a, b, and c = the semi-axes; then the volume $= 4/3\,\pi abc$.

Paraboloid of Revolution generated by revolving a parabola about its own axis (Fig. 18). Let r = radius of base and a = altitude of paraboloid;

then volume = $1/2\,\pi r^2 a$. Volume of a frustum, R and r being radii of bases and h = height (see Fig. 18) is $1/2\,\pi(R^2 + r^2)h$ (approx.).

Surface and Solid of Revolution. The first may be generated by revolving a plane curve about a line in its plane, or else by a straight line about an intersecting line; and the second by revolving a plane area about a line in its plane. The **axis** of the surface or solid is the line about which the revolution takes place. The area and volume can be determined by the principles of Pappus and Guldinus which are:

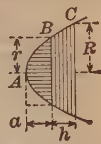

Fig. 18

(a) For area A: let l = length of generating curve (must not cut the axis of revolution) and x_1 = distance of its center of gravity from the axis; then $A = 2\,\pi x_1 l$.

(b) For volume V: let a = area of the generating figure (must not be intersected by the axis) and x_2 = distance of its center of gravity from the axis; then $V = 2\,\pi x_2 a$.

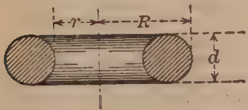

Fig. 19

The revolution of a circle about a line in its plane but not cutting the circle generates a "tore," or "torus" or anchor ring (Fig. 19). The preceding formulas give its area and volume thus: $A = 2\,\pi\,1/2\,(R + r)\,\pi\,d = \pi^2\,(R + r)\,d$, and $V = 2\,\pi\,1/2\,(R + r)\,1/4\,\pi\,d^2 = 1/4\,\pi^2\,(R + r)d^2$.

A Prismoid is a solid with plane faces two being parallel (and called ends) and each of the others containing a part of the perimeter of one end and at least a point in that of the other end. Let V = volume of the prismoid, A_1 and A_2 = areas of the ends, A_m = area of the cross-section of the prismoid midway between the ends and l = length of prismoid (distance between ends); then $V = 1/6\,(A_1 + A_2 + 4\,A_m)l$.

7. Interest and Sinking Fund

Interest. The notation in the formulas is: p = principal, the sum loaned; i = rate of interest, expressed 0.06 or 6/100 for 6%; n = time, term, or period of the loan in years; a = amount due after n years, that is, the sum of the principal and interest. When interest is paid only on the principal and not also on interest which may be due, the interest is simple; then

$$a = p(1 + in) \qquad i = (a - p)/pn \qquad p = a/(1 + in) \qquad n = (a - p/pi$$

The adjoining table gives the simple interest on \$100 at various rates for one year, one month (1/12 year), and one day (1/30 month, bank practice).

	2%	3%	4%	5%	6%	8%
1 year	\$2.00	\$3.00	\$4.00	\$5.00	\$6.00	\$8.00
1 month	0.16-2/3	0.25	0.33-1/3	0.41-2/3	0.50	0.66-2/3
1 day	0.0055-5/9	0.0083-1/3	0.0111-1/9	0.0138-8/9	0.0166-2/3	0.0222-2/9

When interest is not paid periodically but regarded as additions to the principal, also to draw interest during the remainder of the time, then the interest is compound. If additions of interest to principal are made annually, then

$$a = p(1+i)^n, \quad i = \sqrt[n]{(a/p)} - 1, \quad p = a/(1+i)^n, \quad n = (\log a - \log p)/\log\,(1+i)$$

For semiannual compound interest, $a = p(1 + i/2)^{2n}$. The adjoining table gives the amount of one dollar at interest compounded annually at various rates for various periods. Thus, \$2000 at 3% in 20 years amounts to 2000 × \$1.80611 = \$3612.22; the interest earning is \$3612.22 − \$2000, or \$1612.22.

Amount (Principal plus Interest) of $1 at Compound Interest

No. of Years	Rates of compound interest						
	2%	2-1/2%	3%	3-1/2%	4%	4-1/2%	5%
1	1.02000	1.02500	1.03000	1.03500	1.04000	1.04500	1.05000

An Annuity is a succession of equal sums paid regularly, generally annually; each payment is also called annuity, but more properly, installment. The amount of an annuity for a term of years is the sum of the installments plus their interest earnings, interest being generally considered as compound. Let A = amount; i = interest rate expressed decimally (as 0.05 for 5%); n = number of years in the period of the annuity; and I = (annual) installment, one at the end of each year. Then $A = I\,[(1 + i)^n - 1]/i$. The following table gives the amount of an annual annuity of $1 for various periods and various rates of interest. Thus, $200 invested at the end of each year of a 20-year period at 4% amounts to 200 × $29.77808, or $5955.62, at the end of that period; the interest earned is $5955.62 − (20 × $200) = $1955.62.

Amount (Installments plus Interest Earned) of an Annual Annuity of $1

No. of Years	Rates of compound interest						
	2%	2-1/2%	3%	3 1/2%	4%	4-1/2%	5%
1	1.00000	1.00000	1.00000	1.00000	1.00000	1.00000	1.00000

A Sinking or Amortization Fund is one created to provide a definite sum (for canceling a debt, for example) at a certain time; it is usually created by equal and regular contributions or installments and their interest earnings, compounded, that is, by an annuity and its interest earnings. Let S = the amount of a sinking fund; n = number of years for its creation; i = interest rate expressed decimally (as 0.05 when the rate is 5%); and I = annual installment required, paid at the end of each year of the period. Then $I = Si/[(1 + i)^n - 1]$. The following table gives annual installments required to create a fund of one dollar (equal to I/S) in various periods at various interest rates. Thus the annual installment necessary to accumulate $22 000 in 25 years, at 4%, is 22 000 × $0.02401, or $528.22; the interest earning is 22 000 − (25 × 528.22), or $8794.50.

Annual Annuity Required to Accumulate $1 (Installments plus Interest Earnings)

The Present Worth of a given sum due at a future time is such a sum which if now placed at interest, would amount to the given sum at that time. Let p = present worth, a = given sum due in n years from now, and i = interest rate; then on simple interest basis $p = a/(1 + in)$, and on annual compound $p = a/(1 + i)^n$. The following table gives present worths, computed at various rates of compound interest, of $1 due in various periods. For example, an addition to plant necessary 5 years hence will then entail a cost of $8000; how much can one afford to pay for such addition now, it being without use or expense for 5 years? As much as the present worth of $8000 due in 5 years at the current rate of interest, that is, if the rate is 5%, 8000 × $0.78353, or $6268.24.

Present Worth of $1 Due at a Future Date

The present Worth of an Annuity is the sum which now placed at compound interest will reach the same amount as will be reached by the annuity. Let $V =$ the present value of an annuity I; then $V = \frac{I\,[1 - (1 + i)^{-n}]}{i}$. The following table gives values of an annuity of $1 for various periods and various rates. Thus, the present worth of an annuity of $1 for 20 years at 4% is $13.59.

Present Value of an Annuity of $1

Annual Depreciation of a property is the necessary annual installment of the annuity which will amount to the first cost of that property at the expiration of its useful life; annual depreciation is also expressed in percentage of first cost. Thus, if the first cost of a part of a plant is $10 000 and its life is estimated at 40 years, then if money is worth 3%, the annual depreciation is. 10 000 × $0.01326, or $132.60, and the rate of depreciation is 1.326% **Capitalization** of a plant is the sum of the first cost C and the capital necessary to earn annually (a) the annual cost of operation O and (b) the annual depreciation D; that is, if i is the interest rate, capitalization equals $C + (O + D)/i$. Thus, if in the preceding illustration O = $500, the capitalization equals $10 000 + ($500 + ($132.06)/0.03 = $31 068.

The formula for this table is $i/[1 - (1 + i)^{-n}]$.

ADVANCED MATHEMATICS

8. Differential Calculus

Definitions and Symbols. In a discussion of quantities, a constant is one regarded as having the same value throughout, and a variable is one supposed to take different values. When several variables are related, their values being interdependent, each is a function of the others; thus the area and the base of a triangle of constant altitude being definitely related, these quantities are functions of each other. Also any expression containing the symbol of a quantity is a function of that quantity; thus $ax^2 + bx - c$ is a function of x, and $ay^2 + bx$ is a function of x and y. The following abbreviations are used: $f(x)$, $F(x)$, $\phi(x)$, etc., for functions of x; $f(x, y)$ $F(x, y)$, $\phi(xy)$ etc., for functions of x and y, etc. The letters f, F, ϕ, etc., are functional symbols; and $f(x)$ and $f(y)$, or $F(x)$ and $F(y)$, denote the same functions of x and of y; thus if $f(x)$ denotes $x^3 + 6x - 7$, then $f(y)$ denotes $y^3 + 6y = -7$. When $y = f(x)$ as $y = x^3 + 4x$, the equation being solved for y, then y is an explicit function of x; but in $F(x, y) = 0$, as $xy + 4x^2 - y^2 = 0$, the equation not being solved for y, then y is an implicit function of x. If $y = f(x)$, and for each value of x there is only one value of y, then y is a single-valued function of x; if for each value of x there is more than one value of y, then y is a multiple-valued function.

If two variables x and y are related and x is regarded as taking on any values and then y its corresponding values, x is the independent and y the dependent variable. When any variable x changes from a value x_1 to a value x_2, the difference $x_2 - x_1$ is an increment of x; any increment of x is denoted by Δx, also δx. An increment of x may be positive or negative; when negative, the numerical value of the increment is called decrement. A variable regarded as taking on equal increments is an equicrescent variable. If in $y = f(x)$ all equal changes in x produce equal changes in y, then y is a uniform variable with respect to x, and the graph of $y = f(x)$ is straight. The rate of y with respect to x, or the x-rate of y, is the change in y per unit change in x. If $x_2 - x_1$, or Δx (Fig. 20), is any change in x, and $y_2 - y_1$, or Δy, is the corresponding change in y, then the x-rate of y is $(y_2 - y_1)/(x_2 - x_1) = \Delta y/\Delta x$. If in $y = f(x)$ all equal changes in x do not produce equal changes in y, then y varies non-uniformly with respect to x, or at a variable rate; the graph of $y = f(x)$ is a curve. The average rate of y with respect to x, or average x-rate of y, for any change in x, is that constant rate which would give the actual change in y due to the change in x. For the change $x_2 - x_1$ in x (Fig. 21) this constant rate is $(y_2 - y_1)/(x_1 - x_1)$, or $\Delta y/\Delta x$, and is represented by the slope of the chord AB. The actual x-rate of y when $x = x_1$, say, is the value which the average rate $\Delta y/(x_2 - x_1)$ approaches as x_2 is taken closer and closer to x_1; this limiting average rate, or actual rate, is represented by the slope of the tangent at A. As $y = f(x)$, the x-rate of y is also the x-rate of $f(x)$.

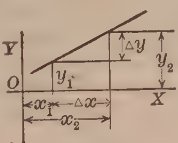

Fig. 20

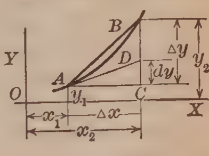

Fig. 21

The Derivative, the differential coefficient, and the derived function of y or $f(x)$, y being equal to $f(x)$, with respect to x are expressions which denote the x-rate of y or of $f(x)$; the first is the most common. There are several standard notations for this quantity: thus, $D_x y$ or $D_x f(x)$, y_x' or $f_x'(x)$ (the subscript is generally omitted), and dy/dx or $d/dx\, f(x)$. The last two are the most common symbols and have the advantage of suggesting how the rate is obtained in the first instance. If the curve in Fig. 21 is the graph of $y = f(x)$, $dy/dx = \tan\alpha$ (when $x = x_1$), α being the slope angle at A. The derivative

dy/dx is essentially one quantity, but may be regarded as a fraction provided that dy and dx is regarded so that their ratio equals $\tan\alpha$; thus if dx is regarded as a finite increment of x, equal to Δx, then dy must be taken as CD, not equal to Δy. So taken, dy is the **differential** of y with respect to x; it is an hypothetical increment of y, equal to the increment which occurs in y for a change in x from x_1 to $x_1 + dx$ on the supposition that the x-rate of y remains constant during the change in x and is equal to its actual value when $x = x_1$. Thus, $dy/dx = \phi(x)$ may also be written $dy = \phi(x)\cdot dx$.

The **fluxion** of a variable function is its time rate. This term was used by Newton but is now uncommon; a fluxion of a variable as y was denoted by him thus, $\dot{y}$.

Differentiation is the process of finding the differential or derivative of a function. The following formulas give differentials (and derivatives by division) of some simple functions. Differentials of many other functions can be obtained by combining formulas; thus according to the formula for $d\,(uv)$, $d\,(\sin x\cdot\cos x) = \sin x\cdot d\,(\cos x) + \cos x\cdot d\,(\sin x)$, and as given $d\,(\cos x) = -\sin x\,dx$ and $d\,(\sin x) = \cos x\,dx$; hence $d\,(\sin x\cdot\cos x) = -\sin^2 x\,dx + \cos^2 x\,dx$. In the formulas, a and n are constants, e is the base of the Napierian system of logarithms, and in each case the differential of the function is given with respect to x.

$$d\,(a+x) = dx \qquad d\,(ax) = a\,dx \qquad dx^n = nx^{n-1}\,dx$$
$$de^x = e^x dx \qquad da^x = a^x \log_e a\,dx \qquad d\log_e x = dx/x$$
$$d\sin x = \cos x\,dx \qquad d\csc x = -\csc x\cot x\,dx$$
$$d\cos x = -\sin x\,dx \qquad d\sec x = \sec x\tan x\,dx$$
$$d\tan x = \sec^2 x\,dx \qquad d\cot x = -\csc^2 x\,dx$$
$$d\,\mathrm{vers}\,x = \sin x\,dx \qquad d\,\mathrm{covers}\,x = -\cos x\,dx$$
$$d\sin^{-1} x = dx/\sqrt{1-x^2} = -d\cos^{-1} x$$
$$d\tan^{-1} x = dx/(1+x^2) = -d\cot^{-1} x$$
$$d\sec^{-1} x = dx/x\sqrt{x^2-1} = -d\csc^{-1} x$$
$$d\,\mathrm{vers}^{-1} x = dx/\sqrt{2x-x^2} = -d\,\mathrm{covers}^{-1} x$$
$$d\sinh x = \cosh x\,dx \qquad d\,\mathrm{csch}\,x = -\mathrm{csch}\,x\coth x\,dx$$
$$d\cosh x = \sinh x\,dx \qquad d\,\mathrm{sech}\,x = -\mathrm{sech}\,x\tanh x\,dx$$
$$d\tanh x = \mathrm{sech}^2 x\,dx \qquad d\coth x = -\mathrm{csch}^2 x\,dx$$
$$d\sinh^{-1} x = dx/\sqrt{x^2+1} \qquad d\,\mathrm{csch}^{-1} x = -dx/x\sqrt{1+x^2}$$
$$d\cosh^{-1} x = dx/\sqrt{x^2-1} \qquad d\,\mathrm{sech}^{-1} x = -dx/x\sqrt{1-x^2}$$
$$d\tanh^{-1} x = dx/(1-x^2) \qquad d\coth^{-1} x = -dx/(x^2-1)$$

In the four following, u, v, w, etc., are functions of x and all differentials are with respect to x:

$$d\,(u+v+w+\ldots) = du + dv + dw + \ldots \qquad d\,(uv) = u\,dv + v\,du$$
$$d\,(uvw\ldots) = [du/u + dv/v + dw/w + \ldots]\,uvw\ldots$$
$$d\,(u/v) = (v\,du - u\,dv)/v^2$$

Partial Derivatives and Differentials. The partial derivative of a function of two or more independent variables with respect to one of them is the derivation of the function obtained on the supposition that the others are for the time being constants; the partial x-derivation of a function u is written $\partial u/\partial x$, also (du/dx); for example, of if $u = y^3 + 4\,xy + x^2 + 2$, $\partial u/\partial x = 4\,y + 2\,x$ and $\partial u/\partial y = 3\,y^2 + 4\,x$. If u (or z) is a function of two independent variables, the partial derivatives have geometrical significance. The equation $z = f\,(x, y)$ represents a surface; suppose that APa, Fig. 22, is its intersection with a plane parallel to ZOX, and BPb its intersection with a plane parallel to ZOY; on these curves, y and x respectively are constant. PT' and PT'' are tangents to the curves at P as shown, and the slopes of these tangents represent $\partial z/\partial x$

and $\partial z/\partial y$ respectively. The partial differential of a function of two or more independent variables with respect to any one of them is the differential of the function obtained on the supposition that the other variables are, for the time being, constants. Thus if $z = y^3 + 4xy + x^2 + 2$, the x-partial differential of z is $4\,ydx + 2\,xdx$ and the y-partial differential is $3\,y^2dy + 4\,xdy$. If z is a function of only two independent variables the partial differentials have geometrical significance. If Pm and Pn are taken to represent the differentials dx and dy respectively, then mT' and nT'' represents the x- and the y-partial differentials of z. Also these partial differentials are equal to $[\partial z/\partial x]\,dx$ and $[\partial z/\partial y]\,dy$.

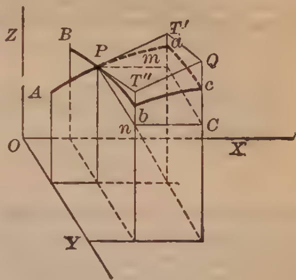

Fig. 22

Total Derivatives and Differentials. The total differential of a function of two or more variables is the differential obtained on the supposition that all change. It equals the sum of the partial differentials of the function with respect to the several variables; thus if $u = f(xyz)$,

$$du = \frac{\partial u}{\partial x}dx + \frac{\partial u}{\partial y}dy + \frac{\partial u}{\partial z}dz$$

If u is a function of only two variables, du has a geometrical significance. Thus if $z = (x, y)$ and Pm and Pn (Fig. 22) are taken as dx and dy respectively, then CQ represents dz. The differential dz then is a hypothetical and not the actual increment, Cc in z due to changes dx and dy in x and y. The total derivative of a function of two or more variables all dependent on a single variable is the rate at which the function changes per unit change of that variable; thus if $u = f(x, y, z)$ and x, y, and z are all functions of t,

$$\frac{du}{dt} = \frac{\partial u}{\partial x}\frac{dx}{dt} + \frac{\partial u}{\partial y}\frac{dy}{dt} + \frac{\partial u}{\partial z}\frac{dz}{dt}$$

and similarly for any number of variables. If the independent variable is x say, then

$$\frac{du}{dx} = \frac{\partial u}{\partial x} + \frac{\partial u}{\partial y}\frac{dy}{dx} + \frac{\partial u}{\partial z}\frac{dz}{dx}$$

Successive Differentiation is the process of finding derivatives or differentials of derivatives or differentials. The successive derivatives and differentials are called first, second, third, etc., derivatives and differentials, and of the first, second, third, etc., order; those of the second, third, etc., order are "higher derivatives" and higher differentials. For the successive x-derivatives of $y = f(x)$ the following symbols are used:

first,	$Dy, y', f'(x)$,	and	dy/dx
second,	$D(Dy)$ or $D^2y, y'', f''(x)$,	and	$d/dx\ dy/dx$ or d^2y/dx^2
third,	$D^3y, y''', f'''(x)$,	and	d^3y/dx^3

The first x-differential of y is dy, the second d^2y, the third d^3y, etc.

For the successive partial derivatives of $u = f(xy)$ the following symbols are used:

first partial x-derivative $\partial u/\partial x$, first partial y-derivative $\partial u/\partial y$
second partial x-derivative $\partial^2u/\partial x^2$, second partial y-derivative $\partial^2u/\partial y^2$

The first partial x-derivative may be taken with respect to x and the second with respect to y; this second is written $\partial^2u/\partial y\partial x$. Similarly $\partial^2u/\partial x\partial y$ means the x-partial derivative of the y-partial derivative of u. But the order of differentiation is immaterial, that is, $\partial^2u/\partial y\partial x = \partial^2u/\partial x\partial y$, and this independence is true for any number of successive differentiations with respect to any number of variables.

Maxima and Minima. A maximum value of a function is one which is algebraically greater than, and a minimum value is one algebraically less than its adjacent values. Thus, if the curve in Fig. 23 is the graph of $y = f(x)$, y_1, y_2, and y_3 are maximum values of y or $f(x)$ and y_4, y_5, and y_6 are minimum values; again, imagine $u = f(x, y)$ graphed, x and y independent variables plotted on horizontal axes and u vertically, thus defining in general an undulating surface; then the values of u corresponding to high and low points of the surface are maximum or minimum values of u or $f(x, y)$. Maximum and minimum values are also known as turning values; the values of the independent variable or variables corresponding to turning values are critical values. The following formulas refer to maxima and minima, like y_1 and y_4, where the tangent line is horizontal and not to those like y_3 and y_5 (rare), where the tangent line is not horizontal. At maxima and minima of the first kind the gradient dy/dx changes sign gradually, and at the peaks the change of sign is sudden. From this property peak values of a function can be obtained " by trial " with dy/dx.

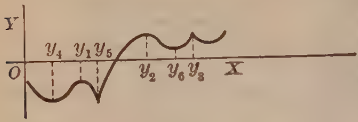

Fig. 23

(1) Turning value of $y = f(x)$: Solve $f'(x) = 0$; any root obtained, as x_1, is a critical value if the lowest x-derivative of y which does not vanish for $x = x_1$ is of an even order; the turning value, $f(x_1)$, is a maximum or minimum according as that lowest x-derivative is negative or positive for $x = x_1$.

(2) Turning value of y in $f(x, y) = 0$: Solve $\partial f(x, y)/\partial x = 0$ and $f(x, y) = 0$ simultaneously for x and y; the values obtained, x_1 and y_1, are critical and turning values respectively if $\partial f(x, y)/\partial y$ does not vanish for $x = x_1$ and $y = y_1$; y_1 is maximum or minimum according as $[-\partial^2 f(x, y)/\partial x^2] \div [\partial f(x, y)/\partial y]$ is negative or positive for $x = x_1$ and $y = y_1$.

(3) Turning values of $u = f(x, y)$: Solve $\partial f(x, y)/\partial x = 0$ and $\partial f(x, y)/\partial y = 0$ simultaneously for x and y; the values obtained, x_1 and y_1, are critical values if $[\partial^2 f(x, y)/\partial x^2]\,[\partial^2 f(x, y)/\partial y^2] - [\partial^2 f(x, y)/\partial x\partial y]^2$ is positive for $x = x_1$ and $y = y_1$;

$$\left.\begin{array}{l} u \text{ is a maximum} \\ u \text{ is a minimum} \end{array}\right\} \text{ if } \frac{\partial^2 f(x, y)}{\partial x^2} \text{ and } \frac{\partial^2 f(x, y)}{\partial y^2} \text{ are both } \left\{\begin{array}{l} \text{negative} \\ \text{positive} \end{array}\right.$$

Indeterminate Forms. In general a function of a variable has a definite value for any particular value of the variable; yet the values of some functions for special values of the variable lead to expressions like $0/0$, $0 \cdot \infty$ and the like, which are so-called indeterminate forms. For example, the function $(1 - \cos x)/x$ for $x = 0$ becomes $0/0$ and $(1/2\,\pi - x) \tan x$ for $x = \pi/2$ is $0 \times \infty$.

(1) The quotient $f(x) \div F(x)$ becomes $0/0$ for a particular value of x as a: the indeterminate form equals the value of $f'(x) \div F'(x)$ when $x = a$; if this ratio is also an indeterminate form, the original one equals $f''(x) \div F''(x)$ when $x = a$.

(2) The quotient $f(x) \div F(x)$ becomes ∞/∞ when $x = a$: the true value may be obtained as in case (1).

(3) The product $f(x) \times F(x)$ becomes $0.\infty$ when $x = a$: the product equals $f(x) \div [1/F(x)]$ which takes the form $0/0$ when $x = a$ and may be evaluated as in (1).

(4) The difference $f(x) - F(x)$ becomes $\infty - \infty$ when $x = a$: the difference equals $\phi(x) \div \psi(x)$, case (1), where $\phi(x) = [1/F(x)] - [1/f(x)]$ and $\psi(x) = 1/[f(x)\,F(x)]$.

(5) The function $[F(x)]^{f(x)}$ becomes 1^∞, 0^0, or ∞^0 when $x = a$: the function equals $e^{f(x) \log F(x)}$ (the logarithm being Napierian), and the value of this form can be got if $f(x) \log F(x)$ can be evaluated; but $f(x) \log F(x)$ falls under case (3).

Maclaurin's Theorem expresses the law for the expansion of a function of a variable in a series of ascending powers of the variable, thus,

$$f(x) = f(0) + \frac{x}{1} f'(0) + \frac{x^2}{2!} f''(0) + \frac{x^3}{3!} f'''(0) + \ldots$$

wherein $f(0)$ means the value of $f(x)$ when $x = 0$ and $f'(0)$ is the value of $f'(x)$ when $x = 0$, etc.

As illustration, $\cos x$ is here expanded by Maclaurin's theorem: $f(x) = \cos x$, $f'(x) = -\sin x$, $f''(x) = -\cos x$, $f'''(x) = \sin x$, $f''''(x) = \cos x$, etc.; $f(0) = 1$, $f'(0) = 0$, $f''(0) = -1$, $f'''(0) = 0$, $f''''(0) = 1$. Hence $\cos x = 1 - x^2/2! + x^4/4! + \ldots$

Taylor's Theorem expresses the law for the expansion of a function of a variable plus an increment in a series of ascending powers of the increment; thus h, denoting an increment of x,

$$f(x+h) = f(x) + \frac{h}{1} f'(x) + \frac{h^2}{2!} f''(x) + \frac{h^3}{3!} f'''(x) + \ldots$$

To expand $\cos(x + h)$ by Taylor's theorem: $f(x) = \cos x$, $f'(x) = -\sin x$, $f''(x) = -\cos x$, $f'''(x) = \sin x$, $f''''(x) = \cos x$, etc., and $\cos(x + h) = \cos x\,(1 - h^2/2! + h^4/4! - \ldots) - \sin x\,(h - h^3/3! + h^5/5! - \ldots)$.

9. Integral Calculus

Definitions and Notation. Integration is the process of determining a function from its derivative or differential; it is the inverse of differentiation. The function is called the integral of the derivative or differential; also anti-derivative and anti-differential. The symbol of integration is $\int$. Thus the x-derivative of $f(x)$ being written $f'(x)$, $\int f'(x) = f(x)$, but integration of the differential instead is generally indicated, as $\int f'(x)\,dx = f(x)$; dx indicates the "variable of integration," $f'(x)$ is called integrand, and the result of the integration, that is, the function determined $f(x)$, is the integral of the derivative or differential from which it is found. Strictly $\int f'(x)$ or $\int f'(x)dx = f(x) + C$, C being a constant, called constant of integration; $f(x)$ is called the indefinite integral and $f(x) + C$ the general integral. In a general integral the constant of integration is an arbitrary constant, but in a particular problem of integration it has a special value determinable from data of the problem. Thus, suppose in a given case it is known that when $x = a$, $\int f'(x) = A$ then $A = f(a) + C$ or $C = A - f(a)$; and $f(x) + A - f(a)$ is a particular integral.

Integral Forms. In the following formulas K is the constant of integration; $a, b, c, A, B, m,$ and n are constants; logarithms indicated are Napierian, and ϵ is the base of that system (Art. 2); Y is an abbreviation for $a + bx$, Z for $a + bx + cx^2$; and u and v are any functions of x.

$$\int a\,du = a \int du \qquad \int (u + v)\,dx = \int u\,dx + \int v\,dx$$

$$\int u\,dv = uv - \int v\,du \qquad \int Y^n dx = \frac{Y^{n+1}}{(n+1)b} + K$$

$$\int \frac{dx}{Y} = \frac{1}{b} \log Y + K \qquad \int \frac{x\,dx}{Y} = \frac{1}{b^2}(Y - a \log Y) + K$$

$$\int \frac{x\,dx}{Y^2} = \frac{1}{b^2}\left(\log Y + \frac{a}{Y}\right) + K$$

$$\int \frac{x^2\,dx}{Y} = \frac{1}{b^3}(1/2\,Y^2 - 2\,aY + a^2 \log Y) + K$$

$$\int \frac{x^2\,dx}{Y^2} = \frac{1}{b^3}\left(Y - 2\,a \log Y - \frac{a^2}{Y}\right) + K$$

$$\int \frac{dx}{xY} = -\frac{1}{a}\log\frac{Y}{x} + K \qquad \int \frac{dx}{xY^2} = \frac{1}{aY} - \frac{1}{a^2}\log\frac{Y}{x} + K$$

$$\int \frac{dx}{x^2Y} = -\frac{1}{ax} + \frac{b}{a^2}\log\frac{Y}{x} + K \qquad \int \sqrt{Y}\,dx = \frac{2}{3\,b}Y^{3/2} + K$$

$$\int x\sqrt{Y}\,dx = -\frac{(2\,a - 3\,bx)\,Y^{3/2}}{15\,b^2} + K$$

$$\int x^2\sqrt{Y}\,dx = \frac{2\,(8\,a^2 - 12\,abx + 15\,b^2x^2)\,Y^{3/2}}{105\,b^3} + K$$

$$\int \frac{dx}{\sqrt{Y}} = \frac{2\sqrt{Y}}{b} + K \qquad \int \frac{x\,dx}{\sqrt{Y}} = -\frac{2\,(2\,a - bx)\sqrt{Y}}{3\,b^2} + K$$

$$\int \frac{x^2\,dx}{\sqrt{Y}} = \frac{2\,(8\,a^2 - 4\,abx + 3\,b^2x^2)\sqrt{Y}}{15\,b^3} + K$$

$$\int \frac{dx}{x\sqrt{Y}} = \frac{1}{\sqrt{a}}\log\frac{\sqrt{Y} - \sqrt{a}}{\sqrt{Y} + \sqrt{a}} + K, \text{ if } a > 0$$

$$= \frac{2}{\sqrt{-a}}\tan^{-1}\frac{\sqrt{Y}}{\sqrt{-a}} + K, \text{ if } a < 0$$

$$\int \frac{\sqrt{Y}dx}{x}\,dx = 2\sqrt{Y} + a\int \frac{dx}{x\sqrt{Y}}$$

$$\int \frac{dx}{x^2\sqrt{Y}} = -\frac{\sqrt{Y}}{ax} - \frac{b}{2\,a}\int \frac{dx}{x\sqrt{Y}}$$

$$\int \frac{dx}{a + bx^2} = \frac{1}{\sqrt{ab}}\tan^{-1}\sqrt{\frac{b}{a}}\,x + K, \text{ if } a > 0 \text{ and } b > 0$$

$$\int \frac{dx}{a - bx^2} = \frac{1}{2\sqrt{ab}}\log\frac{\sqrt{ab} + bx}{\sqrt{ab} - bx} + K, \text{ if } a > 0 \text{ and } b > 0$$

$$= \frac{1}{\sqrt{ab}}\tanh^{-1}\sqrt{\frac{b}{a}}\,x + K, \text{ if } a > 0 \text{ and } b > 0$$

$$\int \frac{x^2\,dx}{a + bx^2} = \frac{x}{b} - \frac{a}{b}\int \frac{dx}{a + bx^2}$$

$$\int \frac{dx}{x^2\,(a + bx^2)} = -\frac{1}{ax} - \frac{b}{a}\int \frac{dx}{a + bx^2}$$

$$\int \sqrt{x^2 \pm a^2}\,dx = \frac{x}{2}\sqrt{x^2 \pm a^2} \pm \frac{a^2}{2}\log\left(x + \sqrt{x^2 \pm a^2}\right) + K$$

$$\int \sqrt{a^2 - x^2}\,dx = \frac{x}{2}\sqrt{a^2 - x^2} + \frac{a^2}{2}\sin^{-1}\frac{x}{a} + K$$

$$\int \frac{dx}{\sqrt{x^2 \pm a^2}} = \log\left(x + \sqrt{x^2 \pm a^2}\right) + K$$

$$\int \frac{dx}{\sqrt{a^2 - x^2}} = \sin^{-1}\frac{x}{a} + K = -\cos^{-1}\frac{x}{a} + K$$

$$\int \frac{dx}{x\sqrt{x^2 - a^2}} = \frac{1}{a}\cos^{-1}\frac{a}{x} + K$$

$$\int \frac{dx}{x\sqrt{a^2 \pm x^2}} = -\frac{1}{a}\log\frac{a + \sqrt{a^2 \pm x^2}}{x} + K$$

$$\int \frac{\sqrt{a^2 \pm x^2}}{x}\,dx = \sqrt{a^2 \pm x^2} + a^2\int\frac{dx}{x\sqrt{a^2 \pm x^2}}$$

$$\int \frac{\sqrt{x^2 - a^2}}{x}\,dx = \sqrt{x^2 - a^2} - a^2\int\frac{dx}{x\sqrt{x^2 - a^2}}$$

$$\int \frac{x\,dx}{\sqrt{a^2 \pm x^2}} = \pm\sqrt{a^2 \pm x^2} + K \qquad \int\frac{x\,dx}{\sqrt{x^2 - a^2}} = \sqrt{x^2 - a^2} + K$$

$$\int\frac{dx}{Z} = \frac{2}{\sqrt{4ac - b^2}}\tan^{-1}\frac{b + 2cx}{\sqrt{4ac - b^2}} + K, \text{ if } 4ac - b^2 > 0$$

$$\int\frac{dx}{Z} = \frac{1}{\sqrt{b^2 - 4ac}}\log\frac{\sqrt{b^2 - 4ac} - b - 2cx}{\sqrt{b^2 - 4ac} + b + 2cx} \text{ if } b^2 - 4ac > 0$$

$$= \frac{-2}{\sqrt{b^2 - 4ac}}\tanh^{-1}\frac{b + 2cx}{\sqrt{b^2 - 4ac}} + K \text{ if } b^2 - 4ac > 0$$

$$\int\frac{x\,dx}{Z} = \frac{1}{2c}\log Z - \frac{b}{2c}\int\frac{dx}{Z}$$

$$\int\frac{x^2dx}{Z} = \frac{x}{c} - \frac{b}{2c^2}\log Z + \frac{b - 2ac}{2c^2}\int\frac{dx}{Z}$$

$$\int\frac{(A + Bx)dx}{Z} = A\int\frac{dx}{Z}\int + B\int\frac{x\,dx}{Z}$$

$$\int\frac{dx}{\sqrt{Z}} = \frac{1}{\sqrt{c}}\log\left(b + 2cx + 2\sqrt{c}\sqrt{Z}\right) + K, \text{ if } c > 0$$

$$= \frac{1}{\sqrt{c}}\sinh^{-1}\frac{b + 2cx}{\sqrt{4ac - b^2}} + K, \text{ if } c > 0 \text{ and } 4ac - b^2 > 0$$

$$= \frac{1}{\sqrt{c}}\cosh^{-1}\frac{b + 2cx}{\sqrt{b^2 - 4ac}} + K \text{ if } c > 0 \text{ and } b^2 - 4ac - b^2 > 0$$

$$= \frac{-1}{\sqrt{-c}}\sin^{-1}\frac{b + 2cx}{\sqrt{b^2 - 4ac}} + K \text{ if } c > 0$$

$$\int\frac{x\,dx}{\sqrt{Z}} = \frac{\sqrt{Z}}{c} - \frac{b}{2c}\int\frac{dx}{\sqrt{Z}}$$

$$\int\frac{(A + Bx)\,dx}{\sqrt{Z}} = A\int\frac{dx}{\sqrt{Z}} + B\int\frac{x\,dx}{\sqrt{Z}}$$

$$\int\frac{x^2dx}{\sqrt{Z}} = \left(\frac{x}{2c} - \frac{3b}{4c^2}\right)\sqrt{Z} + \frac{3b^2 - 4ac}{8c^2}\int\frac{dx}{\sqrt{Z}}$$

$$\int\sqrt{Z}\,dx = \frac{b + 2cx}{4c}\sqrt{Z} + \frac{4ac - b^2}{8c}\int\frac{dx}{\sqrt{Z}}$$

$$\int x\sqrt{Z}\,dx = \frac{Z\sqrt{Z}}{3c} - \frac{b}{2c}\int\sqrt{Z}\,dz$$

$$\int x^2\sqrt{Z}\,dx = \left(x - \frac{5b}{6c}\right)\frac{Z\sqrt{Z}}{4c} + \frac{5b^2 - 4ac}{16c^2}\int\sqrt{Z}\,dx$$

$$\int \sin x\,dx = -\cos x + K \qquad \int \sin(ax+b)dx = -\frac{1}{a}\cos(ax+b) + K$$

$$\int \sin^2 x\,dx = -1/2\cos x \sin x + 1/2\,x + K$$

$$\int \sin^n x\,dx = -\frac{\cos x \sin^{n-1} x}{n} + \frac{n-1}{n}\int \sin^{n-2} x\,dx$$

$$\int \cos x\,dx = \sin x + K \qquad \int \cos(ax+b)\,dx = \frac{1}{a}\sin(ax+b) + K$$

$$\int \cos^2 x\,dx = 1/2\sin x \cos x + 1/2\,x + K$$

$$\int \cos^n x\,dx = \frac{\sin x \cos^{n-1} x}{n} + \frac{n-1}{n}\int \cos^{n-2} x\,dx$$

$$\int \sin x \cos x\,dx = 1/2\sin^2 x + K$$

$$\int \sin ax \cos bx\,dx = -\frac{\cos(a+b)x}{2(a+b)} - \frac{\cos(a-b)x}{2(a-b)} + K$$

$$\int \sin ax \sin bx\,dx = \frac{\sin(a-b)x}{2(a-b)} - \frac{\sin(a+b)x}{2(a+b)} + K$$

$$\int \cos ax \cos bx\,dx = \frac{\sin(a-b)x}{2(a-b)} + \frac{\sin(a+b)x}{2(a+b)} + K$$

$$\int \cos^n x \sin x\,dx = -\frac{\cos^{n+1} x}{n+1} + K \qquad \int \sin^n x \cos x\,dx = \frac{\sin^{n+1} x}{n+1} + K$$

$$\int \sin^m x \cos^n x\,dx = \frac{\sin^{m+1} x \cos^{n-1} x}{m+n} + \frac{n-1}{m+n}\int \sin^m x \cos^{n-2} x\,dx$$

$$= -\frac{\sin^{m-1} x \cos^{n+1}}{m+n} + \frac{m-1}{m+n}\int \sin^{m-2} \cos^n dx$$

$$\int x \sin x\,dx = \sin x - x\cos x + K$$

$$\int x^2 \sin x\,dx = 2\,x\sin x - (x^2-2)\cos x + K$$

$$\int x \cos x\,dx = \cos x + x\sin x + K$$

$$\int x^2 \cos x\,dx = 2\,x\cos x + (x^2-2)\sin x + K$$

$$\int \tan x\,dx = -\log\cos x + K \qquad \int \tan^2 x\,dx = \tan x - x + K$$

$$\int \cot x\,dx = \log\sin x + K \qquad \int \cot^2 x\,dx = -\cot x - x + K$$

$$\int \sec x\,dx = \log\tan\left(\frac{\pi}{4} + \frac{x}{2}\right) + K \qquad \int \csc x\,dx = \log\tan 1/2\,x + K$$

$$\int \sin^{-1} x\,dx = x\sin^{-1} x + \sqrt{1-x^2} + K$$

$$\int \cos^{-1} x\,dx = x\cos^{-1} x - \sqrt{1-x^2} + K$$

$$\int \tan^{-1} x\,dx = x \tan^{-1} x - 1/2 \log (1 + x^2) + K$$

$$\int \cot^{-1} x\,dx = x \cot^{-1} x + 1/2 \log (1 + x^2) + K$$

$$\int \operatorname{vers}^{-1} x\,dx = (x - 1) \operatorname{vers}^{-1} x + \sqrt{2x - x^2} + K$$

$$\int a^x\,dx = \frac{a^x}{\log a} + K \qquad \int \log x\,dx = x \log x - x + K$$

$$\int (\log x)^n\,dx = x (\log x)^n - n \int (\log x)^{n-1}\,dx$$

$$\int \frac{(\log x)^n}{x}\,dx = \frac{1}{n+1} (\log x)^{n+1} + K$$

$$\int \frac{dx}{x (\log x)^n} = -\frac{1}{n-1}\,\frac{1}{(\log x)^{n-1}} + K$$

$$\int \epsilon^{ax}\,dx = \frac{\epsilon^{ax}}{a} + K \qquad \int x \epsilon^{ax}\,dx = \frac{\epsilon^{ax}}{a^2} (ax - 1) + K$$

$$\int x^n \epsilon^{ax}\,dx = \frac{x^n \epsilon^{ax}}{a} - \frac{n}{a} \int x^{n-1} \epsilon^{ax}\,dx$$

$$\int \frac{\epsilon^{ax}}{x^n}\,dx = -\frac{\epsilon^{ax}}{(n-1)\,x^{n-1}} + \frac{a}{n-1} \int \frac{\epsilon^{ax}}{x^{n-1}}\,dx$$

$$\int \epsilon^{ax} \log x\,dx = \frac{\epsilon^{ax} \log x}{a} - \frac{1}{a} \int \frac{\epsilon^{ax}}{x}\,dx$$

$$\int \epsilon^x \sin x\,dx = \frac{\epsilon^x (\sin x - \cos x)}{2} + K$$

$$\int \epsilon^x \cos x\,dx = \frac{\epsilon^x (\sin x + \cos x)}{2} + K$$

Definite integrals result from integration between "limits"; thus $\int_a^b f'(x)\,dx = [f(x)]_b^a = f(b) - f(a)$; a and b are "lower" and "upper limits" respectively and $(b - a)$ is the "range" of integration. Interchanging the limits in a definite integral changes the sign of the result, and a definite integral can be expressed as the sum of several other integrals; thus

$$\int_a^b f(x)\,dx = -\int_b^a f(x)\,dx \quad \text{and} \quad \int_a^c f(x)\,dx = \int_a^b f(x)\,dx + \int_b^c f(x)\,dx$$

Approximate Integration. An approximate value of $\int f(x)\,dx$ between any limits as x_0 and x_n can be obtained as follows: divide the range $x_n - x_0$ into an even number (n) of equal parts (w) and compute the values of $f(x)$ when $x = x_0$, $x_0 + w$, $x_0 + 2w$, . . ., x_n, and call these values $y_0, y_1, y_2, \ldots, y_n$. Then substitute in an approximate formula for the area of an irregular figure (Art. 6), as Simpson's for example; the value obtained for A is an approximate value of the integral. If the values of x and y are plotted and a smooth curve is drawn through the points obtained, then the area between the curve, the x axis and the end ordinates y_0 and y_n represents the integral; and the area according to the proper scale in a given case equals the integral. If the area is cut by the x axis, the parts above and below should be regarded as positive and negative respectively.

10. Plane Analytic Geometry

Plane Coordinate Systems. For rectangular coordinate systems, see Art. 3. An oblique coordinate system is like the rectangular except that the coordinate axes are not at right angles, and in the oblique the x and y coordinates of a point are measured parallel to the x and y axes respectively. Rectangular and oblique systems are called Cartesian. The **polar coordinates** of a point P (Fig. 24) are its distance from some point or pole O and the angle between a reference line as OX and the line joining P and O; the line OP is the radius vector of P. Change or transformation of coordinates from one system to another can be made from $x = r \cos \phi$. $y = r \sin \phi$, or $\sin \phi = y/r$, $\cos \phi = x/r$, $r = \sqrt{x^2 + y^2}$; the reference line and pole of the polar system and the axes of the rectangular system must be related as shown in the figure. For example, the equation of the circle (Fig. 25) with respect to axes OX and OY is $x^2 + y^2 = 2\,ay$, a being the radius; its polar equation with OX as reference line and O as pole is $r^2 \cos^2 \phi + r^2 \sin^2 \phi = 2\,ar \sin \phi$, or $r = 2\,a \sin \phi$.

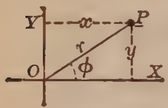

Fig. 24

Transformation from a set of rectangular axes to a parallel set: XOY (Fig. 26) is the original set, UQV the new, and (x_1, y_1) the coordinates of the new origin Q with respect to the original set; then P being any point whose coordinates with respect to the two sets of axes are (x, y) and (u, v) respectively, $x = u + x_1$ and $y = v + y_1$.

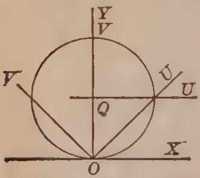

Fig. 25

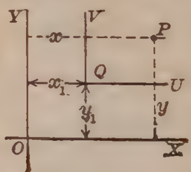

Fig. 26

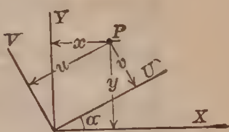

Fig. 27

For example, the equation of the circle (Fig. 25) with respect to the axes XOY being $x^2 + y^2 = 2\,ay$, its equation with respect to UQV is

$$(u + 0)^2 + (v + a)^2 = 2\,a\,(v + a), \text{ or } u^2 + v^2 = a^2$$

Transformation from a set of rectangular axes to another set, having the same origin but different directions: XOY (Fig. 27) is the original set, UOV the new, and α denotes the angle through which OX must be turned to bring it into OU, α being positive for counter-clockwise turning; then P being any point whose coordinates are as shown, $x = u \cos \alpha - v \sin \alpha$ and $y = u \sin \alpha + v \cos \alpha$. For example, the equation of the circle (Fig. 25) with respect to XOY being $x^2 + y^2 = 2\,ay$ its equation with respect to UOV is $(u \cos 45° - v \sin 45°)^2 + (u \sin 45° + v \cos 45°)^2 = 2\,a\,(u \sin 45° + v \cos 45°)$, or $u^2 + v^2 = a\sqrt{2}\,(u + v)$.

Straight Line. When a straight line lies in a coordinate plane (Fig. 28), the slope-angle is the angle through which XM must be turned to bring it into the line, the angle being regarded as positive or negative according as the turning is counter-clockwise or not, and by the slope or gradient of the line is meant the tangent of its slope-angle. OM and ON are the "intercepts" cut off by the line on the coordinate axes, and the intercepts are regarded as positive or negative according as they lie on the positive or negative parts of the coordinate axes. The equation of a straight line is of the first degree, its general form being $Ax + By + C = 0$; written in the form $y = mx + b$,

m is the slope or gradient of the line, and b the intercept on the y axis; written in the form $x/a + y/b = 1$, a and b are the intercepts on the x and y axes respectively. The equation of a line whose slope is m and containing the point (x_1, y_1) is $y - y_1 = m(x - x_1)$; the equation of a line containing the points (x_1, y_1) and (x_2, y_2) is $y - y_1 = (x - x_1)(y_2 - y_1)/(x_2 - x_1)$; the equation of a line whose angle with the x axis is α and distance from the origin is p, is $y \cos\alpha - x \sin\alpha = p$ (See also Art. 3.)

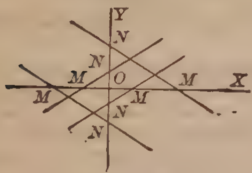

Fig. 28

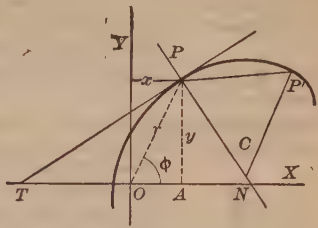

Fig. 29

Equation of a Curve. The equation of a curve referred to any coordinate reference frame is an equation between the coordinates of any and all points on the curve. When rectangular or oblique coordinates x and y are used, it is an equation between x and y; when polar coordinates r and ϕ are used, it is an equation between r and ϕ and is called the polar equation of the curve.

Tangents, Normals, Asymptotes. The **tangent** to a curve at P is the limiting position of a secant PP' (Fig. 29) as P' is taken nearer and nearer to P. The **normal** at P is a perpendicular to the tangent there, and in the plane of the curve. Generally these are understood to be lines of indefinite length, but when they are referred to as of definite lengths, the parts between the points of tangency and the x axis are meant, PT and PN. The subtangent and the subnormal are the projections of the definite tangent and normal on the x axis, AT and AN respectively. If a curve extends to a point of which one (or both) of the coordinates is infinitely great, then the tangent at that point is an **asymptote** of the curve. The equation of the tangent to a curve at a point P at (x_1, y_1) is $y - y_1 = (dy/dx)(x - x_1)$, and the equation of the normal at that point is $y - y_1 = -(dx/dy)(x - x_1)$. The definite tangent $PT = y_1 ds/dy$; the definite normal $PN = y_1 ds/dx$; the subtangent $AT = y_1 dx/dy$; and the subnormal $AN = y_1 dy/dx$.

Curvature. The total curvature of an arc PP' (Fig. 29) is the angle between the tangents to the curve at the points P and P'. The average curvature of the arc is the ratio of the curvature to the length of the arc, or $\Delta\alpha/\Delta s$, if $\Delta\alpha$ is the total curvature and Δs the length of arc. The curvature at a point P of the curve is the limiting value of the average curvature as P' approaches P, that is, $d\alpha/ds$; also curvature at a point is given by

$$\frac{d\alpha}{ds} = \frac{d^2y}{dx^2} \bigg/ \left[1 + \left(\frac{dy}{dx}\right)^2\right]^{3/2}$$

When for any arc the tangent lines are only slightly inclined to the x axis, then dy/dx is nearly zero for all points on the curve and the curvature is approximately equal to d^2y/dx^2

PC and $P'C$ are normals to the curve at P and P'; as P' is taken nearer and nearer to P, the intersection of the normals moves along the normal at ∞, approaching a definite point on that normal. This definite point is the center of curvature of the curve for the point P; the line joining the center and P is the radius of curvature of the curve at P, and a circle with that center and radius is the circle of curvature of the curve at P. If R denotes the radius of curvature, then

$$R = \frac{ds}{d\alpha} = \left[1 + \left(\frac{dy}{dx}\right)^2\right]^{3/2} \div \frac{d^2y}{dx^2}$$

and if x_1 and y_1 denote the coordinates of the center of curvature corresponding to any point (x, y) on a curve, then

$$x_1 = x - Rdy/ds \quad \text{and} \quad y_1 = y + Rdx/ds$$

and for R, dy/ds and dx/ds must be substituted, their values corresponding to the point (x, y).

Evolute and Involute. The line determined by the centers of curvature of a curve is the evolute of the curve, and the curve is an involute of the evolute. Thus C_1, C_2, and C_3 (Fig. 30) being centers of curvature for points on $P_1P_2P_3$, they lie on the evolute of $P_1P_2P_3$. The radii of curvature P_1C_1, P_2C_2, and P_3C_3 are tangent to the evolute; and the free end of a thread fastened at C_3, wound around the evolute and stretched into the position $C_3C_1P_1$, would, when unwound, describe $P_1P_2P_3$, an involute of $C_1C_2C_3$. The free end of a shorter cord, as $C_3C_1Q_1$, would, if unwound, describe $Q_1Q_2Q_3$, another involute of $C_1C_2C_3$. All points of the straight part of the thread describe parallel curves all of which are involutes of $C_1C_2C_3$, and $C_1C_2C_3$ is the evolute of all the parallel curves. The equation of the evolute of a given curve, $f(x, y) = 0$, can be obtained by eliminating x and y from $f(x, y) = 0$ and the equations for the coordinates of the center of curvature; then the final equation (freed from x's and y's) is the equation sought, x_1 and y_1 being regarded as the variables in it.

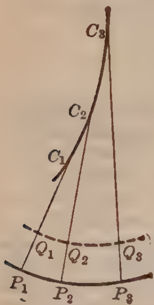

Fig. 30

Gradient, Convexity and Concavity. The slope-angle of a curve at any point of the curve is the angle which the tangent line to the curve makes with the positive x axis; the gradient or slope of the curve there is the tangent of the slope-angle; it is given by the value of dy/dx for that point of the curve. This derivative is positive or negative according as the curve extends upward and to right or left (see Fig. 31 for all possible cases). The second derivative d^2y/dx^2 relates to the bending of the curve. It is positive or negative according as the curve is concave or convex upward (see Fig. 31 for all possible cases).

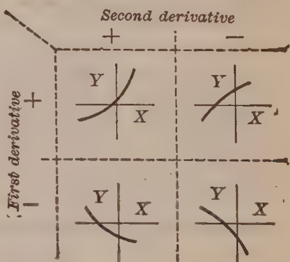

Fig. 31

Envelope. An equation of a curve contains one or more constants, called **parameters**; thus in $y = 4x + 2$, the equation of a straight line, 4 and 2 are parameters. The equation $y = mx + 2$ represents an infinitude of straight lines, one for each possible numerical value of m; a literal parameter, as m, regarded as capable of taking on different values is a variable parameter. The diagram representing an equation with a variable parameter is called a **family of curves**, and the parameter is the parameter of the family. In general the members of the family intersect; the successive intersections of members lie on some line, and the line containing the successive intersections of all members of a family is the envelope of the family. In general, the envelope of a family touches each member. If $f(x, y, a) = 0$ is the equation of a family of curves, the equation of the envelope may be obtained by eliminating a between $f(x, y, a) = 0$ and $\partial f(x, y, a)/\partial a = 0$.

Singular Points. An inflection point of a curve is one where the curve crosses the tangent line at the point and bends away from the tangent in opposite directions on opposite sides of the point (Fig. 32). (The tangent is an inflectional tangent.) At an inflection point $d^2y/dx^2 = 0$, and to locate an inflection point on a curve (having one) whose equation is $y = f(x)$, get

Fig. 32

Fig. 33

Fig. 34

Fig. 35

$f''(x)$, that is, dy^2/dx^2; equate to zero and solve for x; from that value of x and the equation of the curve get y; in general (x, y) is an inflection point. To make sure that it is, determine whether $f''(x)$ changes sign at the point; if so, it is an inflection point. When two or more branches of a curve intersect, or cross one another (Fig. 33), the point of intersection is a multiple point; if two branches cross, the intersection is a node. At a multiple point, dy/dx has two or more real unequal values and y at least two equal values. A cusp is a point of a curve where two branches have a common tangent; if the two branches stop at the point the cusp is single (Fig. 34); if not it is double (Fig. 35).

11. Conic Sections

A Conic is a curve traced by a point moving in a plane so that the distance of the point from a fixed point is in a constant ratio to its distance from a fixed line, the point and line lying in the plane. The fixed point is the focus, the fixed line the directrix, and the constant ratio the eccentricity of the conic. If the directrix is taken as a y axis, a line perpendicular to it and passing through the focus as the x axis, d to denote the distance between focus and directrix, and e the eccentricity, then the equation of the conic is $(x - d)^2 + y^2 = e^2x^2$. If

- $e > 1$, the equation represents a hyperbola
- $e = 1$, the equation represents a parabola
- $e < 1$, the equation represents an ellipse
- $e = 0$, the equation represents a circle

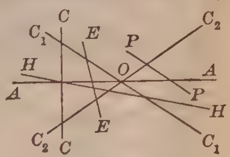

Fig. 36

Hence the circle is a special case of the ellipse, and the parabola is a limiting case for both hyperbola and ellipse.

The general second-degree equation between two coordinates x and y, $Ax^2 + 2\,Hxy + By^2 + 2\,Gx + 2\,Fy + C = 0$, represents a conic. It is an ellipse (or circle), parabola, or hyperbola according as $AB - H^2$ is positive, zero or negative; but if $ABC + 2\,FGH - AF^2 - BG^2 - CH^2 = 0$, the conic is a "degenerate," being a point, two intersecting straight lines, or two parallel straight lines in the three cases respectively.

A conic may be defined with reference to a double right cone with a circular base, whence the name conic. Let AA (Fig. 36) be the axis of such a cone, C_1C_1 and C_2C_2 elements of the surface in the plane of the paper, and let HH, PP, EE, and CC represent planes perpendicular to the paper; then HH, which cuts the elements on opposite sides of the vertex O, cuts a hyperbola from the surface; PP, which is parallel to an element cuts off a parabola; EE which cuts the elements on the same side of O and is not perpendicular to the axis, cuts off an ellipse: and CC, perpendicular to the axis, cuts off a circle.

For mensuration of the conic sections, see Art. 6.

Circle. The equation of a circle of radius r is, if the center is at the origin of rectangular coordinates, $x^2 + y^2 = r^2$; if the center is at a point (a, b) the equation is $(x - a)^2 + (y - b)^2 = r^2$. Any equation of the form $Ax^2 + Ay^2 + 2\,Gx + 2\,Fy + C = 0, A$ not being zero, is the equation of a circle.

An Ellipse is a curve such that the sum of the distances of any and every point on it from two fixed points is always the same (Fig. 37). The two fixed points are foci of the ellipse, and the distances of a point on the curve to the foci are focal distances, or focal radii, of the point. An ellipse has two lines of symmetry, called the axes of the ellipse; the longer is the major axis and the shorter the minor axis. The equation of an ellipse with respect to x and y axes coincident with the major and minor axes respectively, is $x^2/a^2 + y^2/b^2 = 1$, a and b denoting semi-major and semi-minor axis respectively. Any line through the center, terminating in the ellipse, is a diameter. Two diameters are conjugate to each other when either is parallel to tangents to the ellipse at the extremities of the other. The acute angles α and β which two conjugate diameters make with the major axis are related thus: $\tan\alpha \tan\beta = b^2/a^2$, and if A and B are semi-conjugate diameters, $A^2 + B^2 = a^2 + b^2$.

The definition of ellipse here given is in accordance with the one given in the present article under conic, but the focus and directrix there named are in case of the ellipse double; that is, there are two of each. As there, let e = eccentricity of the ellipse, d = distance from either focus to corresponding directrix, also c = distance from center to either focus; then $a = de/(1 - e^2)$, $b = de/\sqrt{1 - e^2}$, $c = de^2/(1 - e^2)$, $e = 1 - b^2/a^2$, $c = ae$, $c^2 = a^2 - b^2$. The latus rectum is the length of the focal chord perpendicular to the major axis; denoting it by p, then $p = 2\,de = 2\,a\,(1 - e^2) = 2\,b^2/a$. The polar equation of the ellipse with F as pole and FA as polar axis (Fig. 37) is $r = p/2\,(1 + e \cos\phi) = a\,(1 - e^2)/(1 + e\cos\phi)$.

Geometric Constructions of Ellipse. (1) To determine the foci of any ellipse, its axes given: from either end of the minor axis draw an arc whose radius equals the semi-major axis; the intersections of the arc and major axis are the foci. (2) To draw a tangent and a normal to the ellipse at any point of it: from the point draw focal radii;

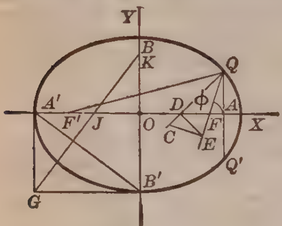

Fig. 37

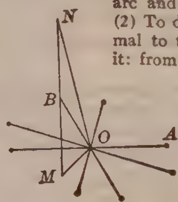

Fig. 38

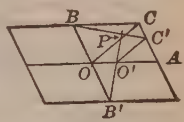

Fig. 39

the bisector of one of the angles between them is the tangent and that of the other angle is the normal. (3) To draw a tangent from a point P without the ellipse: join the point with either focus; on the joining line as diameter construct a circle; on the major axis as diameter construct a circle; the lines connecting the intersections of the two circles with P are tangents. (4) To find the center and the radius of curvature for any point of and ellipse: let Q (Fig. 37) be the point; at Q draw the normal and at its intersection with the major axis erect a perpendicular to the normal; at intersection of this perpendicular with either focal radius from Q erect a perpendicular to that radius; the intersection C of the last line with the normal is the center of curvature and QC is the radius of curvature. This construction fails for a point at either end of the major axis. For such points determine G, and through G draw a perpendicular to $A'B'$; the intersection J is the center of curvature for A' and K for the point B'. (5) To determine the axes of an ellipse from a pair of semi-diameters: from one end B (Fig. 38) of the shorter diameter draw a perpendicular to the longer and make BM and $BN = OA$; then the bisectors of the angles between the lines OM and ON are the directions of the axes; their lengths are $ON + OM$ and $ON - OM$. (6) Construction of an ellipse on its axes: draw auxiliary circles on the axes as diameters (Fig. 40); draw any diameter of these circles; through its intersections b with the small circle draw lines parallel to the major axis; through the intersections a with the other draw lines parallel to the minor axis; the intersections c of these lines are points on the ellipse. (7) Construction of an ellipse on a pair of coordinate diameters: construct a parallelogram on the diameters as medians (Fig. 39); divide OA and CA into proportional parts, beginning at O and at C, readily done by parallels to OC; join any point of division C' on AC with B and determine the intersection of BC' with the line joining B' and the corresponding division point O' on OA; this intersetion P is on the ellipse.

Mechanical Constructions of an ellipse from its axes: (a) First locate the foci; then take an inelastic string and fasten it at the foci so that the length of the loop between the fast points equals that of the major axis; then if the string is pulled out taut into any position, as FPF' (Fig. 40), P is a point on the ellipse, and a moving pencil, or other scribe, pressing against the string at P will describe the ellipse. (b) On a strip of stiff paper or other suitable material, from a point Q (Fig. 40) lay off QM = the semi-major axis and QN = the semi-minor; a pencil, or other scribe, at Q will trace the ellipse when the strip is moved so that M moves along the minor axis and N along the major.

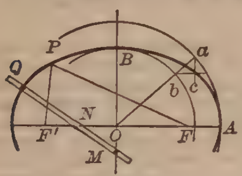

Fig. 40

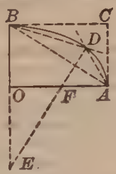

Fig. 41

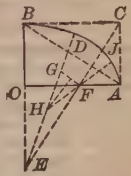

Fig. 42

Approximate Ellipse, consisting of arcs of circles; it is supposed that the axes of the ellipse are given. (1) Semi-ellipse with three centers: OA and OB (Fig. 41) are the given semi-axes; join A and B and bisect the angles CAB and CBA, thus determining D; through D draw a perpendicular to AB, thus determining F and E; from F with radius FA and from E with radius EB draw arcs; they meet tangentially at D. (2) Semi-ellipse with five centers: OA and OB (Fig. 42) are the given semi-axes; join A and B, and through C draw a perpendicular to AB, determining F and E, two of the centers; from E with EB as radius draw an arc BD as long as thought suitable, and join D with E; make $DG = AF$; join F and G; at the center of FG draw a perpendicular to FG and note its intersection H (the third center) with DE; from H with radius HD draw an arc to HF extended, and from F with FA as radius complete the curve.

The Hyperbola is a curve such that the difference between the distances of any and every point on the curve from two fixed points is always the same. The two fixed points are foci, the distances are focal distances, focal radiuses, or radius vectors. A hyperbola has two axes of symmetry (Fig. 43), one cut by the curve; the length AA' cut off by the curve is the transverse or real axis of the hyperbola, and the length BB' on the other line equal to

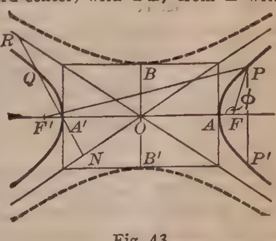

Fig. 43

$\sqrt{(FF')^2 - (AA')^2}$ is the conjugate or imaginary axis. The intersection of the axes is the center of the hyperbola, and any line through the center terminating on the hyperbola is a diameter. The equation of the hyperbola referred to the transverse and conjugate axes as x and y coordinate axes is

$x^2/a^2 - y^2/b^2 = 1$, a and b denoting semi-transverse and conjugate axes respectively. Two diameters are conjugate when each bisects all chords parallel to the other; either of two such diameters is parallel to the tangents at the extremities of the other. The acute angles α and β which two such diameters make with the transverse axis are related thus; $\tan\alpha \tan\beta = b^2/a^2$; if A and B denote semi-conjugate diameters, $A^2 - B^2 = a^2 - b^2$. The two hyperbolas $x^2/a^2 - y^2/b^2 = 1$ and $-x^2/a^2 + y^2/b^2 = 1$ are conjugate hyperbolas; the latter is shown by dotted lines in Fig. 43. They have the same asymptotes.

The definition of hyperbola given above is in agreement with the one given earlier in this article. As there, let e = eccentricity and a = distance between either focus and corresponding directrix; also let c = distance from center to either focus; then

$$a = de/(e^2 - 1) \qquad b = de/\sqrt{e^2 - 1} \qquad c = de^2/(e^2 - 1)$$
$$e^2 = 1 + b^2/a^2 \qquad c = ae \qquad c^2 = a^2 + b^2$$

The latus rectum of a hyperbola is the length of either focal chord perpendicular to the transverse axis; denoting it by p, then $p = 2\,de = 2\,a\,(e^2 - 1) = 2\,b^2/a$. The polar equation of the hyperbola with F as pole and FA as polar axis is

$$r = p/2\,(1 + e\cos\phi) = a\,(e^2 - 1)/(1 + e\cos\phi)$$

A hyperbola whose axes are equal is an equilateral or rectangular hyperbola; the asymptotes are at right angles. The equation of such a hyperbola referred to the axes is $x^2 - y^2 = a^2$, or $-x^2 + y^2 = a^2$; referred to the asymptotes, the equation is $xy = 1/2\,a^2$. The eccentricity is $\sqrt{2}$.

Geometric Constructions of Hyperbola. (1) To determine the foci when the axes are given: make OF and OF' (Fig. 43) equal to AB; then F and F' are the foci. (2) To draw a tangent and a normal at any point of a hyperbola: from the point draw the focal radii; the bisector of one of the angles between the radii is the tangent and that of the other is the normal. (3) To construct the asymptotes to a hyperbola, the axes being given: construct a rectangle on the axes as medians; diagonals of the rectangle extended are the asymptotes. (4) Construction of a hyperbola, its axes AA' and BB' (Fig. 43) being given: (a) Locate the foci F and F', mark any point M on the transverse axis extended but not between the foci; with MA and MA' as radii, strike arcs from F and F' respectively; their intersections are points on the hyperbola. Repeat for other points like M. (b) Draw the asymptotes; through A' draw any oblique line and note its intersections N and R with the nearer and remoter asymptote; lay off from R toward A' a length $RQ = A'N$; then Q is on the hyperbola. Repeat with other oblique lines through A', A, or through any other known point of the curve, as Q.

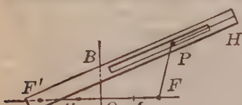

Fig. 44

Mechanical construction of a hyperbola from its axes AA' and BB': Determine the foci F and F' (Fig. 44); pivot one end of a strip of stiff paper or suitable material at F'; fasten an inextensible string HPF at H and F and so that the length HPF is less than HF' by AA'; place a pencil or other scribing point under the string and through the slot; keep the string taut with the pencil and then rotate the strip about F'; the pencil describes an arc of a hyperbola.

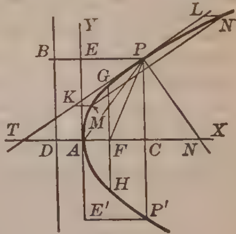

Fig. 45

Parabola. This is a curve such that any and every point of it is equidistant from a fixed point and a fixed line. The point is the focus, the line the directrix of the parabola, and the distance of any point of the curve to the focus is a focal radius, or focal distance. A parabola has a line of symmetry called the axis of the parabola (Fig. 45); it contains the focus F and is perpendicular to the directrix. The vertex is the intersection of the axis with the curve; the latus rectum is the length of the focal chord perpendicular to the axis.

The equations of the parabola referred to the axis as x axis and the vertex tangent as a y axis is $y^2 = px$ where p = latus rectum; the polar equation referred to F as pole and FA as plar axis is $r = p/2\ (1 + \cos\phi)$.

Geometric Properties and Constructions. The vertex is midway between the focus and the directrix. The length of the latus rectum equals four times the distance between focus and vertex. Any line parallel to the axis of a parabola bisects a system of parallel chords and is therefore a diameter of the parabola; the chords are parallel to the tangent at the end of the diameter terminating in the parabola. The extension of a diameter at P to the directrix equals the focal radius at P ($PB = PF$), and the distances from the focus to the ends of a definite tangent are equal ($FT = FP$). The tangent and the normal at any point bisect the angles between the focal radius and the diameter at that point; a subtangent is bisected by the vertex ($AC = AT$), and all subnormals equal one-half the latus rectum (CN = 1/2 GH). The projection of the radius of curvature R at any point on the axis of the parabola equals twice the focal distance of the point, and the extension of R to the directrix also equals twice the focal distance; R at the vertex equals the latus rectum. To construct a parabola: (a) Given the vertex (Fig. 46), the axis AX, and a point P. Join A and P, and through P draw a line parallel to the axis; draw any line as AQ; then perpendicular to the axis a line QR to AP; then parallel to the axis a line RS to AQ; S is a point on the parabola. Repeat for other points Q. Or, divide AB into equal parts and BP into the same number of equal parts; number the points of division, beginning at A on AB and at B on BP; draw lines as shown and note intersections of corresponding lines; they are on the parabola. (b) The vertex A and focus F (Fig. 47) are given. Join A and F and draw a perpendicular to AF at A; draw any line as FB and then BC perpendicular to FB; BC is a tangent to the parabola. Repeat with other lines like FB and BC and thus determine the parobola by means of tangents.

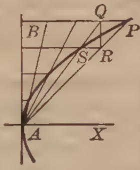

Fig. 46

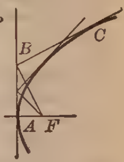

Fig. 47

12. Higher Curves

A Cycloid is the curve generated or traced by any point on the circumference of a circle which rolls on a straight line. Fig. 48 shows one half of one branch of a cycloid OA generated by the point P on the circle PQ rolled on OX; the other half of the branch is symmetrical with respect to AX. Let θ be the angle described by any line of the circle while it rolls from its original position OaY to any other as the one shown, r the radius of the circle, and x and y the coordinates of P relative to the axis shown; then $x = r\ (\theta - \sin\theta)$, $y = r\ (1 - \cos\theta)$, and the equation of the cycloid is $x = r \cos^{-1}(1 - y/r) \pm \sqrt{(2r - y)y}$. A cycloid may be constructed as follows: Draw the circle OaY of the chosen radius r, and make $OX = \pi r$; divide the arc OaY and OX into the same number of equal parts; at two corresponding points of division, as a and b, draw a horizontal and a vertical respectively to their intersection c and make $cd = ae$; then d is a point on the cycloid. Repeat for other points of division. To find the position of the generating circle corresponding to any point of the cycloid as P: make $Pf = gh$, and from f drop a perpendicular to OX; its foot Q is the lowest point of the circle desired. The normal at any point of the cycloid, as P, passes through the lowest point of the corresponding position of the generating circle; $PQ = 2r \sin 1/2\ \theta = \sqrt{2ry}$. The radius of curvature is twice PQ; at the highest point it equals $4r$ and at the lowest 0. The length of any arc as OP beginning at the lowest point is $4r\ (1 - \cos 1/2\ \theta)$

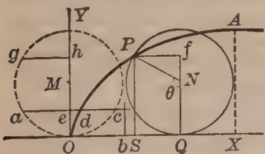

Fig. 48

$= 4r - 2\sqrt{2r(2r - y)}$, y being the ordinate of P; the length of one complete cycloid or $2\,OPA$ is $8r$. The area of any part as $OPSO$ is $r^2(3/2\,\theta - 2\sin\theta + 1/4\sin 2\theta) = 3/2\,rx - 1/2\,y\sqrt{(2r - y)y}$, x and y being the coordinates of P; the entire area between one cycloid and the track, that is $2\,OAXO$ is $3\pi r^2$.

When a circle rolls upon the outside of a fixed circle, each point of the circumference of the rolling circle describes or traces an epicycloid; and when it rolls upon the inside the curve described is a hypocycloid. A point without or within the rolling circle and fixed to it describes a trochoid, and epitrochoid, or a hypotrochoid according as the circle rolls on a straight line, on the outside of a fixed circle, or on the inside of a fixed circle.

The Spiral of Archimedes is a curve generated by a point moving at a constant speed in a given straight line which rotates at constant speed about a fixed point of the line. Fig. 49 shows such a spiral; O is the fixed point and OA the position of the line when the moving point is at the fixed point. The polar equation of the spiral is $r = (r'/2\pi)\phi$, in which r is the distance of the moving point P from O, ϕ the corresponding angle described by the moving line expressed in radians, and r' is the distance traveled by the moving point along the line while the line turns through 360°. To construct the spiral

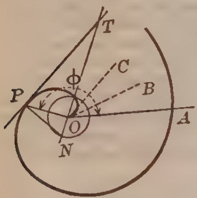

Fig. 49

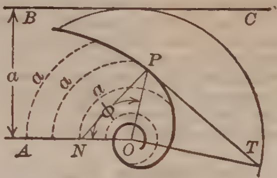

Fig. 50

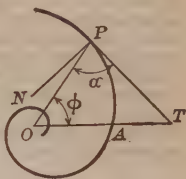

Fig. 51

having selected r': draw lines OA, OB, OC, etc., so that the successive angles between them is $360/n$, n being a convenient number; make $OB = r'/n$; $OC = 2\,r'/n$; $OD = 3\,r'/n$, etc.; B, C, D, etc., are on the spiral. To draw a normal and a tangent at any point P: draw a circle with center at O, and radius $r'/2\pi$; join P and O, and draw a perpendicular to OP at O, and note the intersection N as shown; then PN is the normal and PT (perpendicular to PN) the tangent. The length of any arc OP is $(r'/4\pi)\,[\phi\sqrt{1 + \phi^2} + \sinh^{-1}\phi]$; for many turns it equals approximately $r'\phi^2/4\pi$.

The Hyperbolic Spiral may be constructed as follows: draw a number of concentric circles and then a radius of the largest circle; from this radius measure off on the circles equal arcs all on the same side of the radius; the other ends of the arcs lie on the spiral (Fig. 50). The polar equation of the spiral is $r\phi = a$, a being the constant length of arc referred to, r the distance of any point of the curve as P from O and ϕ the angle between the radius OA and OP. The curve has an asymptote BC distant a from the reference radius. To draw a tangent and a normal at any point P: draw a circle with center at O and radius a, and join P and O; to OP at O draw a perpendicular, and note its intersection T with the circle on the side shown; then TP is the tangent and PN (perpendicular to PT) is the normal.

The Logarithmic or Equiangular Spiral is a curve such that the angles between its tangents and the corresponding radii drawn to the center of the curve are equal. Its polar equation is $r = a\epsilon^{m\phi}$; a is the value of r when $\phi = 0$ and $m = \cot\alpha$, α being the constant angle referred to (Fig. 51). To construct a curve for given values of a and α: compute m and then $m\phi$ for a number of values of ϕ in radians, as $20° = 0.349$ radian, $40° = 0.698$, $60° = 1.047$, etc.; from a table of Napierian logarithms (page 35) find the values of $\epsilon^{m\phi}$ (these are the numbers corresponding to the logarithms $m\phi$); compute values of $a\epsilon^{m\phi}$ or r; then lay off these values of r from a fixed point on radii making the different angles ϕ (20°, 40°, 60°, etc.) with a reference line through the fixed point. The length of any arc as $PO = r/\cos\alpha$.

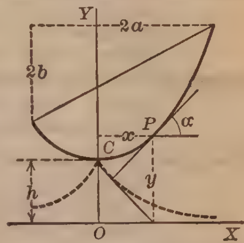

Fig. 52

The Catenary is the curve assumed by a chain suspended from two points. Its equation is $y = 1/2\ h\ (\epsilon^{x/h} + \epsilon^{-x/h}) = h \cosh x/,\ h$ or $x = h \log_\epsilon (y/h \pm \sqrt{(y/h)^2 - 1}) = h \cosh^{-1} y/h$; h is the distance from the lowest point of the curve to the origin (Fig. 52). The gradient at any point P whose coordinates are x and y is given by $\tan\alpha = \sinh x/h$ or $\cos\alpha = h/y$, from which the direction of the tangent line at any point can be computed. The radius of curvature R at any point P is $R = y^2/h = h/\cos^2\alpha$; it also equals the length cut off by the x axis from the normal through P. The length of any arc, as CP, is given by $s = h \sinh x/h = h \tan\alpha = \sqrt{y^2 - h^2}$, and the abscissa of P is

$$x = h \log_e [s/h + \sqrt{1 + (s/h)^2}] = h \sinh^{-1} s/h$$

To locate the origin of coordinates for a chain of length $2\,l$, supported from two points whose horizontal distance is $2\,a$ and vertical distance is $2\,b$: Let A and B denote the distances from the middle of the line joining the points of suspension to the y and x axis respectively; $A = \psi h$ and $B = l \cot\phi$, in which $h = a/\phi$ and $\psi = \tanh^{-1} b/l$, ϕ to be obtained by trial from $a \sinh\phi = \phi\sqrt{l^2 - b^2}$. The catenary is the evolute of the other curve shown in Fig. 52; its tangents are all equal to h. It is also called "anti-friction" curve, being the axial section of the surface of a vertical pivot of uniform wear.

13. Hyperbolic Functions

The Hyperbolic Functions are related to an equilateral or rectangular hyperbola much as the circular functions are related to a circle. Let P (Fig. 53) be a point on the hyperbola $x^2 - y^2 = a^2$; l = arc AP, positive or negative according as P is above or below OX; l/r = the mean of the reciprocals of all radii from O to AP; and $u = l\ (l/r)$. Then

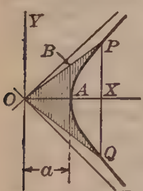

Fig. 53

hyperbolic sine of u, or $\sinh u = y/a$
hyperbolic cosine of u, or $\cosh u = x/a$
hyperbolic tangent of u, or $\tanh u = \sinh u \div \cosh u = y/x$
hyperbolic cotangent of u, or $\coth u = 1/\tanh u = x/y$
hyperbolic secant of u, or $\operatorname{sech} u = 1/\cosh u = a/x$
hyperbolic cosecant of u, or $\operatorname{csch} u = 1/\sinh u = a/y$.

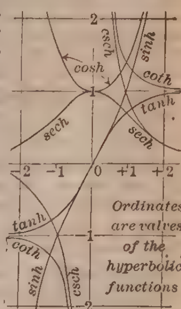

Fig. 54

If a is made 1, then the numerical values of double the area of the hyperbolic sector $OPAO$ equals l/r or u; also $\sinh u = XP$, $\cosh u = OX$; $\tanh u = AB$. See Sect. 1., Art. 22, for tables of hyperbolic functions. Fig. 54, plotted to scale, shows the relations between the functions for values of u from -2 to $+2$; it also indicates the sign of any function of u as dependent on the sign of u. Inverse hyperbolic sine of n means the l/r or u whose hyperbolic sign equals n; it is written $\sinh^{-1} n$; similarly, inverse hyperbolic cosine, tangent, etc.

The hyperbolic functions of u are closely related to the exponential function ϵ^u and ϵ^{-u}, ϵ being the Napierian base, thus

$$\sinh u = 1/2\,(\epsilon^u - \epsilon^{-u}), \quad \cosh u = 1/2\,(\epsilon^u + \epsilon^{-u})$$
$$\tanh u = (\epsilon^u - \epsilon^{-u})/(\epsilon^u + \epsilon^{-u})$$
$$\sinh u + \cosh u = \epsilon^u, \quad \cosh u - \sinh u = \epsilon^{-u}$$

Inverse hyperbolic functions as functions of Napierian logarithms:

$$\sinh^{-1} u = \log_\epsilon (u + \sqrt{u^2 + 1}), \quad \cosh^{-1} u = \log_\epsilon (u + \sqrt{u^2 - 1})$$
$$\tanh^{-1} u = 1/2 \log_\epsilon [(1 + u)/(1 - u)]$$

The hyperbolic functions are related to circular functions, thus ($i = \sqrt{-1}$):

$$i \sinh u = \sin iu \quad \sin u = -i \sinh iu$$
$$\cosh u = \cos iu, \quad \cos u = \cosh iu$$
$$i \tanh u = \tan iu, \quad \tan u = -i \tanh iu$$

The following are some of the relations between hyperbolic functions:

$$\cosh^2 u - \sinh^2 u = 1 \qquad 1 - \tanh^2 u = \operatorname{sech}^2 u$$
$$\coth^2 u - 1 = \operatorname{csch}^2 u$$
$$\sinh (u \pm v) = \sinh u \cosh v \pm \cosh u \sinh v$$
$$\cosh (u \pm v) = \cosh u \cosh v \pm \sinh u \sinh v$$
$$\tanh (u \pm v) = (\tanh u \pm \tanh v)/(1 \pm \tanh u \tanh v)$$
$$\sinh 2u = 2 \sinh u \cosh u$$
$$\cosh 2u = 1 + 2 \sinh^2 u = 2 \cosh^2 u - 1$$
$$\tanh 2u = 2 \tanh u/(1 + \tanh^2 u)$$
$$\sinh 1/2\, u = \sqrt{1/2\,(\cosh u - 1)}$$
$$\cosh 1/2\, u = \sqrt{1/2\,(\cosh u + 1)}$$
$$\tanh 1/2\, u = \sinh u/(1 + \cosh u) = (\cosh u - 1)/\sinh u$$

14. Probability of Errors

The Probability of an event is the ratio of the number of favorable chances of its occurrence to the total number of chances, favorable and unfavorable. Thus, if there are a white and b black balls in a jar, the probability of drawing a white ball at a single trial is $a/(a + b)$. If the probabilities of two independent events are p_1 and p_2, the probability of their concurrence in any single instance is $p_1 p_2$. Thus, suppose that there are two jars, J_1 and J_2, J_1 containing a_1 white and b_1 black balls, and J_2 containing a_2 white and b_2 black balls; the probability of drawing a white ball from J_1 is $a_1/(a_1 + b_1)$, the probability of drawing a white one from J_2 is $a_2/(a_2 + b_2)$, and that of drawing a pair of white balls, one from each jar, in a single trial is $a_1 a_2/(a_1 + b_1)\,(a_2 + b_2)$.

An Error of an Observation is the true value of a quantity minus the observed value. Errors are accidental or systematic; accidental errors are those which in the long run are as often negative as positive, and they affect the mean result but little; systematic errors due to the same cause affect the mean in the same sense, and do not tend to balance each other in the mean. Only accidental errors are referred to in the following. From the theory of probabilities, it has been shown that in a series comprising a great number of observations the relative frequency (proportionate number) of the errors whose values lie between x and $x + \Delta x$ is approximately $(h/\sqrt{\pi})\,\epsilon^{-h^2x^2}\,\Delta x$, and the relative frequency of the errors whose values lie between a and b is $(h/\sqrt{\pi}) \int_a^b \epsilon^{-h^2x^2}\,dx$; here ϵ is the Napierian base (Art. 1) and h a constant for any particular series of observations. The graph of $y = (h/\sqrt{\pi})\,\epsilon^{-h^2x^2}$ (Fig. 55) is a probability or "error curve"; the shaded area represents the relative frequency of the errors between a and b, and the whole area between the curve and the x axis is unity, according to the scale used, and represents the frequency of the whole number of errors that is 1 or 100 %. The dotted curve is also an error curve but the constant h for that curve is greater than for the first; also in the second the relative frequency of small errors is greater and that of large errors is smaller than in the first. Thus the constants h serve as a means for comparing the accuracies of several series of observations, and the value of h for any given series is called the measure of precision for that series.

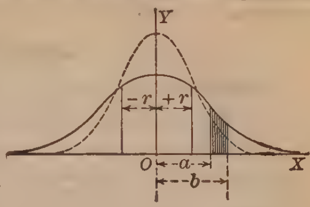

Fig. 55

Another index of accuracy is the so-called probable error of the series, an error of such value that the number of errors in the series less and greater than it are equal, the signs of the errors being disregarded in the count. It is the error r (Fig. 55) corresponding to the symmetrical ordinates which include one-half the whole area below the error curve. This middle error is more often called the **probable error** of a single observation to convey the idea that the error of any subsequent observation in such a series is just as apt to be less as greater than the middle error. The probable error and the measure of precision are always related thus, $rh = 0.4769$. The expression for relative frequency of the errors falling between $-a$ and $+a$ is

$$\frac{h}{\sqrt{\pi}}\int_{-a}^{+a}\epsilon^{-h^2x^2}\,dx = \frac{2}{\sqrt{\pi}}\int_0^{0.4769\,a/r}\epsilon^{-h^2x^2}\,d\,(hx)$$

The table below gives the values of the expressions for the various values of the arguments a/r given therein. Thus, in a large series of observations, the relative frequency of the errors falling between $a = -r$ and $a = +r$ is .500, or 50 %; between $a = -2r$ and $a = +2r$, 0.823, or 82.3 %; the relative frequency of the errors arithmetically greater than $4r$ is 0.007, or 0.7 %; etc.

Values of the Probability Integral

a/r	frqncy	a/r	frqncy	a/r	frqncy	a/r	frqncy	a/r	frqncy
0.	0.000	1.0	0.500	2.0	0.823	3.0	0.957	4.0	0.993
0.1	0.054	1.1	0.542	2.1	0.843	3.1	0.963	4.1	0.994
0.2	0.107	1.2	0.582	2.2	0.862	3.2	0.969	4.2	0.995

0.9	0.456	1.9	0.800	2.9	0.950	3.9	0.991	4.9	0.999
1.0	0.500	2.0	0.823	3.0	0.957	4.0	0.993	5.0	0.999

The probable error r for n observations of equal precision on the same quantity is computed as follows: (1) find the arithmetic mean by adding the observations and dividing by n, (2) subtract each observation from that mean thus obtaining n residuals v_1, v_2, v_3, etc., (3) square each residual and find their sum Σv^2. Then

$$r = 0.6745\sqrt{\frac{\Sigma v^2}{n-1}} \quad \text{and} \quad r_0 = \frac{r}{\sqrt{n}}$$

the first formula giving the probable error of a single observation, while the second gives the probable error of the arithmetic mean. For a numerical example, see below.

14½. Method of Least Squares

An Observation is the result of a measurement, thus when 635.74 ft. is stated as the measured length of a line, the quantity 635.74 ft. is called an observation, it being understood that all constant errors have been removed therefrom; this quantity, however, is still affected by the result of accidental errors. The true value of a quantity cannot be found by measurement, but the best that can be done is to deduce from the observations the most probable value of the quantity. The Method of Least Squares teaches how to obtain the most probable values of observed quantities.

Direct Observations are those which result from measurements made directly upon a single quantity. When only one observation is at hand, it is the most probable value of the quantity. When two or more observations are made with equal precision on the same quantity, their arithmetic mean is the most probable value, and the probable error of this arithmetic mean can be computed by the formulas at the end of Art. 14.

Example: Let a line be measured eight times with equal care by a tape graduated in centimeters and the following results be found, M indicating an observation, v a residual found by subtracting M from the arithmetic mean, and v^2 the square of a residual:

M	789.7	788.1	789.1	789.9	788.3	788.0	788.1	788.8
v	0.95	0.65	.0.35	1.15	0.45	0.75	0.65	0.05
v^2	0.902	0.423	0.122	1.323	0.203	0.562	0.423	0.002

Here, the arithmetic mean, found by adding the observations and dividing by 8, is 788.75, which is the most probable length of the line in centimeters. The eight residuals are some positive, some negative, their sum being zero. The sum of the squares of the residuals is $\Sigma v^2 = 3.96$. Then by the formula at foot of last page $r = 0.51$ cm., which is the probable error of a single observation; also $r_0 = 0.18$ cm., which is the probable error of the arithmetic mean. The final result of this series of observations may then be written 788.75 ± 0.18; that is, the true length of the line is just as likely to be between 788.57 cm. and 788.93 cm. as it is to be outside of those limits.

Weighted Observations. Weights of Observations are numbers proportional to their degrees of precision, so that one observation of weight p is worth as much as p observations of weight unity. When there are n weighted observations, M, with weight p_1, M_2 with weight p_2, and so on, these being made directly upon the same quantity, then the most probable value of the quantity is the weighted mean z, or

$$z = \frac{p_1M_1 + p_2M_2 + \ldots + p_nM_u}{p_1 + p_2 + \ldots + p_n} = \frac{\Sigma pM}{\Sigma p}$$

To find the probable errors, let each observation be subtracted from this mean z, the difference being a residual v, square each residual, multiply each square by its weight, and find the sum Σpv^2, then

$$r = 0.6745\sqrt{\frac{\Sigma pv^2}{n-1}} \quad \text{and} \quad r_0 = \frac{r}{\sqrt{\Sigma p}}$$

the first being the probable error of an observation of the weight unity and the second being the probable error of the weighted mean Z.

Example: Let six observations on the same quantity be made, with weights as in the first line, the sum of these weights being 21. Multiplying each observation M by its weight p, gives the quantities in the third line the sum of which is 3741.36. Then the most probable value of the observed quantity is $z = 3741.36/21 = 178.16$. Subtracting each M from this gives the residuals in the fourth line. The weighted squares of the residuals are in the last line, their sum being $\Sigma pv^2 = 62.95$. Then the preceding formulas give the probable error of an observation of the weight unity as $r = 2.39$ and the probable error of the weighted mean as $r_0 = 0.52$. The final result then is $z = 178.16 \pm 0.52$.

p	5	4	1	4	3	4
M	178.26	176.30	181.06	177.95	176.20	180.85
pM	891.30	705.20	181.06	711.80	528.60	723.40
v	0.10	1.86	2.90	0.21	1.96	2.69
v^2	0.010	3.460	8.410	0.441	3.842	7.236
pv^2	0.05	13.84	8.41	0.18	11.53	28.94

Observation Equations arise when measurements are made to find the values of several quantities. For example, let O be a given bench and Z_1, Z_2, Z_3 three points whose elevations above O are to be determined. Let z_1, z_2, z_3 be the most probable elevations of Z_1, Z_2, Z_3; let five lines of levels be run giving

$$
\begin{array}{llllll}
Z_1 \text{ above } O & = 10 \text{ ft.} & \text{or} & z_1 & & = 10 \\
Z_1 \text{ above } Z_3 & = 2 \text{ ft.} & \text{or} & z_1 & - z_3 & = 2 \\
Z_2 \text{ above } O & = 18 \text{ ft.} & \text{or} & z_2 & & = 18 \\
Z_2 \text{ above } Z_3 & = 9 \text{ ft.} & \text{or} & z_2 & - z_3 & = 9 \\
Z_1 \text{ above } Z_3 & = 2 \text{ ft.} & \text{or} & - z_1 + z_2 & & = 7
\end{array}
$$

The problem is to determine the most probable values of z_1, z_2, z_3.

Normal Equations are derived from observation equations, when these are of equal weight, by the following rule: To find a normal equation for z_1, multiply each observation equation by the coefficient of z_1 in that equation and add the results; similarly a normal equation for each of the other unknown quantities is found; thus, for the above level observations the normal equation for z_1 is found by multiplying the first equation by $+1$, the second by $+1$, the third by 0, the fourth by 0, and the fifth by -1; the addition of these gives $3z_1 - z_2 - z_3 = 5$ as the normal equation for z_1. Similarly the normal equation for z_2 is $-z_1 + 3z_2 - z_3 = 34$, and that for z_3 is $-z_1 - z_2 + 2z_3 = -11$. These three normal equations contain three unknown quantities, and their solution gives $z_1 = 10\text{-}3/8$, $z_2 = 17\text{-}5/8$, $z_3 = 8\text{-}1/2$, which are the most probable elevations of the points Z_1, Z_2, Z_3 above the bench mark O.

General Method. Let the n observation equations be:

$$
\begin{array}{ll}
a_1 z_1 + b_1 z_2 + c_1 z_3 + \ldots\ldots = M_1 & \text{with weight } p_1 \\
a_2 z_1 + b_2 z_2 + c_2 z_3 + \ldots\ldots = M_2 & \text{with weight } p_2 \\
\cdots\cdots\cdots\cdots\cdots\cdots & \\
a_n z_1 + b_n z_2 + c_n z_3 + \ldots\ldots = M_n & \text{with weight } p_n
\end{array}
$$

in which $M_1, M_2 \ldots M_n$ are the observed quantities, z_1, z_2, z_3 are quantities required to be found, and a, b, c, are known coefficients. For each unknown quantity form a normal equation by multiplying each observation equation by the coefficient of that unknown quantity in that equation and also by its weight, and adding the results. If the number of unknown quantities is q the number of normal equations will also be q, thus:

$$
\begin{array}{l}
\Sigma pa^2.z_1 + \Sigma pab.z_2 + \Sigma pac.z_3 + \ldots = \Sigma paM \\
\Sigma pab.z_1 + \Sigma pb_2.z_2 + \Sigma pbc.z_3 + \ldots = \Sigma pbM \\
\Sigma pac.z_1 + \Sigma pbc.z_2 + \Sigma pc_2.z_3 + \ldots = \Sigma pcM
\end{array}
$$

in which $\Sigma pa^2 = p_1a_1^2 + p_2a_2^2 + \ldots p_na^2_n$ and similarly $\Sigma pab = p_1a_1b_1 + p_2a_2b_2 + \ldots p_na_nb_n$. The solution of these normal equations gives the most probable values of the unknown quantities $z_1, z_2, z_3 \ldots z_q$.

After these probable values are found, let them be inserted in the observation equations and the second members be subtracted from the first, thus giving small residuals $v_1, v_2 \ldots v_n$. Then

$$r = 0.6745\sqrt{\frac{\Sigma pv^2}{n-q}} \quad \text{and} \quad r' = \frac{r}{\sqrt{p'}}$$

the first being the probable error of an observation of weight unity, while the second is the probable error of an observation of weight p'.

For an example in which the weights are unequal, see the adjustment of angles at a station in Art. 50 of Sect. 6. When the weights are equal p is to be taken as unity.

Probable Error of a Line. When a line is measured the probable error of an observation increases as the square root of the length of the line. Thus $R = r\sqrt{l}$, where r is the probable error of a line one unit long, and R is the probable error of a line l units long.

The same rule holds good for discrepancies or apparent errors which are found in duplicate measurements of a line. The discrepancy r for a line one unit long may be found as follows: Let a line of length l_1 be measured twice, R_1 being the difference of the observed lenghts; let a second length, l_2, be measured twice, R_2 being the difference of the observed lengths. Then $r = (R_1 - R_2)/(\sqrt{l_1} - \sqrt{l_2})$.

The same rule holds for duplicate lines of levels. Thus, if r is the difference in the results for a line one unit long, then the difference R for a line of length l ought to be $R = r\sqrt{l}$. The practical rules stated at top of page 460 are derived from this principle.

STATICS

15. Forces and Moments

Force. An action of one body upon another which changes or tends to change the state of rest or motion of the body acted upon, is called force. A force has magnitude, direction, and place of application. When the extent of the place of application is negligible, and the force is regarded as applied or concentrated at a point, this is the point of application; and a line through the point parallel to the direction of the force is the line of action. The word " sense " as applied to forces refers to one of the two directions along the line of action of the force. The unit of force commonly used in America is the " pound," which is a force equal to the earth's attraction on the standard of weight, also called pound; this unit of force varies slightly from place to place on the earth, but the variation is negligible in most engineering calculations. Any number of forces considered collectively is a system of forces; a system is **concurrent**, or nonconcurrent, according as the lines of action of the forces do or do not intersect in a point, and it is **coplanar**, or noncoplanar, according as they do or do not lie in a plane. The resultant of a system of forces is the single force which is equivalent to that system, but if a system has no single force equivalent, then the simplest equivalent system may be called the resultant; a resultant never includes more than two forces. The process of determining the resultant is called composition (Art. 16).

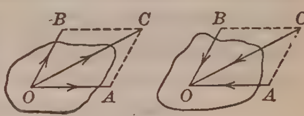

Fig. 56

Parallelogram Law. If magnitudes, lines of action, and senses of two concurrent forces acting on a rigid body are represented by OA and OB (Fig. 56), then the magnitude, line of action, and sense of their resultant is represented by the diagonal OC of the parallelogram $OABC$. The points of application of the forces may be anywhere on the body in the lines OA, OB, and OC, or their extensions. The arrowheads on the lines on AO, OB, and OC all point toward or all away from the point of concurrence O. **Triangle Law:** If the magnitudes and directions of two concurrent forces are represented by AB and BC (Fig. 57 or 58), then the magnitude and direction of the resultant is represented by the side AC of the triangle ABC. The arrowheads on the

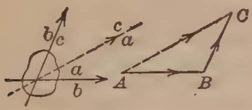

Fig. 57

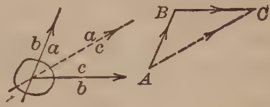

Fig. 58

sides AB and BC are confluent (point the same way around), but the arrowhead on AC is not confluent with the others. The two forces and their resultant being concurrent, the line of action of the resultant is ac, parallel to AC.

The resultant of two concurrent forces may be determined algebraically, thus: let P and Q be the forces and α that angle between their lines of action in which the resultant lies, R the resultant and θ the angle between R and P; then $R = (P^2 + Q^2 + 2\ PQ \cos\alpha)^{1/2}$ and $\tan\theta = (Q \sin\alpha)/(P + Q\cos\alpha)$. If the angle between the given forces is 90°, then $R = \sqrt{P^2 + Q^2}$ and $\tan\theta = Q/P$.

Parallelopiped Law. If the magnitudes and lines of action of three noncoplanar concurrent forces are represented by OA, OB, and OC, then the magnitude and the line of action of the resultant is represented by the diagonal OD of the parallelopiped $OABC - D$ (Fig. 59). This is not a practical device to get numerical results; for a better, see Art. 16. When the three forces are mutually at right angles then the parallelopiped is right-angled, and the resultant can be conveniently determined algebraically, thus: let P, Q, and S denote the three forces, R the resultant and α, β and γ the angles between $R^{1/2}$ and the three forces respectively; then $R = (P^2 + Q^2 + S^2)^{1/2}$, $\cos\alpha = P/R$, $\cos\beta = Q/R$ and $\cos\gamma = S/R$.

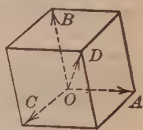

Fig. 59

Resolution of a Force. Two or more forces which together are equivalent to a given force are components of the force. The process of determining components of a force is called resolution; resolution of a force into two components at right angles to each is the common case; such components are "rectangular" and each is a "resolved part" of the given force. (1) Resolution into concurrent components. A force may be resolved into two concurrent components by applying the parallelogram law inversely; thus to resolve the 10 lb. (Fig. 60) into two components: lay off AB by scale to represent 10 lb.; construct a parallelogram on AB as diagonal; then AC and

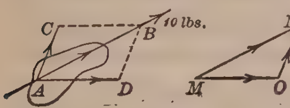

Fig. 60

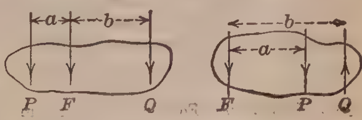

Fig. 61

AD represent components of the given force. Or, by means of the triangle law, thus: lay off MN by scale to represent the magnitude and direction of the given force; construct a triangle on MN as one side, then MO and ON represent magnitudes and directions of two components of the given force, the action lines being concurrent with that of the 10-lb. force. Two rectangular components of a force can readily be found algebraically; each equals the product of the force and the cosine of the acute angle between the force and that component. Three rectangular components of a force can be readily computed if the angles between the force and the desired components are known; each component equals the product of the force and the cosine of the acute angle between the force and that component. (2) Resolution into two components parallel to the force, their lines of action being specified: Let F (Fig. 61) be the force to be resolved into two components P and Q (values and senses unknown), a and b the distances from F to P and Q respectively, and c the distance between P and Q; the principle that the moment of F about a point on either force equals the moment of the other about the same point determines the senses of the components as shown, also their values, $P = Fb/c$ and $Q = Fa/c$. Or, graphically, suppose F (Fig. 62) to be

Fig. 62

the force and P and Q the components; resolve AB (representing magnitude and direction of F) into any two concurrent components AO and OB, action lines in ao and ob; at 1 resolve AO along P and the line 12, and at 2 resolve OB along Q and the line 12; the two components along 12 balance, and those along P and Q represented by AC and CB in value and direction are the desired components. (3) To resolve a force into three nonconcurrent nonparallel forces coplanar with the force: Let P (Fig. 63) be the force, the components to act in F_1, F_2, and F_3; join the intersection of P and F_1 with that of F_2 and F_3; draw AB to represent P and then resolve P into two components along F_1 and the line 12 (represented by AC and CB); then resolve CB into two components along F_2 and F_3 (represented by CD and DB); then AC, CD, and DB are the magnitudes and directions of the desired components.

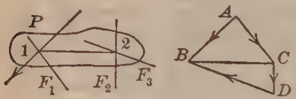

Fig. 63

The Moment of a Force with Respect to a Point is the product of the magnitude of the force and the perpendicular distance between the force and the point; this distance is the "arm" of the force with respect to the point, and the point is the origin or center of moments. Moments are commonly given signs, those corresponding to forces which tend to turn the body acted upon in one direction (clockwise) being given the same sign and all others the opposite. The moment of a force with respect to a point may also be computed by taking the algebraic sum of the moments of its two rectangular components with respect to that point; and it will often be convenient to resolve the force so that one of the components will act through the origin of moments, so that that component will have no moment.

The Moment of a Force with Respect to a Line is the product of its rectangular component perpendicular to the line (the other being parallel) and the distance between the line and the perpendicular component (or the force); the line is the "axis" of moments. If a force is parallel to the axis of moments or if it cuts the axis, then its moment with respect to that axis is zero. Moments of forces about the same axis are commonly given signs; those corresponding to the forces which tend to turn the body acted upon about the axis (regarded as a shaft) in the same direction (clockwise) being given the same sign and others the opposite. The moment of a force with respect to an axis may also be computed by resolving the force into three rectangular components, one being parallel to the axis, the other two perpendicular to it; then the moment of the given force equals the algebraic sum of the moments of the two perpendicular components. If the resolution is made so that one of the perpendicular components cuts the axis, then the moment of the given force equals the moment of the other perpendicular component.

The moment of the resultant of any coplanar forces about a point in their plane (or of any noncoplanar forces about a line) equals the algebraic sum of the moments of those forces about the point (or line). This is called the principle of moments for forces. The word **torque** is frequently used as synonymous with moment of a force, especially when the force is distributed around a circumference.

Couples. Two equal, parallel, and opposite forces are called a couple; the perpendicular distance between the forces is the " arm " of the couple. The moment or torque of a couple with respect to any point or origin in their plane is the algebraic sum of the moments of the two forces with respect to that point; this sum or moment, the same for all origins in the plane, always equals the product of one of the forces and the arm of the couple. Moments of couples whose planes are parallel are sometimes given signs; those corresponding to couples which tend to turn the body in the same direction are given the same sign, and the others the opposite sign. A couple may be represented sufficiently for statical purposes by means of a single vector; the vector is drawn perpendicular to the plane of the couple, and the arrowhead is so placed that it points toward the place from which the rotation appears, say counter-clockwise. Two couples whose vectors are equal—the same in length and direction—have equal moments (sign included) and their planes coincide or are parallel. Such are equivalent couples; that is, either may be substituted for the other without change of effect on the body acted upon if rigid. The resultant of a number of couples is a couple. If the planes of the given couples are parallel or coincident, the resultant couple is one whose plane is parallel to the others and whose moment (with sign) equals the algebraic sum of the moments of the given couples. If the planes of the given couples are not parallel or coincident, then the resultant can be determined from the vectors representing the different couples; thus, add the vectors, that is, find their resultant; this resultant vector represents the resultant couple. A couple can be resolved into component couples thus: resolve the vector of the given couple into component vectors (Art. 16) which are pendicular to the planes of the desired components; these component vectors represent the several component couples.

16. Composition of Forces

The Force Polygon for a system of forces is the figure formed by drawing consecutively lines representing the magnitudes and directions of the forces of a system; the order in which the lines are drawn is immaterial, but the arrowheads on the lines (to indicate the senses of the forces) must be confluent, that is, pointing the same way around. A force polygon, unlike a geometrical one, need not be a closed figure. For a given system, as many different force polygons may be drawn as there are orders of taking the forces; if the number of forces is n, then the number of possible force polygons is $n!$ (see Art. 1). In Fig. 64 there are three different force polygons for the system acting upon the body shown at the left. If a system is not coplanar, then its force polygon is not plane, but is called " gauche."

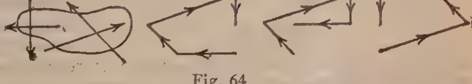

Fig. 64

Concurrent Systems. (1) **Graphic Method:** Draw a force polygon for the system; the magnitude of the resultant is represented by the length of the line joining the ends of the polygon; the sense of the resultant is represented by an arrowhead on that line not confluent with the other arrowheads, and the resultant is concurrent with the given forces. If the forces are noncoplanar, then this method is not practical but it can be used by drawing the force polygon in "plan and elevation." (2) **Algebraic Method:** If the forces F are coplanar, resolve each into components F_x and F_y along axes x and y at right angles to each other; get the algebraic sums of the x and y components, ΣF_x and ΣF_y; then the resultant being called R, and its angle with the x axis α, $R^2 = (\Sigma F_x)^2 + (\Sigma F_y)^2$ and $\tan \alpha = (\Sigma F_y)/(\Sigma F_x)$. The approximate direction of the resultant is apparent from the directions of its x and y components, which respectively equal ΣF_x and ΣF_y. If the forces F are noncoplanar, then each force should be resolved into components parallel to three rectangular axes, x, y, and z. $R^2 = (\Sigma F_x)^2 + (\Sigma F_y)^2 + (\Sigma F_z)^2$, $\cos \alpha = (\Sigma F_x)/R$, $\cos \beta = (\Sigma F_y)/R$, $\cos \gamma = (\Sigma F_z)/R$, α, β, and γ being the angles between R and the x, y, and z axes respectively.

Nonconcurrent Coplanar Systems. (1) **Graphic Method:** If the forces are not parallel or not nearly parallel, find the resultant R_1 of any two forces (Triangle Law, Art. 15), then the resultant R_2 of R_1 and the third force, etc., until all the forces have been compounded. If the forces are parallel or nearly so, the method just explained fails because the lines of action of the several resultants cannot be determined readily on account of inaccessible intersections. In this case, each force may be replaced by two components in a certain way, and then the resultant of these components can be found. Thus, to find the resultant of the three forces ab, bc, and cd acting on the body in Fig. 65: draw a force polygon, as $ABCD$, for the given forces; resolve AB into AO and OB; BC into BO and OC, etc.; O having been taken anywhere, all components except the first and last occur in pairs and the forces of each pair are equal and opposite, thus OB and BO, OC and CO, etc.; choose the action lines of these components so that those of any one pair shall be colinear; thus, insert the components of AB at pleasure as at oa and ob, the components of BC so that the component BO shall act in ob, and hence the component OC is oc, etc.; thus the pairs of components consisting of equal, colinear, and opposite forces each balance, leaving only the first and last components AO and OD acting in ao and od; and their resultant (which is also the resultant of the given forces) is AD (magnitude and direction) ad (action line). The point O (Fig. 65) is called the **pole,** lines OA, OB, OC, etc., are **rays**; oa, ob, oc, etc., are **strings**, and all the strings constitute the **string polygon** for the forces. This polygon is also called "funicular," "link," and "equilibrium polygon," the last being especially appropriate when the given forces are in equilibrium. The part of the drawing which represents the body and the lines of action of the forces is the space diagram; that representing force magnitudes, the vector diagram. If the force polygon closes, then the resultant is in general a couple, the forces of the couple acting in the first and last strings of the string polygon, the magnitude of the forces being represented by the corresponding ray. If it happens that the first and last strings coincide, then the string polygon is closed and the resultant vanishes.

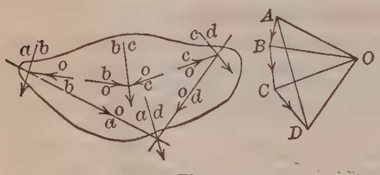

Fig. 65

(2) **Algebraic Method:** When the forces F are parallel, give to the forces in the one direction the same sign, and to the others the opposite; then the resultant R equals ΣF, the sense of R being indicated by the sign of ΣF. The position or line of action of R may be fixed by means of the arm of R, a, with respect to any origin O in the plane of the forces; thus if ΣM denotes the sum of the moments of the given forces with respect to O, then $a = (\Sigma M)/R$, a being measured in such direction from O that the sign of the moment of R will be the same as that of ΣM. If $\Sigma F = 0$, then the resultant of the system is a couple whose moment equals ΣM. When the parallel forces are two in number, P and Q (Fig. 66), then if P and Q act in the same direction, R cuts any line AB internally, and if P and Q are opposite, then externally on the side of the larger force; and in each case the segments of AB are inversely proportional to P and Q, that is, $AC/BC = Q/P$. When the forces are not parallel, compute the algebraic sums of the x and y components of the forces (ΣF_x and ΣF_y) and the algebraic sum of the moments of the forces with respect to any origin O in their plane (ΣM). Then the resultant $R^2 = (\Sigma F_x)^2 + (\Sigma F_y)^2$, its angle with the x axis $= \tan^{-1} (\Sigma F_y)/(\Sigma F_x)$ and its arm with respect to O is $a = \Sigma M/R$. The general direction of R is apparent from the directions of its components ΣF_x and ΣF_y; a must be measured in such a direction from O that the sign of the moment of R will be the same as that of ΣM. If $\Sigma F_x = \Sigma F_y = 0$, the resultant is in general a couple whose moment $= \Sigma M$.

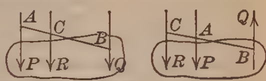

Fig. 66

Nonconcurrent Noncoplanar Systems. The graphic method is generally not advantageous; the algebraic is here given. (1) **Forces Parallel.** Give to the forces F acting in the same direction one sign and to the others the opposite sign; then the resultant $R = \Sigma F$, the sense of R being indicated by the sign of ΣF. Next compute the sums of the moments of the forces with respect to two axes (x and y, say) perpendicular to the forces; call these sums ΣM_x and ΣM_y and the arms of R with respect to those axes respectively a_x and a_y; then $a_x = (\Sigma M_x)/R$ and $a_y = (\Sigma M_y)/R$. The signs in these ratios may be disregarded; a_x and a_y have such positions that the moments of R with respect to the x and y axes have the same signs as those of ΣM_x and ΣM_y respectively. If $\Sigma F = 0$, the resultant in general is a couple which can be determined by finding the resultant of all the forces but one; the resultant and the omitted force constitute the resultant couple.

(2) **Forces Not Parallel.** In general, the resultant is not a single force, but the system can be reduced to a force R acting through any point of the body selected and a couple C; and if desired, R and C can in general be compounded into two nonparallel nonconcurrent forces. To determine R and C: select a set of coordinate axes (x, y, and z) in the body, the origin O being at the selected point referred to; determine the sums of the x, y, and z components of the given forces ($\Sigma F_x, \Sigma F_y$, and ΣF_z) and the algebraic sums of the moments of the forces with respect to the x, y, and z axes (ΣM_x, ΣM_y, and ΣM_z); ΣF_x, ΣF_y, and ΣF_z are the x, y, and z components of R, and ΣM_x, ΣM_y, and ΣM_z are the moments of the components of C perpendicular to the x, y, and z axes respectively.

$R^2 = (\Sigma F_x)^2 + (\Sigma F_y)^2 + (\Sigma F_z)^2$ and $C^2 = (\Sigma M_x)^2 + (\Sigma M_y)^2 + (\Sigma M_z)^2$; if α_1, α_2, and α_3 denote the angles between R and the x, y, and z axes, and θ_1, θ_2, and θ_3 the angles between the vector representing C (Art. 15) and the x, y, and z axes respectively, then

$$\cos \alpha_1 = (\Sigma F_x)/R \qquad \cos \alpha_2 = (\Sigma F_y)/R \qquad \cos \alpha_3 = (\Sigma F_z)/R$$
$$\cos \theta_1 = (\Sigma M_x)/C \qquad \cos \theta_2 = (\Sigma M_y)/C \qquad \cos \theta_3 = (\Sigma M_z)/C$$

The resultant force R and the resultant couple C can be compounded into two forces as follows: take the plane of the couple so that one of the forces of the couple intersects R; find the resultant of this force and R; this resultant and the other force of C are the two forces sought. In general the final two forces are skewed. If the plane of C is parallel to R, then C and R may be compounded into a single force as follows: take forces of the couple so that they are parallel to R; then find the resultant of those forces and R; this is a single force.

17. Principles of Equilibrium

Conditions of Equilibrium. A force exerted on a body (definite portion of matter) by another body is an external force with reference to the first body. A force exerted upon one part of a body by another part of the same body is an internal force. All the external forces applied to a body at rest constitute a system said to be in equilibrium. When a force system is in equilibrium, its resultant is zero; this is the general condition of equilibrium. Detailed conditions for the various kinds of force systems follow, the notation being: F denotes force, F_x, F_y, and F_z, x, y, and z components of F, M denotes moment of F, M_a, M_b and M_c moments of F with respect to points a, b, and c, M_x, M_y, and M_z moments of F with respect to x, y, and z axes respectively. (1) **Colinear System:** $\Sigma F = 0$ or $\Sigma M_a = 0$ (a is not to be taken on the forces). (2) **Coplanar Concurrent System:** $\Sigma F_x = 0$ and $\Sigma F_y = 0$; or $\Sigma F_x = 0$ and $\Sigma M_a = 0$ (the x axis must not be perpendicular to the line joining a and the point of concurrence of the forces); or $\Sigma M_a = 0$ and $\Sigma M_b = 0$ (a, b, and the point of concurrence must not be colinear). For the case of three forces: $F_1 : F_2 : F_3 : : \sin\alpha_1 : \sin\alpha_2 : \sin\alpha_3$; F_1, F_2, and F_3 denote the forces, α_1, α_2, and α_3 the acute angles between F_2 and F_3, F_3 and F_1, and F_1 and F_2 respectively. (3) **Coplanar Parallel System:** $\Sigma F = 0$ and $\Sigma M_a = 0$; or $\Sigma M_a = 0$ and $\Sigma M_b = 0$ (the line joining a and b must not be parallel to the forces). (4) **Coplanar Nonconcurrent Nonparallel System:** $\Sigma F_x = 0$, $\Sigma F_y = 0$, and $\Sigma M = 0$; or $\Sigma F_x = 0$, $\Sigma M_a = 0$, and $\Sigma M_b = 0$ (the x axis must not be perpendicular to the line joining a and b); or $\Sigma M_a = 0$, $\Sigma M_b = 0$, and $\Sigma M_c = 0$ (a, b, and c must not be colinear). (5) **Noncoplanar Concurrent System:** $\Sigma F_x = 0$, $\Sigma F_y = 0$, and $\Sigma F_z = 0$. (6) **Noncoplanar Parallel System:** $\Sigma F = 0$, $\Sigma M_x = 0$, and $\Sigma M_y = 0$ (the x and y axes are not parallel to the forces or to each other). (7) **Noncoplanar Nonconcurrent Nonparallel System:** $\Sigma F_x = 0$, $\Sigma F_y = 0$, $\Sigma F_z = 0$, $\Sigma M_x = 0$, $\Sigma M_y = 0$ and $\Sigma M_z = 0$.

Also, based on graphic methods, these conditions of equilibrium: For concurrent systems, the force polygon closes; for coplanar nonconcurrent systems, the force and string polygons close. Special Principles, applicable in either algebraic or graphic analysis. (1) If three forces are in equilibrium, then they are coplanar, and concurrent or parallel. (2) If four coplanar nonconcurrent nonparallel forces are in equilibrium, then the resultant of any two is concurrent with the other two.

Virtual Work. Any imaginary displacement of a body or system of bodies is a virtual displacement. The work done by a force during a virtual displacement of its point of application is called the virtual work of that force. Virtual works are computed according to the definitions and rules for computing real works (see Art. 28). The quantity here called virtual work is also called "virtual moment." (1) If a rigid body is in equilibrium, then for any infinitesimal virtual displacement the algebraic sum of the virtual works of the external forces equals zero. The work of a force for a displacement of its application point at right angles to the force is zero; and so in applying the principle of virtual work to determine a particular force of a system in equilibrium, it is generally advantageous to take a virtual displacement so that the displacements of the application points of as many forces (particularly unknowns but excepting the one in question) as possible shall be at right angles to the corresponding forces. (2) If any system of particles (constituting a rigid body, a deformable body, or a collection of such bodies) is in equilibrium, then for any infinitesimal virtual displacement of the system the algebraic sum of the virtual works of all external and internal forces acting upon it equals zero. Internal forces occur in pairs, and the forces of any pair are equal, colinear, and opposite. Let S denote the magnitude of either force of a pair (regarded as positive if they are pulls and negative if pushes), and let ds denote the change in the distance between the application points of the forces for infinitesimal virtual displacement of the points (regarded as positive or negative according as the distance is increased or decreased); then in such a displacement the work of the pair is $-Sds$. For any infinitesimal displacement of a rigid body ds is zero for all pairs of internal forces, and the work of each pair (and of all pairs) is zero. In applying the principle to a collection of rigid bodies which press against one another or are connected as by hinges or strings, the equation of virtual work must in general include, besides the external forces, those internal forces which the bodies exert upon each other. But the virtual works of these forces may be zero; thus, the virtual works of the pressures at a frictionless contact is zero for any virtual displacement which preserves the contact, and the virtual work of the binding forces of a string is zero for any virtual displacement which leaves the string taut and unchanged in length.

Stability. When a body (or collection of bodies) is in equilibrium and the state is such that if when displaced slightly in any way the body returns of itself to its original position, then the equilibrium is stable; if when displaced slightly the body moves farther from its original position, then the equilibrium is unstable; and if when displaced slightly it remains in that displaced position, the equilibrium is neutral, or indifferent. The body or collection is also said to be stable, unstable, or neutral (or indifferent) respectively. When a body or collection is stable, its potential energy is a minimum; when unstable, a maximum; and when neutral, constant (or stationary); the converse statements also are true. When the potential energy is gravitational, that is, due to weight, then when a body or collection is stable its center of gravity is in a lowest position; when unstable, in a highest position; and when neutral, at a uniform height, that is, it moves in a horizontal plane if the body or collection is slightly displaced. When a body rests on a number of points, the smallest polygon including all the points is called the supporting base or, simply, base. If the resultant of all forces acting on the body, including its own weight but not the supporting forces, cuts the base, the equilibrium is stable, and the moment of the resultant about the side of the base nearest the resultant is a measure of the stability.

Properties of the Equilibrium or String Polygon. (See also Art. 16.) In the following the force-systems are not assumed to be in equilibrium except where so stated. (1) The line of action of the resultant of any number of coplanar forces which are represented consecutively in a force polygon passes through the intersection of the two strings of the equilibrium polygon which are parallel to the two rays embracing those forces in the force polygon. Thus the resultant of AB, BC, and CD (Fig. 67), acting in ab, bc, and cd, acts through the intersection of ao and od;

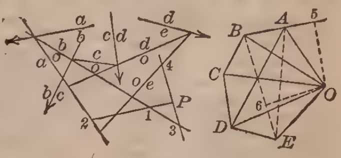

Fig. 67

the resultant of BC, CD, and DE acts through the intersection of ob and oe; etc. (2) If a pole is taken at the beginning of a force polygon for a given force-system, then each string of a corresponding equilibrium polygon is the action line of all the forces from (and including) the first up to that string. Thus, the string od (Fig. 68) is the line of action of the forces AB, BC, and CD, acting in ab, bc, and cd; and ae is the line of action of AB, BC, CD, and DE. (3) If two equilibrium polygons are drawn for a given force-system from the same force polygon but with different poles, then the intersections of corresponding strings will lie on a straight line parallel to that joining the poles. Thus in Fig. 69 there are represented forces AB, BC, and CD, acting in ab, bc, and cd, and two equilibrium polygons are shown corresponding to poles P and Q; corresponding strings intersect in points 1, 2, 3, and 4, all being in a line parallel to PQ. (4) If an equilibrium polygon for a system of forces in equilibrium is regarded as a series of links, jointed at the intersections of the segments of the polygon, by means of which the forces react upon each other, the series would remain at rest under the action of the forces; each link would be under tension or compression, and the ray corresponding to any particular link represents the amount of that tension or compression. In Fig. 70 each link is under compression.

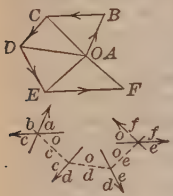

Fig. 68

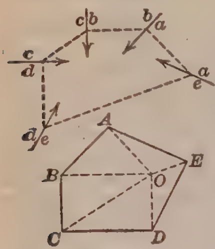

Fig. 69

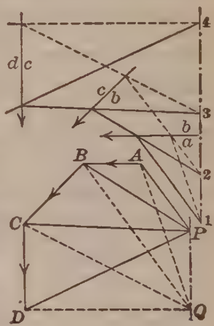

Fig. 70

An equilibrium polygon for a coplanar force-system furnishes a ready means of obtaining the moment of any one of the forces, and of the resultant of any of the forces consecutive in the force polygon. Thus the moment of any force with respect to any origin is the product of its "intercept" and "pole distance"; by intercept of a force is meant the distance (by the space scale) intercepted by the strings corresponding to the force from the line drawn parallel to the force through the origin of moments, and the pole distance of a force is the perpendicular distance (by the force scale) from the pole to the line representing the force in the force polygon. Thus the moment of AB (Fig. 67) acting in ab, about P, is $\overline{12} \times \overline{O5}$, and the moment of the resultant of BC, CD, and DE about P is $\overline{34} \times \overline{O6}$. Both moments are counter-clockwise, determined from the lines of action and senses of forces as related to the origin of moments.

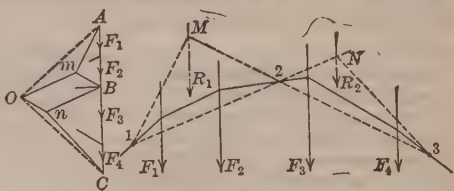

Fig. 71

An equilibrium polygon for a coplanar system of forces can be drawn so as to pass through any three points of the plane of the forces. Thus, to draw one through points 1, 2, and 3 for the forces F_1, F_2, F_3, F_4 (Fig. 71): find the resultants R_1 and R_2 of the forces whose lines of action are cut by the lines joining 1 and 2, and 2 and 3; the first acts in R_1 and the second in R_2 (construction for position not shown), and their values are represented by AB and BC respectively in the force polygon for the forces.

Extend lines R_1 and $\overline{32}$ to their intersection M, and lines R_2 and $\overline{12}$ to their intersection N. From A and B draw lines parallel to $\overline{M1}$ and $\overline{M2}$ to their intersection m, and from B and C draw lines parallel to $\overline{N2}$ and $\overline{N3}$ to their intersection n. Complete the parallelogram $VmnO$; then O is a pole and the corresponding equilibrium polygon, if started through one of the three specified points, will pass through the other two. (It is advisable to draw as first string the one through point 2, parallel to OB.)

18. Typical Problems

In each of the problems following, some of the forces of the system in equilibrium are unknown in sense. In writing an equilibrium equation for the system, senses may be assumed when unknown; if the computed value of a force comes out positive, the sense was guessed correctly; if negative, then incorrectly. In the figure, incorrectly assumed senses are indicated by a short line through the arrowhead.

A Coplanar Concurrent Force-System is in Equilibrium and the forces are all known except two whose action lines only are known; these two are to be determined completely. This is a common problem in the determination of the stresses of a roof or bridge truss, and the numerical illustration is from a truss, but the method of solution is as general as the statement of the problem.

(1) Algebraic Solution: Three sets of equilibrium equations are available (see Art. 17). No general rule covering all cases can be laid down as to which set is best in a particular case, but if a resolution equation ($\Sigma Fx = 0$ or $\Sigma Fy = 0$) is taken first, it is advantageous to take the resolution axis perpendicular to one of the unknown forces. If a moment equation ($\Sigma M = 0$) is taken first, it is advantageous to take the moment origin on the action line of one of the unknowns. Fig. 72 represents a joint of a truss under the action of a load of 1600 lb., a known pull of a member, 2000 lb., and two unknown forces F_1 and F_2; to find these two: Choosing $\Sigma Fx = 0$ and $\Sigma Fy = 0$, with the x axis horizontal, $\Sigma Fy = -1600 + F_1 \sin 30° = 0$, or $F_1 = +3200$ lb., the positive sign indicating that F_1 acts as assumed in the figure. Next $\Sigma Fx = -2000 + 3200 \cos 30° + F_2 = 0$, or $F_2 = -771$ lb., the negative sign indicating that F_2 acts toward the left. Or, beginning with $\Sigma M = 0$, the origin being on F_2, 10 ft. to the right of O, say, then $\Sigma M = -1600 \times 10 + F_1 \times 10 \sin 30° = 0$, or $F_1 = 3200$; F_2 may now be determined as before or from another moment equation with origin anywhere except on F_2. When there are only three forces in the system, then a special condition of equilibrium (Art. 17) may be applied thus: suppose that the three forces are 1600 lb., F_1, and F_2 (Fig. 72); $F_1/\sin 90° = F_2/\sin 60° = 1600/\sin 30°$, which equations furnish values of F_1 and F_2.

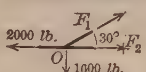

Fig. 72

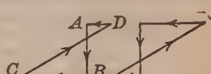

Fig. 73

(2) Graphic Solution: The condition of equilibrium is that the force polygon for the force-system must close; constructing the polygon and making it close will determine the unknown forces. The order in which the forces are represented in the polygon is immaterial, but the knowns must be drawn first of course. To construct a force polygon for the forces: draw AB (Fig. 73) to represent the 1600-lb. force, BC to represent the 2000-lb. force; then from A and C lines parallel to the other two forces; the intersection of these two lines is D, and CD and DA represent the values and directions of the two unknowns. The unlettered polygon in Fig. 73 is another possible force polygon, giving the same results as the one explained.

A Coplanar Parallel Force-System is in Equilibrium and all the forces are known except two whose action lines only are known; these two are to be determined completely. The determination of the reactions on a beam or truss on horizontal supports and under vertical loads is a problem of this sort. Such a beam is used as an illustration, but the method of solution is as general as the statement of the problem.

(1) Algebraic Solution: Either one of two sets of equilibrium equations is available (Art. 17). It will be well to use the two moment equations with origins on the action lines of the two unknown forces. Then after the unknowns have been determined one might test, as a check, whether ΣF is zero. Fig. 74 represents a beam supported at R_1

and R_2, the beam bearing a concentrated load at the left end, a uniform load as shown, and its own weight, 1800 lb.; to determine the reactions. With origin at R_2, the moment equation is $-10\,000 \times 18 - 40\,000 \times 6 - 1800 \times 9 + R_1 \times 10 = 0$, or $R_1 = 43\,620$ lb.; with origin at R_1, it is $-10\,000 \times 8 + 40\,000 \times 4 + 1800 \times 1 - R_2 \times 10 = 0$, or $R_2 = 8180$ lb. As algebraic sum of loads and reactions is zero, the computation checks.

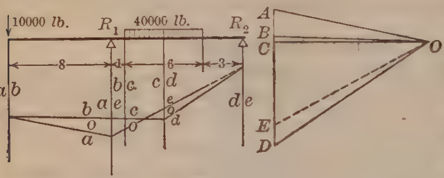

Fig. 74

(2) Graphic Solution. The conditions of equilibrium are that the force and string polygons close; if these are constructed and made to close, the problem will have been solved. Using the preceding illustration again, the 40 000-lb. load is regarded as concentrated at its center; and also the weight of the beam at the middle of the beam; first $ABCD$, the polygon for the known forces, is laid off; the right reaction will be taken next and called DE and the other EA, but E is as yet unknown; next a pole O is chosen, rays are drawn and then the strings or oa, ob, oc, and od; od should be extended to de, and oa to ea. The line oe is the closing string, and a ray parallel to it fixes the point E. Then DE and EA represent the magnitudes of the reactions.

A Coplanar Nonconcurrent Nonparallel Force-System is in Equilibrium, and all the forces are known except two; the action line of one of these and a point in that of the other are known; required to determine these unknowns completely. This problem occurs in the determination of the reactions on a roof truss sustaining wind pressures, the truss being fixed at one end and resting on rollers at the other. This case is used in illustrations below, but the solutions are as general as the statement of this problem.

(1) Algebraic Solution: Calling the first described unknown P and the second Q, imagine Q replaced by two rectangular components Q_x and Q_y acting at the given point of Q; then the unknowns of the system are the magnitudes and senses of P, Q_x, and Q_y. Any one of three sets of equilibrium equations may be used (Art. 17); generally it is advantageous to begin with a moment equation, the origin being at the known point of Q, as such an equation will furnish P directly. Q_x and Q_y can be determined from the other two equations of the set selected, and then Q itself from its components. Fig. 75 represents a roof truss whose span is 60 ft., rise 12 ft., resting on rollers at the left end and pinned to the support at the right; there are four loads as shown; required the reactions. The reaction at the roller end can be vertical only; that at the other end may have any direction. The first is P and the second Q, but Q is represented in the figure by its two unknown components Q_x and Q_y. The moment equation for the system with origin at 1 is $P \times 60 - 1500 \times 55.71 - 3000 \times 44.94 - 3000 \times 34.17 - 1500 \times 23.40 = 0$, or $P = 5933$. Then from $\Sigma M_2 = 0$, or $\Sigma F_y = 0$, Q_y may be found to be 2423, and from $\Sigma F_x = 0$, or $\Sigma M_3 = 0$, Q_x may be found to be 3342.

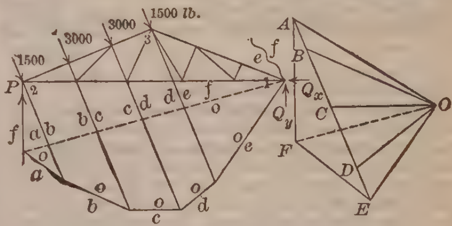

Fig. 75

(2) Graphic Solution: The conditions of equilibrium are that the force and string polygons must close; constructing them and making them close will determine the unknowns. In order to make the construction possible, the first string drawn must be one corresponding to the unknown force Q, one point of which is known, and it must be drawn through that point. The following special graphic solution is simpler in principle: First determine the resultant R of the known forces, and imagine the knowns replaced

by that resultant: then the system consists of three forces, namely that resultant and the two unknowns. If R and the unknown P whose action line is known are not parallel, then the three forces R, P, and Q are concurrent and the action line of Q is determined. The solution of the three-force system can then be made as explained in the first paragraph. If R and P are parallel, then Q is also parallel to P and R; P and Q can be determined most readily algebraically, and graphically by constructing the force and funicular polygons for the three forces. (When R, P, and Q are parallel, this special graphical method is no simpler than the general method first described.) As illustration of the general method the reactions on the truss shown in Fig. 75 are determined thus: The force polygon for the known forces is $ABCDE$; calling the reaction at the fixed end *ef* and the other *fa*, the first string drawn is *oe*; then *od*, *oc*, *ob*, *oa*, and *of* the closing string. Next the ray parallel to *of* is drawn and its intersection with AF determines F; EF and FA represent the magnitudes and directions of the reaction at the fixed and roller ends respectively.

A coplanar nonconcurrent nonparallel force-system is in equilibrium and all the forces are known except three whose action lines only are known. Required to determine these three completely. (This problem is indeterminate if the three unknowns are concurrent or parallel.)

(1) Algebraic Solution: Any one of three sets of equilibrium equations may be used (Art. 15). In general it is advantageous to use a moment equation first, the origin being at the intersection of two of the unknowns; the choice of the other two equations will depend on the particular problem under consideration. For example, consider the overhanging truss (Fig. 76) which sustains three loads as shown and is supported at 1 so that the reaction there acts along the line marked R_1 and at 2 by two forces R_2 and R_3 which are horizontal and vertical respectively. Required R_1, R_2, and R_3. $\Sigma M_1 = -800 \times 20 - 1500 \times 10 + R_2 \times 10 = 0$ or $R_2 = 3100$ lb.; $\Sigma M_3 = 1500 \times 10 + 1000 \times 20 - R_3 \times 20 = 0$, or $R_3 = 1750$ lb.; and $\Sigma F_x = R_1 \cos a - 3100 = 0$, or $R_1 = 3466$ lb.

(2) Graphic Solution: The conditions of equilibrium are that the force and equilibrium polygons must close. In order to construct the equilibrium polygon, the first string must be drawn through the intersection of two of the unknowns. Using the preceding illustration the force polygon for the three known forces is $ABCD$ (Fig. 76). The reaction at 1 is called *de* and the reactions at 2 are called *ef* and *fa*. The first string is *oa* and it is drawn through the intersection of *fa* and *ef*; then *ob*, *oc*, and *od* are drawn, the latter to its intersection with *de*. The closing string is *oe*, and a ray parallel to *oe* determines E, in the line through D parallel to *de*. Then completing the force polygon by line through A and E parallel to R_2 and R_3 respectively determines F, and $FA = R_2$ and $EF = R_3$. The senses of R_1, R_2 and R_3, apparent in this example are given by arrow heads on DE, EF and FA confluent with the senses of AB, BC and CD.

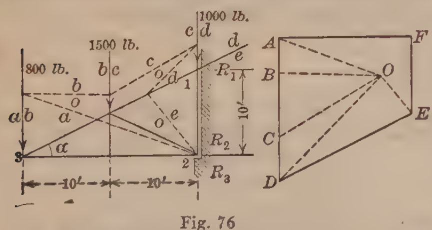

Fig. 76

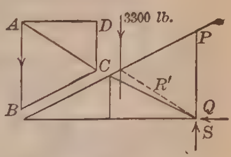

Fig. 77

The following special method is simpler than the foregoing: Determine the resultant R of the known forces, and imagine them replaced by their resultant; then the system consists of R and the three unknowns P, Q, and S. Note that R, P, and the resultant R' of Q and S are concurrent, and by a force triangle determine P and R'; finally resolve R' into its components Q and S. For example, in the preceding illustration, the resultant of the known forces is 3300 lb. as shown in Fig. 77. The resultant R' of Q and S is concurrent with R and P, and acts in the dotted line. The force triangle for R, P, and R' is $ABCA$, AB representing 3300 lb., BC representing P, and CA representing R'. Then resolving CA into Q and S, it is found that CD represents S and DA represents Q.

19. Shears and Moments in Beams

Beams and Trusses are usually subjected to vertical loads and reactions. In such cases, the **vertical shear** at any cross-section of the beam or truss is the algebraic sum of all the loads and reactions on either side of the section; if the shear is computed from the forces (loads and reactions) to the left of the section, then upward forces are given the positive sign, but if from those on the right, then the upward forces are taken as negative. The **bending moment** at any cross-section of a beam or truss is the algebraic sum of the moments of all the loads and reactions on either side of the section, the origin of moments being taken in the section; if the bending moment is computed from the forces to the left of the section, clockwise moments are regarded as positive, but if from those to the right, clockwise moments are taken as negative. V and M are used to denote shear and moment respectively.

Fig. 78*a* represents a cantilever sustaining a concentrated load of 1000 lb. at the free end and uniform load of 2000 lb. on half its length as shown. Fig. 78*b* is a shear diagram for the cantilever as loaded, showing how the external shear varies from section to section; at a section just to the right of the concentrated load $V = -1000$, at the wall $V = -3000$ lb. Fig. 78*c* is a moment diagram for the cantilever as loaded, showing how the bending moment varies from section to section; at the middle $M = 5000$ and at the wall $M = 15\,000$ ft-lb.

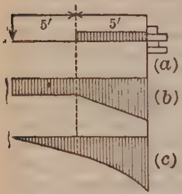

Fig. 78

Fig. 79*a* represents a beam resting on two supports A and B and bearing a uniform load of 1000 lb. per ft. between the supports, and a concentrated load of 2500 lb. at the right end; the reactions at A and B are respectively 4000 and 8500 lb. Fig. 79*b* is a shear diagram for the beam so loaded; just to the right of A, $V = +4000$ lb., just to the left of B, $V = -6000$ lb., and at any section to the right of B, $V = +2500$ lb. Fig. 79*c* is a moment diagram for the beam as loaded; at B, $M = -10\,000$ ft-lb. and the greatest positive value of M is 8000 ft-lb., at the section 4 ft. from the left end.

The equilibrium polygon is a moment diagram for the beam as loaded, the vertical ordinates in it being proportional to the bending moments at the corresponding sections. The bending moment at any particular section is the product of the corresponding ordinate in the equilibrium polygon (according to the scale of the drawing of the beam) and the distance from the pole to the " load line " (according to the scale of the force polygon).

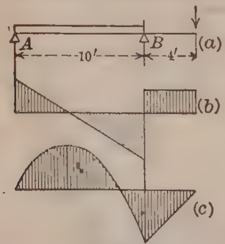

Fig. 79

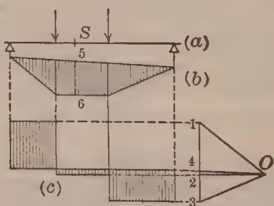

Fig. 80

For example, in Fig. 80, the beam represented is supported at each end and sustains two loads of values 12 and 23; the perimeter of the upper shaded part is an equilibrium polygon and constitutes a moment diagram for the beam as loaded. The bending moment at any section as S equals the product of the distance represented by the ordinate 5-6 and the force represented by the perpendicular from O to the line 1-2-3. The shear diagram (Fig. 80*c*) can be constructed from the force polygon by obvious means.

For a beam bearing a distributed load an approximate moment diagram may be constructed thus: draw an equilibrium polygon for the beam under an approximately equivalent series of concentrated loads obtained by imagining the uniform load divided into parts and each part replaced by a concentrated load equal to that part and applied at its center. See Fig. 81, in which the distributed load is divided into three parts. The true bending moment line is curved below the distributed load, and the curve is tangent to the equilibrium polygon at points immediately below the lines of division of the load.

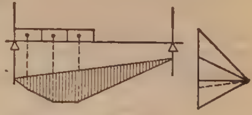

Fig. 81

Properties of Shear and Moment Diagrams. For any part of a beam bearing no load and weight of beam being disregarded, the shear line is horizontal and the moment line is generally inclined; for any part bearing a uniformly distributed load, the shear line is inclined downward to the right, and the moment line is a parabola, convex upward, with axis vertical. The shears on either side of a concentrated load differ by an amount equal to the load, and the moment line changes direction there suddenly. At each end of a beam the shear and moment are zero. Where the shear changes sign, there the moment has a maximum or minimum value.

20. Simple Frameworks

A Truss is a framework intended to carry loads, while each member of the truss is subjected only to longitudinal stress, either tensile or compressive. In this article it is assumed, except as otherwise noted, that (a) the truss under consideration is pin-jointed. that is, the members have " eyes " and are pinned together at the joints, (b) each member is continuous between two joints only, and (c) the loads and reactions are applied to the truss at the joints. When these assumptions are fulfilled the forces acting upon any member, consisting of loads, reactions or pin pressures, are applied at its ends only; and the resultants, R_1 and R_2, of the forces at each end act through both ends, that is, R_1 and R_2 are colinear, and they are equal and opposite. When they are pulls, the member is in tension, and any two parts exert pulls upon each other (Fig. 82); when they are pushes, the member is in compression, and any two parts exert pushes upon each other (Fig. 82). These internal pulls and pushes are each equal to the end pulls or pushes and colinear with them. By force or stress in a member is meant either of the forces which either of the two parts of the member exerts on the other part; the magnitude of a stress is the magnitude of one of the two forces referred to. By analysis of a truss for certain loads is meant the determination of the stresses in its members due to these loads.

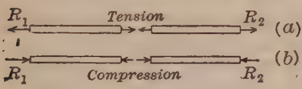

Fig. 82

The assumptions stated above are not realized in all actual trusses; yet if either (a) or (b) is not realized but the joints are properly made, then the methods of analysis here explained, or their equivalent, are used and without practical error; if (c) is not realized, the methods here given require amplification only.

To Determine the Stress in any particular member of a truss due to certain loads: First, determine the reactions on the truss due to the loads; second, imagine the truss separated into two distinct parts (that is, pass a section through the truss) so that the member under consideration is one of the members cut and so that the system of forces, including stresses, acting on either part of the truss is solvable for the desired stress; third, solve the system. (For plane trusses, the system will be coplanar and concurrent, or nonconcurrent; the first kind can be solved completely if it includes not more than two unknown stresses, and the second if not more than three except when these three are concurrent or parallel.)

To illustrate how to pass the section, suppose the stress in HI (Fig. 83) is required, the truss being supported at its ends and bearing five loads L and one P, and suppose the reactions determined. Trying section 1-1, the force system on the left part of the truss (Fig. 83b) is a nonconcurrent one of seven forces, and includes four unknown stresses, S_1, S_2, S_3, and S_4; it is not solvable for the desired stress S_1. Trying section

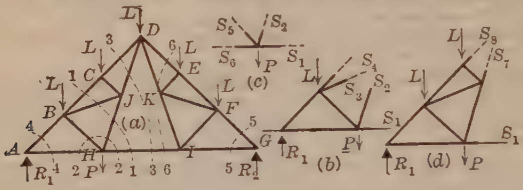

Fig. 83

2-2, the force system on the lower part (Fig. 83c) is a concurrent one, and includes four unknown stresses, S_1, S_2, S_5, and S_6; it is not solvable. Trying section 3-3, the force system on the left part (Fig. 83d) is nonconcurrent with three unknown stresses, S_1, S_7, and S_8; it is solvable. In some instances different sections may be used, each leading to a solution.

An Algebraic Analysis of a Truss is carried out by solving the various force-systems resulting from sections passed, as explained in the foregoing, by algebraic methods. The problems to be solved are generally like one of Art. 18, where methods for their solution are given. In the following the unknown stresses will be assumed to be pulls always; then positive computed stresses will be tension and negative ones will be compression. In a truss with horizontal chords, the stress in any diagonal equals the vertical shear in the panel in which the member is, multiplied by the secant of the angle which the member makes with the vertical. The stress in either chord member of any panel equals the bending moment at the point where the other chord member and the stressed web member of that panel intersect, divided by the height of the truss.

(1) **Roof Truss.** In Fig. 83 angles A and G are 45°, $AH = HI = IG =$ 16 ft.; AB, BC, CD, DE, EF, and FG are equal, also HJ, JD, IK, and KD. Loads L = 800 lb., load P = 1200 lb. The reaction R_1 is found thus: $R_1 \times 48 - 4000 \times 24 - 1200 \times 32 = 0$, or $R_1 = 2800$ lb.; also $R_2 = 2400$ lb.

To determine the stresses: Passing section 4-4, the force-system on the part within the section (Fig. 84a) is concurrent with two unknowns S_1 and S_2. Taking a vertical y axis, $\Sigma Fy = S_2 \sin 45° + 2800 = 0$, or $S_2 = -3960$ lb., the negative sign indicating that S_2 is compressive; next with the corrected direction of S_2, $\Sigma Fx = +S_1 - 3960 \cos 45° = 0$, or $S_1 = +2800$ lb., the positive sign indicating that S_1 is tensile. In a similar manner the stresses in GF and GI might be determined; they are respectively 3394 lb. compression and 2400 lb. tension. No other section than 4-4 or 5-5 can be passed so that the force-system acting on either part of the truss will be concurrent including only two unknown stresses; in fact the only sections leading to solvable force-systems are 3-3 and 6-6. On the left of 3-3 (Fig. 84b) the force-system is nonconcurrent with three unknowns S_3, S_4, and S_5. To determine S_3: $\Sigma M_D = -2800 \times 24 + 1200 \times 8 + 800 \times 8 + 800 \times 16 + S_3 \times 24 = 0$, or $S_3 = +1600$ lb. tension. One might now solve the sytem for S_4 and S_5 or pass a section around joint H or I (Fig. 83), each furnishing a solvable concurrent system. But continuing with Fig. 84b, $\Sigma M_H = -2800 \times 16 + 800 \times 8 - S_5 \times BH = 0$, or $S_5 = -3394$ lb. compression; and $\Sigma M_A = 0$ gives $S_4 = +2530$ lb. tension. Next a section may be passed about H or I as stated, or about C; section about H gives a concurrent system (Fig. 84c) with two unknowns, S_6 and S_7. Taking an x axis at right angles to S_7, $\Sigma Fx = -1200$

$\cos 45° - 2800 \cos 45° + 1600 \cos 45° + S_6 \cos (71° \ 34' - 45°) = 0$, or $S_6 = +1897$ lb. tension; and taking a vertical y axis, $\Sigma F_y = -1200 + S_7 \cos 45° + 1897 \sin 71° \ 34' = 0$, or $S_7 = -847$ lb. compression. Next, passing a section about C, the force-system is concurrent (Fig. 84d) with two unknowns S_8 and S_9. Two resolution equations, the axes being taken along the unknown stresses, are simple; they give $S_8 = -556$ lb. compression, and $S_9 = -3960$ lb. compression. Next passing a section about B gives a concurrent system with one unknown (Fig. 84e) S_{10}. Or, one might pass next a section about J and get a solvable system (Fig. 84f). In similar manner the stresses in the members of the right half of the truss may be determined. When, in the analysis, a force system is reached in which there are fewer unknown stresses than the number of conditions of equilibrium for the system, as in Figs. 83e and f, then a partial check on the preceding computations may be made, thus: determine the unknown stress or stresses and then test whether the force-system satisfies the superfluous or extra equation or equations of equilibrium. Thus for Fig. 84e with the x axis along the two equal stresses, $\Sigma F_x = S_{10} \times \cos 26° \ 34' - 800 \cos 45° = 0$, or $S_{10} = +633$ lb. tension, and $\Sigma F_y = 847 - 800 \sin 45° - 633 \sin 26° \ 34' = -2$, or nearly zero, and so the check is satisfactory.

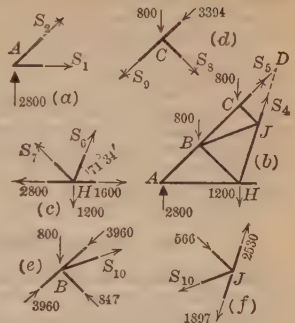

Fig. 84

(2) **Howe Bridge Truss.** The truss represented in Fig. 85 is generally constructed all of wood except the "verticals." The "diagonals" are not connected to other members at the various joints but simply butt up against bearing blocks at their ends, and so can be subjected only to compression. Two diagonals in any panel cannot be stressed at the same time; when the loading is symmetrical with respect to the middle of the truss, those diagonals represented are the ones stressed and they are the main diagonals. The others, not shown, may be stressed only when the truss is partially loaded, and they are counter diagonals, or braces, or simply counters.

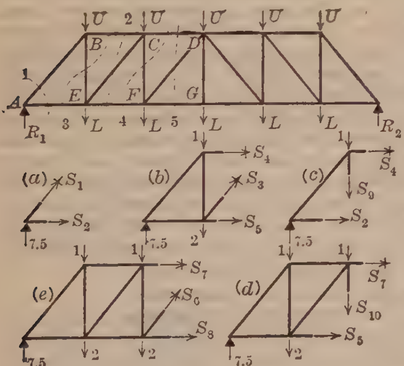

Fig. 85

In the following example the truss is supposed to be loaded symmetrically (see Fig. 85) and the counters are not mentioned. The span is 72 ft., height of truss 15 ft., each upper load U is 1 ton and each lower load L is 2 tons; then each reaction is 7·5 tons. The stress in any diagonal may be found by passing a vertical section through the truss so as to cut the member under consideration and then solving the force system acting on either part of the truss. Thus, to determine the stress in AB, pass the section 1, and solve the system shown in Fig. 85a for S_1; to determine the stress in EC, pass section 2 and solve the system shown in Fig. 85b for S_3; similarly determine the stress in FD, etc. It will be noticed that the vertical component of the stress in any diagonal equals the external shear at the section cutting the diagonal; thus (see Fig. 85b) $S_3 \times \cos \alpha = 7.5 - 2 - 1 = 4.5$. The stress in any vertical, except the middle one if there is one, may be found by passing a section so as to cut only that member and adjacent chord members and then solving the system of forces acting on either part of the truss for the desired stress. Thus, to determine the stress in *BE*, pass section 3, and from the system shown in Fig. 85*c* get $S_9 = 7.5 - 1 = 6.5$ tons; to determine the stress in *CF*, pass section 4, and from the system shown in Fig. 85*d* get $S_{10} = 7.5 - 2 - 1 - 1 = 3.5$ tons. The stress in the middle vertical equals the load at its lower end, 2 tons. The stress in any chord member may be found by passing a section cutting that member and the others in the same panel, and then solving the force-system acting on either part of the truss for the desired stress, the solution is easily made from a moment equation, the origin being taken at the intersection of the other two members cut. Thus to determine the stress in *CD*, pass section 5; the moment equation for the system shown in Fig. 85*e* with origin at the intersection of S_6 and S_8 is $7.5 \times 24 + 3 \times 12 - S_7 \times 15 = 0$, or $S_7 = 9.60$ tons.

21. Stress Diagrams for Trusses

Graphic Methods for Analyzing Trusses are especially well adapted for solving problems like the preceding. As in the algebraic method, the truss is imagined separated into two parts and then the attention is directed to the forces acting upon either part. Graphic instead of algebraic conditions of equilibrium are then applied to the system of forces to determine the unknowns. In making the imaginary separations of the truss, care should be taken to cut not more than three members in which the forces are unknown. It is advantageous to make the separation so that not more than two such members are cut. If that is done, a single force polygon will determine the two unknowns, while if three are cut, a force polygon and an equilibrium polygon, or the equivalent, are necessary for determining the three unknowns. In drawing the force polygon, it will be advantageous to represent the forces in the order in which they occur about the joint. A force polygon so drawn will be called a polygon for the joint; and for brevity, if the order taken is clockwise, the polygon will be called a clockwise polygon, and if counter-clockwise, it is called a counter-clockwise polygon. If the polygons for all the joints of a truss are drawn separately, then the stress in each member will have been represented twice. It is possible to combine the polygons so that it will not be necessary to represent the stress in any member more than once, thus reducing the number of lines to be drawn. Such a combination of force polygons is called a stress diagram. Each triangular space in the truss diagram is marked by a small letter, also the space between consecutive action lines of the loads and reactions. Then the two letters on opposite sides of any line serve to designate that line, and the same large letters are used to designate the magnitude of the corresponding force.

To construct a stress diagram for a truss under given loads:

(1) Determine the reactions. (2) Letter the truss diagram as directed. (3) Construct a force polygon for all the external forces applied to the truss (loads and reactions), representing them in the order in which their application points occur about the truss, clockwise or counter-clockwise. (4) On the sides of that polygon construct the polygons for all the joints. They must be clockwise or counter-clockwise according as the polygon for the loads and reactions was drawn clockwise or counter-clockwise. (The first polygon drawn must be for a joint at which but two members are fastened; the joints at the supports are usually such. Next, that joint is considered, and its polygon is drawn, at which not more than two stresses are unknown.)

(1) **Roof Truss.** Fig. 86 represents a truss sustaining loads of 600, 1000, 1200 and 1800 lb.; the right reaction is 2100 lb. and the left 2500 lb. *ABCDEFA* is a polygon for the loads and reactions, these being represented in the order in which their points of application occur about the truss. The polygon for joint 1 is *FABGF*; the force *BG* acts

toward the joint, hence bg is under compression, and GF acts away from the joint, hence gf is in tension. The polygon for joint 2 is $CDEHC$; the force EH acts away from the joint, hence eh is in tension; and HC acts toward the joint, hence hc is in compression. The polygon for joint 3 is $HEFGH$; the force GH acts away from the joint and hence gh is in tension. If the work has been correctly done, GH is parallel to gh. (In Fig. 86a the polygons are all clockwise, and in Fig. 86b counter-clockwise.)

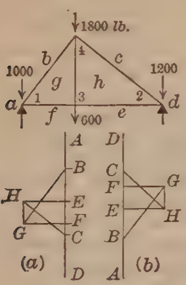

Fig. 86

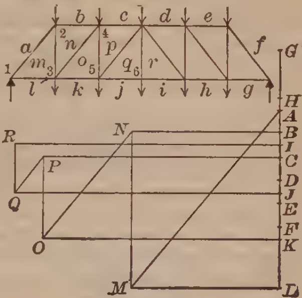

Fig. 87

(2) **Howe Truss.** Fig. 87 represents a Howe Truss, 72 ft. span and 15 ft. high, under five 1-ton loads on the upper chord and five 2-ton loads on the lower. $ABCDEFGHIJKLA$ is a force polygon for all the loads and reactions. Polygon for joint 1 is $LAML$; for joint 2, $MABNM$; for joint 3, $KLMNOK$; for joint 4, $ONBCPO$; for joint 5, $JKOPQJ$; and for joint 6, $IJQRI$.

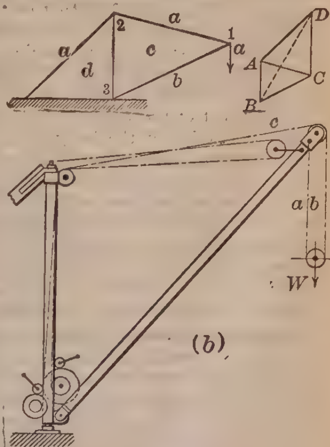

Fig. 88

(3) **Derrick.** Fig. 88a represents a stiff-leg derrick, only one stiff leg, da, shown, and the boom and shown stiff leg in the same vertical plane. For the analysis it is not necessary to determine the reactions first. The polygon for joint 1 may be drawn first; it is $ABCA$, and BC and CA represent compression and tension respectively. The polygon for joint 2 may be drawn next; it is $ACDA$, and CD and DA represent compression and tension respectively. The reaction at 3 equals the resultant of CB and DC, that is DB.

The foregoing analysis is imperfect because it assumes, in part, a single stay along ac, whereas such derricks usually have a multiple stay and a hoisting cable as shown in Fig. 88b. To determine the reaction P_1 at the top of the mast exerted by the stiff leg and that P_2 at its base: P_1 acts nearly along the axis of the stiff leg, and P_2 in a direction unknown as yet; these forces along with the weights of the mast, boom, and load, constitute a system in equilibrium, and it may be solved for P_1 and P_2 as explained in Art. 18. (If hoisting is accomplished not by a winze mounted on the derrick, as assumed, but by an engine, then there must be included in the system described the pull of the engine.) To determine the reaction Q_1 at the base of the boom and the pull Q_2 of the top stay: Q_2 acts along the stay and Q_1 in a direction unknown as yet; these forces along with the weight of the boom, a pull of $1/2W$ in line a, and a pressure at the top pulley pin identical with the resultant of the pulls $1/2W$ in the lines b and c, constitute a system in equilibrium which may be solved for Q_1 and Q_2. (Art. 18.)

GRAVITY AND INERTIA FUNCTIONS

22. Principles of Center of Gravity

Definitions. The resultant of the weights, or parallel forces of gravity, upon all the particles of a body, always passes through a certain particle or point fixed with reference to the body, no matter how the body is turned about; this particle or point is the **center of gravity** of the body. If the body can be supported at its center of gravity, then so supported it would remain at rest in any position. Center of gravity is also called center of mass and center of inertia, especially in discussions relating to the motion of the body. The center of gravity of a line (or length), surface (or area), solid (or volume) is the center of gravity of the line, surface, or solid imagined materialized, that is, conceived as a very slender wire, thin plate, or homogeneous body. Centroid is also used in place of center of gravity as applied to lines, surfaces, and solids. The center of gravity of a line, surface, solid or homogeneous body is a mean point; that is, the distance of the center of gravity from any reference plane is the mean of the distances of all the equal elementary parts of the line, surface, solid, or body from the plane. If the reference plane cuts the line, surface, solid, or body, distances on opposite sides of the plane must be regarded as opposite in sign. **Symmetry:** Two points are symmetrical with respect to a third point if the line adjoining the two is bisected by the third. Two points are symmetrical with respect to a line or a plane if the line joining them is perpendicular to the given line or plane and is bisected by it. A body, line, surface, or volume is symmetrical with respect to a point, a line, or a plane if all the points of the body, line, surface, or volume can be paired off so that each pair is symmetrical with respect to the point, line, or plane. If a line, surface, solid or homogeneous body is symmetrical with respect to a point, line, or plane, then its center of gravity is at the point in the line, or plane. The **statical moment** of a body (or weight), line (or length), surface (or area), or solid (or volume) with respect to any plane is the product of the weight, length, area, or volume and the distance of the center of gravity of the body, line, surface, or solid from the plane. The statical moment of a plane line (or length) or plane surface (or area) with respect to a straight line in the plane is the product of the length or area and the distance of the center of gravity of the line or surface from the reference line. A statical moment is regarded as positive or negative according as the corresponding center of gravity is on the positive or negative side of the reference plane or line. In the foregoing definitions and in the following, the words body, line, surface, and solid are used broadly to include what would ordinarily be described as a collection of bodies, lines, surfaces, or solids.

Methods for Locating Center of Gravity. The statical moment of a body, line, surface, or solid equals the algebraic sum of the statical moments of all the parts into which it is, or is imagined to be, divided. This principle is the basis of all formulas for locating centers of gravity. If the sum of the statical moments is zero, then the center of gravity is in the reference plane or line as the case may be. The position of a center of gravity is generally conveniently specified by its rectangular coordinates $\bar{x}$, $\bar{y}$, and $\bar{z}$.

(1) The formulas for the coordinates of the center of gravity of a body are:

$$W\bar{x} = \int x\,dW \qquad W\bar{y} = \int y\,dW \qquad W\bar{z} = \int \bar{z}\,dW,$$

in which W denotes the weight of the body, dW the weight of any elementary portion, and x, y, and z the coordinates of the center of gravity of that element; the limits of integration must be assigned so that the integration includes all elementary parts of the body. The formulas furnish values of $\bar{x}$, $\bar{y}$, and $\bar{z}$ in any case if the body is mathematically regular and such that the integrations can be performed. The following are corresponding formulas for the coordinates of the center of gravity of lines, surfaces, and solids:

$$L\bar{x} = \int x\,dL \qquad L\bar{y} = \int y\,dL \qquad L\bar{z} = \int z\,dL$$
$$A\bar{x} = \int x\,dA \qquad A\bar{y} = \int y\,dA \qquad A\bar{z} = \int z\,dA$$
$$V\bar{x} = \int x\,dV \qquad V\bar{y} = \int y\,dV \qquad V\bar{z} = \int z\,dV$$

in which L, A, and V denote length, area, and volume respectively.

(2) If a body consists of finite parts whose weights and centers of gravity are known, then the coordinates of the center of gravity of the body can be computed, without integration, from

$$W\bar{x} = W_1\bar{x}_1 + W_2\bar{x}_2 + \cdots \qquad W\bar{y} = W_1\bar{y}_1 + W_2\bar{y}_2 + \cdots$$
$$W\bar{z} = W_1\bar{z}_1 + W_2\bar{z}_2 + \cdots$$

in which W denotes the weight of the body, W_1, W_2, etc., the weights of its parts; $\bar{x}_1$, $\bar{y}_1$, z_1, the coordinates of the center of gravity of W_1; $\bar{x}_2$, $\bar{y}_2$, $\bar{z}_2$, those of the center of gravity of W_2; etc. The following are corresponding formulas for lines, surfaces, and solids:

$$L\bar{x} = L_1\bar{x}_1 + L_2\bar{x}_2 + \cdots \qquad L\bar{y} = L_1\bar{y}_1 + L_2\bar{y}_2 + \cdots \qquad L\bar{z} = L_1z_1 + L_2\bar{z}_2 + \cdots$$
$$A\bar{x} = A_1\bar{x}_1 + A_2\bar{x}_2 + \cdots \qquad A\bar{y} = A_1\bar{y}_1 + A_2\bar{y}_2 + \cdots \qquad A\bar{z} = A_1\bar{z}_1 + A_2\bar{z}_2 + \cdots$$
$$V\bar{x} = V_1\bar{x}_1 + V_2\bar{x}_2 + \cdots \qquad V\bar{y} = V_1\bar{y}_1 + V_2\bar{y}_2 + \cdots \qquad V\bar{z} = V_1z_1 + V_2\bar{z}_2 + \cdots$$

in which the L's, A's, and V's denote lengths, areas, and volumes.

The center of gravity of two bodies, lines, surfaces, or solids is on the straight line joining the centers of gravity of the two, and the center of gravity of the two divides the joining line into segments inversely proportional to their weights, lengths, areas, or volumes. The center of gravity of three bodies, lines, surfaces, or solids is in the plane of the centers of gravity of the three.

If a center of gravity of the parts of a body, line, surface, or solid lies in a plane, the center of gravity of the whole may be found graphically. (1) Let a, b, c, etc., be the centers of gravity of the parts and A, B, C, etc., their weights, lengths, areas or volumes; then imagine parallel forces of values A, B, C, etc., to act through a, b, c, etc., and find the line of action of their resultant; repeat the operation for the parallel forces at an angle (as 90°) with their first positions. The intersection of the resultants is the center of gravity sought. (2) Choose any point O (Fig. 89) in the plane of the centers of gravity as origin; measure Oa, Ob, Oc, etc., and form the products $A\overline{Oa}$, $B\overline{Ob}$, $C\overline{Oc}$, etc. Imagine forces whose values equal the products respectively, to act from O in the lines Oa, Ob, Oc, etc., and find their resultant R (Art. 16). The center of gravity sought, r, lies in the line of action of R at a distance from O equal to $R \div (A + B + C + \cdots)$.

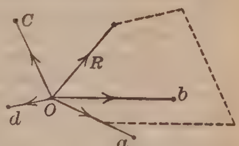

Fig. 89

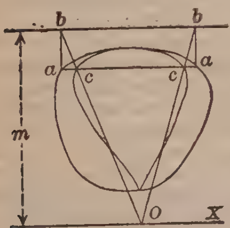

Fig. 90

The center of gravity of an irregular plane figure may be found by cutting out the figure from stiff paper and then determining the center of gravity of the paper experimentally by balancing (see below); this center of gravity gives that of the figure. Or, proceed as follows (Fig. 90): Take a point O and a line bb on opposite sides of the figure at any convenient distance m apart; project any width of the figure parallel to bb as aa on bb, connect the projections bb with O and note the intersections cc;

determine other points cc and draw a smooth curve through them as shown; measure the area A' within the curve cc; then $A'm$ is the statical moment of the given figure with respect to OX; if A is the area of the given figure and y the distance of its center of gravity from OX, $y = A'm/A$. In a similar way the distance of the center of gravity from a line perpendicular to OX can be determined.

Experimental Determination of center of gravity must be resorted to when the body is so irregular that the appropriate formulas given above cannot be applied. (1) Method of Suspension: The body is suspended from one point of it, and the direction of the suspending cord is then marked in some way on the body; the operation is repeated for another point of suspension. The center of gravity is at the intersection of the two lines or directions so fixed in the body. (2) Method of Balancing: The body is balanced on a straight-edge, and the vertical plane containing the edge is marked on the body; the operation is repeated for two more balancing positions of the body. The center of gravity is at the common point of the three planes so fixed in the body. This method is readily applied to a body in the form of a thin plane plate; practically only two balancings are necessary. (3) Method of Weighing: The weight W of the body is determined, and then it is supported on a knife-edge (Fig. 91) and on a point support which rests upon a platform scale; the reaction R of the point support is weighed, the horizontal distance a of the point from the knife-edge is measured; then the distance from center of gravity to knife-edge $\bar{x}$ is Ra/W.

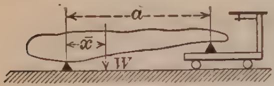

Fig. 91

23. Centers of Gravity of Some Lines and Areas

Circular Arc (Fig. 92): the center of gravity is on the axis of symmetry; its distance from the center is $x = rc/s = r \sin\alpha/\alpha$, the last α being expressed in radians (1 degree = 0.0175 radian). For a semicircle $\bar{x} = 2\,r/\pi + 0.6366\,r$; for a quadrant $\bar{x} = 2\,r\,\sqrt{2}/\pi = 0.9003\,r$, and the distance of the center of gravity from the radius drawn to either end of the arc is $2\,r/\pi = 0.6366\,r$. For flat arcs, α small, the distance from its center of gravity to the chord c is closely equal to $2/3\,h$; the error is less than 1/2% when $\alpha = 30°$, and less than 1.1% when $\alpha = 45°$.

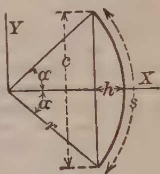

Fig. 92

Triangle: The center of gravity is at the intersections of the medians; its distance (perpendicular) from any side equals one-third the altitude of the triangle measured from that side. When x_1, x_2, x_3 are parallel distances from the vertexes to any plane, then the distance of the center of gravity is $1/3(x_1 + x_2 + x_3)$.

Trapezoid: Let a and z be the parallel bases and h the altitude. For the left-hand diagram in Fig. 92-1/2, where m is the overhang of the right side, the horizontal distance of the center of gravity from the left corner is $\bar{x} = 2/3\,b + 1/3\,m - 1/3\,a(a - m)/(a + b)$. For the right diagram the same formula applies if m is taken as negative. For all cases the distance of the center of gravity above the base b is $y = 1/3\,h(b + 2\,a)/(a + b)$.

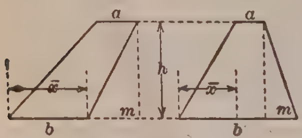

Fig. 92-1/2

When a equals b, then $x = 1/2(b \pm m)$ and $\bar{y} = 1/2\,h$. Geometric determinations of center of gravity: (1) Extend AB (Fig. 93) so that $BE = CD$, and in the opposite direction extend CD so that $DF = AB$; the intersection of FE and the median GH is the center of gravity. (2) Divide the trapezoid (Fig.

93) into triangles by a diagonal as AC; find the centers of gravity G_1 and G_2 of the triangles (construction indicated in the figure); the intersection of G_1G_2 with the median EF is the center of gravity sought.

Quadrilateral: (a) Divide the quadrilateral

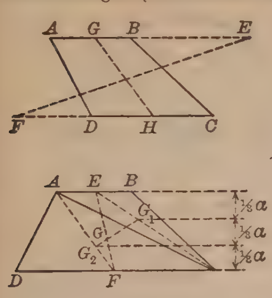

Fig. 93

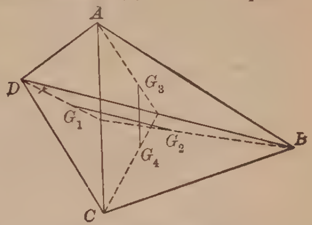

Fig. 94

into triangles by a diagonal AC (Fig. 94) and find their centers of gravity G_1 and G_2; divide it into triangles by the other diagonal and find their centers of gravity G_3 and G_4; the intersections of the lines G_1G_2 and G_3G_4 is the center of gravity sought. (b) Divide the sides into thirds (Fig. 96) and draw lines through the third points as shown; these lines form a parallelogram whose diagonals intersect at the center of gravity of the quadrilateral.

Circular Sector (Fig. 95*a*). The center of gravity is on the axis of symmetry at a distance from the center equal to $\bar{x} = 2/3\ rc/s = 2/3\ r \sin \alpha/\alpha$, the last α being expressed in radians (1 degree = 0.0175 radian). For a semicircle $\bar{x} = 4\,r/3\,\pi = 0.4244\,r$. For a quadrant $\bar{x} = 4\sqrt{2}\,r/3\,\pi = 0.6002\,r$, and distance of the center of gravity from each bounding radius is $4\,r/3\,\pi = 0.4244\,r$.

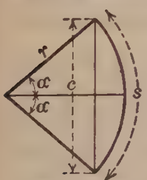

Fig. 95*a*

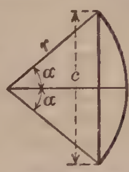

Fig. 95*b*

Circular Segment (Fig. 95*b*). The center of gravity is on the axis of symmetry at a distance from the center equal to $\bar{x} = c^3/12\,A = (2\,r^3 \sin^3 \alpha)/3\,A$, in which A is the area of the segment, or $1/2\,r^2(2\,\alpha - \sin 2\,\alpha)$, the first α being expressed in radians (1 degree = 0.0175 radian).

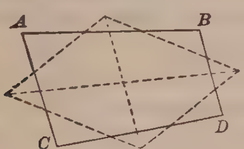

Fig. 96

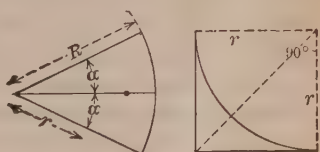

Fig. 97

Sector of a Circular Ring (Fig. 97). The center of gravity is on the axis of symmetry at a distance from the center of the circle which is given by $\bar{x} = 2/3\,(R^3 - r^3) \sin \alpha/(R^2 - r^2)\alpha$, the last α being in radians.

The Surface (Fig. 97) bounded by a circular quadrant and the tangents at its extremities. The center of gravity is on the axis of symmetry at a distance from each tangent equal to $0.223\,r$.

Parabolic Segment (Fig. 98): G_1 and G_2 are the centers of gravity of $OXCO$ and $OYCO$ respectively: $x_2 = 3/5\ a$, $y_1 = 3/8\ b$, $x_1 = 3/10\ a$, $y_2 = 3/4\ b$.

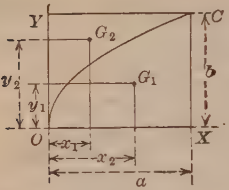

Fig. 98

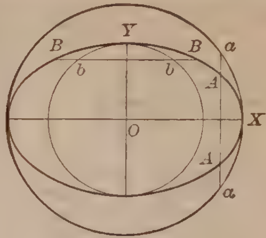

Fig. 99

Symmetric Elliptic Segment (Fig. 99). The center of gravity of $YBBY$ coincides with that of the circular segment $YbbY$, and the center of gravity of $XAAX$ coincides with that of the circular segment $XaaX$.

24. Centers of Gravity of Certain Volumes

Right Circular Cylinder (Fig. 100). The base XOA is normal to the axis of the cylinder, and the top makes an angle α with the base; the radius of the base is r and the mean height is h; then

$$\bar{x} = (r^2 \tan \alpha)/4\ h, \quad \bar{y} = 1/2\ h + (r^2 \tan^2 \alpha)/8\ h.$$

If the oblique top cuts the base in a diameter, $\bar{x} = 3/16\ \pi r$, and $\bar{y} = 3/32\ \pi a$.

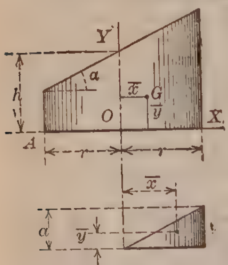

Fig. 100

Cone and Pyramid. The center of gravity of the surface (not including base) is on a line joining the apex with the center of gravity of the perimeter of the base at a distance two-thirds the length of that line from the apex. The center of gravity of the solid cone or pyramid is on the line joining the apex with center of gravity of the base three-fourths the length from the apex.

Frustum of a Circular Cone. Let R = radius of larger base, r = radius of smaller, a = altitude; then distance of center of gravity of the conical surface from larger base is $1/3\ a\ (R + 2\ r)/(R + r)$, from smaller base $1/3\ a(2\ R+r)/(R+r)$, from a plane midway between bases $1/6\ a\ (R-r)/(R+r)$. The distance from the center of gravity of the solid frustum to the larger base is $1/4\ a(R^2 + 2\ Rr + 3\ r^2)/(R^2 + Rr + r^2)$.

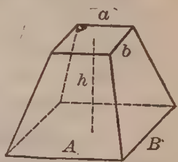

Fig. 101

Frustum of a Pyramid. If the pyramid has regular bases, let R and r be the lengths of sides of the larger and smaller bases, and h the altitude; then the distance from the center of gravity of the surface (not including bases) from the larger base is $1/3\ h(R + 2\ r)/(R + r)$. If A and a are the areas of the large and small bases of the frustum of any pyramid and h the altitude, the distance from the center of gravity of the solid from the larger base is $1/4\ h(A + 2\sqrt{Aa} + 3\ a)/(A + \sqrt{Aa} + a)$.

Obelisk and Wedge (Fig. 101). The distances from the center of gravity to the base AB is $1/2\ h(AB + Ab + aB + 3\ ab)/(2\ AB + Ab + aB + 2\ ab)$.

If $b = 0$, the solid is a wedge, and the distance from the center of gravity to the base is $1/2\ h(A + a)/(2\ A + a)$.

Sphere Parts. The center of gravity of any zone (surface) (Fig. 102) of a sphere is midway between the bases. Segment (solid): height h (Fig. 103),

Fig. 102

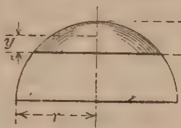

Fig. 103

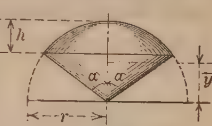

Fig. 104

$\bar{y} = 1/4\ h(4\ r - h)/(3\ r - h)$; when $h = r$ (hemisphere), $\bar{y} = 3/8\ r$. Sector (Fig. 104): $\bar{y} = 3/8\ (1 + \cos\alpha)\ r = 3/8\ (2\ r - h)$.

Ellipsoid. Let the three axes be taken as x, y, and z coordinate axes, and a, b, and c denote the semi-lengths of the corresponding axes of the ellipsoid; the center of gravity of one octant of the solid is given by $\bar{x} = 3/8\ a$, $\bar{y} = 3/8\ b$, and $\bar{z} = 3/8\ c$.

Paraboloid of Revolution formed by revolving a parabola about its axis. Let h = height of the paraboloid, the distance from its apex to the base; then the distance from the center of gravity of the solid to the base is $1/3\ h$.

25. Principles of Moment of Inertia

Definitions. The **moment of inertia** of a surface (figure or area) with respect to or about a line is the sum of the products obtained by multiplying the area of each element of the surface by the square of its distance from the line. Thus, if I denotes moment of inertia, A area, and r distance of any element dA from the line or axes with respect to which I is taken, then $I = \int r^2\, dA$; the limits of integration are to be so chosen that the integration will include all products like $r^2\, dA$ for the surface. The moment of inertia, obviously, of any surface or figure is the sum of the moments of inertia of its parts. The moment of inertia of a plane figure with respect to a line in the plane is called rectangular and one with respect to a line perpendicular to the plane is called polar; these are the only moments of inertia of surfaces that are of practical importance. A unit moment of inertia is four "dimensions" in length, and is called quadric inch, foot, etc., according as the inch or foot is used as unit length; the corresponding abbreviations are in^4, ft^4, etc. **The radius of gyration** of a surface (figure or area) with respect to a line is the length whose square multiplied by the area of the surface equals the moment of inertia of the surface with respect to the same line. Thus if k denotes radius of gyration, A area, and I moment of inertia, $k^2A = I$, or $k = \sqrt{I/A}$. The square of the radius of gyration of a figure with respect to a line is the mean of the squares of the distances of all the elementary parts of the figure from the line. (See also Art. 27.)

The Product of Inertia of a plane surface (figure or area) with respect to a pair of coordinate axes in the plane is the sum of the products obtained by multiplying the area of each element of the surface by its coordinates. Thus if J denotes product of inertia with respect to x and y axes, A area, and x and y the coordinates of any element-area dA, then $J = \int xy\, dA$; the limits of integration are to be so chosen that the integration will include all products like $xy\, dA$ for the surface. A unit product of inertia, like a unit moment of inertia (see foregoing), is four dimensions in length. Unlike moments of inertia, products of inertia may be zero or negative as well as positive. If a figure has an axis of symmetry, then its product of inertia with respect to that axis and one perpendicular thereto is zero.

Graphic Determination of Moment of Inertia. When the outline of a surface is so irregular that the integration in the expression for I cannot be performed, then the following may be resorted to: Let $aaaa$ (Fig. 105) be the outline and XX' the axis with respect to which the moment of inertia is desired; at any convenient distance m from XX' draw two parallels (but if XX' does not cut the figure, then only one parallel, the one on the opposite side of the figure from XX'); draw any line as aa parallel to XX' and project the points aa on the nearer parallel; join the projections bb to any point O in XX' and note the intersections cc on aa; project cc on the same parallel; join the projections dd with O and note the intersections ee on aa. In a similar manner determine points like ee for other widths like aa, and connect all points e as shown. Then measure the area of the loops OPO and OQO; denoting this combined area by A'', $I = A''m^2$. (There will be only one loop if only one parallel, bb, is used.)

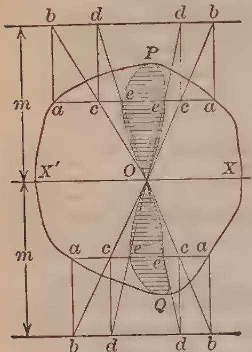

Fig. 105

Transformation Formulas. (1) Let I = moment of intertia of a figure with respect to any line or axis, $\bar{I}$ = that with respect to a parallel axis passing through the center of gravity of the figure, d = distance between the axes, k and $\bar{k}$ = the radii of gyration with respect to the same axes respectively, and A = area of the figure; then

$$I = \bar{I} + Ad^2 \qquad \text{and} \qquad k^2 = \bar{k}^2 + d^2$$

These show that with respect to all parallel axes the moment of inertia and the radius of gyration is least for the one passing through the center of gravity of the figure. (2) Let I_x, I_y, and I_z = the moments of inertia of a plane figure with respect to x, y, and z axes respectively, the axes being at right angle to each other and the x and y axes in the plane; and let k_x, k_y, and k_3 = the corresponding radii of gyration; then

$$I_x + I_y = I_z \qquad \therefore \qquad k_x^2 + k_y^2 = k_z^2$$

(3) Let J = the product of inertia of a plane figure with respect to a pair of coordinate axes in the plane, and $\bar{J}$ = that with respect to a parallel pair whose origin is at the center of gravity; $\bar{x}$, $\bar{y}$ the coordinates of the center of gravity referred to first pair, and A the area of the figure; then $J = \bar{J} + A\bar{x}\bar{y}$. (4) Let XOY and UOV (Fig. 106) be two sets of rectangular coordinate axes with a common origin and in a given plane figure; I_x, I_y, I_u, I_v = moments of inertia of the figure with respect to x, y, u, and v axes respectively, J_{xy} and J_{uv} = its products of inertia with respect to the sets of axes respectively; α = angle through which x axis must be rotated to bring it into u axis, regarded as positive or negative according as the turning is counter-clockwise or clockwise. Then $I_u + I_v = I_x + I_y$, and

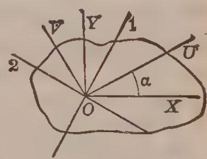

Fig. 106

$$I_u = I_x \cos^2\alpha + I_y \sin^2\alpha - J_{xy} \sin 2\alpha$$
$$J_{uv} = 1/2\,(I_x - I_y) \sin 2\alpha + J_{xy} \cos 2\alpha.$$

Principal Axes of Inertia. In general, the moments of inertia of a plane figure with respect to different lines through any point of the plane are unlike; for one axis the moment is greater and for another less than for any other axis through the point. The principal axes for a plane figure at a particular point of the plane are the two axes for which the moments of inertia are greater and less than for any other axis through the point and in the plane; the corresponding moments of inertia are called the **principal moments of inertia** of the figure at the point. The principal axes are always at right angles to each other.

With respect to the principal axes, the product of inertia is zero; from this principle the principal axes can readily be found in some cases. Thus, at a corner of a square the principal axes are the diagonal through that corner and a line perpendicular to it, for with respect to those lines the product of inertia of the square is zero (see under Product of Inertia). In any case, the principal axes of a figure at a point of it can be found from the following formula if the moments of inertia and the product of inertia of the figure with respect to two rectangular axes through the point and in the plane are known; thus let the two rectangular axes be OX and OY (Fig. 106), I_x, I_y the corresponding moments of inertia, J_{xy} the corresponding product of inertia, and θ the (unknown) angle through which OX must be turned counter-clockwise to bring it into either principal axis, $O1$ or $O2$; then $\tan 2\theta = 2J_{xy}/(I_y - I_x)$, which gives always two values of θ differeing by 90° unless Jxy and $Iy - Ix$ are both zero. In that case the figure has no principal axis at the point, and the moments of inertia with respect to the different lines through the point are all equal.

The Principal Moments of Inertia I_1 and I_2 can be computed from

$$I_1 = I_x \cos^2\theta_1 + I_y \sin^2\theta_1 - J_{xy} \sin 2\theta_1,$$

and

$$I_2 = I_x \cos^2\theta_2 + I_y \sin^2\theta_2 - J_{xy} \sin 2\theta_2$$

θ_1 and θ_2 being the two values of θ given by the formula above for principal axes. Or, after I_1 is determined, $I_2 = I_x + I_y - I_1$.

The Inertia-Circle and Ellipse. The inertia-circle is a device for determining the moment of inertia of a plane figure with respect to any line of the plane and the principal axes and principal moments of inertia at any point graphically. To construct the circle, it is necessary to know the moments of inertia and the product of inertia with respect to two rectangular axes through the point, in the plane figure. Thus if I_u and I_1 and I_2 at O (Fig. 107) are desired, I_x, I_y, and J_{xy} being known: By any scale, lay off $OX = I_x$, $OY = I_y$, and $YA = J_{xy}$, upwards or downwards from XY according as J_{xy} is positive or negative; bisect XY and from the middle point C as center describe a circle passing through A; this is the inertia-circle for axes xOy. Draw a secant through A parallel to the u axis, and from its intersection B with the circle draw a perpendicular BU to XY; then $OU = I_u$, by the scale used (and $BU - J_{uv}$). Lines through O parallel to AP and AQ are principal axes at O; and OP and OQ represent the corresponding principal moments of inertia respectively by the scale used.

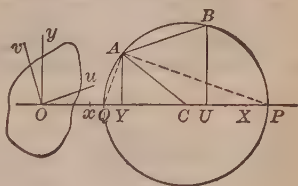

Fig. 107

The inertia-ellipse like the inertia-circle shows the relations between the moments of inertia of a plane figure for different axes through a point of the plane; for qualitative results the ellipse is preferable, generally, but for quantitative results, the circle. The inertia-ellipse for a plane surface at any particular point has its center at the point and is so drawn that the distance from any diameter to either parallel tangent equals the radius of gyration of the figure with respect to that diameter. An inertia-ellipse of a figure at its center of gravity is the central inertia-ellipse. In general, the ellipse is determined most readily thus: determine the principal axes at the point in question and the corresponding principal radii of gyration; from the point lay off on each axis in each direction distances equal (by some scale) to the radius of gyration with respect to the other axis; construct the ellipse on those two lengths as axes (Art. 11).

26. Moments of Inertia of Certain Plane Figures

Rectangle. Let b = base and h = altitude; about a line through center parallel to b, $I = 1/12\ bh^3$; about a line through the center parallel to h, $I = 1/12\ hb^3$; about side b, $I = 1/3\ bh^3$; about side h, $I = 1/3\ hb^3$; about a diagonal $I = 1/6\ b^3h^3/(b^2 + h^2)$; about a line through the center perpendicular to the diagonal $I = 1/12\ (bh^3 + hb^3)$.

Square. Make $b = h$ in foregoing. The moment of inertia is $1/12\ h^4$ for all axes in the plane of the square and passing through the center.

Hollow Rectangle. Let B and b = outer and inner breadths, and D and d = outer and inner depths; about an axis parallel to B and b and passing through the center $I = 1/12\ (BD^3 - bd^3)$.

Triangle. Let b = base and h = altitude; about the base $I = 1/12\ bh^3$; about a line through the center of gravity parallel to the base $I = 1/36\ bh^3$; about a line through the vertex parallel to the base $I = 1/4\ bh^3$.

Regular Polygon. Let A = area, R = radius of circumscribed circle, r = radius of inscribed circle, and s = length of a side; about any axis through the center and in the plane of the polygon $I = 1/24\ A\ (6\ R^2 - s^2) = 1/48 A\ (12\ r^2 + s^2)$; about a line perpendicular to the plane of the polygon passing through the center I = double the preceding I.

Trapezoid. Let B = long base, b = short base, h = altitude; about long base $I = 1/12\ (B + 3\ b)\ h^3$; about short base $I = 1/12\ (3\ B + b)h^3$; about a line through center of gravity and parallel to bases $I = 1/36\ (B^2 + 4\ Bb + b^2)\ h^3/(B + b)$.

Circle. Let d = diameter and r = radius; about a diameter $I = 1/64\ \pi d^4 = 1/4\ \pi r^4$, and $k^2 = 1/16\ d^2 = 1/4\ r^2$; about a line through the center and perpendicular to the circle $I = 1/32\ \pi d^4 = 1/2\ \pi r^4$, and $k^2 = 1/8\ d^2 = 1/2\ r^2$.

Semicircle. Let d = diameter and r = radius; about the bounding diameter or about the line of symmetry $I = 1/128\ \pi d^4 = 1/8\ \pi r^4$; about a line through the center of gravity parallel to the bounding diameter $I = (9\ \pi^2 - 64)\ d^4/1152\ \pi = 0.00686\ d^4 = 0.110\ r^4$.

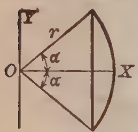

Fig. 108

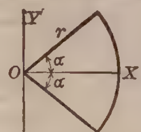

Fig. 109

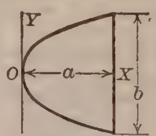

Fig. 110

Hollow Circle. Let D and d = outer and inner diameters, and R and r = outer and inner radii; about a diameter $I = 1/64\ \pi\ (D^4 - d^4) = 1/4\ \pi\ (R^4 - r^4)$, and $k^2 = 1/16\ (D^2 + d^2) = 1/4\ (R^2 + r^2)$; about a line through the center and normal to circle $I = 1/32\ \pi\ (D^4 - d^4) = 1/2\pi(R^4 - r^4)$, and $k^2 = 1/8\ (D^2 + d^2) = 1/2\ (R^2 + r^2)$.

Circular Segment (Fig. 108). Let A = area of the segment;

$$I_x = 1/4\ Ar^2\ [1 - 2/3\ (\sin^3\alpha\cos\alpha)/(\alpha - \sin\alpha\cos\alpha)],$$
$$I_y = 1/4\ Ar^2\ [1 + (2\sin^3\alpha\cos\alpha)/(\alpha - \sin\alpha\cos\alpha)].$$

Circular Sector (Fig. 109). Let A = area of the sector; $I_x = 1/4Ar^2\ (1 - \sin\alpha\cos\alpha/\alpha)$, $I_y = 1/4\ Ar^2\ (1 + \sin\alpha\cos\alpha/\alpha)$; with respect to a line through O perpendicular to the sector, $I = 1/2\ Ar^2$.

Parabolic Segment (Fig. 110). $Ix = 4/15\ ab^3$, $Iy = 4/7\ ba^3$.

Ellipse. Let $2\,a$ and $2\,b$ = lengths of the axes of the ellipse; about the $2\,a$ axis $I = 1/4\,\pi ab^3$; about the $2\,b$ axis $I = 1/4\,\pi ba^3$; about a line through the center and perpendicular to the ellipse $I = 1/4\,\pi ab\,(a^2 + b^2)$.

27. Moments of Inertia of Bodies

Definitions. The **moment of inertia of a body** with respect to or about a line is the sum of the products obtained by multiplying the mass of each elementary part by the square of its distance from the line. Thus I denoting moment of inertia, m mass, and p the distance of any element dm from the line of reference, $I = \int p^2\,dm$. The moment of inertia of a body is, obviously, the sum of the moments of inertia of its parts. A unit moment of inertia of a body is one dimension in mass and two in length. The **center of gyration** of a body with respect to a line is a point at such a distance from the line that if the entire mass of the body were concentrated there, the moment of inertia of the mass-point would be the same as that of the body; the distance of the center of gyration from the line is the radius of gyration with respect to the line. Thus k denoting radius of gyration, $k^2m = I$, or $k = \sqrt{I/m}$. The **product of inertia** of a body with respect to two coordinate planes is the sum of the products obtained by multiplying the mass of each element of the body by the two coordinates of the element with reference to those planes. Thus with respect to YOZ and ZOX (Fig. 111), ZOX and XOY, and XOY and YOZ planes, the products of inertia are respectively $\int xy\,dm$, $\int yz\,dm$, and $\int zx\,dm$. A unit product of inertia is, like a unit moment of inertia, one dimension in mass and two in length. Unlike moments, products of inertia may be zero or negative as well as positive.

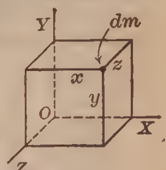

Fig. 111

Transformation Formulas. (1) If I denotes the moment of inertia of a body with respect to any line or axis, $\bar{I}$ that with respect to a parallel line through the center of gravity, d the distance between the axes, and m the mass of the body, then

$$I = \bar{I} + md^2; \quad \text{also} \quad k^2 = \bar{k}^2 + d^2$$

k and $\bar{k}$ denoting radii of gyration corresponding to the axes named respectively. (2) Let I_x, I_y, and I_z denote the moments of inertia of a body with respect to rectangular axes x, y, and z respectively; J_{xy}, J_{yz}, and J_{zx} its products of inertia with respect to yz and zx planes, zx and xy planes, and xy and yz planes respectively; I the moment of inertia of the body with respect to a line through the origin of coordinates having direction-angles α, β, and γ; then

$$I = I_x \cos^2\alpha + I_y \cos^2\beta + I_z \cos^2\gamma - 2\,J_{yz}\cos\beta\cos\gamma - 2\,J_{zx}\cos\gamma\cos\alpha - 2\,J_{xy}\cos\alpha\cos\beta$$

Principal Axes and Moments of Inertia. The values of moments of inertia of a body for all axes through a given point are in general unequal; for one axis the moment of inertia is greater and for another it is less than for any other axis through the point. These two axes are at right angles, and they together with one at right angles to their plane and passing through the point are principal axes of the body at the point; the corresponding moments of inertia are the principal moments of inertia of the body at the point. If the point is the center of gravity of the body, then the axes and moments are called central principal axes and central principal moments of inertia.

If $J_{xy} = J_{yz} = 0$, the y axis is a principal axis at the origin,
If $J_{yz} = J_{zx} = 0$, the z axis is a principal axis at the origin,
If $J_{xz} = J_{xy} = 0$, the x axis is a principal axis at the origin.

If a body has a plane of symmetry, then any perpendicular to the plane is a principal axis of the body at the point where the line pierces the plane. If a body has two planes of symmetry at right angles to each other, then their intersection is a principal axis at any point of the intersection, the other two being in the planes of symmetry. If a body has three planes of symmetry their lines of intersection are the central principal axes of the body.

Special Cases. The bodies are supposed to be homogeneous; m = the mass of the body in each instance and δ = its density, that is, its mass per unit of volume. In any system, like the C.G.S. or Engineers' (see Art. 29), $m = W/g$ and $\delta = w/g$, wherein W denotes the weight of the body, w its weight per unit volume, and g the acceleration of a freely falling body.

Straight Rod. Let l = its length; about a line making an angle α with the axis of the rod and passing through its center of gravity $I = 1/12\, ml^2 \sin^2 \alpha$; about a line through one end of the rod $I = 1/3\, ml^2 \sin^2 \alpha$.

Rod Bent into a Circular Arc (Fig. 112). $I_x = 1/2\, mr^2\, [1 - \sin \alpha \cos \alpha)/\alpha]$; $I_y = 1/2\, mr^2\, [1 + (\sin \alpha \cos \alpha)/\alpha]$; about a line perpendicular to the plane of the arc and through the center of the circle, $I = mr^2$.

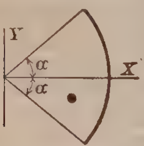

Fig. 112

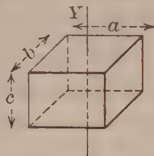

Fig. 113

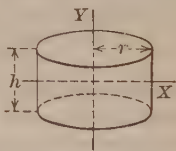

Fig. 114

Right Prism. Let h = its altitude and A = area of base; about any line perpendicular to the bases, $I = \delta h \times$ moment of inertia of a base about the same line; about a line through its center of gravity and perpendicular to the axis of the prism $I = 1/12\, \delta A h^3 + \delta h \times$ the moment of inertia of the central cross-section about the line.

Right Parallelopiped (Fig. 113). $I_y = 1/12\, m\, (a^2 + b^2) = 1/12\, abc\delta\, (a^2+b^2)$; the y axis passes through the center of gravity and is parallel to the edge c.

Right Circular Cylinder (Fig. 114). $I_y = 1/2\, mr^2 = 1/2\, \pi r^4 h\delta$; $I_x = 1/12\, m\, (3\, r^2 + h^2) = 1/12\, \pi r^2 h\delta\, (3\, r^2 + h^2)$. The y axis is the axis of the cylinder, and the x axis is perpendicular to it and passes through the center of gravity.

Hollow Right Circular Cylinder. Let R and r be the outer and inner radii, and axes taken as in Fig. 114. $I_y = 1/2\, m\, (R^2 + r^2) = 1/2\, \pi h\delta\, (R^4 - r^4)$, $I_x = 1/4\, m\, (R^2 + r^2 + 1/3\, h^2) = 1/4\, \pi\, (R^2 - r^2)\, h\delta\, (R^2 + r^2 + 1/3\, h^2)$.

Right Rectangular Pyramid (Fig. 115). $I_y = 1/20\, m\, (a^2 + b^2) = 1/60\, abh\delta\, (a^2 + b^2)$ and $I_x = 1/20\, m\, (3/4\, h^2 + b^2) = 1/60\, abh\delta\, (3/4\, h^2 + b^2)$; the y is the axis of the pyramid and x axis passes through the center of gravity and is parallel to side a.

Right Circular Cone (Fig. 116). $I_y = 3/10\, mr^2 = 1/10\, \pi r^4 h\delta$, $I_x = 3/20\, m\, (r^2 + 1/4\, h^2) = 1/20\, \pi r^2 h\delta\, (r^2 + 1/4\, h^2)$, $I_z = 3/20\, m\, (r^2 + 4\, h^2)$; the y is the axis of the cone, the x is parallel to the base and passes through the center of gravity, and the z is parallel to the base and passes through the apex.

Frustum of a Cone. Let R and r = radii of larger and smaller bases, h = altitude; about the axis of the frustum $I = 3/10\, m\, (R^5 - r^5)/(R^3 - r^3) = 1/10\, \pi h \delta\, (R^5 - r^5)/(R - r)$.

Sphere. Let r = its radius; about any diameter $I = 2/5\, mr^2 = 8/15\, \pi r^5 \delta$.

Hollow Sphere. Let R and r = the outer and inner radii; about any diameter $I = 2/5\, m\, (R^5 - r_5)/(R^3 - r^3) = 8/15\, \pi\delta\, (R^5 - r^5)$.

Ellipsoid. Let $2\,a$, $2\,b$, and $2\,c$ = the lengths of the axes; about the axis $2\,c$, $I = 1/5\, m\, (a^2 + b^2) = 4/15\, \pi abc\delta\, (a^2 + b^2)$.

Paraboloid generated by revolving a parabola about its axis. Let h = its height and r = radius of base; about the axis of revolution $I = 1/3\, mr^2 = 1/6\, \pi h r^4 \delta$.

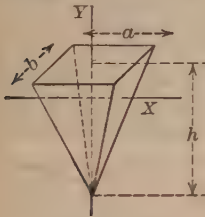

Fig. 115

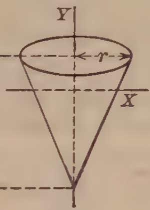

Fig. 116

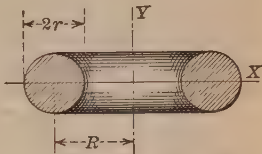

Fig. 117

Ring (Fig. 117). $I_y = m\,(R^2 + 3/4\, r^2) = 1/2\, \pi^2 R r^2\, (4\, R^2 + 3\, r^2)\, \delta$, $I_x = m\,(1/2\, R^2 + 5/8\, r^2) = \pi^2 R r^2\, (R^2 + 5/4\, r^2)\, \delta$; both axes, x and y, pass through the center of gravity as shown.

DYNAMICS

28. Dynamical Quantities

Weight and Mass. In common parlance the word weight is used in at least two senses: thus a body is said to be heavy, its weight is 500 lb., etc., the reference being to the earth-pull or gravity on the body; also a cask is said to contain much sugar, its weight is 500 lb., etc., the reference here being to quantity of material, matter or stuff of a certain kind (sugar). Doubtless the legal definitions of our standards of weight imply the second sense, since they were framed primarily to standardize weight measures of commodities made in trade. For the sake of clearness, many writers restrict the use of the word weight to one meaning, namely the first, that is, earth-pull; and to denote the second, quantity of substance, they employ the term mass. This usage is employed in the present chapter.

Force has been previously defined (Art. 15). Every so-called practical unit of force is a force equal to the earth-pull on a standard of mass, and the name given to such unit force is the same as the name given to the standard or unit of mass. Thus, a force equal to the weight or gravity of a pound mass is a unit of force, and that unit is called a pound force; a force equal to the weight or gravity of a kilogram mass is a unit of force and is called a kilogram force, etc. These units are called gravitational units.

Some writers seeking to make gravitational units of force absolute specify that the pound force, for example, is the weight or gravity of the pound mass at London or at sea level 45° latitude. However, the actual pound forces used in different places are the earth-pulls on pound masses at those places; hence gravitation units of force as used are not absolute; the magnitudes of the units for two places are as the values of g for those places. To make the unit force absolute and to simplify certain dynamical equations, units of force have been proposed based on the following: In any system of dynamical units the unit force is one which applied to the unit mass of that system produces the unit acceleration of that system. Thus in the C.G.S. system the unit of force is that force which applied to a gram mass gives it an acceleration of one cm. per sec. per sec.; this unit is called dyne. And, in the F.P (mass)S. system (never widely used), the unit is the force which applied to the pound mass gives it an acceleration of 1 ft. per sec. per sec.; it is called poundal.

Work. When the point of application of a force moves, so that the force has a component along the displacement of its application point, the force is said to do work; also the body exerting the force is said to do work. If the force is constant in magnitude and in direction and the displacement is straight, then the magnitude of the work is the product of the component of the force along the displacement and the displacement; if this component is in the direction of the displacement the work is regarded as positive; if opposite, the work is negative. Thus in the displacements of the body C (Fig. 118) from A to B, the works of the several forces are respectively $+F_1 s$, $-F_2 s$, $+F_3 \cos\theta \cdot s$, $-F_4 \cos\phi \cdot s$, and 0. If the force varies in magnitude or direction, or if the displacement of its application point is curved, the work must in general be computed by an integration; the general expression for work in

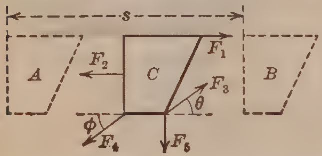

Fig. 118

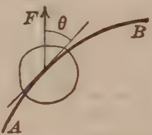

Fig. 119

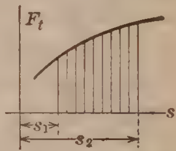

Fig. 120

this case is $\int F \cos\theta \cdot ds$, in which F denotes the force, ds elementary part of the displacement, and θ the angle between F and the direction of the elementary displacement (Fig. 119); the limits of integration must be assigned so as to include the entire displacement A to B. $F \cos\theta$ is the component of F along the tangent to the curve of displacement; denoting this component by F_t, the work is also given by $\int F_t ds$. The work can also be regarded as the product of the force and the component of the displacement along the action line of the force; this component is called the distance through which the force acts, and so work is also said to equal force times distance through which it acts. The work done by a force can be represented by a work diagram, which is constructed by plotting a line showing how the component of the force along the displacement Ft varies with the displacement (Fig. 120). The area included between the curve, the displacement axis, and two ordinates represents the work done by the force during the corresponding displacement $s_2 - s_1$. This diagram suggests also that the work done by a force equals the product of the average value of the tangential or working component and the displacement.

The Unit of Work depends on the units used for force and distance; thus, there are the foot-pound, the foot-ton, the dyne-centimeter (for which there is a special name, erg), etc. The joule is a practical electrical unit of work and equals 10 000 000 ergs; also the kilogrammeter, equal to 100 000 ergs. Work is also expressed in horsepower-hours, watt-hours, etc.; the horsepower-hour is the amount of work done in one hour at the rate of one horsepower, and the watt-hour is the amount of work done in one hour at the rate of one watt.

Power. By power of a force or agent doing work is meant the time-rate at which the work is done. Some units of power are: foot-pound per second;

dyne-centimeter (or erg) per second; horsepower (abbreviated hp.) = 550 foot-pounds per second, or 33 000 foot-pounds per minute; watt = one joule (10 000 000 ergs) per second; kilowatt = 1000 watts; the metric or French horsepower = 75 kilogram-meters per second.

1 ft-lb. per sec.	= 0.13820 kg-m. per sec.	1 kg-m. per sec.	= 7.233 ft-lb. per sec.
1 Engl. hp.	**= 746 watts**	**1 kilowatt**	**= 1.34 Engl. hp.**
1 Engl. hp.	**= 1.0136 Fr. hp.**	**1 Fr. hp.**	**= 0.98 3 Engl. hp.**

Energy. When the condition or state of a body, or system, is such that it can do work, it is said to possess energy; and by its amount or store of energy is meant the amount of work which the body can do in passing to some standard state. Thus, a body in motion has energy, and the amount of its energy is the amount of work it can do in coming to rest; also a stretched spring has energy, and the amount of its energy is the amount of work which it can do in assuming its natural unstretched state. Energy is expressed in the same units as work, foot-pound, foot-ton, dyne-centimeter (erg), etc. Energy which a system has in virtue of its velocity is called kinetic energy. The **kinetic energy** of a particle of mass m moving with velocity v is $1/2\ mv^2$, and the kinetic energy of any body is the sum of the kinetic energies of its particles. In translation: kinetic energy $= 1/2\ Mv^2 = 1/2\ (W/g)v^2$, M denoting mass of the body, W its weight, v its velocity, and g acceleration of gravity; the last form gives energy in foot-pounds if W is expressed in pounds, v in feet per second, and g is taken as 32.2. In rotation: kinetic energy $= 1/2\ I\omega^2 = 1/2\ Mk^2\omega^2 = 1/2\ (W/g)\ k^2\omega^2 = (W/g)\ k^2\ 2\ \pi^2 n^2$, I being the moment of inertia of the body with respect to the axis of rotation, k the corresponding radius of gyration, ω its angular velocity expressed in radians per unit time, W its weight, g the acceleration of gravity, and n the number of revolutions per unit time; the last form gives energy in foot-pounds if W is expressed in pounds, k in feet, n in revolutions per second, and g is taken as 32.2. **Potential energy** is that energy which a system has in virtue of its configuration. The earth and a body elevated above the earth's surface constitute a system having potential energy. Because the energy can be withdrawn only from the elevated body it is said to possess the energy. The amount of potential energy possessed by an elevated body (rigid or not) $= Wh$, W denoting the weight of the body and h the vertical distance through which its center of gravity can descend.

Kinetic energy and potential energy are also called mechanical energy. There are other forms of energy which may not be mechanical, as thermal, chemical, and electrical. But the thermal energy of a body is generally regarded as due to the motions of the ultimate particle constituents of the body, thus being kinetic; much of chemical energy is regarded as due to the relative positions of ultimate particles, thus potential; the nature of electric energy is even less understood than that of chemical and thermal energy.

The Impulse of a force which remains constant in magnitude and direction for any time is the product of the magnitude of the force and the time. The unit of impulse depends on the units used to express the force and the time; thus there are the pound-second, dyne-second, etc. If the force F varies in magnitude but is constant in direction, then its impulse for the interval of time $t_2 - t_1$ is $\int_{t_1}^{t_2} F\,dt$. If the force varies in magnitude and in direction, its impulse can be computed from the impulses of its x, y, and z components; thus if F_x, F_y, and F_z denote these components of F, then the component impulses are $\int F_x\,dt$, $\int F_y\,dt$, and $\int F_z\,dt$, and the impulse of F equals the square root of the sum of the squares of the components. The angular impulse of a force about any line for an element of time is the product of the moment of the force about the line and the element of time, that is, $M\,dt$, if M denotes the moment of the force; and the angular impulse for any interval of time $t_2 - t_1$ is $\int_{t_1}^{t_2} M\,dt$.

The Momentum of a particle is the product of its mass and velocity. The unit of momentum depends on the units of mass and velocity used; the dimensions of unit momentum are the same as those of unit impulse (see preceding). The momentum of a body is the resultant of the momentums of its particles. This resultant is not the scalar but the vector-sum of the momentums, that is, the resultant is to be computed as the resultant of a number of forces is, the separate momentums being regarded as having the directions of the velocities of the several particles and acting at the particles. In a translation the momentum is $Mv = (W/g)v$, M denoting the mass of the body, W its weight, v its velocity, and g the acceleration of gravity; the second form gives momentum in pound-seconds if W is expressed in pounds, v in feet per second, and g is taken as 32.2.

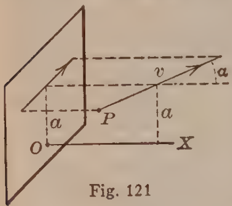

Fig. 121

The angular momentum of a particle about a line is the moment about that line of its momentum; thus, if the particle at P (Fig. 121) has a mass m and a velocity v, its momentum is mv acting in the line v and its angular momentum about OX is $(mv \sin \alpha)\,a$. The angular momentum of a body about a line is the algebraic sum of the angular momentums of its constituent particles. A rotating body has angular momentum about the axis of rotation equal to $I\omega = Mk^2\omega = (W/g)k^2\omega = (W/g)k^2\,2\pi n$, I denoting the moment of inertia of the body with respect to the axis, k its corresponding radius of gyration, W its weight, ω its angular velocity in radians per unit time and n in revolutions per unit time, and g the acceleration of gravity.

Dimensions of Units. All mechanical and nearly all physical units can be defined in terms of one or more of three units arbitrarily defined, that is, without reference to other units. These three are fundamental units and the others derived units. In theorectical mechanics and physics the fundamental units chosen are those of length, mass, and time; in applied mechanics, units of length, force, and time are generally more convenient. A statement of the way in which a derived unit depends on the fundamental ones is a statement of the dimensions of the derived. Thus a unit of velocity depends on the units of length and time used, but is independent of the third fundamental unit; and the magnitude of a unit of velocity varies directly as the unit of length and inversely as the unit of time used. Denoting the first set of fundamental units by L, M, and T respectively, and the unit of velocity by V, the dimensional statement is written thus, $V = L^1M^0T^{-1}$, and is called the dimensional formula for V.

The dimensional formulas may be used to test the accuracy of equations between mechanical quantities. Such an equation, if rationally and correctly deduced, is **homogeneous**; that is, its terms are of the same kind. To ascertain whether terms are the same in kind, substitute for each quantity the dimensional formula for its unit, then treating the symbols L, M or F, and T as quantities, reduce each term; if the reduced terms are alike, then the equation is correct dimensionally. Thus in the equation $24\,EIy = W\,(4l^3x - x^4)/l$, E denotes modulus of elasticity, I moment of inertia of an area, W a load, l, x, and y lengths, and the dimensional form is (dropping abstract members) $L^{-2}F^1L^4L^1 = F\,(L^3L^1 - L^4)/L^1$, which reduces to $L^3F = L^3F - L^3F$, and so the original equation is correct dimensionally.

29. Dynamical Principles

Laws of Motion. (1) The normal state of the center of mass of a body is one of rest or uniform rectilinear motion; a departure from this state is due to force applied to the body. (2) When a single force acts upon a body, the center of mass sustains an acceleration in the direction of the force and proportional to the force directly and to the mass of the body inversely; if several forces act on the body, the acceleration is given by the vector sum of the accelerations which would be produced by the forces acting singly. (By vector sum is meant the result reached by adding according to the parallelogram law.) (3) When one body exerts a force upon another the second also exerts one upon the other first, and the two forces are equal, colinear, and opposite. If F = force, m = mass, and a = acceleration, then the second law can be written $a \propto F/m$ or $a = kF/m$, k being a constant whose value depends on units used in F, m, and a. It is possible to make $k = 1$ by proper choice of units. Such choice was made in the so-called absolute systems of dynamical units; first units of length, mass, and time were selected and then as unit of F such a force which produces unit acceleration in unit-mass. For example, in the C.G.S. system these units are respectively the centimeter, gram, second, and dyne, the latter about 1/981 gram weight. The constant k may also be made unity in so-called gravitational systems; units of length, force, and time are first taken (that of force as the weight of something), and then the unit of m as that mass which sustains unit acceleration when acted on by unit force. For example, in the **engineers' system,** these units are respectively foot, pound force, second, and the unit of m a mass equal to about 32.2 pounds. In any system in which $F = ma$, then also $m = W/g$, m and W being the mass and weight of the body and g the acceleration of gravity, all three quantities being expressed in units of that system.

Laws of Impulse and Momentum. When external forces act upon a body or collection of bodies they produce in general a change in the momentum of the body or collection. In any interval, the change in the component of the linear momentum along any line equals the algebraic sum of the components of the impulses of the forces along that line for the same time; and the change in any interval in the angular momentum about any line equals the algebraic sum of the angular impulses of the forces about that line for the same time. When no external forces are acting, the component linear momentum along any line and the angular momentum about any line remain constant; these are the principles of conservation of linear and angular momentum.

Principles of Work and Energy. In general, the kinetic energy of a body changes value during a change of its position or form, and the external and the internal forces acting on the body do work. The increment in the kinetic energy equals the sum total of work done by all the external and internal forces. In applying this principle, signs must be given to the works of the various forces as explained on p. MM; then if the total work is positive, the increment is positive and there is a real gain in kinetic energy, and if negative then there is a loss. If the body is a rigid one, the internal forces do no work in any displacement of the body, and the increment in kinetic energy equals the total work done by the external forces acting on the body. If a body or system of bodies is isolated so that it neither receives nor gives out energy, then its total store of energy, all forms included, remains constant; there may be a transfer of energy from one part of the system to another, but the total gain or loss in one part is exactly equivalent to the loss or gain in the remainder. This is the principle of conservation of energy.

30. Rectilinear Motion

Motion of a Point. The velocity of a moving point at any instant is the time-rate at which it is describing distance then; the symbol is v. In uniform motion (equal distances described in all equal intervals of time) the rate is constant and $v = \Delta s/\Delta t$, Δs denoting the distance described in the interval Δt.

In non-uniform motion the rate varies, and $\Delta s/\Delta t$ is the average velocity for the interval Δt; the actual velocity at any instant is the value of ds/dt for that instant. The acceleration of a point at any instant is the rate at which its velocity is changing then; the symbol is a. If v changes uniformly the rate is constant, and $a = \Delta v/\Delta t$, Δv denoting the velocity-change occurring in the interval Δt. If v does not change uniformly $\Delta v/\Delta t$ is the average acceleration for the interval Δt; the actual acceleration at any instant is the value of dv/dt for that instant. The general differential equations of rectilinear motion are $v = ds/dt$, $a = dv/dt = d^2s/dt^2$, $vdv = ads$; their integral forms are

$$s_2 - s_1 = \int_{t_1}^{t_2} v\,dt \qquad v_2 - v_1 = \int_{t_1}^{t_2} a\,dt \qquad v_2^2 - v_1^2 = \int_{s_1}^{s_2} a\,ds$$

in which s_1, v_1, and t_1 are corresponding or simultaneous values of s, v, and t, likewise s_2, v_2, and t_2.

Space-time, velocity-time, acceleration-time, velocity-space, acceleration-space curves respectively are graphs showing the relations between s and t, v and t, a and t, v and s, a and s (Figs. 122–126; they do not correspond to the same motion). (1) In the s–t diagram, the slope of the curve at any point represents the corresponding

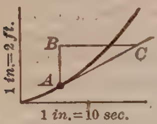

Fig. 122

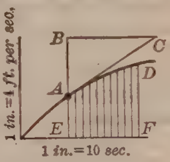

Fig. 123

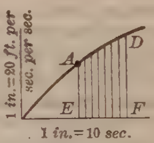

Fig. 124

velocity. If AB and BC are measured by the s and t scales of the drawing respectively, then the slope equals the velocity; thus if $AB = 0.2$ in. and $BC = 0.4$ in., $v = 0.4 \div 4 = 0.1$ ft. per sec. (2) In the v–t diagram, the slopes represent the accelerations; if AB and BC are measured by the v and t scales respectively, then the slope equals the acceleration; thus if $AB = 0.3$ in. and $BC = 0.5$ in., $a = 1.2 \div 5 = 0.24$ ft. per sec. per sec. The area included between any two ordinates (as AE and DF), the curve, and the t axis represents the displacement of the moving point in the time EF. If the area is computed by multiplying its average ordinate measured by the velocity scale (thus giving the average velocity) by EF measured by the time scale, then the product equals the displacement; thus if the average ordinate is 0.35 in., and EF is 4 sec., the displacement $= 1.4 \times 4 = 5.6$ ft. (3) In the a–t diagram the slope represents the rate at which the acceleration is changing. The area included between any two ordinates (as AE and DF), the curve, and the t axis represents the velocity change in the time EF. Thus if the average ordinate is 0.3 in. and EF is 2 sec., then the velocity change $= (0.3 \times 20) \times 2 = 12$ ft. per sec. (4) In the v–s diagram, the subnormals represent the accelerations. If the length of the subnormal is multiplied by the square of the velocity scale number and the product divided by the space scale number, the result will equal the acceleration; thus suppose that the subnormal $BC = 1/3$ in., then $a = (1/3 \times 25) \div 10 = 0.83$ ft. per sec per sec. (5) In the a–s diagram, the area included between two ordinates (as AC and BD), the curve, and the s axis represents the change in the velocity square. If the area is computed by multiplying the mean ordinate measured by the acceleration scale by CD measured by the space scale, the product equals the change in the velocity square; thus if the average ordinate $= 0.3$ in., and $CD = 0.4$, then the change $= 2.4 \times 4 = 9.6$.

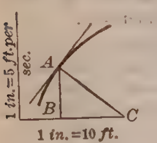

Fig. 125

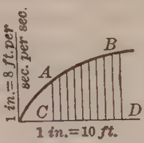

Fig. 126

Uniformly Accelerated Motion, constant acceleration. Let v_1 and v_2 denote the velocities at times t_1 and t_2, s_1 and s_2 the corresponding values of space, and

a = acceleration. Then the velocity change is $v_2 - v_1 = a\ (t_2 - t_1)$; the space traversed is $s_2 - s_1 = 1/2\ (v_1 + v_2)\ (t_2 - t_1) = v_1\ (t_2 - t_1) + 1/2\ a\ (t_2 - t_1)^2$; also $v_2^2 - v_1^2 = 2\ a\ (s_2 - s_1)$.

Falling Body. The acceleration due to gravity (denoted by g) is approximately 32.2 ft. per sec. per sec. It changes slightly with elevation above sea level and with latitude; denoting elevation in feet by e and latitude by ϕ, then in feet per second per second

$$g = 32.0894\ (1 + 0.0052375 \sin \phi)\ (1 - 0.0000000957\ e)$$

At the equator sea level $g = 32.0894$ and at the poles 32.254; the extreme values for the United states are roughly 32.19 (in latitude 49° sea level) and 32.09 (in latitude 25° and 10 000 ft. above sea).

A body dropped without initial velocity falls in a vacuum according to the laws

$$v = gt \qquad h = 1/2\ gt^2 \qquad v^2 = 2\ gh$$

wherein v = velocity and h the descent at the time t. A body projected downward in a vacuum with initial velocity v_1 moves according to

$$v = v_1 + gt, \qquad h = v_1 t + 1/2\ gt^2, \qquad v^2 = v_1^2 + 2\ gh.$$

These three formulas apply to upward projection if the sign + is changed to −; h then denotes ascent in the time t, after projection. The total ascent (to highest position) and the corresponding time are respectively $v_1^2/2\ g$ and v_1/g.

Simple Harmonic Motion. If a point moves in a circle with constant speed, then the motion of the projection of the point on any diameter of the circle is simply harmonic; other motions resembling this are also called simply harmonic. Simple harmonic motion may also be defined as any rectilinear motion in which the acceleration is always directed toward a fixed point in the path and is proportional to the distance between that and the moving point. Taking the first definition, let P (Fig. 127) be the point moving in the circle and regard the motion of its projection on the vertical diameter. The period is the time of one revolution of P, or one complete oscillation of Q; the frequency is the number of revolutions of P, or oscillations of Q, per unit time; the amplitude is half the length of the path of Q or the radius of the circle; the displacement at any time is the ordinate of Q from the center of the path; the phase is the angle at any time from OX to OP (thus when Q is at the top of its path the phase is 90°, when at the center going down, 180°, when at the lowest point, 270° or − 90°). If, in the description of a simple harmonic motion, time is reckoned from the instant when the phase angle is not zero, then that motion is said to have a lead or a lag according as the initial phase (angle) is between 0 and 180° or 0 and − 180°, and the value of the angle is called lead or lag as the case may be. Let ϵ = lead or lag, t = time elapsed after starting (motion from P_0 to P), ω = angular velocity of OP, T = period, n = frequency, r = amplitude, y = displacement, v = velocity of Q and a = its acceleration. The following are the general relations between the quantities involved:

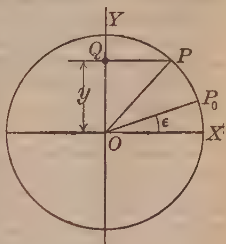

Fig. 127

$$n = 1/T \qquad \omega = 2\ \pi n = 2\ \pi/T \qquad y = r \sin (\omega t + \epsilon)$$

$$v = \omega r \cos (\omega t + \epsilon) = \omega \sqrt{r^2 - y^2} \qquad a = -\ \omega^2 r \sin (\omega t + \epsilon) = -\ \omega^2 y$$

If the time is reckoned from the instant when Q is in its mid-position, $\epsilon = 0$. The three curves (Fig. 130) OA, $O'B$, OC are the space-time, velocity-time, and acceleration-time curves for one complete period of a simple harmonic motion; $\epsilon = 0$; Ot represents the period; the values of y, v, and a marked are for position Q shown. In

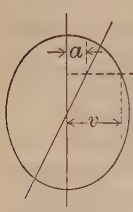

Fig. 128

Fig. 129

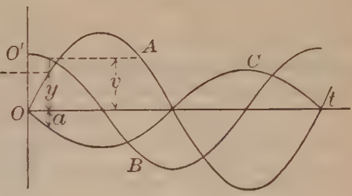

Fig. 130

Fig. 128 the curve is the velocity-space curve, and the inclined line the acceleration-space curve. They show how v and a vary with the displacement of the moving point; thus for the moving point Q v and a have values as marked.

Translation is a motion of a body such that the lines joining all pairs of points of the body remain fixed in direction. In any interval of time all points describe equal paths; at any instant all points have identical velocities and identical accelerations. Translations in which each point of the body describes straight lines are the common ones, and translation is defined sometimes as any rectilinear motion of a body. The resultant of all forces acting on the body passes through the center of gravity of the body; that force and the acceleration have at each instant the same direction, and $R = ma = (W/g)\,a$, wherein R = resultant force, a = acceleration, m and W = mass and weight of the body respectively, and g = the acceleration of gravity. Also if a_x = the x component of the acceleration at any instant and ΣF_x = the algebraic sum of the x components of all the external forces, then $\Sigma F_x = ma_x$; and similarly for y and z axes, the three axes being fixed and rectangular.

For example, consider the motion of a parallel rod of a locomotive, weighing 275 lb., running at constant velocity of 60 mi. per hr. on a level track, the driver diameter being 5.5 ft. and the crank length 1 ft. The forces acting on the rod are its weight and the pressures of the crank pins at its ends; the latter each are represented (Fig. 131) by their horizontal and vertical components. Since the resultant of all these forces acts through the center of gravity, $V_1 = V_2$; also $2\,V_1 - 275 = (W/g)\,ay = 8.55\,ay$ and $H_1 - H_2 = (W/g)\,ax = 8.55\,ax$. To determine ax and ay: The velocity of the center of either crank pin relative to the locomotive is $(88 \times 1)/2.75 = 32$ ft. per sec. (60 mi. per hr. = 88 ft. per sec.), and the relative motion of the pin being circular at constant velocity, the relative acceleration is toward the center of the crank-pin circle at all times and equals $32^2/1 = 1024$ ft. per sec. per sec. This is also the absolute acceleration of the crank pin, since the locomotive is assumed to have no acceleration. But the rod has the same acceleration as the crank pin; hence $ax = 1024 \sin\theta$ and $ay = 1024 \cos\theta$. In the lowest position of the rod $\theta = 0$, $ax = 0$, $ay = 1024$, $H_1 = H_2$, $V = 1/2\,(8755 + 275) = 4515$. In a mid-position when $\theta = 90°$, $ax = 1024$, $ay = 0$, $H_1 - H_2 = 8755$, and $V = 1/2\ 275 = 137.5$. In the highest position, $\theta = 180°$, $ax = 0$, $ay = -1024$, $H_1 = H_2$, and $V = 1/2\,(275 - 8755) = -4240$, the negative sign meaning that V acts downward on the rod.

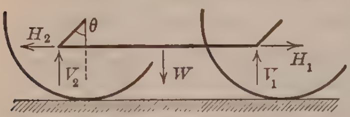

Fig. 131

If the translation is rectilinear and R is constant in value, then

$$Rt = mv_2 - mv_1 \quad \text{and} \quad Rs = 1/2\,mv_2^2 - 1/2\,mv_1^2$$

wherein v_1 and v_2 are the values of v at ends of any interval of time t, and s the distance described in that time. These formulas are the principles of impulse and momentum, and of work and energy for this special motion. If the translation is not rectilinear: According to the principle of impulse and momentum, $\Sigma\int_{t_1}^{t_2} Fxdt = m\,v''x - mv'x$ and similar equations for y and z directions; the left-hand member is the algebraic sum of the x components of the impulses of the forces acting on the body for the time $t_2 - t_1$, and $v'x$ and $v''x$ are the x components of the velocity at the times t_1 and t_2. According to the principle of work and energy, $\Sigma\int_{s_1}^{s_2} Ftds = 1/2\, mv_2^2 - 1/2\, mv_1^2$; the left-hand member is the algebraic sum of the works done by all the forces acting on the body while its velocity changes from v_1 to v_2, and the displacement is $s_2 - s_1$.

31. Curvilinear Motion

Curvilinear Motion of a Point. If the motion is uniform (equal distances traversed in all equal intervals of time), $v = \Delta s/\Delta t$, and if non-uniform, $v = ds/dt$, just as in rectilinear motion; the velocity of the moving point is directed along the tangent to the path at the point. But acceleration formulas for rectilinear motion do not hold for this case; here it is important to note that the velocity varies in direction continually, and that acceleration is the rate at which the velocity-changes (including magnitude and direction) occur. These complete velocity-changes for a given motion are exhibited by the **Hodograph** for the motion. A hodograph is constructed by drawing from any point O' (Fig. 132) vectors which represent the velocities of the moving point at a number of its successive positions and then joining the free ends of the vectors by a smooth curve. The velocity-change occurring in any motion as from A to B is represented by the vector $A'B'$. If Δt is the time in which this occurred, then the magnitude of the average acceleration for that time is (chord $A'B')/\Delta t$, $A'B'$ being measured by the scale of the hodograph diagram, and the direction of that average acceleration is that of the vector $A'B'$. The actual acceleration at A, say, is the limit of this average as B is taken closer and closer to A; that is, a at A is the value of ds'/dt at A' (s' denoting distance on the hodograph), and the direction of a is that of the tangent at A'. It will be noticed that the acceleration of the moving point is represented by the velocity of its corresponding point in the hodograph (A' is A's corresponding point).

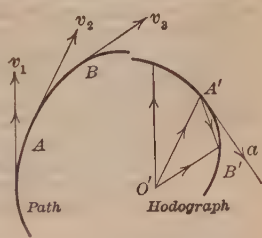

Fig. 132

Velocities and accelerations may be resolved; let α, β, and γ' denote the direction angles of v (with respect to x, y, and z axes), vx, vy, and vz the components of v parallel to these axes (axial components), x, y, and z the coordinates of the moving point. Then $vx = v\cos\alpha = dx/dt$, $vy = v\cos\beta = dy/dt$, $vz = v\cos\gamma = dz/dt$. Let ax, ay, and az denote the axial components of a, and λ, μ, and ν the direction angles of a; then $ax = a\cos\lambda = dvx/dt = d^2x/dt^2$, $ay = a\cos\mu = dvy/dt = d^2y/dt^2$, $az = a\cos\nu = dvz/dt = d^2z/dt^2$. Let at and an denote the components of a along the tangent and normal to the path, ϕ the angle between the tangent and a, θ that between normal and a, and r the radius of curvature at the moving point; then $at = a\cos\phi = dv/dt = d^2s/dt^2$, $an = a\cos\theta = v^2/r$. The tangential acceleration corresponds to change in value of velocity, and the normal acceleration to change in direction of velocity. When a point moves in a circle with constant speed v, then $at = 0$ and $a = an = v^2/r$, and a is directed along the radius toward the center of the circle.

Motion of a Projectile. In the following formulas air resistance is neglected; v_0 = velocity of projection, θ = angle of projection (Fig. 133), x and

y = coordinates of the projectile at any time t after projection, v = velocity, v_x and v_y = x and y components respectively of v, r = range on the horizontal plane through O, and h = greatest height attained. The path of the projectile, or the trajectory, is a parabola as represented, and its equation is $y = x \tan\theta - gx^2/2\,v_0^2\cos^2\theta$. Also

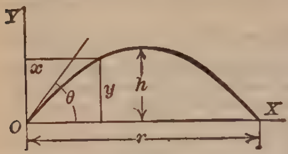

Fig. 133

$$v_x = v_0\cos\theta \quad v_y = v_0\sin\theta - gt \quad v = \sqrt{v_0^2 - 2\,gy}$$
$$x = v_0\cos\theta\cdot t \qquad y = v_0\sin\theta\cdot t - 1/2\,gt^2$$
$$h = \sin^2\theta\cdot v_0^2/2\,g \qquad r = \sin 2\,\theta\cdot v_0^2/g$$

If the direction of projection is horizontal, $\theta = 0$; the equation of the path is $y = -gx^2/2\,v_0^2$, and $x = v_0t$ and $y = -1/2\,gt^2$.

Relative Motion. Description of motion requires the use of coordinate axes or other equivalent means of reference for the specification of positions of the moving point. Motion relative to a body is described by means of coordinate axes fixed in or on the body. Thus, suppose that in a given time a body A (Fig. 134) moves from A' to A'', and a point B from B' to B'': In the first position the coordinates of B are 0.3 and 0.2 in., and in the second 0.5 and 0.4. Then the x and y components of the relative displacement of B with respect to A are $0.5 - 0.3 = 0.2$ and $0.4 - 0.2 = 0.2$, and the total relative displacement is $\sqrt{0.2^2 + 0.2^2} = 0.28$ in. Motion relative to a point is described by means of coordinate axes having the point as origin and their directions remaining constant (relative to the body to which the motion of the point itself is referred). Thus suppose that in a certain time a point A moves from A' to A'' and another B from B' to B'' (Fig. 135); the x and y component displacements of B relative to A are 0.2 and 0.1 in. respectively and the displacement of B relative to A is $\sqrt{0.2^2 + 0.1^2}$. The displacements, velocities, and accelerations of two points relative to each other at any instant are equal and opposite. The velocities of three points A, B, and C relative to each other are related as shown in Fig. 136; V_{ab} means velocity of A relative to B and V_{ba} means velocity of B relative to A. Among three points there are six relative velocities, and

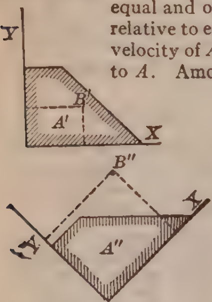

Fig. 134

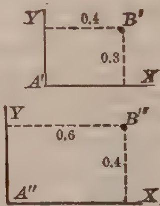

Fig. 135

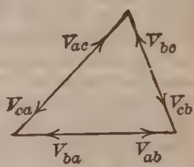

Fig. 136

when any two (except the velocities of two points with respect to each other) are known, the others can be computed by compounding as may be seen from the figure. Among three points there are six relative accelerations; their relations are similar to those of the velocities, and the figure shows the relations, V being now taken to mean acceleration.

Force and Acceleration. The forces acting on a body and the motion of its center of gravity are simply related; the algebraic sum of the components of all the external forces acting on the body along any line equals the product of the mass of the body and the component of acceleration of its center of gravity along that line. In general, the principle leads to

$$\Sigma F_x = m\bar{a}_x, \qquad \Sigma F_y = m\bar{a}_y, \qquad \Sigma F_z = m\bar{a}_z$$

where in m = mass = weight ÷ g; the left-hand members are the sums of the components of the forces along three rectangular axes, and $\bar{a}_x$, $\bar{a}_y$, and $\bar{a}_z$ are the corresponding components of the acceleration of the center of gravity. Or, if the directions of resolution are taken along the tangent to the path described by the center of gravity, the principal normal and a line perpendicular to the principal normal and tangent (the binormal), then

$$\Sigma F_t = m\bar{a}_t \qquad \Sigma F_n = m\bar{a}_n \qquad \Sigma F_b = 0.$$

The resultant of the normal components, ΣF_n, is called the centripetal force on the body; it is always directed inward toward the center of the curved path just as $\bar{a}_n$ is. The reaction corresponding to ΣF_n, exerted by the body on those that exert the centripetal force, is called centrifugal force.

For example, consider a car rounding a curve of radius r at a constant speed v. Imagine the rail pressure on each wheel resolved into three components, one parallel to the rails, one parallel to the ties, and one perpendicular to the track; call the resultants of these sets of components respectively R_1, R_2, and R_3 (Fig. 137). Also let P_1 and P_2 denote the pulls at the front and rear ends of the car. The components of the rail pressures parallel to the rails, P_1, and P_2, are practically parallel to the tangent to the path of the center of gravity of the car at that point. The velocity of the car is constant, so $\bar{a}_t = 0$; also $\bar{a}_n = v^2/r$. Hence

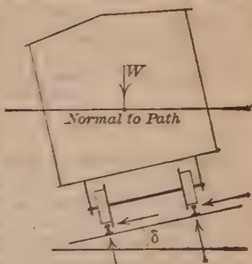

Fig. 137

$$\Sigma F_t = P_1 - P_2 - R_1 = (W/g)\,\bar{a}_t = 0$$
$$\Sigma F_n = R_2 \cos\delta + R_3 \sin\delta = (W/g)\,\bar{a}_n = (W/g)\,v^2/r$$
$$\Sigma F_b = R_3 \cos\delta - R_2 \sin\delta - W = 0.$$

The first equation shows that $P_1 - P_2 = R_1$, and the second and third solved simultaneously give $R_2 = (W/g)(v^2/r)\cos\delta - W\sin\delta$ and $R_3 = (W/g)(v^2/r)\sin\delta + W\cos\delta$. To make $R_2 = 0$, $(W/g)(v^2/r)\cos\delta = W\sin\delta$ or $\tan\delta = v^2/gr$. This value of tilt of track will not necessarily make each component rail pressure parallel to ties zero, but the resultant of all such components will be zero.

32. Rotation

Rotation of a Body is motion such that one straight line in the body or in its extension remains fixed. This line is the axis of the rotation, and all points of the body not on the line describe circles whose centers are on the line. All lines of the body perpendicular to the axis describe equal angles in equal times; angle described by the body means the angle described by any of the lines just mentioned. The angular velocity of the body at any instant is the rate at which it is describing angle then; the symbol is ω. In uniform rotation (equal angles described in all equal intervals of time) the rate is constant and $\omega = \Delta\theta/\Delta t$, $\Delta\theta$ denoting the angle described in the interval Δt. In non-uniform rotation, the rate varies and $\Delta\theta/\Delta t$ is the average angular velocity for the interval; the actual value of ω at any instant is the value of $d\theta/dt$ for that instant. The angular acceleration of a rotating body is the rate at which its angular velocity is changing; the symbol is α. If the ω changes uniformly the rate is constant and $\alpha = \Delta\omega/\Delta t$, $\Delta\omega$ denoting the velocity-change in the interval Δt. If ω does not change uniformly, then the rate varies, and $\Delta\omega/\Delta t$ is the average angular acceleration for the interval Δt; the actual value of α at any instant is the value of $d\omega/dt$ at that instant. The general differential equations of rotation are $\omega = d\theta/dt$, $\alpha = d\omega/dt = d^2\theta/dt^2$, $\omega d\omega = \alpha d\theta$; their integrated forms are

$$\theta_2 - \theta_1 = \int_{t_1}^{t_2} \omega \, dt \qquad \omega_2 - \omega_1 = \int_{t_1}^{t_2} \alpha \, dt \qquad \omega_2^2 - \omega_1^2 = 2\int_{\theta_1}^{\theta_2} \alpha \, d\theta$$

in which θ_1, ω_1, and t_1 are corresponding or simultaneous values of θ, ω, and t, likewise θ_2, ω_2, and t_2. If the agnular velocity is constant, the angular displacement in the interval $t_2 - t_1$ is $\theta_2 - \theta_1 = \omega\,(t_2 - t_1)$; if the angular acceleration is constant the velocity-change $\omega_2 - \omega_1 = \alpha\,(t_2 - t_1)$, the change in the velocity square, $\omega_2^2 - \omega_1^2 = 2\,\alpha\,(\theta_2 - \theta_1)$, and $\theta_2 - \theta_1 = 1/2\,(\omega_1 + \omega_2)(t_2 - t_1)$. The relations between θ, ω, and t can be represented by curves exactly analogous to the curves described on page 118. The corresponding variables are θ and s, ω and v, and α and a.

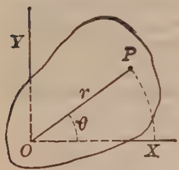

Fig. 138

Let the irregular line in Fig. 138 represent a body rotating about a line through O perpendicular to the paper, OP a line of the body, and OX and OY fixed axes of reference; also θ = angle XOP, $r = OP$, v and a velocity and acceleration respectively of P, a_t and a_n the components of a perpendicular and parallel to OP, and ω and α the angular velocity and acceleration of the body. If the radian is used in θ, ω, and α, then

$$v = r\omega, \quad a_t = ra, \quad a_n = r\omega^3, \quad a = r\,(\alpha^2 + \omega^4)1/2$$

any units of time and length may be used. If n = the angular velocity in revolutions per unit time, $\omega = 2\,\pi n$, and this value may be substituted for ω in the foregoing. If the rotation is uniform $\alpha = 0$, and $a = r\omega^2 = v^2/r = 4\,r\,\pi^2 n^2$.

Relation between Forces and Motion. The angular acceleration of a rotating body depends only on the moments of all the external forces acting on the body about the axis of rotation and on the moment of inertia of the body about the same axis. If ΣM = the algebraic sum of moments of the forces, I the moment of inertia, m the mass of the body, W its weight, and k its radius of gyration with respect to the axis of rotation, then

$$\Sigma M = I\alpha = mk^2\alpha = (W/g)\,k^2\,\alpha$$

Let ω_1 and ω_2 = the angular velocities of a rotating body at time t_1 and a later time t_2; then according to the principle of angular impulse and momentum $\Sigma \int_{t_1}^{t_2} M\,dt = I\omega_2 - I\omega_1$. The left-hand member is the algebraic sum of the angular impulses, about the axis of rotation, of all the external forces for the time $t_2 - t_1$. If the moments of all the forces are constant during the time, the left-hand member becomes $\Sigma M\,(t_2 - t_1)$. According to the principle of work and energy $\Sigma \int_{s_1}^{s_2} F_t ds = 1/2\,I\omega_2^2 - 1/2\,I\omega_1^2$. The left-hand member is the algebraic sum of the works done on the body by all the external forces for the interval $t_2 - t_1$.

Centrifugal Force. Suppose that P is a particle of a body rotating with angular velocity ω, and let dm = mass of P, r = radius of the circle described by P. The resultant of all the forces acting on P may be resolved into two components, one along the radius r and one along the tangent to the path of P; the radial or normal component $= dmr\omega^2$ and acts from P toward the axis of rotation; the tangential component $= dmr\alpha$. The normal component is called the centripetal force on P; it (and the other component also) is exerted on P by other things (neighboring particles, usually). P reacts on the other things with a force whose radial and tangential components equal the two above but in the opposite directions. The normal component, $dmr\omega^2$ outward, is called the centrifugal force of P; the resultant of the centrifugal forces of all the particles is the centrifugal force of the body; in general the resultant of the centrifugal forces of all the particles is not a single force, but in certain common cases there is a single force resultant. Thus if m = mass of the body ($= W/g$), $\bar{r}$ the radius of the circle described by the center of gravity G (Fig. 139), n = revolutions per unit time ($\omega = 2\pi n$), and the body is homogeneous, then (a) when the body is symmetrical about a plane perpendicular to the axis of rotation, the centrifugal force $= m\bar{r}\omega^2$ and acts in the line OG; (b) when the body is symmetrical about a line parallel to the axis of rotation, the centrifugal force $= m\bar{r}\omega^2$ and it acts in the line OG; (c) when the body is symmetrical about a plane containing the axis of rotation, the centrifugal force $= m\bar{r}\omega^2$, acts in the plane of symmetry, is parallel to OG at a distance from any XY plane equal to $\left(\int dmxz\right) \div m\bar{r}$. If ω is in radians per second, n in revolutions per minute, $\bar{r}$ in feet, W (weight of body) in pounds, $\bar{v}$ (velocity of center of gravity) in feet per second, then centrifugal force in pounds is

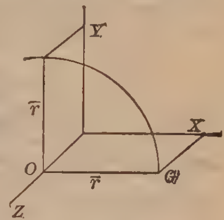

Fig. 139

$$\frac{W}{g}\bar{r}\omega^2 = \frac{W}{g}\frac{\bar{v}^2}{r} = \frac{W\bar{r}\,4\pi^2 n^2}{g\,3600} = \frac{W\bar{r}n^2}{2937} = 0.000341\,W\bar{r}n^2.$$

When a body is rotating with constant angular velocity, then the resultant of all the actual external forces acting on the body (weight, reactions of axle bearings, belt pulls, etc.) is equal and opposite to the resultant centrifugal force of the body. For example, in Fig. 140 PC is a rod supported by a pivot at P and by a cord AB so that the rod can be rotated about AP. During rotation it is under the action of the pivot pressure represented by components P', P'', and P''' (not shown), the pull of the cord T, the weight of the rod W, air resistance, and the driving force F (not shown). When the speed is constant, then the resultant of all these is as described under (c) above. If air resistance and pivot friction are negligible, no driving force is required to maintain speed, and $P''' = 0$; T, P', and P'' can be determined as follows (supposing $PC = 6$ ft., $PB = 5$ ft., $PG = 3$ ft., $ABP = 90°$, $APB = 30°$, $W = 100$ lb., and $n = 60$ rev. per min.): Since the resultant of T, P', P'', and W is horizontal, the sum of their vertical components $= 0$, or $T \sin 30 + P'' - 100 = 0$; the sum of their horizontal components $= m\bar{r}\omega^2$, or $T\cos 30° + P' = (100/32.2)1.5(2\pi\, 60/60)^2 = 184$; the resultant acts at a point Q whose distance above PX equals $\int dmxz \div m\bar{r} = 3.46$ ft., and $PQ = 4$ ft.; the moment sum of all the forces about $Q = 0$, or $- T \times 1 - 100 \times 1/2 + P' \times 3.46 + P'' \times 2 = 0$. The three equations solved simultaneously give $T = 157.5$, $P' = 47.5$, and $P'' = 22.5$ lb.

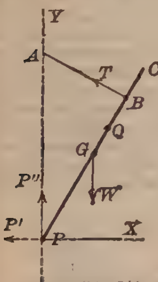

Fig. 140

33. Balancing

The reacting forces which support a rotating body depend in general not merely on the weight of the body and applied forces but also on the speed, the mass, and shape of the body; moreover, the components of the supporting forces which depend on the speed, mass, and shape change direction continually. Thus in the preceding illustration, when the rod is not rotating $T = 30$ lb., $P' = 26$ lb., and $P'' = 85$ lb., values quite different from those for motion. Or, consider a body weighing 100 lb. mounted on a shaft supported in bearings equally distant from the body and the center of gravity 2 in. from the axis of the shaft. When the system is at rest, the bearing pressures (due to the body) = 50 lb. each and act vertically, but when the system rotates at constant speed the bearing pressures have additional components each equal to 1/2 (100/32.2)(1/6) $4\pi^2 n^2$, n being the speed in revolutions per second. These components are said to be due to centrifugal action or centrifugal force, and will be called centrifugal components. If the center of gravity of the rotating system is in the axis of rotation, the system is said to have standing balance; such a system with shaft horizontal would not turn of itself from any position into which it might be placed (see Fig. 141). If the centrifugal force of the rotating system is zero, then the system is said to have or be in running balance. Standing balance is a necessary condition for running balance but not a sufficient one; thus in Fig. 141 there is standing but obviously not running balance. In fact the centrifugal forces of the two bodies are equal, (100/32.2) (1/6) $4\pi^2 n^2$ and (200/32.2) (1/12) $4\pi^2 n^2$ or $20.4\,n^2$, and opposite but not colinear and so they constitute a couple. The centrifugal components of the reactions of the bearings are therefore each $20.4\,n^2 \times 4 \div 9 = 9.07\,n^2$, and directed as shown, P and Q. If these bearings were not firmly supported, then the rotating system would wobble.

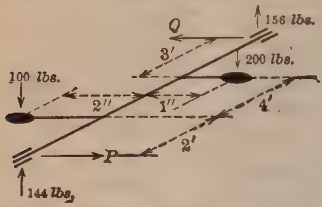

Fig. 141

Balancing a system out of running balance requires the rearrangement of the rotating material or the addition or removal of material. Car wheel-pairs are balanced experimentally by running them in spring-supported bearings and adding material here and there to the wheels, by trial, until steady running is secured. An unbalanced system can always be balanced by the addition of two bodies rotating about any two arbitrarily selected points on the axis of rotation; moreover the weights of these bodies and their exact positions relative to the rotating system can be computed provided the centrifugal force of the unbalanced system is known or if the unbalanced system can be divided up into parts the centrifugal forces of which are known. Thus suppose that it is desired to balance the body of weight W (Fig. 142 or 143), out of center a distance r (center of gravity to axis of shaft = r) by means of two bodies rotating about A and B.

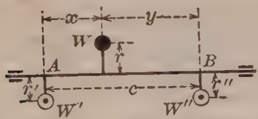

Fig. 142

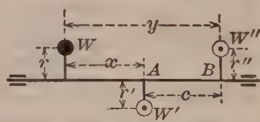

Fig. 143

In order that there may be running balance: (1) the centers of gravity of the three bodies and the axis of the shaft must be in a plane, and (2) the sun of moments of the centrifugal forces of the three bodies must be zero about any point in the plane. Condition (2) requires that the middle one of the three bodies, counting along the shaft, shall be alone on one side of the shaft, and further, that

$$W'r' = Wry/c \qquad \text{and} \qquad W''r'' = Wrx/c$$

where W' and W'' are the weights of the balancing bodies rotating about A and B respectively and r' and r'' are their distances out of center. Any unit of weight and of distance may be used in these formulas.

For example, consider the balancing of the cranks and crank pins on a pair of locomotive drive wheels. In Fig. 144 the cranks are set 90° apart, the planes of rotation of their centers of gravity are 62 in. apart, and the planes of rotation of the centers of gravity of the pins are 72 in. apart; for each crank pin $W = 25$ lb. and $r = 12$ in.; for the unbalanced part of each crank $W = 30$ lb. and $r = 5$ in.

The counter (or balancing) weights are to rotate about A and B with radii $= r$ inches say. To balance P_1 requires a_1 and b_1 (see figure), such that for a_1, $Wr = (25 \times 12)\ 66/60 = 330$, and for b_1, $Wr = (25 \times 12)\ 6/60 = 30$ in-lb.; similarly to balance P_4 requires a_4 and b_4, and for a_4, $Wr = 30$ and for b_4, $Wr = 330$ in-lb. To balance P_2 requires a_2 and b_2 and so that for a_2, $Wr = (30 \times 5)\ 61/60 = 152.5$ in-lb and for b_2, $Wr = (30 \times 5)\ 1/60 = 2.5$ in-lb.; similarly to balance P_3 requires a_3 and b_3, and for a_3, $Wr = 2.5$ and for b_3, $Wr = 152.5$ in-lb. These eight bodies a_1, b_1, a_2, b_2, etc., would balance the cranks and pins; it remains to find two substitutes for the weight. Now a_1 and a_2 can be combined, giving $Wr = 330 + 152.5 = 482.5$; a_3 and a_4, giving $2.5 + 30 = 32.5$; b_1 and b_2, giving 32.5; and b_3 and b_4, giving 482.5 in-lb. The centrifugal forces of a' and a'' (whose $Wr = 482.5$ and 32.5) have a simple resultant, and a single body whose centrifugal force is identical with that resultant can be found thus: treat 482.5 and 32.5 as though they were forces acting from A to a' and A to a'' and find their resultant; it is 484 in-lb. directed along Aa, the angle $a'Aa$ being nearly 4°; then any body the radius to whose center of gravity lies along Aa and whose $Wr = 484$ in-lb. will serve as one counterweight. In a similar manner the other counterweight may be determined; its $Wr = 484$ and its radius lies along Bb. (It should be noted that the effects of coupling and connecting rod are not considered.)

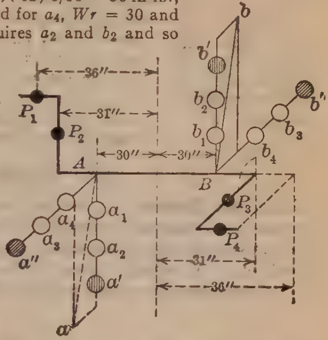

Fig. 144

34. Pendulums

The Compound or Physical Pendulum is a body suspended on a horizontal axis so it can oscillate freely under the influence of gravity. Let G (Fig. 145) be the center of gravity of the pendulum, O the center of suspension, $a = OG$, and $k =$ the radius of gyration of the pendulum with respect to its axis of suspension, and $T =$ the time of one oscillation (from one extreme position of the pendulum to the opposite extreme position); then if the oscillation is small, $T = \pi\sqrt{k^2/ag}$. If $\alpha =$ the maximum angle which OG makes with the vertical, that is, if 2α is the complete angle described by the pendulum in one oscillation, then more correctly,

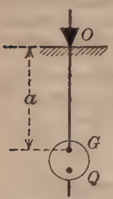

Fig. 145

$$T = \pi\sqrt{\frac{k^2}{ag}}\left[1 + (1/2)^2 \sin^2\frac{\alpha}{2} + (1/2\cdot 3/4)^2 \sin^4\frac{\alpha}{2} + \cdots\right]$$

If $\alpha = 8°$, the bracket is only 1.00122 and nearer unity for smaller values of α. T for a given pendulum is hence practically independent of α, if α is small; that is, for small angles a pendulum is practically isochronous. The point Q in the line OG extended and $OQ = k^2/a$ is called the center of oscillation corresponding to the center of suspension O; it is also called center of percussion (Art. 37). The centers of suspension and oscillation are interchangeable, that is, the times of oscillation about axes through O and Q are equal. This property is made use of in pendulum determinations of g as follows: the pendulum is made so that it can be suspended from two points O at a known distance d apart; then the times of oscillation for the two points O are compared and by trial are made equal by shifting a weight along the stem of the pendulum; either of these points then is the center of oscillation for the other as center of suspension, and $d = k^2/a$; then $g = \pi^2 d/T^2$.

A Simple Pendulum is a very small sphere supported by a cord; its length is the distance from the center of the sphere to the point of suspension. A physical and a simple pendulum whose times of oscillation are equal are said to be equivalent. A seconds pendulum is one whose time of oscillation is one second. The length of the equivalent seconds pendulum at New York is 39.101 in.

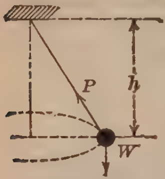

Fig. 146

The Conical Pendulum consists of a body suspended from a fixed point and so that it can rotate about a vertical axis through the point. The height of the pendulum h (Fig. 146) depends only on the angular velocity; thus for n revolutions per unit time $h = g/4\,\pi^2 n^2$. If g is taken as 32.2 ft. per sec. per sec., then n must be taken in rev. per sec.; h will be in feet. If n is less than $\sqrt{g/l} \div 2\,\pi$, the ball will not fly out or remain in any deflected position. If P = tension in the cord, l = length of pendulum, W = weight, then $P = Wl\,4\,\pi^2 n^2/g$.

35. Uniplanar Motion

Uniplanar Motion is a motion such that each point of the moving body remains at a constant distance from a fixed plane. Examples: motion of the connecting rod of a steam engine, rolling of a wheel, rotation of a fly wheel, etc. All straight lines of the body which are parallel to the plane of the motion describe equal angles during any displacement of the body, and

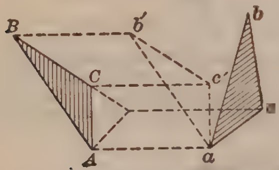

Fig. 147

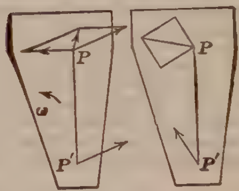

Fig. 148

by angle described by the body is meant the angle described by any of the lines mentioned. The angular velocity of the body at any instant is the rate at which it is describing angle then. The angular acceleration at any instant is the rate at which its angular velocity is changing then. Any displacement may be accomplished by a translation of the body which will bring one line of it which is perpendicular to the plane of the motion into final position followed by a rotation of the body about that line into final position. Thus the displacement of a body from ABC to abc (Fig. 147) may be accomplished by a translation from ABC to $ab'c'$ followed by a rotation about a into position abc. The amount of translation depends on the line of the body selected as axis of the rotation; the amount of the rotation does not. The actual state of (uniplanar) motion of a body at any instant may be regarded as consisting of two components, a translational and a rotational. And the velocity v of any point P of the body (Fig. 148) may be regarded as the resultant of two velocities, one the actual velocity v' of a second point P', and the other the velocity of P about (relative to) P', $r\omega$, where ω = angular velocity of the body and $r = PP'$. Likewise the acceleration a of P may be regarded as the resultant of the actual acceleration a' of P' and the acceleration of P about (relative to) P'.

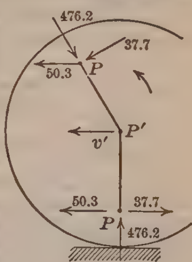

Fig. 149

For example, when a wheel 8 ft. in diameter rolls uniformly at 2 rev. per sec., or $\omega = 12.56$ radians per sec., then taking P' at the center (Fig. 149), $v' = \pi\,8 \times 2$

$= 50.3$ ft. per sec., and $a' = 0$; the velocity of a point P 3 ft. from the center relative to P' is 37.7 ft. per sec. directed as shown, and the actual velocity of P is the resultant of 50.3 and 37.7; the acceleration of P relative to P' is $3\ \omega^2 = 476.27$ ft. per sec. per sec. (see page 122) directed as shown, and since $a' = 0$, the acceleration of P is 476.2.

Uniplanar Displacement can also be accomplished by a single rotation about some line. Thus the displacement from ABC to abc (Fig. 147) can be made by a rotation about the intersection of the perpendiculars to Aa and Bb at their centers. Any uniplanar motion may be regarded as a continual rotation about a line which in general is continually shifting its position in space and in the body or its extension. This line is called **instantaneous axis** (of rotation), and any point of it the instantaneous center. In uniplanar motion, the velocity of any point of the body at any instant equals the product of the angular velocity of the body then and the distance of the point from the instantaneous center, and the direction of the velocity is perpendicular to the line joining the point and the instantaneous center; the velocities of different points of the body are as their distances from the instantaneous axis. The instantaneous center may be determined when the directions of the velocities of any two points of the body (the line joining which is parallel to the plane of the motion) are known, provided these directions are not parallel, as follows: at each of the two points draw a line parallel to the plane of motion and perpendicular to the direction of the velocity of that point, and determine their intersection; this is the instantaneous center.

For example, consider the motion of the connecting rod of an engine. The velocity of the crank end of the rod is perpendicular to the crank and the velocity of the other end is parallel to the guides; hence for any particular position of the rod the instantaneous center is at the intersection of the crank (radius) extended and a line perpendicular to the guides at the guide end of the rod.

The relation between the external forces and the motion produced is expressed thus: take x and y axes of reference parallel to the plane of motion; then

$$\Sigma F_x = m\bar{a}_x \qquad \Sigma F_y = m\bar{a}_y \qquad \Sigma M = I\alpha = mk^2\alpha = (W/g)k^2\alpha$$

wherein ΣF_x and ΣF_y denote the sums of the x and y components of all the external forces, $\bar{a}_x$ and $\bar{a}_y$ the x and y components of the acceleration of the center of gravity, α the angular acceleration of the body, m its mass, W its weight, ΣM the algebraic sum of the moments of external forces about an axis through the center of gravity and perpendicular to the plane of motion, I the moment of inertia, and k the radius of gyration of the body with respect to the same axis. For example, consider a cylinder of radius r and weight W rolling down an inclined plane. The forces acting on the cylinder are its weight W and the reaction of the plane regarded as replaced by its two components N and F (Fig. 150); taking the x axis along the plane and the y normal to it, the three formulas become $(W \sin\phi - F) = (W/g)\bar{a}$, $N - W\cos\phi = 0$, and $Fr = 1/2(W/g)r^2\alpha$, $1/2(W/g)r^2$ being the moment of inertia of the cylinder with respect to its axis. (It is assumed that there is no indentation of the roadway, that is, no rolling resistance.) If there is no slipping, then $\bar{a} = r\alpha$, which equation combined with the first and third above gives $\bar{a} = 2/3\ g \sin\phi$, $\alpha = 2/3\ (g/r) \sin\phi$, and $F = 1/3W \sin\phi$; also $N = W\cos\phi$.

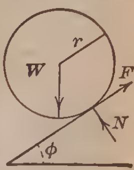

Fig. 150

The Kinetic Energy of translation and rotation combined is $1/2\ m\bar{v}^2 + 1/2\ \bar{I}\omega^2$, where m denotes the mass of the body, $\bar{v}$ the velocity of its center of gravity, $\bar{I}$ its moment of inertia with respect to a line through the center of gravity and perpendicular to the plane of motion, and ω its angular velocity. The first term is sometimes called the translational and the second the rotational part of the kinetic energy. It is also given by $1/2\ I\omega^2$, where I denotes the moment of inertia of the body with respect to its instantaneous axis (at the instant for which the energy is to be figured) and ω is the angular velocity.

For example, take a cylinder of radius r and weight W rolling at n revolutions per unit time: $m = W/g$, $v = 2\pi rn$, $\bar{I} = 1/2(W/g)r^2$ (see page 110), and $\omega = 2\pi n$; hence the kinetic energy $= 3(W/g)\,\pi^2 r^2 n^2$, one-third of which is rotational. Also $I = \bar{I} + (W/g)r^2 = 3/2(W/g)r^2$; hence according to the second formula the kinetic energy is $1/2(3W/2\,g)\,r^2\,4\,\pi^2 n^2 = 3\,(W/g)\,\phi^2 r^2 n^2$ as before.

36. Three-dimensional Motion

Any motion of a body may be regarded as consisting of two components: one, a translation equal to that of the center of gravity and the other a rotation about some axis through the center of gravity. These motions may be said to be produced independently by the forces acting on the body; thus (a) the acceleration of the center of gravity is the same as if the whole mass were concentrated at the center of gravity and acted upon by forces equal in magnitude to and same in direction as the actual external forces; and (b) the angular acceleration is the same as if the center of gravity were fixed and the actual external forces applied. The reasonableness of this will be seen from the following: imagine each force acting on the body replaced by a force acting at the center of gravity G and a couple; the resultant of all the forces acting at G is a single force R, and the resultant of all the couples is a single couple C; R cannot turn the body but gives it a motion of translation only, and C cannot move G but merely turns the body about some line through G. In general C does not cause turning about a line perpendicular to the plane of C, only so if the plane of C is perpendicular to one of the principal central axes of the body (see page 123). To determine the acceleration of the center of gravity, take fixed x, y, and z axes outside the body and resolve all external forces F_1, F_2, etc., into x, y, and z components; then

$$\Sigma F_x = m\bar{a}_x \qquad \Sigma F_y = m\bar{a}_y \qquad \Sigma F_z = m\bar{a}_z$$

m denoting the mass of the body. To determine the angular acceleration of the body, take moments of all the forces F_1, F_2, etc., about the three central principal axes; calling the sums of the moments about these axes ΣM_1, ΣM_2, and ΣM_3, the components of the angular acceleration α_1, α_2, and α_3, the components of the angular velocity ω_1, ω_2, and ω_3, then

$$\Sigma M_1 = I_1\alpha_1 + (I_3 - I_2)\,\omega_2\omega_3, \qquad \Sigma M_2 = I_2\alpha_2 + (I_1 - I_3)\,\omega_3\,\omega_1,$$
$$\Sigma M_3 = I_3\alpha_3 + (I_2 - I_1)\,\omega_1\,\omega_2$$

wherein I_1, I_2, and I_3 denote the three central principal moments of inertia of the body. In any motion of a body, the kinetic energy may be computed in two parts: (1) the kinetic energy of the whole body moving with a velocity equal to that of the center of gravity, and (2) the sum of the kinetic energies of the constituent particles of the bodies due to their velocities relative to the center of gravity.

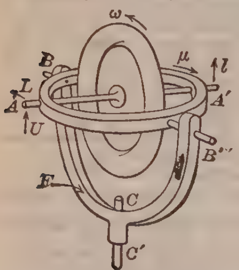

Fig. 151

Gyrostat (Fig. 151). The wheel ω and axle can rotate about AA', the supporting ring $ABA'B'$ can rotate about BB' and the supporting frame F can rotate about CC'. If the disk or wheel is spinning rapidly in the direction indicated by ω and an upward force U is applied at A, the axle AA' will not rotate about BB' but about CC' in the direction indicated by the arrowhead u; a downward force causes rotation in the opposite direction. A horizontal force L to the left would cause the axle AA' to rotate not about CC' but about BB' in the direction indicated by the arrow l; a force to the right would cause rotation in the opposite direction. These rotations of the axle of spin are called precessional motions, the wheel being said to precess. The precession of the axle of spin, AA', tends to convert the existing spin of the wheel into a spin about the axis of the applied moment and in the direction required by that moment.

A Mono-rail Car, as its name implies, runs on a single rail; and the Brennan car is wholly above the rail. Stability of this car is furnished by two gyrostats mounted in the car as shown in plan and elevation (Fig. 152). W is one of the gyrostat wheels (W' the other); it is mounted rigidly on the axle A, the bearings of which are on the frame or case C. (These cases wholly enclose the gyrostat wheels, and a vacuum is maintained in the cases to reduce the windage of the wheels; the wheels are driven electrically—indeed the wheels are motor armatures—in opposite directions.) The case C has trunnions T and T supported in bearings on the double frame F, which also supports the other gyrostat case C'. The double frame F is supported on an axle X parallel to the rail, on which the whole gyrostat system can turn. To the two upper trunnions T and T' are keyed two spur-toothed segments which mesh at G; thus the cases C and C' can rotate on their trunnions only together, in opposite directions, and equal amounts. R and R' are wheels or rollers which turn on bearings fixed to the cases C and C'. Rigidly fastened to the car are four shelves M, M', N, and N'; as shown in the plan these do not extend beyond the line OO'. When for any reason the axles A and A' are at OP and $O'P'$ say, or OQ and $O'Q'$, and the car is tipping either way relative to the gyrostat system, then one shelf, and only one, will come up against an axle end or roller; for instance when the axles are at OP and $O'P'$ and the car tips clockwise, then the shelf M comes up against the axle A.

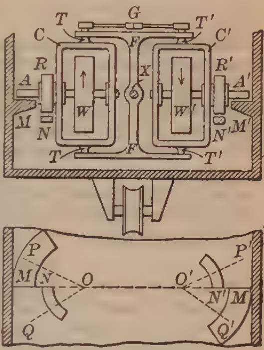

Fig. 152. (After Perry)

When the car is running straight, erect, and balanced, the axles A and A' are in line, across the car, and this is the normal position of the gyrostats. Now suppose a disturbance, as a wind pressure on the left side, tips the car clockwise; the shelf M comes up against the axle A and causes precession of A away from the reader, which continues as long as there is contact at A. The rapidly rotating axle slips on the shelf M and is itself subjected to a friction which tends to hurry the precession, the effect of which is to increase the pressure on the shelf. This pressure down arrests the tipping and pushes the car back against the wind to the neutral position, in which the wind and gravity moments are balanced. This neutral position is reached with a certain momentum, and the car is carried past it, the shelf M recedes from A with the axles of the gyrostats in positions as OP and $O'P'$, and eventually the shelf N' comes up under the roller R'. The upward pressure on the roller causes precession of A' toward the reader, which continues as long as there is contact at the shelf N'. The friction of the roller on its axle tends to retard this precession, and the correcting pressure of the roller on the shelf N' is not so great as that of the axle A on M (in similar circumstances), and the gyrostats are returned to the normal position with the car still tilted to the left of the neutral position. But the gyrostats reach the normal position with velocity and swing beyond it; the roller R' runs off the end of the shelf N' and the axle A' comes into contact with the shelf M'. The pressure of M' on A' causes precession of A' toward the reader, the friction on A' tends to hurry the precession, and A' reacts strongly on the shelf M', bringing it to its neutral position and beyond. Eventually M' recedes from A', the shelf N coming up against the roller R, with the gyrostats in the positions OQ and $O'P'$. The shelf N, like N', brings the gyrostats into normal position and then shelf M into play; and so the operations described are repeated. But the oscillations of the car and the swings of the gyrostats rapidly decay, and the car settles down into its neutral position quickly. Geared together and spinning in opposite directions, the two gyrostats work together in the above described actions. A single gyrostat might furnish the stability on a straight track, but two gyrostats are essential for running on curves. In Oct., 1909, Mr. Brennan operated a mono-rail car 40 ft. long, weighing 22 tons, and designed to carry a load of 10 to 15 tons; it is furnished with an 80 and a

20-hp. petrol-electric set for running the car and the gyrostats; each gyrostat weighs about 3/4 ton, is 3 ft. 6 in. in diameter, and is run at 3000 r.p.m.; the vacuum of the gyrostat cases is equivalent to about 1/2 to 5/8 in. of mercury. The car was run on a curve of 105-ft. radius at 7 mi. per hr., and over reverse curves of 35-ft. radius without "appreciable disturbance" of the level of the car floor.

37. Impact

Direct Central Impact is such that before collision the centers of gravity of the bodies move along the same straight line. Central impact is collision during which the forces which the bodies exert on each other are directed along the line joining the centers of gravity. In any collision, the forces which the two bodies exert on each other are equal and opposite at each instant; hence the total impulses of these forces during the collision are equal and opposite, and according to the principle of impulse and momentum the changes in the momentum of the bodies produced by the collision must be equal and opposite; or, otherwise stated, the total momentum of the two bodies is unchanged by the collision. Or, for direct central impact:

$$m_1 v_1 + m_2 v_2 = m_1 V_1 + m_2 V_2$$

wherein m_1 and m_2 = the masses of the bodies, v_1 and v_2 their velocities before and V_1 and V_2 their velocities after the collision; but in numerical substitution velocities in one direction are given the same sign and those in the other direction the opposite sign.

Experiments on direct central impact of spherical bodies have shown that the relative velocities of spheres after impact are always less than before the impact and that these relative velocities are opposite in direction. The ratio of the relative velocities after impact to that before impact is called coefficient of restitution; it seems to depend only on the material of the impinging spheres. For glass the coefficient is 15/16, for steel and cork 5/9, ivory 8/9, wood about 1/2, clay and putty 0. If e = the coefficient, then

$$(v_1 - v_2) = -e\,(V_1 - V_2)$$

This equation and the preceding one solved simultaneously show that

$$V_1 = v_1 - \frac{(1+e)\,m_2}{m_1 + m_2}(v_1 - v_2) \qquad V_2 = v_2 - \frac{(1+e)\,m_1}{m_1 + m_2}(v_2 - v_1)$$

During impact there is, in general, loss of kinetic energy; the loss is $1/2\,(v_1 - v_2)^2 (1 - e^2)\,m_1 m_2/(m_1 + m_2)$. Bodies for which $e = 0$ are said to be inelastic; and those for which e is nearly 1 are said to be nearly perfectly elastic. When a sphere is dropped on a horizontal surface of a large body from a height h, and if H = the height of rebound, then $H = e^2 h$. This equation furnishes a means of computing e.

Force of a Blow. By this is meant the actual pressure between two bodies in collision. This pressure or force varies during the collision from zero at the beginning up to a maximum value and then down to zero at the end. Curves showing how the force varies with respect to the time and with respect to the displacement of the point of contact during the collision are quite dissimilar. The average values of the force as shown by these two curves are unequal. The first is called the time-average and the second the space-average force of the blow. Let F_t and F_s denote these averages respectively and t and s the total time and displacement; then $F_t t$ = the impulse exerted on either body, and if the impact is direct and central, $F_s s$ = the work done on either body by the force of the blow. When any object is struct by a hand-hammer for example, the momentum of the hammer is changed; calling the change M, then $F_t t = M$, or $F_t = M/t$. That is, for a given change in momentum the time-average force of a blow varies inversely as the time of the impact. The energy of the hammer is also changed; calling this change E, if the energy dissipated (in vibration of the hammer) is negligible, $F_s s = E$, or $F_s = E/s$. That is. for a given change in energy the space-average force of a blow varies inversely as the space through which the force acts. (It is assumed in the preceding that no other force than that of the blow affects the momentum and the energy changes)

A pile-driver hammer of weight W falling a height h to a pile which it drives a distance s is given an amount of energy equal to $W(h + s)$ by gravity before the hammer is arrested. This energy is delivered to the pile and is wasted against resistance between earth and the pile, in vibration of the pile and adjacent earth. Calling the space-average resistance R and neglecting the energy lost in vibration, then $Rs = W(h + s)$, or $R = W(1 + h/s)$. This formula is in use for computing the bearing capacity of a pile; h being the drop of the hammer and s the penetration of the pile in the last blow (or average penetration for last few blows), W weight of hammer, and R ultimate bearing capacity, safe capacity being generally taken as 1/5 or 1/6 of R. As 1 is small compared to h/s, the formula may be written, safe load = 1/5 or 1/6 Wh/s.

Ballistic Pendulum. This is a device formerly used to measure the velocity of a projectile; it is essentially a pendulum with a massive bob into which the projectile may be fired and arrested (Fig. 153). Let v = velocity of the projectile, m its mass, M the mass of the pendulum ($= W/g$, W denoting its weight and g acceleration of gravity), k its radius of gyration with respect to the axis of suspension (for determination of which see below), a the distance from the axis to the center of gravity and r that to the path of the projectile, and θ deflection of pendulum caused by projectile; then

$$v = \sqrt{2\,ga\,(1 - \cos\theta)}\,(m + Mk^2/r^2) \div (mk/r)$$

If the weight of the bob is large compared to that of the suspending rod, then $k/r = 1$ nearly. If a pendulum in its vertical position is struck a horizontal blow through the center of gravity and perpendicular to the axis of suspension, the whole pendulum tends to move in the direction of the blow. But such translation is prevented by the support which exerts a sudden reaction opposite to the blow. If the pendulum is struck below the center of gravity the blow tends to produce a translation in its direction and a rotation about the center of gravity. There would still be a sudden reaction of the support on the pendulum to overcome the tendency to the motion there unless the translation and the rotational velocities of the center of suspension, which the blow tends to produce, are equal. That point of impact for which the blow produces no sudden reaction at the center of suspension is called **center of percussion**; it coincides with the center of oscillation (see page 125). Its distance from the center of suspension $= k^2/a$.

Fig. 153

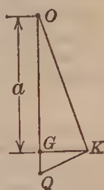

Fig. 154

The distance k^2/a can be determined experimentally thus: let the pendulum oscillate and ascertain the time T of one swing, extreme to extreme position; then $k^2/a = gT^2/\pi^2$; if g is taken in feet per second per second and T in seconds, then k^2/a is in feet. Let k_G be the radius of gyration of the pendulum with respect to a line through its center of gravity and parallel to the axis of suspension. When k_G is known the center of percussion Q (Fig. 154) can be located graphically thus: at G draw GK perpendicular to OG and make $OG = k_G$; join O and K and draw a perpendicular to OK at K; Q is the intersection of this perpendicular and OG extended.

The Moment of Inertia I of an irregular or nonhomogeneous body with respect to a specified line can be determined best experimentally; thus proceed as described above to determine k^2/a, then $I = (W/g)k^2 = WT^2/a\pi^2$. If the specified line passes through the center of gravity of the body then, since the body would not oscillate about such line, proceed thus: determine I about any parallel line distant a from the center of gravity, then the desired moment of inertia $= I - (W/g)a^2$. If it is impossible or inconvenient to suspend the body at the specified line, then suspend and oscillate it about any line parallel to the specified line, and determine I as explained about such parallel line; calling the distances of the parallel and specified lines from the center of gravity a and b respectively, then the desired moment of inertia $= I - (W/g)a^2 + (W/g)b^2 = I - (a^2 - b^2)W/g$.

FRICTION

38. Static Friction

Static Friction, or **Friction of Rest** is the friction between two bodies when there is a tendency to, but not actual, slipping of one relative to the other. Let P (Fig. 155) = a pull applied to a body A which is supported by a body B, R = the reaction of B on A; then the component F of R along the surface of contact is the friction, and the component N perpendicular to the surface is the normal pressure. So long as there is no slipping $F = P$, but the greatest value of F obtains when slipping impends; this value of F is called limiting friction. The coefficient of static friction for two bodies is the ratio of their limiting friction to the accompanying normal pressure; it is denoted by f. The angle between R and N changes as F changes, and its greatest value obtains when motion impends; this value is called the angle of friction for the two bodies, and it will be denoted by ϕ. When a body A is supported on an inclined plane B, and no forces act on A except its own weight and the supporting force, then that inclination of the plane to the horizontal which will just cause slipping of A is called the angle of repose for A and B; it also will be denoted by ϕ because the angles of repose and friction for two bodies are equal. Also the tangents of these angles equal the coefficient of friction,

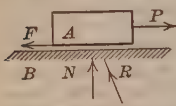

Fig. 155

$$F \leqq fN \qquad \therefore f = \tan\phi$$

Suppose the body A (Fig. 156) is supported by a body B, let Q denote the resultant of all the forces acting on A excepting the supporting force; and suppose that the line of action of Q cuts the surface of contact at a; then the cone with vertex at a, axis normal to the contact surface and apex angle equal to double the angle of friction, is called a cone of friction for the bodies A and B. If Q falls within the cone, motion will not ensue for any value of Q, but if without, then Q will move A.

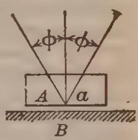

Fig. 156

The coefficient of static friction for two bodies A and B may be determined thus: (1) Place A on B as in Fig. 155 and determine the pull P which will just start A; then $f = P$ divided by the weight of A. Or (2) tilt B and determine the inclination at which gravity will start A down; then f = the tangent angle of that of inclination. In either method, several determinations must be made to obtain a fair average value of the coefficient.

Coefficients of Static Friction depend on the nature of the materials, character of rubbing surfaces, and kind of lubricant, if any is used. Early experimenters reported (Coulomb 1871, Rennie 1828, Morin 1834, and others) that the coefficient is independent of the intensity of normal pressure; although this announcement was clearly subject to the limitation of the range of the experiments performed, yet it was generalized and long accepted as a universal law of friction. But the universality of the law has been questioned; Morin himself pointed out that length of the time of contact of the two bodies influences the coefficient and obviously the coefficient changes when the intensities of pressure get so high as to affect the character of the surfaces in contact. Messiter and Hanson report practical constancy of coefficiency for yellow pine and spruce (Eng. News, 1895, vol. 33, p. 322), the first for a range from 100 to 1500 lb. per sq. in. and the second for a range from 100 to 800. They report for planed or sandpapered yellow pine: $f = 0.25$–0.32; average 0.29, for 100 to 1000 lb. per sq. in.; for spruce: $f = 0.18$–0.53; average 0.42, for 100 to 600 lb. per sq. in. The variation depends on relation of grain of wood to direction of slide.

Coefficients of Static Friction

Metals on metals	0.25 to 0.15	Earth on earth, shingle and gravel	0.81 to 1.11

Coil Friction. When a rope wholly or partially encircles a pulley or drum (Fig. 157) the tensions P_1 and P_2 may be quite different on account of the friction on the rope. The difference is greatest when slipping impends; if α = arc of contact in radians, ϵ = Napierian base = 2.718, the maximum ratio $P_2/P_1 = \epsilon^{f\alpha}$.

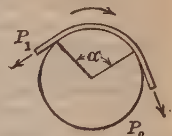

Fig. 157

Maximum Ratio P_2/P_1 (Slipping Impending)

$\alpha/2\pi$	f = 1/4	f = 1/3	f = 1/2	$\alpha/2\pi$	f = 1/4	f = 1/3	f = 1/2
0.1	1.17	1.23	1.37	0.7	3.00	4.33	9.00
0.2	1.37	1.51	1.87	0.8	3.51	5.34	12.34
0.3	1.60	1.87	2.57	0.9	4.11	6.58	16.90
0.4	1.87	2.31	3.51	1.0	4.81	8.12	23.14
0.5	2.19	2.85	4.81	2.0	23.1	66.0	535.5
0.6	2.57	3.51	6.59	3.0	111	535	1239.0

Belting. The formula $P_2/P_1 = \epsilon^{f\alpha}$ applies here also. Single (thickness) leather belt varies from 3/16 to 7/32 in. thick; double leather (two thicknesses glued) belt varies from 3/8 to 1/2 in. thick. Cement splices are nearly as strong as the belt; lace joints average 70% as strong as the belt; metal fastenings generally less. Working strengths of 400 lb. per sq. in. for endless (cement spliced) belts and 200 to 300 for laced belts are safe, but smaller values are advised by F. M. Taylor (Trans. A. S. M. E., 1894, vol. 15, p. 204). These figures correspond to 100 lb. per inch of width for cemented single belt, 50 to 75 for laced single belt, and twice these for double belt.

The horsepower which a belt transmits is given by $(T - Z)Cv/550$, wherein T = total tension in tight side of belt in pounds, v = velocity of belt travel in feet per second, Z = a quantity depending on centrifugal action (table below), C = a quantity depending on coefficient of friction and angle of wrap on the pulley (table below). The formula is Nagle's (Trans. A. S. M. E., 1881, vol. 2, p. 91) but modified by Kimball and Barr.

For a leather belt which weighs 0.035 lb. per cu. in. when:

v (ft. per sec.) =	50	60	70	80	90	100	110	120	130	140	150
Z (lb.) =	32.5	47.0	64.2	83.4	105	130	158	188	220	256	293

Values of C in Formula hp. = (T − Z)Cv/550

39. Sliding Friction

Kinetic Friction. Friction of Motion, or sliding friction, is the friction between two bodies when sliding actually occurs. The coefficient of kinetic friction for two bodies is the ratio of the kinetic friction to the corresponding normal pressure between them. One of the so-called laws of friction states that the kinetic coefficient is less than the static coefficient and implies that there is a sudden or abrupt change in the values of the coefficients. Experiments by Jenkin and Ewing (Phil. Trans. Roy. Soc., 1877, vol. 167, Part 2) on the kinetic coefficients at speeds as low as 0.0002 ft. per sec., about 3/4 ft. per hour, lead them to conclude that "it is highly probable that the kinetic coefficient gradually increases when the velocity becomes extremely small, so as to pass without discontinuity into the static coefficient." Experiments by Kimball (Am. Jour. Sci., 1877, vol. 13, p. 353) also indicate that there is no abrupt change from static to kinetic coefficient. Moreover they show that the kinetic coefficient may be greater than the static. For dry surfaces, the kinetic coefficient probably decreases progressively from the value of the static coefficient, as the velocity increases as indicated by the following table from Galton and Westinghouse's experiments (Proc. Inst. Mech. Engrs., 1879).

Coefficients of Friction at Various Speeds for Cast-iron Brake Shoes and Steel-tired Wheels

Velocity		Coefficients			Number of tests
Mi. per hr.	Ft. per sec.	Maximum	Minimum	Mean	
0+	0+	....	....	0.330	
5−	7−	0.340	0.156	.273	20
7.5	11	.325	.123	.244	28
10	14.5	.281	.161	.242	54
15	22	.280	.131	.223	78
20	29	.240	.133	.192	69
25	36.5	.205	.108	.166	70
30	44	.196	.098	.164	94
35	51	.197	.087	.142	80
40	59	.194	.088	.140	70
45	66	.179	.083	.127	77
50	73	.153	.050	.116	55
55	81	.136	.060	.111	67
60	88	.123	.058	.074	12

The foregoing given coefficients were obtained from measurements taken very soon after application of brakes.

The rubbing of dry surfaces abrades them and decreases the kinetic coefficient. The following table shows how this coefficient changed with lapse of time after rubbing began.

Coefficient of Friction as Affected by Time of Rubbing

Cast-iron brake shows on steel-tired wheels

Miles per hour	Time after applying brakes				
	0+	5 sec.	10 sec.	15 sec.	20 sec.
20	0.182	0.152	0.133	0.116	0.099
27	.171	.130	.119	.081	.072
37	.152	.096	.083	0.69	
47	.132	.080	.070		
60	.072	.063	.058		

The discrepancies between the two tables are due in part to the fact that the values at time 0+ in the second table are averages based on comparatively few experiments. In the second table preceding there is a wide variation from the mean value of the coefficient for each velocity. The variation was due in part at least to differences in intensities of pressure in the various runs of each velocity. In general, the coefficients decrease with increase of intensity.

Coefficients of Friction for Wheels Skidded on Rails

Galton-Westinghouse Experiments

Wheels skidded on rails gave much smaller coefficients than brake shoes, as shown by the adjacent table.

Approximate velocity		Steel tire on	
Ft. per sec.	Mi. per hr.	Steel rail	Iron rail
0+	0+	0.242	0.247
10	6.8	0.88	.095
20	13.6	.072	.073
40	27.3	.070	
50	34.1	.065	.070
60	40.9	.057	
70	47.7	.040	.060
80	54.5	.038	
88	60	.027	

Kinetic Coefficients for Brake Shoes

From Experiments by Ernest Wilson (Eng. News, 1909, vol. 62, p. 736)

Materials	Pressure, Lb. per sq. in.	Vel., Mi. per hr.		Lubrication
		7	15	
Cast iron....	10	0.43	0.37	none
Cast iron....	40	.36	.30	none
Oak........	10	.60	.55	none
Oak........	40	.43	.40	none
Poplar......	10	....	.72	none
Poplar......	40	....	.53	none
Cast iron....	20	.32	.28	water
Cast iron....	80	.30	.26	water
Oak........	40	.037	.032	water
Oak........	120	.073	.055	water
Poplar......	40	.041	.038	water
Poplar......	120	.070	.053	water

The adjacent table furnishes additional information on the variation of the kinetic coefficient with the intensity of pressure and on the velocity; also on the influence of water lubrication.

Coefficients of Kinetic Friction (rough averages)

Compiled by Rankine from Experiments by Morin and others

Wood on wood, dry	0.25 to 0.50	Leather on oak	0.27 to 0.38
soapy	.2	Leather on metals, dry	.56
Metals on oak, dry	.5 to .6	wet	.36
wet	.24 to .26	greasy	.23
soapy	.2	oily	.15
Metals on elm, dry	.2 to .25	Metals on metals, dry	.15 to .2
Hemp on oak, dry	.53	wet	.3
wet	.33		

Pivots. Let W = load (lb.), μ = coefficient of kinetic friction, n = speed (r.p.m.), m = moment of the frictional resistance about the axis of the shaft (in-lb.), w = work done against friction per revolution (in-lb.), P = power lost through friction (hp.), dimensions as marked in figures (in.). Flat Pivot (Fig. 158): $m = 2/3\,\mu W r$; $w = 4/3\,\pi\mu W r = 4.187\,\mu W r$; $P = 4/3\,\pi\mu W r n/396\,000 = \mu W r n/94\,700$. Collar Bearing (Fig. 159): $m = 2/3\,\mu W\,(R^3 - r^3)/(R^2 - r^2)$; $w = 2\,\pi m$; $P = 2\,\pi m n/396\,000 = mn/63\,000$.

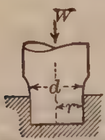

Fig. 158

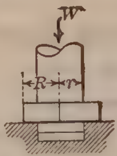

Fig. 159

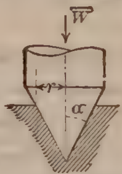

Fig. 160

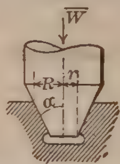

Fig. 161

Conical Pivot (Fig. 160): $m = 2/3\,\mu W r/\sin\alpha$; $w = 4/3\,\pi\mu W r/\sin\alpha$; $P = 4/3\,\pi\mu W r n/396\,000 \sin\alpha = \mu W r n/94\,700 \sin\alpha$. Frustrated Conical Pivot (Fig. 161): $m = 2/3\,\mu W\,(R^3 - r^3)/R^2 - r^2)\sin\alpha$; $w = 2\,\pi m$; $P = 2\,\pi m n/396\,000 = mn/63\,000$.

Journal Friction. The coefficient of journal friction is the ratio of the frictional resistance at the journal to the pressure between journal and bearing. The pressure is not uniformly distributed over the surface of contact between journal and bearing. By nominal (intensity) of pressure is meant the whole pressure divided by product of length and diameter of bearing.

For example, suppose a fly wheel and shaft weighing 6000 lb. are supported midway between two bearings, the diameter of the wheel is 8 ft. (or 96 in.), that of the journal is 6 in., and that a force of 10 lb. applied to the rim is necessary to overcome friction to maintain a constant speed. Then the frictional resistance is $(10 \times 48) \div 3 = 160$ lb., 80 at each journal; the pressure at each journal is 3000 lb., and the coefficient of journal friction is $160 \div 3000 = 0.053$. If the length of bearing is 10 in., the nominal (intensity) of pressure is $3000 \div (6 \times 10) = 50$ lb. per sq. in.

Energy Lost at Journals, Work Done Against Friction. Let W = total load on bearing (lb.), d = diameter of journal (in.), f = coefficient of journal friction, n = number of revolutions per minute; then

work done per revolution (ft-lb.) $= fW\pi d/12$
work done per minute (ft-lb.) $= fW\pi dn/12$
power lost (hp.) $= fW\pi dn/396\,000 = Wdn/126\,000$

Coefficients of Journal Friction depend on (1) the method of lubrication, (2) the lubricant, (3) its temperature, (4) the velocity of rubbing, and (5) the intensity of pressure (lb. per sq. in.) on the bearing.

(1) The relative intensities of friction for different methods of lubrication are as follows according to Tower (Proc. Inst. Mech. Engs.) and Goodmann (Mechanics Applied to Engineering):

Method	Tower	Goodman
Bath.	1.00	1.00
Saturated pad.	....	1.32
Ordinary pad.	6.48	2.21
Siphon.	7.06	4.20

Tower found that in bath lubrication the load is completely oil-borne, in other words that a continuous film separates journal and bearing. For any given pressure there seems to be a minimum velocity below which the oil film will not form. H. F. Moore also found (Am. Mach., 1903) that this pressure velocity relation is approximately $p = 7.47\sqrt{v}$, p being in lb. per sq. in. and v in ft. per min. Moore used mineral oil at 90° temperature. The friction then is wholly fluid friction and not solid. (2) In the following table the figures are based on mean actual frictional resistances at the surface of the journal at speed of 300 r.p.m. with all nominal loads from 100 to 310 lb. per sq. in.; the temperature was 90°; the journal was steel, 4 in. in diameter and 6 in. long; the bearing a gun-metal brass embracing somewhat less than half the circumference of the journal. The relative frictional resistances for various lubricants, according to Tower, are 1.00 for sperm oil, 1.06 for rape oil, 1.29 for mineral oil, 1.35 for lard oil and olive oil, 2.17 for mineral grease. Tower states also: "The numbers represent the relative thickness or body of the various oils, and also in their order, although perhaps not exactly in their numerical proportions, their relative weight-carrying power. Thus sperm oil, which has the highest lubricating power, has the least weight-carrying power; and, though the best oil for light loads, would be inferior to the thicker oils if heavy pressures or high temperatures were to be encountered." (3) The coefficient decreases

Coefficient of friction

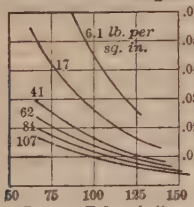

Fig. 162

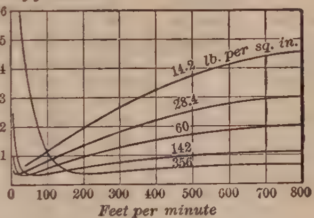

Fig. 163

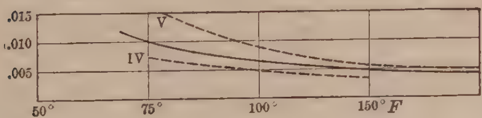

Fig. 164

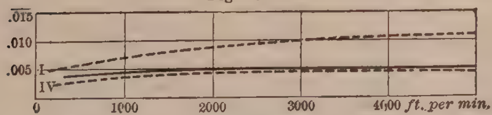

Fig. 165

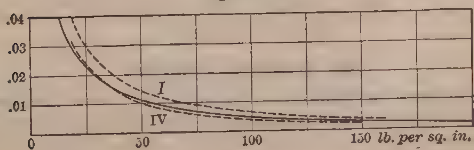

Fig. 166

with increased temperature (see Figs. 162 and 164). But if the temperature gets so high as greatly to lower the viscosity, the lubricant gets squeezed out and then the coefficient increases. (4) In general the coefficient increases with increase of speed (see Figs. 163 and 165 and accompanying explanations). But at the lower speeds the coefficient may decrease with increase of speed (see Fig. 163). (5) The coefficient decreases with increase of intensity of pressure (see Figs. 163 and 166). But the intensity may become so great that the lubricant gets squeezed out and then the coefficient increases and seizing occurs.

Figs. 162 and 163 show the relation between coefficient and temperature, and coefficient and velocity. Sellers bearing, length 13 in. and diameter 2.75 in.; ring oiler; "gas motor oil"; oil temperature 77°; velocity 846 ft. per min. (Stribeck, Zeit. Ver. Deutsch. Ing., vol. 46, p. 1341.) Figs. 164, 165, and 166 show respectively relations between coefficient and temperature, velocity, and pressure. In 164, p = 92.5 lb. per sq. in. and v = 197 ft. per min.; in 165, p = 92.5 lb. per sq. in. and t = 112°; in 166, t = 112°; and v = 197 ft. per min. The heavy line represents an average law for forced lubrication on five different journals as described below, and the other curves relate to the two journals which departed most widely from the average. (Lasche, Zeit. Ver. Deutsch. Ing., vol. 46.)

Number	Journal	Bearing	Number	Journal	Bearing
I	steel	white metal	IV	nickel steel	bronze
II	nickel steel	white metal	V	ingot iron	white metal
III	nickel steel	mercury alloy

40. Rolling Friction

Rolling Resistance (or Friction). When a roller or wheel is made to roll, the reaction of the roadway has a component opposite to the direction of rolling, and this component is the rolling resistance. Thus R (Fig. 167) represents the reaction of the roadway, and its horizontal component is the rolling resistance. The distance c is called coefficient of rolling resistance. Let W = weight of roller or the load on the roadway, and P = driving force; when applied as in Fig. 167, then $Pr = Wc$; when at the top of the roller $P\,2\,r = Wc$. When a roller is interposed between a load and roadway so that there is rolling resistance at two places, then $P\,2\,r = W\,2\,c$. Few determinations of the coefficient c have been made; it has been reported as independent of W and r, and also as independent of W but varying with $\sqrt{r}$. "Laws" of rolling resistances certainly remain to be established. The following are some reported values of the coefficient of rolling resistance:

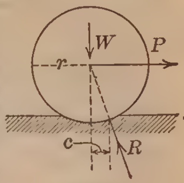

Fig. 167

Lignum vitæ roller on oak track, 0.019 in.
Elm roller on oak track, .032
Cast-iron wheel (20 in. diam.) on cast-iron rail, 0.018–0.019.
Railroad wheels (39.4 in. diam.) 0.020–0.022.
Iron or steel wheels on wood track, 0.06–0.10

Roller Bearings offer less resistance than ordinary bearings. C. H. Benjamin has made a comparison (Machinery, N. Y., Oct., 1905) between the friction in a flexible roller, a solid roller, and ordinary bearing. The speed was 560 revolutions per minute and the loads varied from 113 to 456 lb. Under 470-lb. load the flexible bearing developed end thrust of 13.5 lb. and the solid roller bearing one of 11 lb.

Coefficients of Journal Friction

Diameter of Journal	Flexible rollers			Solid Rollers			Babbitt bearing		
	Max.	Min.	Mean	Max.	Min.	Mean	Max.	Min.	Mean
1-1/16	0.032	0.012	0.018	0.033	0.017	0.022	0.074	0.029	0.043
2-3/16	.019	.011	.014	......	......	......	.088	.078	.082
2-7/16	.042	.025	.032	.028	.015	.021	.114	.083	.096
2-15/16	.029	.022	.025	.039	.019	.027	.125	.089	.107

Stribeck (Zeit. Ver. Deutsch. Ing., 1902, vol. 46, p. 1463) from experiments of four different makes of roller bearings, proposes the following: Let W = load on bearing (lb.), n = number of rollers, l = length of each (in.), r = radius of convex bearing surface for rollers (in.), d = diameter of rollers (in.), D = diameter of circle described by centers of rollers (in.), $2\,r + d = D$, c = coefficient of rolling resistance, f = coefficient of friction such that fW = total resistance to turning as though applied tangentially at surface of bearing and fWr = moment of resistance to turning; then $f = 1.2\,cD/rd$, and c has following values:

for $5\,W/lnd$ =	50	75	100	150	200 lb. per sq. in.
c =	0.0041	.0032	.0028	.0022	.0019 in.

He also states that the resistance of roller bearings is nearly independent of velocity; that the value of the highest roller pressure is 5 times the average, that is, $5\,W/n$; and he proposes as formula for safe load in lb. on the bearing $kldn/5$, where k may be taken from 85 to 155 lb. per sq. in. for unhardened rollers and bearing surfaces. F. R. Jones proposes (Machine Design, Part II) as formula for safe load for a well-made solid roller journal bearing of six or more rollers $100\,000\,d^2ln/3\,v$, where v is the velocity of the convex bearing surface in feet per minute; but values of v less than 50 should not be used in the formula; for such velocity the safe load is practically the same as for $v = 50$.

Ball Bearings. Stribeck reports extensive tests (Zeits. Ver. Deutsch. Ing., 1901, vol. 45, p. 121) from which the following is taken. The ball cases were grooves, cross-sections of which were arcs of circles of radius $2/3\,d$, thus aording two points of contact for each ball, $d = 7/8$ in. $D = 4$ in.

Coefficients of Friction for a Ball Bearing

Load in pounds	Revolutions per minute		
	65	385	780
840	0.0033	0.0035	0.0037
1 870	.0020	.0021	.0022
2 420	.0017	.0018	.0019
3 480	.0016	.0016	.00165
4 500	.0015	.0015	.0015
6 600	.0015	.0013	.0013
10 800	....	....	.0011

Stribeck also states that when the number of balls, n, in a race is between 10 and 20, the greatest pressure on any ball is about $5\ W/n$, where W is the load per race; then if P is the safe load for a single ball, the safe load per race is $Pn/5$. Of course, in a good thrust bearing the load is uniformly distributed among the balls. He also recommends as safe loads per ball $2100\ d^2$ for two-point bearing balls, and from $500\ d^2$ to $750\ d^2$ for three- or four-point bearings.

A Comparison of Some Bearings for Line Shafts

The table (from Trans. Am. Soc. Mech. Engrs., Vol. 35, page 593) gives relative amounts of power consumed in friction of three kinds of bearings for a 2-7/16-in. line shaft. Grease was used for the ball bearings and a mineral oil for the other two, applied by rings in the case of babbitt. Temperatures refer to lubricant and are Fahrenheit.

Bearings	100 ft. per min.		300 ft. per min.	
	77°	100°	77°	100°
Ball........	1	1	1	1
Flexible roller	2.2	2.5	2.7	3
Babbitt.....	3	3.6	4.5	4

41. Efficiency of Machines

Efficiency. A machine in operation receives and transmits or delivers energy. The energy received is called input, that transmitted or delivered is called output; the latter is also called the useful work of the machine. The output is always less than the input, some of the energy miscarrying as it were. The difference between output and input is the lost work, or simply loss. The efficiency of a machine is the ratio of output to input. The efficiency of a combination or succession of machines, the first receiving energy, transmitting to the second, the second to the third, etc., is the continued product of their separate efficiencies.

Efficiency of Some Machine Elements

(Kimball and Barr, Elements of Machine Design)

Common bearing, singly	96–98%
Common bearing, long lines of shafting	95
Roller bearing	98
Ball bearings	99
Spur gear cast teeth, including bearings	93
Spur gear cut teeth, including bearings	96
Bevel gear cast teeth, including bearings	92
Bevel gear cut teeth, including bearings	95
Belting	96–98
Pin-connected chains, as used on bicycles	95–97
High-grade transmission chains	97–99

In some simple machines, the energy is supplied by means of a single force called the effort; for example in a hoisting tackle, the pull applied is the effort. The force against which the useful work is done is called load; in the illustration the weight of the lifted body is the load. The mechanical advantage of a machine is the ratio of the load to the effort. While the effort works or acts through any particular distance, the load acts through a definite distance also; the ratio of the former to the latter distance is called the velocity ratio of the machine. Mechanical advantage depends on efficiency of the machine; velocity ratio does not. In any case mechanical advantage = velocity ratio × efficiency.

Inclined Plane and Wedge. Let W = weight of body, f = coefficient of static friction, ϕ = angle of repose = angle of friction and $f = \tan\phi$, α = inclination of plane and θ inclination of P (Fig. 168), θ being positive as shown and negative when the inclination of P to the horizontal is less than α. (1) To start the body up, $P = W \sin(\phi + \alpha)/\cos(\theta - \phi)$. P is least when $\theta = \phi$, its value then being $W \sin(\phi + \alpha)$. (2) When α is greater than ϕ, gravity would overcome friction and the body, if not prevented by some pull as P, would slip down. To prevent slipping

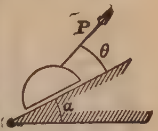

Fig. 168

$$P = W \sin(\alpha - \phi)/\cos(\theta + \phi)$$

P is least when $\theta = -\phi$, its value then being $W \sin(\alpha - \phi)$. When α is less than ϕ, there is no danger of slipping. To start the body down

$$P = W \sin(\phi - \alpha)/\cos(\theta - \phi)$$

this is least when $\theta = -\phi$, its value then being $W \sin(\phi - \alpha)$. When the body is being dragged up, let ϕ = angle of kinetic friction, that is, the angle whose tangent equals the kinetic coefficient, and e = efficiency. Then

$$e = \sin\alpha \cos(\theta - \phi)/\cos\theta \cdot \sin(\phi + \alpha)$$

e is maximum when P is minimum, that is, when $\theta = \phi$.

To start the wedge (Fig. 169) against the resistances R, $P = 2R\tan(\alpha + \phi)$, ϕ being the angle of static friction. If the forces R continue to act and P ceases, the wedge will be pushed up if α is greater than ϕ. If α is less than ϕ, the pull required to start the wedge out is $P = 2R\tan(\phi - \alpha)$. The efficiency of the wedge is $\tan\alpha/\tan(\alpha + \phi)$. In Fig. 170 there are three rubbing surfaces here assumed equally rough. To start the wedge in, $P = R\tan(\alpha + 2\phi)$ and the efficiency is $(\tan\alpha)/\tan(\alpha + 2\phi)$.

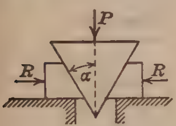

Fig. 169

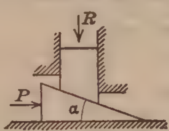

Fig. 170

To pull the wedge out, when α is less than 2ϕ, $P = W\tan(2\phi - \alpha)$.

Screw. Let p = pitch, r = mean radius of screw thread, d = diameter, α = angle of pitch ($\tan\alpha = p/\pi d$), f = static, and μ = kinetic coefficient, and ϕ_s and ϕ_k = the corresponding angles of friction ($f = \tan\phi_s$ and $\mu = \tan\phi_k$). The turning moment required to raise or lower a load W is

$$Wr(f\cos\alpha \pm \sin\alpha)/(\cos\alpha \mp f\sin\alpha)$$

the upper sign for raising and the lower for lowering the load. The efficiencies for raising and lowering are $(\tan\alpha)/\tan(\alpha + \phi_k)$ and $[\tan(\alpha - \phi_k)]/\tan\alpha$.

The following table gives highest and lowest efficiencies of some screws tested by Albert Kingsbury (Trans. A. S. M. E., vol. 17, p. 96). Mean diameter of thread = 1.352 in., pitch = 1/3 in., depth of nut 1-1/16 in., area of rubbing surface of thread about 1 sq. in.; the threads were cut carefully and worn to good condition before tested; speed about one-half r.p.m. There were 5 screws and 4 nuts as follows: S1 mild steel; S2 wrought iron; S3 cast iron; S4 cast bronze; S5 mild steel, case-hardened; N1 mild steel; N2 wrought iron; N3 cast iron; N4 cast bronze.

Efficiencies of Square Threaded Screws (Kingsbury)

Pressure on thread, Lb. per sq. in.	Lubrication	Highest	Lowest
10 000	machinery oil	0.20, S5 N4	0.11, S3 N3
10 000	lard oil	0.25, S4 N4	0.09, S3 N3
10 000	machinery oil and graphite	0.15, S5 N1	0.03, S5 N4
3 000	machinery oil	0.19, S5 N2	0.11, S2 N4

Tackle. Fig. 171 represents a fixed pulley, Fig. 172 a movable pulley lifting and Fig. 173 a movable pulley lowering the load. Let P = pull in lead line or off side, Q = that in following or on side; then $k = P/Q$, where k is a coefficient always greater than unity. Its value depends on the stiffness or rigidity of the rope and the pin friction; this has been proposed:

Fig. 171

Fig. 172

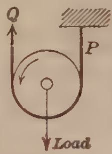

Fig. 173

$$k = 1 + Cd^2/a + 2\,fr/a$$

where d = diameter of rope, a = distance center of pin to center of rope, r = pin radius, f = coefficient of axle or pin friction, C an experimental coefficient. $C = 0.46$ has been recommended for hemp rope; with that value, and $a = 4\,d$, $r = d/2$, and $f = 0.08$,

for d =	1/2	3/4	1	1-1/2 in.
k =	1.08	1.11	1.13	1.19

Some experiments by the American Bridge Co. (Trans. Am. Soc. C. E., vol. 51, p. 161) indicate that C itself depends on rope diameter. The following table gives values of C adopted and k computed from the formula preceding with $f = 0.08$; values of d, a, and r are in inches.

	Hemp rope				Wire rope
d	1-1/4	1-1/2	1-3/4	2	3/4
a	3-7/8	4-9/16	5-3/8	6-/12	7-3/8
r	7/8	1	1-1/8	1-3/8	2-1/2
C	0.46	0.40	0.38	0.34	1.8
k	1.20	1.21	1.23	1.23	1.15

It may be noted that the pin friction contributes little to the value of k; in the cases above, 0.02 for the hemp and about 0.01 for the wire rope. The efficiencies for a single pulley are: if fixed $1/k$, movable lifting $(1 + k)/2\,k$, movable lowering $2/(1 + k)$. The following table gives the ratios of load to pull for tackles of manila rope, as determined by experiments of American Bridge Co. (see Engr. Record, vol. 48, p. 307).

Ratios of Load to Lead-line Pull for Manila Rope

No. of Parts	Diameter of rope, inches							
	3/4	7/8	1	1-1/4	1-1/2	1-3/4	2	2-1/4
2	1.93	1.92	1.93	1.92	1.91	1.91	1.91	1.90
3	2.73	2.68	2.74	2.68	2.67	2.64	2.65	2.63
4	3.48	3.37	3.50	3.37	3.36	3.30	3.32	3.28
5	4.12	3.95	4.16	3.95	3.93	3.84	3.87	3.80
6	4.71	4.48	4.77	4.48	4.45	4.33	4.37	4.28
7	5.23	4.92	5.30	4.92	4.89	4.72	4.78	4.65
8	5.71	5.32	5.80	5.32	5.28	5.08	5.14	5.00
9	6.12	5.66	6.23	5.65	5.61	5.37	5.45	5.27
10	6.50	5.96	6.63	5.96	5.91	5.64	5.72	5.52
11	6.83	6.22	6.98	6.21	6.15	5.85	5.94	5.72
12	7.14	6.45	7.30	6.44	6.38	6.04	6.15	5.90
13	7.40	6.64	7.58	6.63	6.56	6.20	6.31	6.04
14	7.64	6.82	7.85	6.81	6.73	6.34	6.46	6.17

Number of parts means number of runs of rope to movable block. Efficiency in per cent for any case = ratio divided by number of parts. Example: The fixed and movable blocks of a tackle are each double (two sheaves in each), and the rope is fastened to the fixed block; rope diameter is one inch. Then the number of parts is 4 and the load is 3.50 times the pull; the efficiency is $3.50/4 = 87.5\%$.

42. Muscular Exertion or Labor

Power and Work of Men and Animals. The power or rate of working of any agent (man or beast) depends on several factors, the principal ones being the duration and form of the exertion. For example, in raising his own weight (climbing a stairs) man has worked (against gravity) at the average rate of 1-1 2 hp. for 6 seconds; but only at the average rate of about 1/8 hp. for a day of 10 hours, and in this case the (necessary) descents were made without effort on his part. In one day a man can do about three times as much work pulling horizontally as in lifting weights.

Daily total work or performance depends on resistance overcome, velocity at which it is overcome, and length of the working day. The possible daily performance of any agent in any given form of exertion depends on proper choice or adjustment of these three factors. This is well illustrated by a celebrated example developed by Dr. J. F. Taylor: At a certain steel works the regular performance of men loading pig iron onto cars from piles on the ground was 12-1/2 tons per day; the men best adapted to such labor were induced to work according to a suitable program of working and resting, whereby their output reached 47-1/2 tons per day. It may be noted that this performance was not all work in the mechanical sense, but partly transport; see following paragraphs.

In trials, horses have overcome resistance equal to one-half their own weight through 100 ft. of distance. A draft or resistance of one-fourth the weight of the horse is regarded as heavy. For steady work during a day of 10 hours, a draft equal to 1/10 to 1/8 of the weight of the horse exerted at 2.5 miles per hour, is regarded as full demand on the animal. Under these circumstances a 1000-lb. horse works at 0.67 to 0.83 hp.

The two tables on next page in the main are from Rankine on the authority principally of Coulomb, Navier and Poncelet.

Explanation of Table. R = resistance overcome in pounds; v = effective velocity in feet per second, or distance through which R is overcome divided by total time occupied, including time of moving unloaded if any; Rv = effective power, foot-pounds per second; T = hours per working day; Rvt = daily work, in foot-pounds. In item 6, 132 is the weight of earth in the barrow, and .075 is the vertical velocity of the laborer when pushing the loaded barrow. Therefore Rv and Rvt (for this item) do not include all the mechanical work done by the laborer.

Transport by Men and Draft Animals. When a man stands and supports a load on his back he is subject to more or less fatigue and ordinarily he regards himself as working. But he is doing no work in the technical or mechanical sense, "overcoming resistance through distance." When he is walking under this load, he does some mechanical work, for he lifts the load slightly at each step, but even this is a small part of his exertion. In order to express amount of exertion involved in transporting loads horizontally, where the main effort is to support the load, Rankine uses product of load and distance transported, and he calls the product transport. Thus like work transport is product of force and distance but in the latter case the force and distance are at right angles to each other, whereas in the former they are directed along the same line. Transport then may be expressed in foot-pounds. Railroad traffic engineers use a similar concept, freight (hauled) or traffic, and measure it in ton-miles.

Work by Man and Horse

Kind of Exertion	R	v	Rv	T	Rvt
Man					
1. Raising own weight up stair or ladder	143	0.5	72.5	8	2 088 000

14. Trotting, driving a gin or mill	66	6.5	429	4-1/2	6 950 000

Transport by Man and Horse

Kind of Exertion	L	v	Lv	T	Lvt
Man					
1. Walking unloaded, transferring own weight	140	5	700	10	25 200 000
2. Carrying burden, returning unloaded	140	1-2/3	233	6	5 032 800
3. Traveling with burden	90	2-1/2	225	7	5 670 000
	252	0	0		
4. Carrying burden, 30 seconds only	126	11.7	1574.2		
	0	23.1	0		
5. Wheeling load L in 2-wheeled barrow, returning unloaded	224	1-2/3	372	10	13 428 000
6. Wheeling load L in 1-wheel barrow, returning unloaded	132	1-2/3	220	10	7 920 000
Horse					
7. Carrying burden, walking	270	3.6	972	10	34 992 000
8. Carrying burden, trotting	180	7.2	1296	7	32 659 200

Explanation of Table. L is the weight or load transported in pounds; v is "effective velocity" as in preceding table; Lv = rate of transport in foot-pounds per second; T = hours per working day; and Lvt = transport in foot-pounds per day.

MATHEMATICAL TABLES

APPENDIX TO SECTION I

26. Six-Place Logarithms of Numbers

The small table on page 173 gives logarithms of the natural numbers from 1 to 100 with their characteristics.

The extended table on pages 147 to 173 gives the logarithms of the natural numbers from 100 to 10 000 without their characteristics which are to be supplied by the rules of Art. 24, Sect. 1. For example

$$\log 112 = 2.049218 \qquad \log 1126 = 3.051538$$

Logarithms of numbers with more than four figures are to be found by help of the last column giving differences and the proportional parts at the foot of each page. For example when the number 17 456 is given first find log 1745 = 241795 and the difference 249. Then the proportional part corresponding to 6 in the last place is 149 and log 17456 = 241795 + 149 = 241944 to which the characteristic is to be prefixed; hence log 17456 = 4.241944. Similarly log 174567 = 5.241795 + 149 + 17 = 5.242061.

When a logarithm is given to find the corresponding number: If log is 2.932220 the number is 855.5. When the logarithm is not found exactly in the table take the next smaller one and find the difference between it and the given logarithms; then divide that difference by the number in the column Diff. and add the quotient to the smaller logarithms. For example, given 2.932260, the next smaller logarithm is 2.932220 corresponding to the number 855.5; the logarithm of this is 40 units less than the given one and the Diff. is 51 then 40/51 = 8 so that the number corresponding to the logarithm 2.932260 is 855.58. The table of proportional parts at the foot of the page shows 8 immediately as the figure to be added.

R signifies equal to rad; ∞ signifies infinite; O signifies evanescent.

27. Six-Place Logarithmic Sines, Cosines, Tangents and Cotangents

In the following pages, 175 to 219, characteristics of logarithms are increased by 10 in order to avoid negative ones. Thus log sin 1° 10′ = 8.308794 or $\bar{2}$.308794, log cot 1° 10′ = 11.691116 or 1.691116, log tan 0° 30′ = 7.940858 or $\bar{3}$.940858.

Pages 175 to 219 give values of these functions to six decimal places for every minute of the first and second quadrants. The degrees are at the top and bottom of the pages and the minutes at the sides below or above the degrees. For example, on page 185 the angles 10° 26′ and 169° 34′ have log sin = 9.257898, while 79° 20′ and 100° 40′ have log cot = 9.274964.

The columns headed D. 1″ enable interpolation to be made for seconds; thus for 10° 26′ 15″ the D. 1″ is 11.42 for log sin, whence 11.42 × 15 = 171 and log sin for this angle is 9.257898 + 171 = 9.258069. Also for 163° 38′ 15″ the log tan is 9.467880 − 117 = 9.467763. The computed difference is to be added or subtracted according as the tabular values of the function increase or decrease with an increase in the angle.

The columns of D. 1″ are omitted on pages 175 and 176, except for log cos; while other columns are added which enable intermediate values of the other functions to be found for small angles more accurately than can be done by interpolation. Thus to find log sin A and log tan A, when A contains seconds, the equations

$$\log \sin A = S + \log A'', \qquad \log \tan A = T + \log A'',$$

are to be used, A'' signifying the number of seconds in the angle A. For example, let the angle A be 1° 6′ 33″ or 3993″; for 1° 6′ the value of S is taken from the fourth column on page 176 and log 3993 from Table 26. Then

$$\begin{array}{ll} \text{For } 1^\circ\ 6' & S = 4.685548 \\ \log 3993 & = 3.601299 \\ \hline \log \sin 1^\circ\ 6'\ 33'' & = 8.286847 \end{array}$$

Similarly for 0° 54′ 12″ or 3252″ the log tan is found as follows:

$$\begin{array}{ll} \text{For } 0^\circ\ 54' & T = 4.685611 \\ \log 3252 & = 3.512151 \\ \hline \log \tan 0^\circ\ 54'\ 12'' & = 8.197762 \end{array}$$

To find log cot for a small angle the equation log cot $A = C - \log A''$ is to be used where C is taken from the eighth column. For example, for 1° 0′ 16″ or 3616″ the value of C is 15.314381 and that of log 3616 is 3.558228, whence log cot 1° 0′ 16″ = 11.756153.

To find the angle from a given logarithmic function, the eye must run along the table until the tabular value nearest to it is found. Thus, when log tan is given as 9.516910 this is found on page 193 and the angle is either 18° 12′ or 161° 48′. Again, when log tan is given as 9.526004, this is found to lie between 9.525778 and 9.526197; to the first value corresponds the angle 18° 33′ and the D. 1″ is 6.98; the difference 9.526004 − 9.525778 is 226 and 226/6.98 = 32.4″, so that the required angle is 18° 33′ 32″.4.

When the given function falls on page 175 or 176, the number of seconds is found by the equations

$$\log A'' = \log \sin A - S, \quad \log A'' = \log \tan A - T, \quad \log A'' = C - \log \cot A.$$

For example, given log tan A as 8.465371 for which T is 4.685700, then log A'' = 8.465371 − 4.685700 = 3.779671 from which by Table 26 there is found A'' = 6021″ and hence A = 1° 40′ 21″.

SECTION 3

PHYSICS, METEOROLOGY, WEIGHTS AND MEASURES

ORIGINALLY WRITTEN * BY

LOUIS A. FISCHER

LATE CHIEF OF DIVISION OF WEIGHTS AND MEASURES, NATIONAL BUREAU OF STANDARDS

CHEMISTRY

PHYSICS

METEOROLOGY

WEIGHTS AND MEASURES

* The material under Section 3 was revised in 1929 under the direction of Wilmer Souder, Physicist, National Bureau of Standards, assisted by the following collaborators:

H. L. Dryden, Scientist, Physicist, National Bureau of Standards (Art. 24).
J. F. Meyer, Scientist, Physicist, National Bureau of Standards (Art. 7).
Wm. Parry, Administrative Assistant, National Bureau of Standards (Arts. 25–31).
O. S. Peters, Associate Engineer, National Bureau of Standards (Art. 23).
C. E. Waters, Chemist, National Bureau of Standards (Arts. 1–4).
H. T. Wensel, Scientist, Physicist, National Bureau of Standards (Arts. 9–14).
Edgar W. Woolard, Meteorologist, U. S. Weather Bureau (Arts. 16–22).

CHEMISTRY

1. The Chemical Elements

In the following table, in every case the atomic number is given as well as the atomic weight. The list is the same as that in International Critical Tables, Vol. I, pp. 43–45. The atomic weights are those of 1929.

Name *	Symbol	Atomic number	Atomic weight	Nature
Actinium	Ac	89		
Aluminum	Al	13	26.97	Metal
Antimony (stibium)	Sb	51	121.77	Metal
Argon	A	18	39.94	Inert gas
Arsenic	As	33	74.96	Metalloid
Barium	Ba	56	137.36	Metal
Beryllium (glucinum)	Be	4	9.02	Metal
Bismuth	Bi	83	209.00	Metal
Boron	B	5	10.82	Metalloid
Bromine	Br	35	79.916	Liquid
Cadmium	Cd	48	112.41	Metal
Calcium	Ca	20	40.07	Metal
Carbon	C	6	12.000	Metalloid
Cassiopeium (see lutecium)	Cp	71		
Celtium (see hafnium)	Ct	72		
Cerium	Ce	58	140.13	Metal
Cesium	Cs	55	132.81	Metal
Chlorine	Cl	17	35.457	Gas
Chromium	Cr	24	52.01	Metal
Cobalt	Co	27	58.94	Metal
Columbium (niobium)	Cb	41	93.1	Metal
Copper (cuprum)	Cu	29	63.57	Metal
Dysprosium	Ds or Dy	66	162.46	Metal
Erbium	Er	68	167.64	Metal
Europium	Eu	63	152.0	Metal
Fluorine	F	9	19.00	Most active gas
Gadolinium	Gd	64	157.26	Metal
Gallium	Ga	31	69.72	Metal
Germanium	Ge	32	72.60	Metal
Glucinum (same as beryllium)	Gl	4		
Gold (aurum)	Au	79	197.2	Metal
Hafnium (celtium)	Hf	72	178.6	Metal
Helium	He	2	4.002	Inert gas
Holmium	Ho	67	163.5	Metal
Hydrogen	H	1	1.0078	Lightest gas
Indium	In	49	114.8	Metal
Iodine	I	53	126.932	Metalloid
Iridium	Ir	77	193.1	Metal
Iron (ferrum)	Fe	26	55.84	Metal
Krypton	Kr	36	82.9	Inert gas
Lanthanum	La	57	138.90	Metal
Lead (plumbum)	Pb	82	207.22	Metal
Lithium	Li	3	6.940	Metal
Lutecium (cassiopeium)	Lu	71	175.0	Metal
Magnesium	Mg	12	24.32	Metal
Manganese	Mn	25	54.93	Metal
Masurium	Ma	43		
Mercury (hydrargyrum)	Hg	80	200.61	Metal
Molybdenum	Mo	42	96.0	Metal

* Names of the more abundant elements are in bold-face type

Name	Symbol	Atomic number	Atomic weight	Nature
Neodymium	Nd	60	144.27	Metal
Neon	Ne	10	20.183	Inert gas
Nickel	Ni	28	58.69	Metal
Niobium (see columbium)	Nb	41		
Niton (see radon)	Nt	86		
Nitrogen	N	7	14.008	Gas
Osmium	Os	76	190.8	Metal
Oxygen	O	8	16.000	Gas
Palladium	Pd	46	106.7	Metal
Phosphorus	P	15	31.02	Metalloid
Platinum	Pt	78	195.23	Metal
Polonium	Po	84	(210)	
Potassium (kalium)	K	19	39.10	Metal
Praseodymium	Pr	59	140.92	Metal
Protoactinium	Pa	91	°	
Radium	Ra	88	225.97	Metal
Radium emanation	Em	86	222.	
Radon	Rn	86	222.	
Rhenium	Re	75	188.7	
Rhodium	Rh	45	102.91	Metal
Rubidium	Rb	37	85.44	Metal
Ruthenium	Ru	44	101.7	Metal
Samarium	Sa or Sm	62	150.43	Metal
Scandium	Sc	21	45.10	Metal
Selenium	Se	34	79.2	Metalloid
Silicon	Si	14	28.06	Metalloid
Silver (argentum)	Ag	47	107.880	Metal
Sodium (natrium)	Na	11	22.997	Metal
Strontium	Sr	38	87.63	Metal
Sulfur	S	16	32.06	Metalloid
Tantalum	Ta	73	181.5	Metal
Tellurium	Te	52	127.5	Metalloid
Terbium	Tb	65	159.2	Metal
Thallium	Tl	81	204.39	Metal
Thorium	Th	90	232.12	Metal
Thulium	Tm or Tu	69	169.4	Metal
Tin (stannum)	Sn	50	118.70	Metal
Titanium	Ti	22	47.90	Metal
Tungsten (wolfram)	W	74	184.0	Metal
Uranium	U	92	238.14	Metal
Uranium-X_2(isotope of protoactinium)	UX_2	91	(234)	
Vanadium	V	23	50.96	Metal
Xenon	Xe	54	130.2	Inert gas
Ytterbium	Yb	70	173.6	Metal
Yttrium	Y or Yt	39	88.92	Metal
Zinc	Zn	30	65.38	Metal
Zirconium	Zr	40	91.22	Metal

A Chemical Element is a substance that can not by any ordinary means be separated into two or more different substances. This definition does not exclude the possibility of decomposing an element into others by radioactive or similar agencies. **Chemical Compounds** are pure substances which can, by ordinary chemical means, be separated or decomposed into different elements, or which can be made by combining different elements. The **molecules** of a compound are regarded as aggregates of smaller particles of the elements, known as **atoms,** into which the compound can be broken up. The atoms are regarded the smallest mass-elements which occur separately in the structure of the molecules of either compounds or elementary substances, so far as can be determined by ordinary chemical means. The molecule of an element consists of a definite (usually small) number of its atoms. The molecule of a compound consists of one or more atoms of each of its several elements, the numbers of the various kinds of atoms and their arrangement being definite and fixed, and determining the character of the compound.

Although the atom is the smallest mass of any element that can exist either alone or in a compound, it is itself complex, being made up of charges of positive and negative electricity. Various theories concerning the structure of the atom have been proposed. Bohr, whose ideas have at present the most supporters, believes that in the atom there is a central nucleus made up of one or more charges of positive electricity, the **protons** in close connection with charges of negative electricity, the **electrons.** Around the nucleus revolve other electrons in definite orbits. By deductions from, and amplification of, Bohr's theory, it has been found possible to account for the more important chemical and physical properties of the elements in a consistent and logical manner. The property of an element which is in many ways the most important is its **atomic weight** or the mass of one atom compared with the mass of an atom of oxygen, which by definition equals 16,000. The **atomic number** of an element represents the position of the element in the series of elements arranged in the order of their atomic weights from hydrogen = 1.0078 to uranium = 238.14. It is equal to the number of electrons outside of the nucleus.

Radioactivity is one of the consequences of the structure of the atom, and is evidence of the loss of protons or electrons. When such loss occurs, not only are the various types of rays emitted, but the complex which remains is found to be an element of lower atomic number. Thus when uranium (at. no. 92) breaks down, it yields helium and lead (at. nos. 2 and 82). Ordinary lead has an atomic weight of 207.22, while that from uranium has the atomic weight 206.06. Thorium (at. no. 90) in breaking down yields helium and lead which has the atomic weight 208.00. The name **isotope** is applied to the different forms of lead and of other elements which are formed in a similar way. A third of the elements may exist in only one form; the other two-thirds must exist in two or more forms. Little has been done on the separation of the elements into their isotopes.

2. Combustion and Fuels

Carbon is the principal constituent of solid, liquid, and gaseous fuels; it is either free, as in charcoal and coke, or combined with hydrogen, oxygen, or with both. In burning, the carbon and hydrogen combine with oxygen from the air, yielding, when combustion is complete, carbon dioxide and water vapor. When insufficient air is admitted over the bed of fuel, or into the fire-box when liquid or gaseous fuels are used, much of the fuel may be lost, either as free carbon (smoke, soot) or in the form of unburned gases, especially carbon monoxide. It is almost impossible to attain complete combustion of solid fuels by forcing air under the grate and through the bed of coals, because part of the carbon dioxide formed near the grate is reduced to carbon monoxide on passing through the overlying layers of hot fuel. This monoxide, which has a high heating value, can be burned completely only when a plentiful supply of air is admitted over the bed of fuel. The blue flames seen when anthracite, coke, or charcoal is burned are due to carbon monoxide. It is not economical to supply sufficient air by forced draft through the fuel, because the excessive temperatures rapidly burn out the grate bars, and also because of the increased mechanical wear on the boiler tubes due to the greater number of fine particles of coal and ash driven through them.

Wood consists mainly of lignin and cellulose, compounds of carbon with hydrogen and oxygen, together with varying amounts of water and mineral matter. The latter largely remains behind in the ash.

Charcoal is made by piling wood into heaps which are covered with earth, leaving a few small openings to admit a limited amount of air and allow the products of combustion to escape when the wood is ignited. When sufficient wood has burned to insure thorough charring ("destructive distillation") of the remainder, the openings are closed and the pile allowed to cool completely. By this method of making charcoal only a little tar is obtained and all the volatile constituents are allowed to escape. When wood is heated in closed retorts, large amounts of tar, creosote, wood or methyl alcohol, acetone, and pyroligneous (acetic) acid, etc., are obtained. The yield of charcoal is also nearly doubled. Charcoal consists of carbon and the mineral matter of the wood. Its value in metallurgy is due to its low content of phosphorus and sulfur. The calorific value of charcoal is about 75% that of anthracite.

Peat is formed by the partial decay of mosses and other bog plants under water. Even when compressed and dried it contains much water and its mineral content may be high. Its calorific value is 3000 to 4000 cal. per kg.

Lignite or brown coal, is a stage beyond peat in the formation of coal. It contains much moisture and ash and is often high in sulfur content. Its calorific value is 4000 to 5500 cal. per kg. Owing to its large amount of volatile matter, lignite burns with a long, smoky flame.

Bituminous Coal is formed by the further transformation of lignite by heat and pressure. It comprises many varieties, including gas, coking, steam, and cannel coals. They differ principally in their content of volatile matter, the "fat" coals having at times as high as 50% of compounds of carbon and hydrogen, which are readily driven off by heating. The length of flame of burning bituminous coal depends on the percentage of volatile matter

Anthracite Coal is produced by the further action of heat and pressure upon bituminous coal, whereby nearly all the volatile constituents are driven off, leaving mainly carbon and mineral matter. These coals burn with little flame and smoke, and do not cake. Their calorific value may be 9000 to 9500 cal. per kg.

Coke. As charcoal is the residue left by heating wood in retorts or partially burning it with a limited air supply, so coke is made by heating bituminous coals. In some types of coke ovens the gaseous and liquid products formed by the destructive distillation are allowed to escape into the air; with other types of ovens this loss is not permitted and valuable by-products are obtained, such as ammonia, fuel and illuminating gas, and coal tar. Coke is mainly carbon, but contains also the mineral constituents of the coal. It is low in volatile matter and sulfur. Upon this and its infusibility and resistance to crushing depends its value as a fuel in blast furnaces. Its calorific value is about 90% that of the much more expensive anthracite.

Chemical Examination of Coal and Coke. The heating value of any fuel can be determined conveniently by means of one of the numerous forms of bomb calorimeters. But this leaves unanswered many questions which have a very practical bearing, for example, the percentages of volatile matter, sulphur, and ash, and the amount of coke the coal will yield. In general, the lower the percentage of ash the better the quality of the fuel. The only mineral constituent that has any heating value is the sulfur of pyrites. But as sulfur is injurious in practically all metallurgical operations and the oxides of sulfur have a corroding effect upon boiler tubes, etc., a coal high in either pyritic or organic sulfur is undesirable. Gas coals and coal for use in certain metallurgical operations requiring long reducing flames should be high in volatile matter. Coals that are to be worked economically for coke may be low in volatile matter, but must possess the property of partially fusing or caking together when heated in the ovens.

In taking samples, for calorimetric determinations or for chemical analysis, the accepted method is to select a large number of pieces, representing as nearly as possible in size, etc., the whole load. These must be chosen from all parts of the coal to be tested and taken from the top and down through the whole mass. These lumps should then be broken into nearly uniform size, thoroughly mixed together, and a smaller sample obtained by "quartering." If this sample is still too large it should be further broken up and again quartered until a sample that can readily be enclosed in air-tight jars is obtained. In sampling at the mine, the coal should be cut from a freshly exposed face, and the sample, after quartering to suitable size, should fairly represent not only the actual coal but also the interpenetrating veins of shale, etc., if these are regularly mined with the coal. It is very important to prepare the sample, not only with great care but also as rapidly as possible, to minimize the inevitable loss of moisture in breaking up the lumps. This explains the necessity of placing the fuel sample in air-tight receptacles, such as fruit jars with rubber rings. The volatile matter in coal is highly explosive when mixed with air in the proper proportion; therefore care should be taken to ensure thorough ventilation of all places where coal, especially bituminous, is stored.

3. Liquid and Gaseous Fuels

Crude Petroleum is the most important of the liquid fuels. It owes its importance not only to its comparative cheapness but also to the ease with which it is handled and its high efficiency, which is two or more times that of anthracite. It is usually burned in the form of a spray obtained by means of a blast of air or superheated steam. Petroleum residues and coal-tar residues are also burned to some extent. Their calorific value is not as great as that of crude petroleum, but may run as high as 16 000 cal.

Gasoline is the lowest boiling distillate from crude petroleum, or from the "cracking" of the higher boiling fractions by high temperature, usually under excess pressure, and sometimes in the presence of catalysts which facilitate the breaking down of the more complex hydrocarbon molecules into simpler ones. **Casinghead gasoline** is condensed from natural gas by compression and cooling, before the gas enters the mains through which it is distributed. It is too volatile to be used alone for ordinary purposes, but large quantities of it are mixed with the other forms of gasoline. Each of the kinds of gasoline is a mixture of hydrocarbons containing different percentages of carbon and hydrogen. When mixed with the proper amount of air the vapors form a mixture which is readily ignited and burns with explosive violence. If the vapor is largely in excess of the proportion needed for complete combustion the force of the explosion is weakened, so that, apart from the actual loss of unburned gases, the fuel is not used economically. There is a similar loss in power when too much air is present. For the complete combusion of one cubic foot of the vapor of the hydrocarbon hexane,

C_6H_{14}, 45.2 cu. ft. of air are required, whereas the same volume of heptane (C_7H_{16}) vapor requires 52.4 cu. ft. of air, or 16% more.

The chief use for gasoline is as the fuel for internal-combustion engines. Most of it is used without the addition of anything else, but there are on the market various mixtures of gasoline with benzol from coal tar, and with alcohol. The value of a motor fuel depends not only upon its volatility and calorific value, but also upon its "anti-knocking" characteristics, upon the degree to which the mixture of its vapor with air can be compressed without pre-ignition, upon its relative freedom from sulfur compounds, which yield sulfuric acid when burned, and upon other factors.

Natural Gas is the most efficient as well as the cheapest of all fuels, though its use is of course limited by the distance to which it can be economically piped. It consists mainly of methane, CH_4, with 10% or less of hydrogen and other gases. Methane is also known as marsh gas, from its abundant formation when vegetable matter decays under water. The name fire damp refers to its occurrence in coal mines, where it is one of the causes of explosions.

Coal Gas which is made by distilling bituminous coal in retorts, contains 80 to 85% of a mixture of nearly equal parts of hydrogen and methane, with much smaller amounts of oxygen, nitrogen, carbon monoxide and dioxide, etc. It is used to some extent in gas engines, and as a fuel.

Water Gas is formed by the action of superheated steam upon white-hot coal or coke. The steam gives up its oxygen to the carbon of the fuel, forming carbon monoxide, CO, and leaving hydrogen, thus, $C + H_2O = CO + 2\,H$. The reaction is endothermic, that is, it requires the addition of heat, so that it is necessary to cut off the steam every few minutes and reheat the fuel by an air blast. Water gas consists of about 45% each of hydrogen and carbon monoxide, with small percentages of oxygen, nitrogen, carbon dioxide, etc. The first two gases burn with very hot, non-luminous flames. For use as an illuminant is must be "enriched" with naphtha or other similar oil.

Producer Gas is made in much the same way as water gas, except that only air and no steam is passed through the incandescent coal or coke. The carbon is burned to carbon monoxide, which makes about 25% of the gas. Small amounts of hydrogen, methane, and carbon dioxide are present. There is also nearly 65% of nitrogen from the air which is used. This is unavoidable, though the presence of such a large amount of inert gas reduces the thermal efficiency. The reaction whereby carbon is burned to carbon monoxide is accompanied by the evolution of about one-third the total heating value of the fuel. It is evident that if the gas can be burned without allowing it to cool, a great saving of heat can be effected. This is not always feasible and it is the practice, with some forms of producers, to pass some steam with the air, thus making a mixed water-producer gas. The heat which would otherwise be lost is used up in forming water gas, and the resultant fuel gas has an increased fuel value. It is much more economical to convert the fuel into producer gas and use it in explosion engines than to burn it under steam boilers.

4. Explosives

The Fundamental Property of an explosive is that when ignited or subjected to a sudden shock it shall decompose, or its components react, suddenly yielding a relatively large volume of highly heated gas. This definition includes not only gunpowder, nitroglycerin, and similar substances, but mixtures of inflammable gases and vapors with air; or even coal dust, fine sawdust, or flour suspended in the air. The last three have all been the cause of disasters, the reason being that when some of the particles are ignited the flame is rapidly communicated to adjacent ones, yielding large volumes of highly heated gaseous products of combustion, in addition to which the surrounding air is also heated. Thus, one gram of anthracite, of specific gravity 1.5, occupies a volume equal to only 2/3 cubic centimeter. If it contains 95% of carbon, it will yield when burnt about 1761 cc., or 2642 times its own volume, of carbon dioxide measured at 0° C. and 760 mm. pressure. If suspended as dust in a large volume of air and burned in a fraction of a second, it is evident that the large amount of hot gases must expand with explosive violence.

Gunpowder is a mixture of 75 parts by weight of saltpeter, or potassium nitrate, 15 parts of charcoal, and 10 parts of sulfur, made by grinding the ingredients together with enough water to moisten the mass. It is then compressed into a cake and broken into grains, which are glazed by revolving with graphite and sorted into sizes by sieves. The larger grains are used for blasting, and the smaller ones for small arms. **Blasting powder** is frequently made with the cheaper Chile saltpeter, or sodium nitrate, which produces a cheaper and less powerful powder than that made from ordinary saltpeter. Chile saltpeter, however, has the disadvantage of absorbing moisture from the air, and powder made from it cannot be kept too long or stored in a damp place. The proportions used are 73 parts of Chile saltpeter, 16 parts of charcoal, and 11 parts of sulfur.

Guncotton, Nitrocellulose, typical of the second class of explosives, is made by the action of a mixture of nitric and sulfuric acids upon cotton. When only moderately strong acids are allowed to act on the cotton for a short time, the product is pyroxylin, or soluble nitrocellulose, used for making collodion and celluloid. By longer action with more concentrated acids, guncotton is formed. It is then washed in a machine of the kind used for making paper pulp to remove all traces of acids that might cause spontaneous explosions. While still moist, it is compressed into blocks or sticks. Guncotton is usually stored and transported in a moist condition, and can be exploded without drying. It is comparatively safe to handle, as ordinary shocks do not explode it readily. In the open, it burns with extreme rapidity.

Nitroglycerin is made by the cautious addition of glycerin to a well-stirred and cooled mixture of the strongest nitric and sulfuric acids. The oily product is washed to remove all traces of acids that might cause spontaneous explosion. Under the most favorable conditions, nitroglycerin is not safe to handle. The fact that it is a liquid with consequent liability to leakage from containers greatly increases the danger of transportation and storage. For this reason, it is commonly mixed with some absorbent or transformed into a gelatinous mass.

Dynamite is a mixture of nitroglycerin with infusorial earth, powdered "rottenstone," or similar porous material, known as "dope." Instead of these inactive dopes that take no part in the explosion, explosive mixtures are often used to absorb the nitroglycerin. Gunpowder is one of these. Dynamite consisting of 40% nitroglycerin, 44% sodium nitrate, 15% wood pulp, and 1% calcium carbonate, is an example of dynamite with an active dope.

Explosive gelatin is a jelly-like mass made from a solution of soluble nitrocellulose in nitroglycerin. Too powerful for common work, it is used with success for very hard rock in tunnels. Gelatin dynamite is a mixture of explosive gelatin with a dope such as sodium nitrate and wood pulp; it is not so powerful as the straight gelatin. Smokeless powder is a general term covering many modifications of explosive gelatin, and mixtures of nitrocellulose with nitrobenzene, etc.; they are usually given fanciful names, as ballistite, cordite, indurite, and so forth. Nitroglycerin and mixtures containing it are all liable to freeze at moderately low temperatures. They cannot be used satisfactorily in that condition, and should not be thawed by placing them near a fire or on steam pipes but by leaving them in a warm chamber kept at a temperature not over 90° F.

Picric Acid or trinitrophenol, is made by the action of nitric and sulfuric acids upon phenol (carbolic acid). It is a yellow, crystalline substance, formerly used only as a dye for silks and so forth. For years it was not known as an explosive, but it is now known that it will explode with great violence when detonated. If ignited, it usually burns without exploding and is not very susceptible to shock. Lyddite, melinite, and shimose are composed of picric acid. Some of the salts, or picrates, are exploded by slight blows.

Nitrocellulose, Nitroglycerin, and Nitrostarch are true nitrates, as they all contain the atomic group NO_3. They are chemically quite different from the true nitro-compounds, such as picric acid, which contain the atomic group NO_2. Benzene, toluene, naphthalene, and other substances obtained from coal tar yield nitro-compounds when treated with nitric acid. The best known of these is trinitrotoluene, or "TNT," which was used in such enormous quantities in the Great War. These are all more or less unstable and are used as components of explosives, mixed with either ammonium nitrate or other nitrates, or with chlorates, which are good oxidizing agents, or they may be used in dynamite because they lower the freezing point of the nitroglycerin. Rack-a-rock, roburite, bellite, and securite are typical of the explosives made from these nitro-compounds and oxidizing agents.

A Detonator contains a high explosive, too powerful and unstable to be employed alone, which by its sudden disruptive force brings about the instantaneous explosion of a large amount of a more stable explosive. The ones commonly in use consist of copper capsules containing a definite amount of a mixture of chlorate of potash and mercury fulminate, which is exploded either by a fuse or a wire heated electrically. The fulminate is made by mixing a solution of mercury in strong nitric acid with alcohol. The gray, crystalline powder which is precipitated must be well washed to remove all acid. It is sensitive to shock and may explode even when wet.

Explosives must be selected with reference to the character of the work. For quarrying building stone, those that act slowly, with little shattering effect, must be chosen. When the stone is to be crushed after quarrying, or for breaking up rock so that it can be handled by a steam shovel, a quick shattering effect is desired. In all open work, the character of the gases arising from the explosion may be disregarded, but in tunnels or mines, especially if not well ventilated, this factor is of great importance. No explosive is absolutely safe in this respect. In coal mines, where the presence of fire damp (methane) is a menace, no explosive giving a long flame or a high heat of detonation should be used. Even in the absence of gas, there is danger of igniting the coal dust.

Explosives should be stored in a dry place so that the sodium or ammonium nitrates will not take up enough moisture to lessen their power. But if in too dry a place, they may lose the moisture they naturally contain, which will change their speed of explosion and thus modify the character of the results obtained. Explosives should not be stored for a longer time than absolutely necessary, on account of the possibility of chemical changes taking place in the nitro-compounds most of them contain.

PHYSICS

5. Physical Properties of Solids

The properties of substances nominally the same differ so widely that it would be misleading to give more than two or three significant figures in most cases without such detailed specification of conditions as would make the tables too voluminous. Lower and upper limits of values found for different specimens are given when warranted by the data available.

Mohs' Scale of Hardness: 1. Talc; 2. Gypsum; 3. Calc spar; 4. Fluorspar; 5. Apatite; 6. Feldspar; 7. Quartz; 8. Topaz; 9. Sapphire; 10. Diamond.

Density. The terms True Density and Apparent Density are used in describing certain porous bodies to distinguish between the density of the substance and the average density of the substance plus the pores. The terms Density and Specific Gravity are synonymous in engineering work.

Thermal Conductivity. The value given in the tables is the number of gram-calories that will pass per second through every square centimeter of a plane section within the substance when the temperature is uniform over the section and falls along the normal to it at the rate of 1° C. per cm.

1 gm.-cal. per sec. per sq. cm. for a temperature gradient of 1° C. per cm. = 360 kg.-cal. per hr. per sq. m. for a temperature gradient of 1° C. per m. = 2.90×10^3 B.t.u. per hr. per sq. ft. for a temperature gradient of 1° F. per in.

Electrical Resistivity. Each value given in the table of metals and alloys is the resistance in microhms between the opposite faces of a cube 1 cm. on each edge when at 18° C. (64.4° F.). This increases bR for every degree C., or $5/9\, bR$ for every degree F., that the temperature of the substance exceeds 18° C. 1 microhm to the sq. cm. of cross-section per cm. of length = 6.015 ohms to the circular mil of cross-section per foot of length.

7. Light and Illumination

The Unit of Light Intensity is the **international candle,** as agreed upon by England, France and the United States in July, 1909. The **Hefner,** which is the legal unit in Germany and certain other European countries, is 9/10 of the international candle. The international candle is maintained by the National Bureau of Standards at Washington, by means of groups of carbon filament incandescent electric lamps.

The relations between other units of light intensity are: 1 international candle = 1 pentane candle = 1 bougie decimale = 0.104 Carcel unit = 1.11 Hefner Kerze.

Candlepower is luminous intensity expressed in candles. Light sources are measured in horizontal candles, in spherical candles, or in **lumens.** One spherical candle is equal to 4π (12.57) lumens.

The Color of Light is determined by its spectral distribution and is the subjective evaluation by the eye of the quality of light flux. The easily visible spectrum extends from about $\lambda = 380$ mμ, to $\lambda = 780$ mμ, violet to red.

Wave-lengths, λ, are commonly expressed in microns (μ) or millimicrons (mμ). 1 micron (μ) = 10^3 millimicrons (mμ) = 10^{-3} mm.

The Speed of Light in a vacuum is approximately 300,000 kilometers per second (186,000 miles per second.) (The most recent measurements, made by Michelson in 1926, give a value 299,796 km. per sec.)

When a ray of light strikes the plane surface of a transparent body, in passing to an optically denser medium, it is refracted toward the normal to that plane. The ratio of the sine of the angle between the original ray and the normal to the sine of the angle between the refracted ray and the normal is called the index of refraction.

The ratio of the speed of light in a vacuum to that in any substance is equal to the index of refraction of the substance.

Incandescent Electric Lamps are the generally used light sources. These lamps are rated commercially in total watts at a definite voltage or current, in lumens, or in spherical candles, depending on size and type. Lamps for ordinary lighting service on multiple circuits are designated in watts; lamps for street lighting service on series circuits. in lumens; and lamps for automobile service, in spherical candles. Inside-frosted lamps have replaced clear and frosted lamps up to and including the 100-watt size for general lighting service.

Standard specifications for the purchase of incandescent lamps have been issued by the Bureau of Standards, Washington, D. C.

Illumination is measured in foot-candles. A point source of one candle (4π or 12.57 lumens) produces an illumination of one foot-candle on a surface 1 ft. from the source. A foot-candle is equivalent to one lumen per square foot. The light output, or luminous flux of lamps should be redirected by shades and reflectors for good illumination. Illuminations of from 10 to 15 foot-candles are considered good practice in lighting offices and drafting rooms.

Direct sunlight from the noon-day sun gives an illumination of from 6000 to 10 000 foot-candles; full moon about 0.02 foot-candle. Daylight illuminations vary very greatly.

The Absorption, Transmission and Reflection of materials used as enclosing, diffusing and reflecting devices, and the color and surface of walls, ceilings and surroundings affect interior illumination obtained from light sources of definite light output.

Polished silver reflects approximately 92% of the incident light flux, aluminum 68%, nickel 65%, silver-backed glass 88%. Enclosing and diffusing glassware, as commonly used on lighting units, transmits from 75% to 85% of the incident light.

8. Microscopes and Telescopes

Magnification, increasing visibility of detail, is secured by bringing the image of an object nearer to the eye, or by any other means of increasing the visual angle which the object subtends. Vision with the unaided normal eye is, however, most distinct at a distance of 25 to 30 cm. because the accommodating mechanism of the eye is unable to focus sharply on the retina points nearer than this. A magnifying optical system produces in effect the required increase in the visual angle while forming an image (real or virtual) farther from the eye than the least distance of distinct vision. Often the arrangement is such that the eye views a virtual image at an infinite distance, so that the muscles of accommodation may be completely relaxed.

The Simple Microscope (Fig. 1). A single converging lens if placed closer to an object than the principal focal length produces an enlarged virtual image, which is seen on looking through the lens. The magnification produced is $1 + d/f$ for an eye whose least distance of distinct vision is d. A simple plano-convex lens, with the plane side toward the eye, gives good images for magnification less than eight diameters, that is, with focal lengths greater than about 3 cm. The image may be much improved, especially where the magnification is considerable, by the use of special combinations of lenses designed to reduce spherical and chromatic aberration so as to give a fairly large field of view approximately free from distortion and color.

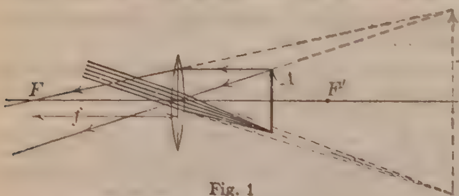

Fig. 1

The Ramsden or Positive Eyepiece (Fig. 2) consists of two converging lenses, usually plano-convex, with their convex surfaces facing each other, of equal focal length, and separated by 2/3 the focal length of either. A virtual image of the object or real image A is formed by the field-lens L_1 at A'. The eye-lens L_2 forms an image of this at infinity. This eyepiece is fairly, but not quite, achromatic.

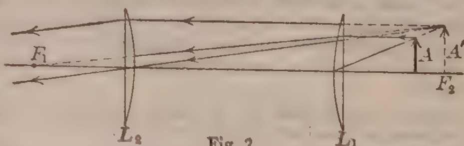

Fig. 2

Huyghens or Negative Eyepiece (Fig. 3). Two converging lenses, usually plano-convex, with the plane surfaces toward the eye, are so arranged as to divide equally between them the

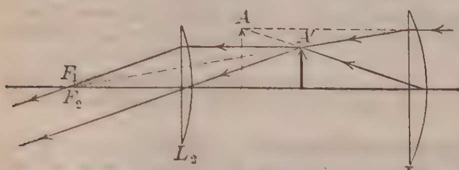

Fig. 3

deviation produced on incident light parallel to and close to the axis. The field-lens L_1 has three times the focal length of the eye-lens L_2, and the two are separated by the difference in their focal lengths. Light which if unhindered would converge at A is deviated by L_1 to form an image at A', of which L_2 forms an image at infinity. This eyepiece is highly achromatic and free from disturbing spherical aberration.

For Measuring Microscopes and Telescopes in which the eyepiece is fitted with cross-hairs, the positive eyepiece is far more suitable than the negative because the image of the hairs being formed by both lenses is corrected for both chromatic and spherical aberration, and because the cross-hairs can be easily adjusted to suit different eyes by altering their distance from the eyepiece.

The Compound Microscope (Fig. 4) in its simplest form consists of two converging lenses. The objective L_1 forms within the tube a real, inverted, magnified image A' of the object A. This image is viewed through the eyepiece L_2 and further magnified. A microscope is usually fitted with either a Huyghens or a Ramsden eyepiece, according to the purpose for which it is to be used. The objective is also generally a combination of several lenses to overcome spherical and chromatic aberration while admitting as much light as possible. In microscopes of the highest power a drop of oil of cedar is placed between the side and the objective; this is known as "immersion." The smallest interval that can be optically resolved is about 0.00005 mm., and the limit of resolution of the microscope is attained when the total magnification is about 1200.

Fig. 4

The Astronomical Refracting Telescope differs from the compound microscope in that the objective forms a reduced image of a distant object. The objective is generally a compound lens consisting of a convex lens of crown and a concave lens of flint glass. A Huyghens or a Ramsden eyepiece is ordinarily used; but the best instruments employ eyepieces embodying later improvements.

The Terrestrial Telescope (Fig. 5) produces an erect image by an inverting system between the eyepiece and the inverted image formed by the objective. One form of inverting system consists of two converging lenses of equal focal length so placed that the inverted image A formed by the objective is at the principal focus of the first lens. An erect image A' is then formed at the principal focus of the second lens, and is magnified by an eyepiece.

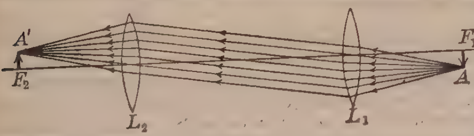

Fig. 5

Galileo's Telescope (Fig. 6) consists of a convex lens L_1 for objective and a concave lens L_2 for eyepiece. The light from L_1 converging so that if unhindered it would form at A' a real, inverted image of the distant object A, is intercepted by L_2 and rendered parallel or slightly divergent as if it came from A'', which is a virtual, erect

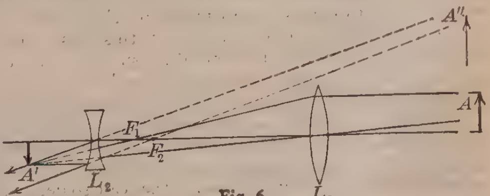

Fig. 6

image of A. The use of the diverging eye-lens limits considerably the angular field of view. Ordinary field-glasses and opera-glasses are Galilean telescopes.

The Prism Binocular (Fig. 7) secures the wide field of view that accompanies the use of a converging eyepiece, while at the same time it avoids the inconvenient length of the ordinary terrestrial telescope. This is accomplished by employing four total reflections within two right-angled prisms to invert the image formed by the objective. Otherwise the construction is the same as that of the astronomical telescope. This prism construction permits a considerable shortening of the telescope by separating the prisms, since the light traverses the distance between them three times. In addition the stereoscopic effect due to binocular vision may be greatly increased by placing the centers of the objectives much farther apart than the pupils of the eye. The increased field of view is obtained at a sacrifice of illumination.

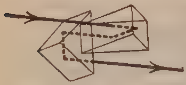

Fig. 7

In Reflecting Telescopes the object lens is replaced by a concave mirror. Being strictly achromatic, reflecting telescopes are valuable for certain classes of astronomical work. Mirrors as large as 100 in. in aperture have been made. The mirror is of glass, upon which a thin film of silver has been deposited.

9. Temperature and Temperature Scales

The Temperature of a body may be defined as its thermal state considered from the standpoint of its ability to communicate heat to other bodies. When two bodies are placed in thermal communication, the one which loses heat to the other is said to be at the higher temperature.

Certain thermal states or " temperatures " may be reproduced and recognized by the fact that definite physical phenomena occur at these temperatures. Such thermal states are called " fixed points " and may, quite apart from any temperature scale, be specified by the physical phenomena characteristic of those temperatures. For example we may speak of the temperature of freezing water (ice point), the boiling point of water under a specified pressure (steam point), the freezing point of gold (gold point), etc. The purpose of establishing a temperature scale is to assign a number to every thermal state or temperature, and to provide a means for determining the temperature of any particular body.

A Temperature Scale may be defined by (1) selecting definite numbers for certain fixed points, (2) selecting some physical property of a definite substance which varies with temperature, and (3) selecting a mathematical law expressing temperatures on the scale in question in terms of the selected property of the thermometric substance. For example, on the centigrade mercury-in-glass scale, the ice and steam points are numbered 0 and 100 respectively, the relative or " apparent " expansion of a volume of mercury enclosed in glass of a definite kind is the property used, and the mathematical relation used to express temperature on this scale is that equal increments of apparent volume of the mercury in this glass correspond to equal increments of temperature. If some other substance is substituted for mercury or if glass of a different kind is used, another scale would be obtained which would agree with it at 0 and 100 but not at other temperatures.

Although, in general, a temperature scale depends on the thermometric substance as well as on the expression for the temperature in terms of some property of this substance, Lord Kelvin has shown that if the property selected is the availability of energy, the scale so defined is wholly independent of the substance and depends only on the mathematical relation chosen. Any scale so defined is known as a thermodynamic scale.

The Kelvin Scale finally chosen by Lord Kelvin, is the one on which the temperature interval from the ice point to the steam point is 100° and the ratio of the values of any two temperatures is equal to the ratio of the heat taken in to the heat rejected by a reversible thermodynamic engine working with a source and refrigerator at the higher and lower temperatures respectively. On this scale, which is also known as the absolute thermodynamic scale, the lowest attainable temperature is 0 and the ice point is found experimentally to be 273.10°. The steam point therefore is 373.10° or 100° higher.

The Absolute Fahrenheit Scale is identical with the Kelvin scale except that the interval from the ice to the steam point is taken as 180°. Any temperature on this scale is therefore 1.8 times the same temperature expressed on the Kelvin scale.

The Thermodynamic Centigrade Scale is derived by subtracting from the Kelvin scale a constant number of the proper magnitude to make the ice point 0°. On this scale, therefore, the ice and steam points are 0° and 100° respectively, and the so-called " absolute zero " is − 273.10°.

While other thermodynamic scales may be devised, such as the first one proposed by Lord Kelvin on which temperatures ranged from $-\infty$ to $+\infty$, the three described above are the only ones that have ever been widely used.

The International Temperature Scale for national and international use was adopted at the September 1927 meeting of the General Conference of Weights and Measures at Sèvres, France.

The international temperature scale, given below in detail, does not purport to replace the thermodynamic scale. It is, in fact, a practical representation of the thermodynamic centigrade scale to a degree of accuracy as great as is possible with present-day apparatus and methods. It is therefore to be regarded as susceptible of revision and amendment as improved and more accurate methods of measurement are evolved.

Definition of International Temperature Scale

1. The thermodynamic Centigrade scale, on which the temperature of melting ice and the temperature of condensing water vapor, both under the pressure of one standard atmosphere, are numbered 0° and 100° respectively, is recognized as the fundamental scale to which all temperature measurements should ultimately be referable.

2. The experimental difficulties incident to the practical realization of the thermodynamic scale have made it expedient to adopt for international use a practical scale, designated as the International Temperature Scale. This scale conforms with the thermodynamic scale as closely as is possible with present knowledge, and is designed to be definite, conveniently and accurately reproducible, and to provide means for uniquely determining any temperature within the range of the scale, thus promoting uniformity in numerical statements of temperature.

3. Temperatures on the International Scale will ordinarily be designated as " ° C." but may be designated as " °C. (Int.) " if it is desired to emphasize the fact that this scale is being used.

4. The International Temperature Scale is based upon a number of fixed and reproducible equilibrium temperatures to which numerical values are assigned and upon the indications of interpolation instruments, calibrated according to a specified procedure at the fixed temperatures.

5. The basic fixed points and the numerical values assigned to them for the pressure of one standard atmosphere are given in the following table, together with formulas which represent the temperature (t_p) as a function of vapor pressure (p) over the range 680 mm. to 780 mm. of mercury.

6. Basic Fixed Points of the International Temperature Scale:

(a) Temperature of equilibrium between liquid and gaseous oxygen at the pressure of one standard atmosphere (oxygen point), −182.97° C.

$$t_p = t_{760} + 0.0126\,(p - 760) - 0.0000065\,(p - 760)^2$$

(b) Temperature of equilibrium between ice and air saturated water at normal atmospheric pressure (ice point), 0.000° C.

(c) Temperature of equilibrium between liquid water and its vapor at the pressure of one standard atmosphere (steam point), 100.000° C.

$$t_p = t_{760} + 0.0367\,(p - 760) - 0.000023\,(p - 760)^2$$

(d) Temperature of equilibrium between liquid sulfur and its vapor at the pressure of one standard atmosphere (sulfur point), 444.60° C.

$$t_p = t_{760} + 0.0909\,(p - 760) - 0.000048\,(p - 760)^2$$

(e) Temperature of equilibrium between solid silver and liquid silver at normal atmospheric pressure (silver point), 960.5° C.

(f) Temperature of equilibrium between solid gold and liquid gold at normal atmospheric pressure (gold point), 1063° C.

Standard atmospheric pressure is defined as the pressure due to a column of mercury 760 mm. high, having a mass of 13.5951 grams per cm.^{3}, subject to a gravitational acceleration of 960.665 cm./sec.^{2} and is equal to 1.013.250 dynes/cm.^{2}

It is an essential feature of a practical scale of temperature that definite numerical values shall be assigned to such fixed points as are chosen. It should be noted, however, that the last decimal place given for each of the values in the table is significant only as regards the degree of reproducibility of that fixed point on the International Temperature Scale. It is not to be understood that the values are necessarily known on the Thermodynamic Centigrade Scale to the corresponding degree of accuracy.

7. The means available for interpolation lead to a division of the scale into four parts.

8. **From the ice point to 660° C.** the temperature t is deduced from the resistance R_t of a standard platinum resistance thermometer by means of the formula

$$\mathbf{R_t = R_0\,(1 + At + Bt^2)}$$

The constants R_0, A, and B of this formula are to be determined by calibration at the ice, steam, and sulfur points, respectively.

The purity and physical condition of the platinum of which the thermometer is made should be such that the ratio R_t/R_0 shall not be less than 1.390 for t = 100° and 2.645 for t = 444.6°.

9. **From −190° C. to the ice point** the temperature t is deduced from the resistance R_t of a standard platinum resistance thermometer by means of the formula

$$\mathbf{R_t = R_0\,[1 + At + Bt^2 + C\,(t - 100)\,t^3]}$$

The constants R_0, A, and B are to be determined as specified above, and the additional constant C is determined by calibration at the oxygen point.

The standard thermometer for use below 0° C. must in addition have a ratio R_t/R_0 less than 0.250 for t = −183°.

10. **From 660° C. to the gold point,** the temperature t is deduced from the electromotive force e of a standard platinum vs. platinum-rhodium thermocouple, one junction of which is kept at a constant temperature of 0° C. while the other is at the temperature t defined by the formula

$$\mathbf{e = a + bt + ct^2}$$

The constants a, b, and c are to be determined by calibration at the freezing point of antimony, and at the silver and gold points.

11. **Above the gold point** the temperature t is determined by means of the ratio of the intensity J_2 of monochromatic visible radiation of wavelength λ cm. emitted by a black body at the temperature t to the intensity J_1 of radiation of the same wavelength emitted by a black body at the gold point, by means of the formula

$$\log_e \frac{J_2}{J_1} = \frac{c_2}{\lambda}\left[\frac{1}{1336} - \frac{1}{(t + 273)}\right]$$

The constant c_2 is taken as 1.432 cm. degrees. The equation is valid if $\lambda(t + 273)$ is less than 0.3 cm. degrees.

Recommended Experimental Procedure

1. Oxygen. The temperature of equilibrium of liquid and gaseous oxygen has been best realized experimentally by the static method, the oxygen vapor-pressure thermometer being compared with the thermometer to be standardized in a suitable low temperature bath.

2. Ice. The temperature of melting ice is realized experimentally as the temperature at which pure finely divided ice is in equilibrium with pure, air-saturated water, under standard atmospheric pressure. The effect of increased pressure is to lower the freezing point to the extent of 0.007° C. per atmosphere.

3. Steam. The temperature of condensing water vapor is realized experimentally by the use of a hypsometer so constructed as to avoid superheat of the vapor around the thermometer, or contamination with air or other impurities. If the desired conditions have been attained, the observed temperature should be independent of the rate of heat supply to the boiler, except as this may affect the pressure within the hypsometer, and of the length of time the hypsometer has been in operation.

4. Sulfur. For the purpose of standardizing resistance thermometers, the temperature of condensing sulfur vapor is realized by adherence to the following specifications relating to boiling apparatus, purity of sulfur, radiation shield and procedure.

The boiling-tube is of glass, fused silica or similar material, and has an internal diameter of not less than 4 nor more than 6 cm. The vapor column must be sufficiently long that the bottom of the radiation shield is not less than 6 cm. above the free liquid surface and its top is not less that 2 cm. below the top of the heat insulating material surrounding the tube. Electric heating is preferable although gas may be used, but the source of heat and all good conducting material in contact with it must terminate at least 4 cm. below the free surface of the liquid sulfur. Above the source of heat the tube is surrounded with insulating material. Any device used to close the end of the tube must allow a free opening for equalization of pressure.

The sulfur should contain not over 0.02% of impurities. Selenium is the impurity most likely to be present in quantities sufficient to affect the temperature of the boiling point.

The radiation shield is cylindrical and open at the lower end, and is provided with a conical portion at the top, to fit closely to the protecting tube of the thermometer. The cylindrical part is 1.5 to 2.5 cm. larger in diameter than the protecting tube of the thermometer and at least 1 cm. smaller in diameter than the inside of the boiling tube. The cylinder should extend at least 1.5 cm. beyond each end of the thermometer coil. There should be ample opening at the top of the cylindrical and below the conical portion to permit free circulation of vapor. The inner surface of the shield should be a poor reflector. The shield may be made of sheet metal, graphite, etc.

In standardizing a thermometer the sulfur is heated to boiling and the heating so regulated that the condensation line is at least 1 cm. above the top of the insulating material. The thermometer with its radiation shield is inserted in the vapor, and when the line of condensation again reaches its former level simultaneous observations of resistance and barometric pressure are made. In all cases care should be taken to prove that the temperature is independent of vertical displacements of the thermometer and shield.

5. Silver and Gold. For standardizing a thermocouple, the metal to be used at its freezing point is contained in a crucible of pure graphite, refractory porcelain, or other material which will not react with the metal so as to contaminate it to an appreciable extent.

Silver must be protected from access of oxygen while heated.

The crucible and metal are placed in an electric furnace capable of heating the contents to a uniform temperature.

The metal is melted and brought to a uniform temperature a few degrees above its melting point, then allowed to cool slowly with the thermocouple immersed in it as described in the next paragraph.

The thermocouple, mounted in a porcelain tube with porcelain insulators separating the two wires, is immersed in the molten metal through a hole in the center of the crucible cover. The depth of immersion should be such that during the period of freezing the thermocouple can be lowered or raised at least 1 cm. from its normal position without altering the indicated e.m.f. by as much as one microvolt. During freezing, the e.m.f. should remain constant within one microvolt for a period of at least 5 minutes.

As an alternative to displacing the couple, as a means of testing the absence of the influence of external conditions upon the observed temperature, both freezing and melting points may be observed, and if these do not differ by more than 2 microvolts the observed freezing point may be considered satisfactory.

6. **The Standard Platinum Resistance Thermometer**. The diameter of the wire should not be smaller than 0.05 or larger than 0.2 mm.

The platinum wire of the thermometer must be so mounted as to be subject to the minimum of mechanical constraint, so that dimensional changes accompanying changes of temperature may result in a minimum of mechanical strain being imposed upon the platinum.

The design of the thermometer should be such that the portion, the resistance of which is measured, shall consist only of platinum, and shall be at the uniform temperature which is to be measured. This may be accomplished by either of the accepted systems of current and potential, or compensating leads.

After completion the thermometer should be annealed at a temperature of at least 660°.

7. **The Standard Thermocouple.** The platinum of the standard couple shall be of such purity that the ratio R_t/R_0 is initially not less than 1.390 for $t = 100°$. The alloy is to consist of 90% platinum with 10% rhodium. The completed thermocouple must develop an electromotive force, when one junction is at 0° and the other at the freezing point of gold, not less than 10 200 nor more than 10 400 international microvolts. The diameter of the wires used for standard thermocouples should lie between the values 0.35 mm. and 0.65 mm.

The freezing point of antimony, specified for the standardization of the thermocouple, lies within the range of 0° to 660° where the International Scale is fixed by the indications of the standard resistance thermometer, and the numerical value of this temperature is therefore to be determined with the resistance thermometer. In the appendix the result of such determinations is given as 630.5°, but the temperature of any particular lot of antimony which is to be used for standardizing the thermocouple is to be determined with a standard resistance thermometer.

The procedure to be followed in using the freezing point of antimony as a fixed temperature is substantially the same as that specified for silver. Antimony has a marked tendency to undercool before freezing. The undercooling will not be excessive if the metal is heated only for degrees above its melting point and if the liquid metal is stirred. During freezing, the temperature should remain constant within 0.1° for a period of at least 5 minutes.

1. **Secondary points.** In addition to the basic fixed points the temperatures of a number of other points are available and may be used in the calibration of secondary temperature measuring instruments. These points and their temperatures on the International Scale are listed below. The temperatures given are those corresponding to a pressure of one standard atmosphere. The formulas for the variation of vapor pressure with temperature are valid for the range from 680 to 780 mm.

Secondary Points

	Deg. C.
Temperature of equilibrium between solid and gaseous carbon dioxide.....	−78.5
$t_p = t_{760} + 0.1443\ (t_p + 273.2) \log_{10}(p/760)$	
Temperature of freezing mercury..........	−38.87
Temperature of transition of sodium sulfate..........	32.38
Temperature of condensing naphthalene vapor..........	217.96
$t_p = t_{760} + 0.208\ (t_p + 273.2) \log_{10}(p/760)$	
Temperature of freezing tin..........	231.85
Temperature of condensing benzophenone vapor..........	305.9
$t_p = t_{760} + 0.194\ (t_p + 273.2) \log_{10}(p/760)$	

Temperature of freezing cadmium	320.9
Temperature of freezing lead	327.3
Temperature of freezing zinc	419.45
Temperature of freezing antimony	630.5
Temperature of freezing copper in a reducing atmosphere	1083.
Temperature of freezing palladium	1555.
Temperature of melting tungsten	3400.

10. Temperature-measuring Equipment

The Platinum vs. Platinum-Rhodium Thermocouple may be used to measure temperatures up to 1600° C. At this high temperature, however, the life of a couple is very short. When suitably protected, a couple of this kind may be used for long periods up to 1300° C. In a reducing atmosphere such couples are contaminated by the reduction to silicon of the silica in porcelain protection tubes. These couples can be used at any lower temperatures, of course, but below about 1000° C. base metal couples often are to be preferred, being less expensive and giving a higher electromotive force.

Base Metal Couples of copper vs. constantan may be used for temperatures below 500° C. For extreme precision this couple should not be used above 350° C. Iron vs. constantan couples may be used up to 900° C., while chromel vs. alumel couples may be used for continuous service up to 1100° C. In the accompanying table are given the calibration data for representative couples of these four types with the cold junctions at 0° C. If the cold junctions are not at 0° C., the e.m.f. in the table corresponding to the temperature of the cold junction must be added to the observed e.m.f. before using table.

Example. Chromel-alumel couple with cold junction at 12° C. yields at e.m.f. of 24.5 millivolts.

24.5 millivolts observed e.m.f.
.5 millivolt e.m.f. at 12° C.
25.0 millivolts

Therefore the temperature of the hot junction is 601° C.

The e.m.f. may be measured by means of a portable potentiometer or millivoltmeter. If a millivoltmeter is used it should have a high resistance, preferably 300 ohms or more.

Mercury-in-Glass Thermometers may be used for measuring temperatures from − 38° C. up to about 500° C. Fused silica thermometers filled with gallium are usable up to 1000° C.

Pyrometric Cones are used for the control of numerous industrial processes, notably in the ceramic industry. The temperatures determined by the Bureau of Standards at which the American cones (made by the Standard Pyrometric Cone Co. of Columbus, Ohio) start to bend and the temperatures at which the tip falls to the level of the base or "end points" are shown for two different rates of heating in the second table herewith. The Bending Interval is the difference between the "end point" and the temperature at which bending starts.

The temperatures in the table on page 265, as determined under standardized and reproducible conditions (controlled rate of heating in clean air) will apply with fair approximation for the cones when heated in kilns where the gases are normally oxidizing and free from sulfur oxides. If the cones show a visible hardening of the surface or a skin effect resulting from exposure to kiln gases containing insufficient oxygen, small corrections may be necessary. Such surface action is most frequently noticed with cones 015 to 01. In kilns fired with fuel containing appreciable amounts of sulfur, or where the ware gives off sulfur dioxide the end points may be noticeably different from those given in the table.

Calibration Data of Representative Couples with One Junction at 0° C. and the Other at T° C.

Note. This table may be used to get approximate temperatures. For accurate work each individual couple must be calibrated.

Optical and Radiation Pyrometers may be used to measure any temperature above 700° C. The indications of a radiation pyrometer depend on the whole spectrum of radiant energy emitted by a body, while the optical pyrometer indicates temperature by measuring the brightness of the light of one particular wavelength emitted by an incandescent body.

Radiation and optical pyrometers are usually calibrated to read correctly when sighted into a uniformly heated hollow enclosure such as a furnace with an opening small in comparison with the walls of the furnace. Under such conditions, called "black body" conditions, the pyrometer receives not only the energy radiated directly by the part of the wall or other surface sighted upon, but also the energy which is emitted by other portions of the furnace and reflected by this surface into the pyrometer. Surfaces which have a high radiating power have a low reflecting power, the lack of energy directly emitted being in all cases exactly compensated for by the energy reflected. Under black body conditions, therefore, the energy received is independent of the radiating characteristics of the surfaces and depends only on the temperature. When an optical or radiation pyrometer is sighted upon a surface in the open, it receives only the light directly emitted and consequently always reads low. The temperature indicated by a pyrometer when sighted upon a surface in the open, the pyrometer being calibrated to read correctly when sighted into a black body, is called the " apparent " or " black body " temperature of the object viewed. The difference between the true and apparent temperatures for any surface is between four and five times as great in the case of measurements with a radiation pyrometer. This fact renders the radiation pyrometer unsuitable for the measurement of

the temperature of bodies in the open. The radiation pyrometer finds its best application under black body conditions where a fixed installation is possible and an automatic record is desired. When used as a portable instrument it is not satisfactory; the optical pyrometer should be used in such cases. In the table are noted the relations between the true and apparent temperatures of various surfaces for optical and radiation pyrometry.

11. Heat

Heat is defined as energy in the process of transfer from one body to another by a thermal process, i.e., by radiation, convection, or conduction.

The Gram-Calorie is a unit of heat, being the heat per degree centigrade required to raise the temperature of 1 gram of water at some specified temperature. The 15° calorie, the 20° calorie, and the mean calorie (0° to 100° C.) are in common use.

The B. t. u. (British thermal unit) is the quantity of heat per degree Fahrenheit required to raise the temperature of one pound of water, at some specified temperature.

The Specific Heat of a substance is the number of calories per degree centigrade required to raise the temperature of one gram of the substance.

In the case of gases, this depends largely upon how the pressure and volume change during the heating. Two special values are of importance in the case of a gas: C_p, the specific heat at constant pressure, and C_v, the specific heat at constant volume.

The Latent Heat of Fusion is the amount of heat that must be added to unit mass of a solid substance to change it to a liquid without any change in temperature.

The Latent Heat of Vaporization is the amount of heat required to change unit mass of a substance from a liquid to saturated vapor without any change in temperature.

12. Heat Transfer

By Radiation. The energy radiated per unit area per unit time from a substance is approximately proportional to the fourth power of the absolute temperature. (For a black body the proportionality is exact.) The net loss per unit of time depends on the surroundings, being the difference between the energy radiated and the energy received by radiation from surrounding bodies.

By Convection. Transfer of heat by convection occurs in liquids and gases, the transfer being accomplished by the motion of the fluid from a locality where it receives heat to a locality where it gives up heat.

By Conduction. Transfer of heat by conduction occurs through continuous materials in which energy is transferred directly between adjacent molecular aggregates without mass motion of the materials.

When heat flows in a solid, homogeneous body in only one direction, the time rate of heat flow, after a steady state has been reached, across a given area will be proportional to the temperature drop per unit length in the direction of the flow of heat. The factor of proportionality is, by definition, the thermal conductivity.

If $\frac{dQ}{dt}$ = the time rate of heat flow;

A = the area measured perpendicular to the direction of flow;

$\frac{dT}{dx}$ = the temperature gradient;

and K = the thermal conductivity;

$$\frac{dQ}{dt} = KA\frac{dT}{dx}$$

for a steady state where $\frac{dT}{dt} = 0$ at all points.

13. Thermal Insulation

The heat conductivity of a material is a measure of the insulating value of that material; the lower the conductivity, the greater the insulating value. Obviously the best conductor of heat is the poorest heat insulator. The customary measure of the conductivity K of a material is the amount of heat in B.t.u. (British thermal units) which will flow in one hour through a layer of the material one square foot in area when the temperature difference between the surfaces of the layer is 1° F., per inch of thickness.

The thermal conductivity K is a property of a material itself, and does not depend upon the size or shape of a particular piece of the material in question. The insulating value of a layer of material of any thickness

T depends upon the thickness as well as upon the thermal conductivity of the material of which the layer is composed. In general the insulating value, i.e., the resistance to heat flow, R, of a flat layer of any material is equal to the thickness of the layer divided by the thermal conductivity of the material of which the layer is composed.

The same principles are involved in what is sometimes called "insulation against cold" as in "insulation against heat." The only difference is the point of view, with regard to the direction of heat flow. The insulation of a building against the outside cold is merely a question of reducing the heat flow from the inside to the outside. The insulating value of a material depends somewhat upon the temperature of the material, but this effect is small over the small temperature ranges occurring in buildings. The same layer of material would be somewhat more effective as house insulation than as oven insulation. . . .

The first of the two tables following gives the thermal conductivities and weights per cubic foot of various materials which have been tested at the Bureau of Standards. The weights do not include the paper or other coverings confining loose materials. The second table is a more practical table for general use. It gives the conductances of commercial thicknesses of various materials, and in another column gives the insulating value of the commercial thicknesses. The insulating value is merely the reciprocal of the conductance, in accordance with the definition of insulating value previously stated, namely, the thickness of the material divided by its thermal conductivity. The weights per square foot given include the surface coverings, if any are present. In all cases the tabulated values are the average of tests on a number of samples of each material. Since materials of this general class are not very uniform, differences in conductivity amounting to one or two in the last figure have no particular significance.

The figures in both tables correspond to an average temperature of 90° F., e.g., 110° F. on one surface of the insulating layer, and 70° F. on the other. At lower temperatures, corresponding more nearly to actual conditions in practice, the conductivities are a few per cent lower. For practical comparative purposes, the values at 90° F. are sufficiently good.

Thermal Conductivity of Materials *

D = Weight in pounds per cubic foot.
K = Thermal conductivity in B.t.u. per hour, square foot, and temperature gradient of 1° F. per inch of thickness. The lower the conductivity, the greater the insulating values.

The insulating value, except at elevated temperatures of an ordinary enclosed air space of width greater than 1/2 in. is equivalent to approximately 1/3 in. of good insulating material. At high temperatures air spaces have but little insulating value because of the rapid increase of radiation with increase in temperature.

14. Changes Due to Heating

Heat and Expansion. Although most substances expand as they are warmed, or if hindered from expanding freely will exert pressure upon their containers, water between 0° and 4° C., quartz-glass below −84° C., and some other substances are exceptions to the general rule. When heating causes a body to change its state of aggregation (melt, vaporize, etc.) there is also change in volume. This may be either an expansion or a contraction, and may be accompanied by little or no change of temperature until after the process is completed.

Thermal Hysteresis. When a solid has its temperature changed, especially by rapid cooling, slow changes in its dimensions continue long after it has attained the same temperature throughout its entire extent. These changes are often so minute as to require extremely delicate means for detection; but in such cases as glass they are very marked. The gradual contraction of thermometer bulbs has been observed to continue for over a quarter of a century, causing the zero reading to rise. The zero point of even a good thermometer may be shifted many degrees in a few minutes by heating to several hundred degrees. (Bul. Bureau Standards, vol. 2, 1906, p. 189.) Most of this after-effect disappears in a few hours or days, and the process is considerably accelerated by prolonged heating at a high temperature followed by slow annealing.

Laws of Change. As long as a physically homogeneous body is not subjected to treatment that causes more or less permanent alterations in its structure, its volume appears to be a definite function of its temperature and pressure, when these are uniform throughout its entire extent. The amount of expansion under constant pressure caused by a given change of temperature depends upon the material of the body. Solids and liquids differ considerably among themselves and follow no regular law. Gases, on the other hand, show remarkable uniformity, all expanding about 100/273 = 0.367 of their volumes at 0° C. when warmed from this temperature to 100° C. (Law of Gay-Lussac.) Besides, all gases expand very nearly alike throughout great ranges of temperature; and the particular pressure under which a gas is warmed makes very little difference.

Coefficients of Expansion. If the volume at $t°$ is V and at 0° is V_0, then the rate at which unit volume changes under constant pressure with change of temperature is $(dV/dt)/V$ which is called the **true** coefficient of cubical expansion at $t°$; while $(V - V_0)/V_0t = \alpha$ is called the **mean-zero** coefficient from 0° to $t°$. Similarly, if L represents the length of a solid, then $(L - L_0)/L_0t = \beta$ is the mean-zero coefficient of **linear** expansion from 0° to $t°$. These definitions give $V = V_0 (1 + \alpha t)$ and $L = L_0 (1 + \beta t)$. Usually α and β are so small that one may assume $\alpha = 3\beta$.

Values of the coefficient of linear expansion for solids are given above in Art. 7. The coefficient of cubical expansion is three times the linear. Art. 7 gives values for the Centigrade degree.

Dalton's Law. In a mixture of several gases or vapors that do not react upon each other chemically the pressure exerted is approximately the same as if each constituent exerted the full pressure it would exert if it alone filled the entire volume; that is to say, if volumes V_1, V_2, V_3, . . . , of different gases and vapors, all under the same pressure p and at the same temperature, when mixed fill a volume V, then $P = p_1 + p_2 + p_3 + \ldots$, approximately, where $p_1 = pV_1/V$; $p_2 = pV_2/V$; etc. This relation is more accurately fulfilled the farther all the vapors are from the conditions under which they liquefy and the less their liquids dissolve one another. p_1, p_2, etc., are spoken of as the partial pressures exerted by the different components.

15. Sound and Acoustics

Velocity of Sound in air at 0° F. is 1050 ft. per sec., and it increases 1.1 ft. per sec. for each 1° F. rise in temperature. A few values are

Temperature, F.	−10°	+10°	+30°	+50°	+70°	+90°
Velocity, ft. per sec.	1039	1061	1083	1105	1127	1149

At 0° C. the velocity of sound in dry air is **331 meters per sec.** and it increases 0.609

meters per sec. for a rise of each degree of the centigrade scale. At +30° C. the velocity is about 349 meters per sec

The velocity of sound in air is independent of the barometric pressure, and hence is the same on high mountains as at sea level, the temperature being the same in both cases. It is said to be little influenced by fog or rain but materially altered by aqueous vapor and also by wind.

A formula for velocity of sound in any solid or liquid is $v = \sqrt{Eg/w}$, where E = modulus of elasticity; w = weight per cubic unit of the substance; and g = acceleration of gravity. Mean values of v are as follows in ft. per sec.:

Fresh water	4 700	Copper	11 700
Salt water	4 765	Cast iron	12 400
Timber	13 200	Wrought iron	15 500
Silver	8 550	Steel	17 200

Stress is transmitted through a solid with the same velocity as sound.

The velocities of sound in different gases at the same pressure and temperature vary inversely as the square roots of their densities. Thus, using densities of air and hydrogen as given on p. 254, the velocity in hydrogen at 0° F. is 3980 ft. per sec.

In open air the intensity of sound varies inversely as the square of the distance of the source from the ear. For air in a pipe this law does not hold, but the intensity remains the same for considerable distances, being diminished only by internal frictional resistances. The intensity also depends on the medium; the ticking of a watch is heard 2-1/2 times as far under water as in air. It also depends on the volume of sound produced by the sonorous body; the explosion of a volcano has been heard at a distance of 300 miles.

When a sonorous body approaches the ear the tone perceived is higher than the true, and when it recedes the tone is lower. This is because high tones are produced by short waves, and in the case of approach to the ear, the sound waves are crowded together or shortened.

Architectural Acoustics. Acoustical properties of rooms are readily adjusted by the use of materials of proper absorbing values. The optimum values to produce satisfactory reverberation will depend upon the purpose for which the room is to be used. Excessive absorption gives the open or out-of-doors type of acoustical defect.

In new or remodeling operations proper wall and ceiling designs may be used to enhance or reduce the acoustical values as desired to a more satisfactory condition.

The following paragraphs and tables are from Bureau of Standards Circular 300, Architectural Acoutics (Available from the Supt. of Documents, Washington, D. C., at 5 cents a copy).

Different materials differ considerably in their absorbing powers for sound. The most complete absorber known is an open window. It is theoretically possible that a small amount of sound may be sent back by diffraction from the edges of the window, but this quantity is so small that it is permissible to say that an open window is a perfect absorber. The next most perfect absorber of sound is probably hair felt, which may absorb, perhaps, half as much sound as an equal area of open window. In other words, if it may be said that an open window absorbs (or transmits) all the sound that falls upon it, its coefficient of absorption is unity, while that of the sample of hair felt quoted would be 0.50.

In like manner, every substance may be said to have its own absorption coefficient. This constant was measured by Sabine for a number of common materials, and later workers have extended the list.

The first of the following tables gives the absorption coefficients for a number of substances. Strictly speaking, these coefficients will vary somewhat with the frequency of the incident sound, and the values given are for a frequency of 512 (Watson).

In the second table are given values of the total absorption of individual objects, and in the third table absorption coefficients of various substances for different sound frequencies, as determined at the Bureau of Standards.

Sound Absorption Coefficients

Akoustolith (artificial stone)	0.36

METEOROLOGY

16. Signals of United States Weather Bureau

Flag Signal for cold wave warning is shown in Fig. 8. Color Key

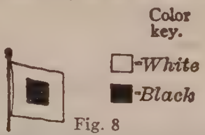

Fig. 8

Storm and Hurricane Warnings are given by the flags in Fig. 9.

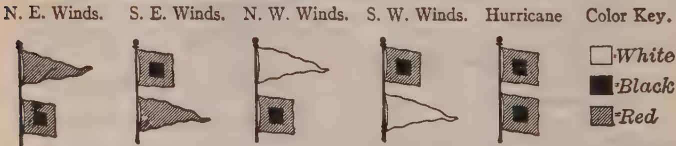

Fig. 9. Storm and Hurricane Flags

A red flag with a black center indicates that a storm of marked violence is expected. The pennants displayed with the flags indicate the direction of the wind; red, easterly (from northeast to south); white, westerly (from southwest to north). The pennant above the flag indicates that the wind is expected to blow from the northerly quadrants; below from the southerly quadrants. By night a red light indicates easterly winds, and a white light below a red light, westerly winds.

Two red flags with black centers, displayed one above the other, indicate the expected approach of a tropical hurricane, or one of those extremely severe and dangerous storms which occasionally move across the Lakes and northern Atlantic coast. No night hurricane warnings are displayed

Wind Pressure on Flags. Tests at the U. S. Navy Yard, Washington, D. C., using the largest flags that could be handled in the wind tunnel, form the basis for an empirical formula for determining the pressure of wind on flags, for use in designing flagpoles. Two sizes of flags were used—one 3 × 5-1/2 ft. and the other 2-1/2 × 4-1/4 ft.—and velocities varying from 20 to 60 miles per hour were applied. The following formula was found to represent the results, the constant varying but slightly with size of flags, being less for the larger flag:

$$R = 0.0003 A V^{1.9}$$

in which R is the resistance in pounds, A is the area of flag in square feet, and V is the velocity of wind in miles per hour. This formula is for steady wind pressure. It was not found practicable to measure the forces produced by wind gusts.

17. Local Weather Predictions

The wind and barometer indications for the United States are generally summarized in the following table (E. B. Garriott, U. S. Dept. Agriculture).

Wind direction	Barometer reduced to sea level	Character of weather indicated
SW to NW	30.10 to 30.20 and steady.......	Fair, with slight temperature changes, for 1 to 2 days
SW to NW	30.10 to 30.20 and rising rapidly	Fair, followed within 2 days by rain
SW to NW	30.10 to 30.20 and falling slowly	Warmer, with rain within 24 to 36 hours
SW to NW	30.10 to 30.20 and falling rapidly	Warmer, with rain within 18 to 24 hours
SW to NW	30.20 and above and stationary	Continued fair, with no decided temperature change
SW to NW	30.20 and above and falling slowly	Slowing rising temperature and fair for 2 days
S to SE...	30.10 to 30.20 and falling slowly	Rain within 24 hours
S to SE...	30.10 to 30.20 and falling rapidly	Wind increasing in force, with rain within 12 to 24 hours
SE to NE.	30.10 to 30.20 and falling slowly	Rain in 12 to 18 hours
SE to NE.	30.10 to 30.20 and falling rapidly	Increasing wind, and rain within 12 hours
E to NE..	30.10 and above and falling slowly	In summer, with light winds, rain may not fall for several days. In winter, rain within 24 hours
E to NE..	30.10 and above and falling rapidly	In summer, rain probable within 12 to 24 hours. In winter, rain or snow, with increasing winds, will often set in when the barometer begins to fall and the wind sets in from the NE
SE to NE.	30.00 or below and falling slowly	Rain will continue 1 to 2 days
SE to NE.	30.00 or below and falling rapidly	Rain, with high winds, followed, within 36 hours, by clearing, and in winter by colder
S to SW...	30.00 or below and rising slowly	Clearing within a few hours, and fair for several days
S to E....	29.80 or below and falling rapidly	Severe storm imminent, followed, within 24 hours, by clearing, and in winter by colder
E to N....	29.80 or below and falling rapidly	Severe northeast gale and heavy precipitation; in winter, heavy snow, followed by a cold wave
Going to W	29.80 or below and rising rapidly	Clearing and colder

As a rule winds from the east quadrants and falling barometer indicate foul weather; and winds shifting to the west quadrants indicate clearing and fair weather. The rapidity of the storm's approach and its intensity are indicated by the rate and the amount in the fall of the barometer.

The indications afforded by the wind and the barometer are the best guides for determining future weather conditions. As low barometer readings usually attend stormy weather, and high barometer readings are generally associated with clearing or fair weather, it follows that falling barometer indicates precipitation and wind, and rising barometer, fair weather or the approach of fair weather. As atmospheric areas of high barometer and areas of low barometer are, by natural laws, caused to assume circular or oval forms, the wind directions with reference to areas of low barometer are spirally and contraclockwise inward toward the region of lowest atmospheric pressure, as indicated by readings of the barometer. The areas of high barometer, on the contrary, show winds flowing spirally clockwise outward from the region of highest barometric pressure.

The wind directions thus produced give rise to, and are responsible for, all local weather signs. The south winds bring warmth, the north winds cold, the east winds, in the middle latitudes, indicate the approach from the westward of a low barometer, or storm, area, and the west winds show that the storm area has passed to the eastward. The indications of the barometer generally forerun the shifts of the wind. This much is shown by local observations.

During the colder months, when the land temperatures are below the water temperatures of the ocean, precipitation will begin along the seaboards when the wind shifts and blows steadily from the water over the land without regard to the height of the barometer. In such cases the moisture in the warm ocean winds is condensed by the cold of the continental area. During the summer months, on the contrary, the onshore winds are not necessarily rain winds, for the reason that they are cooler than the land surfaces and their capacity for moisture is increased by the warmth that is communicated to them by the land surface. In such cases thunderstorms commonly occur when the ocean winds are intercepted by mountain ranges or peaks. If, however, the easterly winds of summer increase in force, with falling barometer, the approach of an area of low barometric pressure from the west is indicated and rain will follow within a day or two.

From the Mississippi and Missouri valleys to the Atlantic coast, and on the Pacific coast, rain generally begins on a falling barometer, whereas in the Rocky Mountain and Plateau districts, and on the eastern Rocky Mountain slope, precipitation seldom begins until the barometer begins to rise, after a fall. This is true as regards the eastern half of the country, however, only during the colder months, and in the presence of general storms that may occur at other seasons. In the warmer months summer showers and thunderstorms usually come about the time the barometer turns from falling to rising. It is important to note the fact that during practically the entire year precipitation on the great western plains and in the mountain regions that lie between the plains and the Pacific coast districts does not begin until the center of the low barometer area has passed to the eastward or southward, and the wind has shifted to the north quadrants, with rising barometer.

18. Weather Observations

Mean Temperature. When maximum and minimum readings of temperature are taken, the mean of the two may be taken as the mean temperature of the day. The mean of all the daily means in a month is the mean temperature of the month. When a recording thermometer is used the area between the curve and an axis of abscissas is to be divided by the length of that axis in order to obtain the mean temperature for the elapsed time.

Rainfall. The rain gage used by voluntary observers consists of a cylindrical receiver 8 in. in diameter which has a funnel-shaped bottom that discharges into a tube 2.53 in. in diameter. The cross section of tube is one-tenth that of the receiver, and hence height of water in tube is ten times as

great as actual rainfall. The depth in the tube is measured by a stick which is so graduated as to read the true rainfall in inches. The tube is 20 in. long so that a precipitation of 2 in. or less can be measured without emptying it.

Self-registering rain gages are used at main stations of U. S. Weather Bureau. Snowfall is caught, melted, and then measured; roughly 10 in. of snow make 1 in. of water. A rain gage at the top of a building gives a less rainfall than one on the ground.

Voluntary observers of the Weather Bureau record maximum and minimum temperature, precipitation, wind direction, general character of day, and miscellaneous phenomena such as halos, dates of frost, hail, sleet, auroras, and tornadoes. The general character of the day is recorded "clear" when the sky is 3/10 or less obscured, "partly cloudy" when from 4/10 to 7/10 is obscured, and "cloudy" when more than 7/10 is obscured.

19. Rainfall and Evaporation

Mean Annual and Monthly rainfall at many stations are given in Sect. 9, Art. 40. The term Rainfall includes both rain and melted snow.

Measurements of Evaporation are made by placing water-tight pans at

Place	Position of pan	Diameter of pan, ft.	Annual evaporation in.
Salton Sea, Calif	1500 ft. inland	2	164.50
Salton Sea, Calif	500 ft. at sea	4	108.65
Salton Sea, Calif	7500 ft. at sea	4	106.45
Indio, Calif	15 miles from Salton Sea	6	119.33
Mecca, Calif	1/2 mile from Salton Sea	6	107.81
Brawley, Calif	20 miles from Salton Sea	6	103.55
Mammoth, Calif	40 miles from Salton Sea	6	125.53
N. Yakima, Wash	1/2 mile west of city	4	67.96
Hermiston, Ore	On raft in reservoir	4	68.05
	On ground	3	97.29
Granite Reef, Ariz	Floating in Salt River	4	97.74
	On ground	4	115.18
California, Ohio	Floating in reservoir	4	45.99
Birmingham, Ala	Floating in reservoir	4	51.74
Dutch Flats, Neb	A few miles from Mitchell	4	65.67
Deer Flat, Idaho	On raft near water edge	4	77.43
	On ground of embankment	3	79.00
Ady, Ore	Floating in borrow pit	4	53.45
Fallon, Nev	Floating in canal	4	53.65
Lake Tahoe, Calif	2 ft. above water	4	42.21
Elephant Butte, N. Mex	Near Rio Grande River	4	86.95
Carlsbad, N. Mex	In the city	4	107.25
	In an alfalfa field	4	94.35
Lake Avalon, N. Mex	A few miles from Carlsbad	4	94.51

The evaporation from a pan 2 ft. in diameter is about 75%, that from a pan 4 ft. in diameter is about 50%, and that from a pan 6 ft. in diameter is about 30% greater than the evaporation from a large pond or lake. The above figures may be roughly corrected by using these percentages; thus, at Birmingham, Ala., the true annual evaporation is 34.50 in.

The U. S. Weather Bureau maintains at selected locations hook gage measurements of evaporation losses from cylindrical pans 10 in. deep and 4 ft. in diameter, exposed on wood frames, bottom of pans 1 in. above the ground, generally on level ground, and in full sunshine. Detailed description published in Monthly Weather Review, December, 1916, or in Circular L, Instrument Division, Weather Bureau, No. 559. From comparisons available, it appears that losses from bodies of water of considerable area are 50 to 60% as great as from pans exposed as above. The records are published in detail in the reports issued by the state section directors of the U. S. Weather Bureau, and in the Annual Reports of the Chief of the Weather Bureau.

the level of the ground and noting daily the variations in depth, together with the rainfall. On a water surface similar measurements may be made by floating boxes. It is found that the evaporation from water surfaces is greater than that from land, that it is greater in dry and desert regions than in cultivated ones, that it is less in low lands than on mountains, that it decreases as the humidity of the air increases, and that it increases with the temperature of the air and the velocity of the wind. In the North Atlantic states the annual evaporation from land surfaces is, on the average, about 40%, while that from water surfaces is about 60% of the annual rainfall. In low and level localities these percentages are decreased, while for high regions and steep slopes they are increased. In some arid localities west of the Rocky Mountains nearly all the rainfall evaporates from land surfaces, while the evaporation from water surfaces may be several times as great as the rainfall.

Experiments made in 1909-10 by the U. S. Department of Agriculture gave the following figures for the annual evaporation at twenty places in the United States, the evaporating pan being at or very near the surface of the ground or water.

Maximum Intensity of Rainfall

Station	Inches per hour for			Station	Inches per hour for

This table has been compiled from all the available records at stations of the U. S. Weather Bureau which are equipped with self-registering rain gages.

20. Speed of Winds in the United States

U. S. Weather Bureau Records of the average speed of wind in miles per hour at selected stations, and the highest speeds ever reported for a period of five minutes.

The Beaufort Scale is used by seamen. In following table the corresponding velocity per hour in statute miles and in nautical miles is added.

Station	Average	Highest	Station	Average	Highest
Abilene, Texas	10	66	Louisville, Ky	8	74
Albany, N. Y	7	76	Lynchburg, Va	5	63

Knoxville, Tenn	6	84	Wilmington, N. C	8	68

Intensity or force of wind, Beaufort's scale	Velocity	
	Statute miles per hour	Nautical miles per hour
0. **Calm.** Full-rigged ship, all sail set, no headway	0 to 3	0 to 2.6
1. **Light Air.** Just sufficient to give steerage-way	8	6.9
2. **Light Breeze.** Speed of 1 or 2 knots, "full and by"	13	11.3
3. **Gentle Breeze.** Speed of 3 or 4 knots, "full and by"	18	15.6
4. **Moderate Breeze.** Speed of 5 or 6 knots, "full and by"	23	20.0
5. **Fresh Breeze.** All plain sail, "full and by"	28	24.3
6. **Strong Breeze.** Topgallant sails over single-reefed topsails	34	29.5
7. **Moderate Gale.** Double-reefed topsails	40	34.7
8. **Fresh Gale.** Treble-reefed topsails (or reefed upper topsails and courses)	48	41.6
9. **Strong Gale.** Close-reefed topsails and courses (or lower topsails and courses)	56	48.6
10. **Whole Gale.** Close-reefed main topsail and reefed foresail (or lower main topsail and reefed foresail)	65	56.4
11. **Storm.** Storm staysails	75	65.1
12. **Hurricane.** Under bare poles	90 and over	78.1 and over

The words "intensity" and "force," used in connection with this scale, have no direct relation to pressure, but refer to speed or velocity.

21. Barometric Observations

Whenever pressure is specified in terms of the height of a column of mercury, it is always tacitly understood that it is the height the column balancing the pressure would have under "standard conditions," that is, at 0° C. and where g has the standard value $g_0 = 980.665$ cm. per sec. per sec. adopted by the International Committee of Weights and Measures. In all cases where the mercury column (if of average barometric height and at ordinary atmospheric temperature) is to be read closer than 2 or 3 mm. (0.1 in.) one or more of the corrections described below must be made or the accuracy of the reading will be imaginary.

Corrections. Let l be the height of the mercury column as read at $t°$ C. with a scale correct at $t_0°$ C. whose coefficient of linear expansion is β. Let ϕ be the latitude and H the elevation in meters above sea level.

(1) Temperature of the Mercury. Subtract $0.000182\ lt$.

(2) Temperature of the Measuring Scale. Add $\beta\ (t - t_0)\ l$. For brass $\beta = 0.000019$; for glass $\beta = 0.000008$. If, as is usual, the scale is correct at 0° C., the complete correction, (1) and (2), for the expansion of both the mercury and the scale may be made by subtracting from the observed reading $(0.000182 - \beta)\ lt$, which gives

$0.000163\ lt$ for a brass scale, and
$0.000174\ lt$ for a glass scale.

Under ordinary conditions the correction may amount to as much as 4 mm.

(3) Capillary Depression in a Cistern Barometer. Add to the reading of the top of the meniscus the amount given in the table below corresponding to the internal diameter of the tube and the height of the meniscus. This somewhat uncertain correction can be avoided by using a tube at least 25 mm. in diameter.

Capillary Depression of Mercury

(After Mendeléeff and Gutkowsky. Kohlrausch, 1910)

Diameter	Height of the meniscus in mm.							
	0.4	0.6	0.8	1.0	1.2	1.4	1.6	1.8
mm.	mm.	mm.	mm.	mm.	mm.	mm.	mm.	mm.
4	0.83	1.22	1.54	1.98	2.37	....	....	....
5	0.47	0.65	0.86	1.19	1.45	1.80	....	....
6	0.27	0.41	0.56	0.78	0.98	1.21	1.43	....
7	0.18	0.28	0.40	0.53	0.67	0.82	0.97	1.13
8	....	0.20	0.29	0.38	0.46	0.56	0.65	0.77
9	....	0.15	0.21	0.28	0.33	0.40	0.46	0.52
10	....	....	0.15	0.20	0.25	0.29	0.33	0.37
11	....	....	0.10	0.14	0.18	0.21	0.24	0.27
12	....	....	0.07	0.10	0.13	0.15	0.18	0.19
13	....	....	0.04	0.07	0.10	0.12	0.13	0.14

(4) Pressure of the Mercury Vapor. This causes a slight depression at high temperatures, but is less than 0.01 mm. under 40° C.

(5) Variation of weight with Latitude and Elevation. Multiply by $g/g_0 = (1 - 0.0026 \cos 2\phi - 0.000\,000\,2\ \mathrm{H})$, the local height obtained by applying the above corrections to the reading. The correction for elevation is only 0.1 mm. at 700 m., but the correction for latitude may amount to as much as 2 mm.

Mean Barometer-height b at an Elevation of H Meters above Sea Level. (Kohlrausch)

Air at 10° C. (50° F.) b_0 = 760 mm.

H =	0	100	200	300	400	500	600	700	800	900	1000 m.
b =	760	751	742	733	724	716	707	699	690	682	674 mm.
H =	1000	1100	1200	1300	1400	1500	1600	1700	1800	1900	2000 m.
b =	674	666	658	650	642	635	627	620	612	605	598 mm.

The international meteorological formula * for reducing height b of mercurial barometer at $t°$ C. and latitude ϕ to height b_0 at 0° C. and latitude 45° is

$$\log_\epsilon b_0 = \log_\epsilon b + \frac{H\,(1 - 3/8\ \epsilon/b)}{(18\,429 + 67.5\,t + 0.003\,H)\,(1 + 0.0026\cos 2\phi)}$$

22. Humidity

There is always present in the atmosphere a greater or less quantity of invisible water vapor, mixed with the other gases. The **absolute humidity** is the mass of water vapor present per unit volume; and the gas pressure which this water vapor is exerting is called the **vapor pressure.** The ratio of the actual absolute humidity to the maximum quantity of water vapor that could be present at the existing temperature is the **relative humidity.** By means of suitable tables, the relative humidity may be computed from the difference between simultaneous readings of an ordinary thermometer and a thermometer with a wetted and amply ventilated bulb. The temperature at which the actual absolute humidity would be the maximum possible—i.e., the temperature at which the existing quantity of water vapor would produce saturation—is called the **dew point.**

23. Protection against Lightning

The following discussion and rules have been abstracted from a Safety Code for Protection against Lightning which has been prepared for the American Engineering Standards Committee under the sponsorship of the Bureau of Standards and the American Institute of Electrical Engineers. The material included here is intended to indicate the general principles to be followed. For details as to materials and methods reference should be made to the Code.

Protection of Buildings and Miscellaneous Property

Fundamental Principles of Protection. The fundamental theory of lightning protection for buildings is to provide means by which a discharge may enter or leave the earth without passing through a nonconducting part of the structure, as for example, parts which are made of wood, brick, tile or concrete. Damage is caused by the heat and mechanical forces generated in such nonconducting portions by the discharge, whereas in metal parts the heat and mechanical forces are known to be of negligible effect if the metal has sufficient cross-sectional area. It is further known that there is a strong tendency for lightning discharges on structures to travel on the metal parts, especially those which extend in the general direction of the discharge. Hence, if metal parts are provided, of proper proportions and distribution, damage can be largely prevented. However, because lightning has such a wide range of characteristics, it is difficult to provide any practical means which will afford absolute protection under

* For a more complete treatment and application of this formula and for other forms of this equation see: (a) Smithsonian Meteorological Tables, 4 ed., pp. XXXXIX, also pp. 85-158; or (b) W. J. Humphreys, Physics of the Air, chap. V.

* Not computed

all conditions, although the degree of protection afforded by present practice is high if the installation is properly made.

The required condition that there be a metallic path for the part of the discharge which is intercepted is met most fully by a grounded metal or metal-covered structure which presents what might be thought of as an infinite number of parallel conductors from the uppermost part of the structure to earth. It is substantially met by a steel-framed structure, which, though faced with brick, terra-cotta, or other building material, usually has, or at relatively small cost can be equipped with, a sufficient number of metal terminals or receiving points on the upper portions which connect with the frame to protect it thoroughly.

For a structure which is built wholly or partly of non-conducting materials, one of the best defenses against direct hits by lightning is to surround it with a ring of grounded metallic masts or poles of sufficient height. Or, if the structure is not large, a single mast erected nearby may be sufficient. Experiments have indicated that, under certain assumed test conditions, such a vertical conductor will generally divert to itself all direct hits which might otherwise fall within a cone-shaped space of which the apex is the top of the conductor, and the base a circle of radius two to four times the height of the conductor. This agrees with theoretical deductions. Incidentally, any metallic structure, or adequately protected structure, will function in the same manner as a mast. Thus a tall steel windmill or water-tower or rodded steeple will tend to protect nearby structure of less height, although before relying upon such protection care should be taken to see that the structure lies well within the cone-shaped space mentioned above.

Generally, however, on account of architectural considerations, the mast type of protection is not feasible. More suitable protection is provided by the installation of lightning conductors. Here the required conditions of protection are closely approximated by placing air terminals or receiving points on the uppermost parts of the building, with interconnecting and grounding conductors attached to the building itself. By this means a relatively small amount of metal properly proportioned and distributed is made to afford a satisfactory degree of protection and at the same time, if necessary, to afford a minimum of interference with the contour of the structure. It should be stated, however, that this type of protection is to be considered only for structures in which very small induced sparks do not present an appreciable element of danger, as they do in oil tanks, cotton warehouses and powder storage houses. The latter require much more elaborate precautions to insure their safety than do the general run of buildings.

When designing and installing a system of protection of the lightning-rod type the following principles should be followed:

(a) The structure should be examined and all points or parts most likely to be struck by lightning should be noted, with the view of erecting air terminals thereon for the reception of the discharge. The object is to intercept the discharge immediately above the parts liable to be struck rather than to attempt to divert it in a direction it is not likely to take. The receiving points should be placed high enough above the structure to obviate danger of fire from the arc; the more inflammable the roof material the higher the points should be placed.

(b) Conductors should be installed with the view of offering the least possible obstruction to the passage of a stroke between air terminals and ground. The most direct path is in general the best, and there should be no sharp bends or loops for the lightning to jump across. The obstruction is practically inverse to the number of widely separated paths, so from each air terminal there should be at least two paths to ground and more if practicable. The number of paths is increased and the obstruction lessened by connecting the conductors to form a cage enclosing the building.

(c) When a stroke is about to take place to earth the surrounding surface of the ground for a radius of several miles carries an electric charge. As the discharge takes place this surface charge moves radially toward the ground end of the air path, forming an electric current in the ground. Near the point where the discharge enters the ground the current density becomes high, and if the flow takes place through the foundation wall of a building damage may result. Ground connections should therefore be distributed more or less symmetrically about the circumference of a structure rather than grouped on one side. With ground connections properly distributed the current will be collected at the outer extremities and a flow underneath the building minimized. In every case, for the foregoing reason, at least two ground connections should be made at opposite extremities of the structure. Satisfactory ground connections are made in the majority of cases by extending the rod into the earth to a distance of 6 to 10 ft. Driven rods or plates may be used as alternatives. If there is a water pipe nearby connection should be made to it

(d) If a lightning conductor system is placed on a building within or about which are metal objects of considerable size within a few feet of the conductor, there will be a strong tendency for sparks, or sideflashes, to jump from the conductor to the metal at its nearest point. To prevent damage an interconnecting conductor should be provided at all places where sideflashes are likely to occur.

(e) Within buildings where metallic objects may be liable to a dangerous rise of potential due to a lightning flash, the metal, if not interconnected with the lightning-rod system, should under some circumstances be independently grounded.

(f) Since a lightning condutor system as a general rule is expected to remain in working condition for long periods with little attention, the mechanical construction should be strong and the materials used such as to offer high resistance to corrosion.

(g) The minimum permissible weight of copper conductor for all ordinary buildings is 187-1/2 lb. per 1000 ft. The foregoing general principles are embodied in the detailed specifications mentioned at the beginning of this section, which correspond to the approval requirements of underwriters' laboratories. An approved lightning conductor, therefore, will meet the requirements of the Safety Code.

Protection of Structures Containing Inflammable Liquids and Gases from Lightning

Lightning is responsible for a majority of the tank fires of the petroleum industry. In a Report on Records of Oil Tank Fires in the United States, 1915-1925, published by the American Petroleum Institute, it is stated that lightning caused 55% of the fires recorded.

1. Reduction of Damage. Certain types of structures used for the storage of inflammable liquids and gases are essentially self-protecting. Protection, of a greater or less degree, may be secured in the case of others through the installation of various types of protective equipment, such as screens, rods, protective towers and by other means.

2. Fundamental Principles of Protection. Protection of structures and their contents from lightning involve the following principles.

(a) The storage of inflammable liquids and gases in all-metal structures essentially gas-tight.

(b) The use in all necessary breathing vents of efficient flame arresters.

(c) The maintenance of containers in good condition, so far as potential hazards from electrical discharges are concerned.

(d) The avoidance, so far as possible, of the accumulation of explosive mixtures, in and about such structures.

(e) The avoidance of spark gaps in metallic conductors or between metallic conductors at points where there may be an accumulation of explosive mixtures or an escape of inflammable vapors or gases to the air.

(f) In connection with structures not inherently self-protecting, the establishment of cones of protection through the use of grounded screen, rods or towers, or the equivalent.

(g) The location of structures containing inflammable liquids and gases not inherently self-protecting, in positions of lesser exposure with regard to lightning. Thus elevated positions should be avoided.

24. Wind Pressure on Structures

Air Resistance of Automobiles and Trains; Laws of Flight of Airplanes

Windstorm Damage. According to the statistics of one of the large insurance companies * well over one-half of the total windstorm damage is caused

* Associated Factory Mutual Fire Insurance Co., Boston, Mass. Handbook on Windstorms.

by the high winds that accompany ordinary storms and thunder-storms. Much of the loss is directly attributable to the omission of anchorage of buildings to foundations, of roofs to the walls, to inadequate fastening of tiles and other roof coverings and to similar neglect of good practice in construction details. It is not customary to design such details for definite wind loads and aside from exceptional cases any reasonable provision gives ample strength.

Protection against very severe storms can be accomplished only by adequate engineering design of the whole structure.

Wind Velocity Measurement. When it is desired to design a structure to withstand high winds, great difficulty is experienced in determining the maximum wind velocity to which the structure will be exposed. The records of the Weather Bureau give the maximum average velocity indicated for a five-minute period, known as the "**maximum**" and the velocity of the fastest mile, known as the "**extreme.**" At 100 miles per hour average velocity the **extreme** velocity is really the average over a period of 36 seconds. The maximum gust velocities are known to be much greater. What then shall be the speed for which the design is to be made?

Fig. 10

When the records at any one place are examined, it is found that the high velocities occur very infrequently. Therefore in the case of such structures as telephone or power lines an attempt is made to balance the cost of replacement against the cost of insurance. In other words, it is cheaper to rebuild occasionally than to build the structure strong enough initially to withstand the maximum wind speeds. In buildings and other structures the element of human safety enters and the considerations of cost are not the only ones. Yet so far as tornadoes are concerned, it is usually felt to be impracticable to build strong enough to withstand the maximum speeds. The cost of insurance is far less than the increased construction costs.

Robinson Anemometers. The official Weather Bureau Instrument is a Robinson type cup-anemometer. Prior to January 1, 1928, a four-cup driving unit was used but on that date a change was made to a three-cup unit because of the large errors of the older instrument at high speeds.

Pitot Tubes. The standard instrument adopted by the Bureau of Standards, National Physical Laboratory and other scientific organizations for the measurement of air velocities is a Pitot-static tube of proper design. The instrument consists of an open tube facing into the wind and a concentric tube closed to the air stream except for several small holes drilled radially and sufficiently far from the nose that the air flows by smoothly when the tube is in line with the wind direction. A pressure gage is used to measure the difference in the pressure between the two tubes. The second tube gives the static pressure, i.e., the pressure that would be shown by a gage moving with the air. The first gives the static pressure plus the increased pressure produced by reducing the velocity to zero at the mouth of the tube. The differential pressure is $\frac{1}{2}\, dV^2$, where d is the density of the air and V the

wind speed, and is known as the velocity pressure. Pitot-static tubes of poor design usually indicate a higher pressure because of a failure to give the true static pressure. Values of the velocity pressure at various wind speeds are given in the table below for an air density of 0.07651 lb. per sq. ft. corresponding to 15° C., 760 mm. Hg.

True wind speed, miles per hour	Velocity pressure, lb. per sq. ft.	True wind speed, miles per hour	Velocity pressure, lb. per sq. ft.	True wind speed, miles per hour	Velocity pressure, lb. per sq. ft.	True wind speed, miles per hour	Velocity pressure, lb. per sq. ft.

30	2.30	60	9.21	90	20.71	120	36.82

Note. The formula becomes $\frac{1}{2g}\,dV^2$ if the pressure is measured in pounds per square foot and the density in pounds per cubic foot.

The dimensions of several standard Pitot tubes, which may be used without calibration if the supporting bracket is at least 20 diameters behind the static holes, are given in the figure.

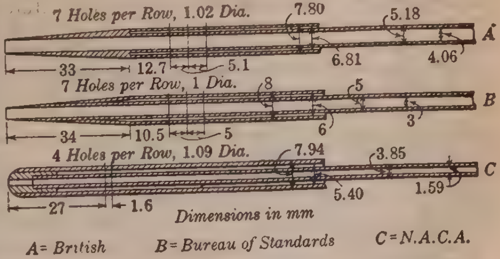

Fig. 11

Dines Tube Anemometer. The laboratory standard Pitot tubes are not suitable for use in field measurements of wind velocity but an instrument of this general type is in occasional use, namely, the Dines Tube Anemometer. In this instrument, the impact tube is kept pointed into the wind by means of a weather vane while the static tube is vertical. Because of this arrangement of the static tube a calibration factor is necessary and it has recently been shown that the factor depends to some extent on the wind direction and on the exact constructional details of the instrument.*

The pressures developed are transmitted to a float whose motion is recorded by a pen on a chart. Gusts are shown in the records and average velocities over comparatively short intervals of time can be estimated by a consideration of the inertia effects.

Electrical Anemometers. Recently several instruments giving an indication and record of wind velocity have been developed. the most widely known being the Burton anemometer. The instrument consists of an electric generator driven by either a four-cup or three-cup Robinson anemometer wheel. The voltage is indicated or recorded, the scale being graduated in terms of wind velocity. Gust velocities are indicated and can be evaluated for comparatively short time intervals by a consideration of the inertia effects.

Bridled Cup Anemometer. Still another type of instrument available for field indication of wind velocity is the bridled cup anemometer, available in an instrument developed by Julien P. Friez. A multi-blade turbine wheel is rotated against a spring system to a position of equilibrium such that the spring torque balances the wind torque on the wheel. The spring system is arranged to give a uniform wind velocity scale on the indicating dial.

Interpretation of Records. The only records available in sufficient quantity to be of any service to the engineer are those of the Weather Bureau for the maximum velocity over a five-minute period and the velocity of the fastest mile. The use and interpretation of these records in connection with any particular engineering project must be left to the judgment of the engineer in charge. If it is desired to build so strong that the structure will not fail under any possible circumstances, it is believed that the design should be made for a wind speed of 150 miles per hour.

It is commonly believed that the natural gusty wind imposes severe racking stresses which are greater than those imposed by a steady wind of the same speed. This is probably true only in rare instances for most of the puzzling effects of high winds in lifting roofs, causing walls to fail outwards, etc., are readily explained by the nature of the pressure distribution in a steady wind.

Design Practice. The current practice of most structural engineers is to consider neither the shape of the structure, the nature of the exposure, nor the probable maximum wind velocity. All of these variable factors are lumped together in a design wind load of usually 20 to 30 lb. per sq. ft. In addition, the usual factors of safety for the material are often waived, and the allowable working stresses increased 25, 50, or even 100%; a procedure described by Fleming† as giving an intellectual assent to the theories of the textbook and ignoring them in actual practice. It would seem to be more logical to retain the same working stresses and to design for a properly selected wind velocity. To that end we attempt to give experimental data known to apply with sufficient accuracy for design purposes on the wind pressures on various engineering structures. From these data the wind load actually encountered at a selected wind velocity may be computed.

* Annual Report of the National Physical Laboratory, 1926, p. 217.

† Wind Pressure on Structures. Robin Fleming (Engineering News Co., 1915). This book gives a good summary of current design practice.

Method of Giving Wind Pressure Data.* The nature of the reaction between the wind and an obstacle to its progress is extremely complicated. Two characteristics should be emphasized. First, the reaction consists of a surface distribution of pressure and the representation of the action by a single resultant force or by an average wind pressure is only a convenient device useful for certain purposes. Second, when there is no wind there is a distribution of pressure over the surface due to the normal atmospheric pressure of approximately 14.7 lb. per sq. in. The effect of the wind is a modification of this normal pressure, at some points an increase, at others a decrease in pressure. The magnitude of these changes is only a small percentage of the normal atmospheric pressure, and the words " suction " or " vacuum " as commonly used in this connection do not imply any large change in density or pressure. The changes are usually less than 2% of the normal atmospheric pressure (0.3 lb. per sq. in. or 42 lb. per sq. ft.).

The maximum increase in pressure produced by the wind is equal to $\frac{1}{2}\, dV^2$, where d is the density of the air, and V the wind speed. This pressure, usually termed the velocity pressure or impact pressure, is indicated by a Pitot-static tube of standard design. Values have already been given in a preceding table.

It is found convenient to express all observed pressure differences including the average wind pressure as ratios to the velocity pressure. Although the maximum increase in pressure is equal to the velocity pressure, pressure decreases of greater amount frequently occur and the force resulting from the surface distribution over a structure is frequently greater than the velocity pressure times the projected area. We may regard the ratio, or coefficient as it is sometimes called, as a shape factor. Thus if the shape factor is 1.5, we may readily find the average pressure at any wind speed by multiplying by 1.5 the velocity pressure taken from the table.

The shape factor for a thin square flat plate normal to the wind is 1.12 and therefore the wind force on such a plate is 1.12 times the velocity pressure times the area. On an infinitely long thin rectangular plate the shape factor is 2.0. Other values are given later.

In the above examples the shape factor is very nearly independent of size or wind speed. In general, the shape factor depends to some degree on the size and speed, the variations being said to be due to scale effect. For bodies with flat surfaces and sharp edges, the scale effect is in general so small as to be negligible for the present purpose. For spheres and cylinders the variation is great and critical regions of speed and size occur where the shape factor decreases very rapidly. In these cases it is difficult to predict the average pressure on a full-scale structure from model tests. The important practical structure of this type is the tall chimney.

It should be especially emphasized that there is no single value of the wind pressure applicable to all types of structures for a given wind velocity. The variations in shape factor are sufficiently large to demand individual treatment.

Flat Plates, Signs, etc. The shape factor for a thin flat plate depends on the ratio of length to breadth. With the wind normal to the plate, the shape factor varies from 1.12 for a square or round plate to 1.33 for a rectangular plate of length-breadth ratio equal to 6. The wind force also varies with the angle of the plate to the wind. The direction of the resultant force is very nearly at right angles to the plate, and if the force is expressed as an average pressure over the area of the plate (*not* projected normal to the wind), the

* From Sci. Paper 523, Bureau of Standards.

maximum shape coefficients observed are 1.75 for a square plate, 1.00 for a rectangular plate of length-breadth ratio equal to 3 and 1.34 for a rectangular plate of length-breadth ratio equal to 6. The detailed values for several angles to the wind are given in International Critical Tables, Vol. 1, p. 406. For approximately square signs, a shape factor of 1.75 should be used. For rectangular signs, the factor may be reduced as indicated by the above values.

Structural Shapes, Bridge Trusses. The shape factor for a very long thin flat plate is 2. In attempting to apply this value to built-up structures such as bridge trusses or radio towers difficulty is experienced due to shielding. Experiments on built-up members have recently been published in Ergebnisse der Aerodynamischen Versuchsanstalt zu Göttingen, Vol. III, 1927; and experiments are in progress at the National Physical Laboratory of Great Britain. Reference should be made to the original publication for details as to the variation of the shape factors with angle.

On simple structural steel shapes such as angles, I beams and built-up columns, the wind pressure is referred to the product of the length of the section by the greater dimension of the cross-section. The resultant force is resolved parallel to this dimension and perpendicular to it and two shape factors are given. We consider here only the shape factor for the component perpendicular to the greater dimension of the cross section; i.e., the component giving the higher stress. The maximum values observed ranged from 1.6 to 2.2, in most cases being about 2 and occurring when the wind was normal to the face of greater area. We may therefore conclude that a safe value for isolated structural steel shapes is 2.

A number of model bridge trusses were tested. When used singly, the shape factors were from 1.4 to 1.6 referred to the projected area of the truss. When two trusses were placed one behind the other with wind normal to the plane of the truss, the shape factor for the front truss was from 1.4 to 1.6 for all positions of the rear truss, and for all models, whereas that for the rear truss varied, with the distance apart from 0.0 to 1.2, depending on the ratio of open to closed area.

Further experiments were made on one model at a given spacing (2.75 times the vertical dimension of truss) by varying the wind direction in both horizontal and vertical directions. Variation in the vertical plane is most important, the shielding effect disappearing at an angle of 15°.

A further experiment was made on a model consisting of two trusses spaced a distance equal to the maximum vertical dimension of the truss with floor between. In this case the shape factor referred to the area of *one* truss reached the value 1.85, and at varying angles in the vertical plane a large lifting force was found. Bridges across deep canyons or in other locations where variations of the wind direction in a vertical direction are possible may need some provision to take care of possible lifting forces.

It appears that in general a shape factor of 2 on the area of one truss is sufficient, although if the trusses are farther apart than the maximum vertical dimension of one truss or if the wind direction may vary in the vertical plane, a factor of at least 2.5 applied to the area of one truss should be used. Under exceptional conditions a factor of 3 applied to one truss may be demanded. In any large project where wind forces are an important item, wind tunnel tests of a model will more than pay their cost.

Buildings, Skyscrapers. For tall buildings of usual proportions it appears that a shape factor in the neighborhood of 1.5 is required.* For slender

* Scientific Paper 523, Bureau of Standards.

towers the factor probably approaches 2.0 as for a long prism. For buildings of approximately cubical form, the factor is from 0.8 to 1.0. As in the case of bridge structures, model tests are justified in important projects. Otherwise an estimate should be made from the known shape factors given in the table below:

Cube	0.8
Thin square flat plate	1.1
Prism 1x1x3	1.5
Very long prism	2.0

In many cases, questions arise as to the strength of individual walls. Here the load depends on the pressure in the interior of the building which in turn depends on the number, size, and location of openings. It seems probable that in many cases the average pressure on a wall may equal twice the velocity pressure. The average pressure over small areas may reach three times the velocity pressure. It should especially be noted that the force may be in either direction depending on the pressure within the building, and the outward collapse of walls in high winds is readily explained without the necessity of assuming a very low barometric pressure.

Roofs. The force on a roof also depends on the pressure within the building, which is somewhat indeterminate. The distribution on the outer surface is such as to give ordinarily a lifting force provided the pitch of the roof does not exceed 30 deg. There seems to be no occasion for providing for a wind load acting downward on the roof under these conditions. There is every reason to provide for substantial lifting forces which are present even when the wind does not penetrate beneath the roof covering. If the interior is not subject to the full velocity pressure through broken windows or otherwise, the upward loading is of the order of 0.7 to 1 times the velocity pressure. Under special circumstances such as in a factory type building with windows broken on the windward side, the loading may reach twice the velocity pressure. The roof should accordingly be securely anchored to the walls and the walls in turn to the foundations.

When the pitch of the roof exceeds 30 deg., regions of increased pressure appear as shown by the experiments of T. E. Stanton (Proc. Inst. C. E., London, 156, 1903-04, p. 78).

Recently a large number of measurements of wind pressure on roofs and buildings have been published in Jahrbuch der Deutschen Gesellschaft für Bauingenieurwesen, 1927, p. 87.

Volume 97 of Engineering News-Record contains analyses of the effects of the Florida hurricane of 1926 which show that pressures of 55 to 65 lb. per sq. ft. were obtained. The wind velocity was independently estimated as 132 miles per hour which would give the observed pressures on structures having a shape factor of 1.5.

Additional model experiments on an approximately cubical structure are given in Volume 100, No. 13, p. 508, by Professor Dawley of the Kansas State Agricultural College. These give shape factors from 0.7 to 0.85, depending on the presentation of the model to the wind and the presence or absence of windows and doors.

Chimneys, Standpipes, Gas-holders, Flag Poles, Transmission Lines. If the product of diameter in feet by wind speed in miles per hour is less than about 40, the shape factor for cylindrical structures may be taken from the table at the top of the next page.

The flow about cylinders in this region in a steady wind is very definitely periodic, the frequency in cycles per second being equal to about 0.3 times

Ratio of length to diameter	Shape factor	Ratio of length to diameter	Shape factor
1	0.63	10	0.83
2	0.69	20	0.92
3	0.75	40	1.00
5	0.74	Infinite	1.20

the ratio of the wind speed in miles per hour to the diameter in feet. Care should be taken that the natural period of vibration of the structure does not correspond to the above eddy frequency at high wind speeds. It is understood that in some cases transmission lines have been observed to vibrate (in segments) with the eddy frequency and in certain conditions cause fatigue failures.

When the product of diameter in feet by wind speed in miles per hour exceeds 40, the shape factor is found to decrease to a comparatively low value. Experiments on full-scale cylinders in a natural wind indicate a value as low as 0.3 to 0.4. The flow is no longer definitely periodic but is very irregular and often unsymmetrical. Sufficient information is not available to justify such a radical reduction in the shape factor. Until the flow about large cylinders is fully understood, it is recommended that the same shape factors be used as for small cylinders.

In transmission lines, the problem of shielding again appears since individual wires are near each other. It is common practice to compute the wind force not on the actual wire but on the wire assumed coated with ice 1/2 in. in thickness. The shielding depends on the spacing of the wires, and on the wind speed. With a spacing of about 1 ft., the force on the shielded wires is about 50% of that on the front unshielded wire. The factor for an unshielded wire may be taken from the table above.

If the wind blows at an angle to a single wire, the force remains nearly normal to the wire and the magnitude of the force falls off approximately as the square of the sine of the angle of the wire to the wind.

The only measurements known of the wind pressure on flags gave a shape factor of approximately 0.1 applied to the area of the flag. The measurements were made at the Washington Navy Yard wind tunnel and the actual empirical formula given was $P = 0.0003\,A\,V^{1.9}$ where P is the pull of the flag in pounds, A the area of the flag in square feet, and V the wind speed in miles per hour.

General Remarks on the Choice of Shape Coefficients. It has been assumed in the foregoing treatment that the winds of high velocity might come from any direction and the maximum shape coefficients only are given. Under certain special conditions it may be found that high winds are only likely to prevail from certain directions. In such a case some further study than that given here is necessary.

In any extensive construction where wind loads are an important factor, the shape factor should be determined by wind tunnel experiments on a model.

Air Resistance of Automobiles. The observed shape coefficients found for automobiles of conventional design vary from about 0.75 to 1.35 * depending on the exact shape. Special stream line automobiles and racing cars have

* Public Roads, Vol. 6, No. 9, Nov. 1925, p. 203. Zeitschrift fur Flugtechnik und Motorluftschiffahrt, 15, 1924, p. 22; also 13, 1922, p. 201. Motorwagen, 26, 1923, p. 355.

been designed for which the shape coefficient is as low as 0.4. The area to which the shape coefficients apply is the area of projection on a plane normal to the usual direction of motion.

An average value is of doubtful service since in most cases the resistance of a particular automobile is desired for certain specified conditions of car speed, wind speed, and wind direction. This is most readily found by wind tunnel experiments on a model, since full-scale conditions are not easily controlled. Some unpublished experiments at the Bureau of Standards show that when the relative wind strikes the car at an angle of only 5 deg. there is a lateral force tending to skid the car equal to about 50% of the head resistance. An angle of 5 deg. requires a side wind of a speed equal to only 11% of the automobile speed. The force is much greater for a closed car than for an open car. The effect of natural winds especially as regards direction is therefore a very important one and it is regrettable that more information is not available.

Air Resistance of Trains. A few papers have appeared on the determination of the air resistance of trains.* It appears from the experiments of Goss that the shape factor for an isolated car is about 0.5, applied to the area of projection normal to the usual direction of motion. For the first car in a train, the factor is about 0.4, second car about 0.036, other intermediate car about 0.04, last car 0.1.

The French experiments were carried out on a train consisting of locomotive, tender, and two cars, the dimensions of which are not given. The coefficients appear to be of the same order of magnitude as those found by Goss, except in the case of the intermediate car. Those interested should consult the original papers for details as to the shapes of the cars.

No information is available on the effect of angle of the train to the relative wind. It seems probable that as in the case of automobiles a comparatively small side wind will introduce a fairly large side force.

Laws of Flight of an Airplane.† Airplanes are supported by the dynamic reaction of the air on large fixed surfaces called wings. The necessary relative motion is provided by driving the airplane forward by means of a motor and propeller. Other types of heavier-than-air craft have been proposed, namely, the helicopter, which depends for its lift on the direct vertical thrust of air propellers, and the ornithopter, in which the wings are made to flap like the wings of a bird. So far only the airplane can be said to be successful.

In all instances in which a force is obtained by dynamical means certain fundamental principles apply and operate to limit the possible efficiency. According to Newton's laws of motion, a force, F, can be secured by dynamical means only by continuously imparting a velocity, V, to a mass, M, each second such that $\mathbf{MV} = \mathbf{F}$. Thus if F is the lift of an airplane, M is the mass of air deflected downward each second with a velocity V. Or if F is the thrust of an airplane propeller, M is the mass of air passing through the propeller each second and having its velocity increased by an amount V.

* Atmospheric Resistance to the Motion of Railway Trains, W. F. M. Goss; Proceedings Western Railway Club, 1897-98, Vol. 10, p. 347. Mésure de la resistance de l'air sur le matériel des chemins de fer; Ch. Maurain, A. Touissant, R. Pris, Comptes Rendus, 177, July 1923, p. 308.

† The development of aeronautics in recent years has been so great that many textbooks and handbooks are now available. An attempt is made here to give a few fundamental principles, but the reader is referred to books such as Aerodynamics by E. P. Warner (McGraw-Hill, 1927) or Applied Aerodynamics by Leonard Bairstow (Longmans, Green, 1920) for more complete technical information.

There is as a consequence an amount of energy imparted to the air each second equal to $\frac{1}{2}\, MV^2$ or $\frac{1}{2}\, FV$. It is apparent that some energy is always necessary to produce a force, F, and that the energy, $\frac{1}{2}\, FV$, for a given force, $F = MV$, increases as V increases, or as M decreases, since MV is constant, which means usually as the area of the wings or propeller decreases. The advantage of an airplane depends partly on this fact, for successful helicopters find it necessary to use propellers comparable in size to airplane wings. Another advantage of an airplane is that to produce a given lift, the required towing force is equal to less than one-seventh or one-eighth, in some cases only one-twentieth, the lift, so that a propeller of moderate size is able to develop the required force with a high efficiency. Finally, the airplane moving forward very rapidly is able to come in contact with a large mass of undisturbed air each second, thus making M very large and V small.

The relations given above express the essential physical relations but are of little quantitative value because of the difficulty of determining M and V and of the added energy losses due to friction and to turbulent motion. Recourse is had to experiment on surfaces of various shapes. In some early airplanes, the wing surfaces were merely flat plates and the laws of the air force received great attention. These formulas are now of only historic interest since all airplane wings are curved and of some thickness. Such curved surfaces are technically known as airfoils.

The direction and magnitude of the air force at different angles to the wind and at different air speeds is determined in an artificial air-stream in a wind tunnel. For convenience the force is resolved into a lift component perpendicular to the wind and a drag component parallel to the wind. The results are then given in the form of lift and drag coefficients, C_L and C_D, defined by the relations $\mathbf{L} = \mathbf{C_L\, A}\, \frac{1}{2}\, \mathbf{dV^2}$, $\mathbf{D} = \mathbf{C_D\, A}\, \frac{1}{2}\, \mathbf{dV^2}$, where L is the lift, D the drag, A the wing area, d the air density and V the speed, all expressed in a consistent system of units in which case C_L and C_D are independent of the particular system of units employed. Non-dimensional quantities are used throughout. The system of units used must however be self-consistent, such as force in pounds, mass in slugs, distance in feet, time in seconds, etc. These coefficients vary very greatly with angle of attack and to a small extent with size of model and speed of test. Engineers sometimes prefer to write $\mathbf{L} = \mathbf{K_l AV^2}$, $\mathbf{D} = \mathbf{K_d AV^2}$ where L and D are in pounds, A in square feet, and V in miles per hour. For standard air density, $K_l = .00255\ C_L$, $K_d = .00255\ C_D$. The wind tunnel test also gives the point of intersection of the line of action of the force with the chord-line of the airfoil which is usually expressed as the ratio of the distance of the point of intersection x from the nose to the chord length c.

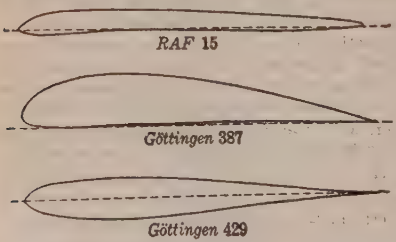

Fig. 12

There are now available atlases of airfoil characteristics containing data on over 600 sections.* It is manifestly impossible to even abstract these data. For illustrative

* Aerodynamic Characteristics of Airfoils, Technical Reports 93, 124, 182, 244 and 286 of the National Advisory Committee for Aeronautics (Government-Printing Office).

purposes, data are given on three representative airfoil sections. The shapes of the sections are given by Cartesian coordinates of the upper and lower surfaces from the chord line and vertical through the nose. The models were 6-in. chord (along wind) by 36-in. span (across the wind) and were tested in a 7.5-ft. wind tunnel at 40 miles per hour.

It is evident that the mass of air, M, affected by an airplane wing is proportional to the air density, d, the area of the wing, A, and the forward velocity of the wing, V. Prandtl has computed the constant of proportionality to be $\pi/4$ times the ratio of span b (dimension across wind) to the chord, c (dimension along wind). The ratio b/c, known as aspect ratio, R, plays an important part in determining the air forces on an airfoil. We may write $M = \frac{\pi}{4}\frac{b}{c}dAV = \frac{\pi}{4}RdAV$. The lift, L, equals M times the downward velocity, v, imparted to the air and hence $v = \frac{4L}{\pi RdAV} = \frac{2V}{\pi R}C_L$. The required energy to produce the lift is $\frac{1}{2}Mv^2 = \frac{dAV^3}{2\pi R}C_L^2$. If we regard this as due to a drag D, we may write the energy equal to DV or $C_D = \frac{D}{\frac{1}{2}dV^2} = \frac{C_L^2}{\pi R}$. As stated before, C_D, C_L, and R are dimensionless quantities, provided a self-consistent system of units is used. This drag coefficient, known as the induced drag coefficient, accounts for nearly one-half the drag at large lift coefficients. It is the minimum drag coefficient possible for a given lift coefficient. Its value decreases as the aspect ratio increases; hence the typical plan form of airplane wings.

The production of the induced drag may be regarded as due to a change in the angle at which air strikes the airfoil, some of the downward velocity beginning before the airfoil is reached. If the change in angle is called α, we may regard the drag as a component, $L\alpha$, of the lift in the direction of motion. It is easily verified that $\alpha = \frac{C_L}{\pi R}$ and that the downward velocity at the airfoil is one-half the final downward velocity. This angle is called the induced angle of attack.

To a first approximation we may regard the total drag coefficient as the sum of the variable induced drag coefficient and a constant profile drag coefficient. We may therefore write $C_D = C_{D_0} + \frac{C_L^2}{\pi R}$ and $\alpha = \alpha_0 + \frac{C_L}{\pi R}$ and compute from a test of one aspect ratio the values for all other aspect ratios. If R is greater than 3, the formulas are found to give results as accurate as the experimental data.

In the case of level horizontal flight, neglecting the forces on other parts of the airplane, we may write the weight, W, as equal to the lift. Hence $W = L = C_L \frac{1}{2} dV^2A$ or $V = \sqrt{\frac{2}{d}\frac{W}{A}\frac{1}{C_L}}$. When C_L reaches its maximum, V reaches a minimum, and hence the maximum value of C_L determines the landing speed. The speed of a given airplane can be varied only by varying C_L which is done by moving the elevator to trim the airplane to a new angle of attack. The power does not enter into this relation. If it is not sufficient to give horizontal flight, the airplane loses altitude in a glide but the speed and angle of attack remain nearly the same. If the power is greater than that required, the airplane will climb, but again the speed and angle of attack will be nearly the same as before.

The power required for level flight equals the drag, D, times the forward speed, V, or $C_D A \frac{1}{2} d V^3$; or substituting the value of V above, $\frac{C_D}{C_L^{3/2}}\sqrt{\frac{2}{d}\frac{W^3}{A}}$. The ratio $\frac{C_D}{C_L^{3/2}}$ for a given airfoil is a measure of the power required for a given weight and wing area of the airplane.

The reader is referred to some of the textbooks on aeronautics for a further account of performance prediction, choice of airfoils, control and stability, etc.

Skin Friction. Even as late as Langley's experiments, skin friction in air was regarded as a negligible quantity, but the extensive experiments of Zahm showed that it was appreciable. Wieselsberger * gives the following formula for the surface friction on well varnished surfaces:

$$R_F = 0.0375\ AqR^{-0.15}$$

where R_F is the frictional force on the area, A, exposed to the stream, q is the dynamic pressure, $\frac{1}{2}\,dV^2$, d being the air density, and V the air speed, and R the Reynolds number $\frac{VLd}{m}$, L being the length parallel to the wind, and m the viscosity. Any self-consistent system of units may be used. The accompanying table was computed from this equation for standard density (0.002378 slugs per cubic foot) and viscosity $\left(\frac{\text{viscosity}}{\text{density}} = 0.0001535 \text{ sq. ft. per sec.}\right)$.

The values given in the table on next page differ somewhat from the older values of Zahm but are believed to be more reliable because of improvements in experimental methods. In any case the values apply strictly to plane surfaces parallel to the wind and application to curved surfaces can be expected to give only approximate results. The effect of roughness is comparatively large. The following papers may be consulted in addition to the one referred to:

WEIGHTS AND MEASURES

25. The Metric System

Units of Length and Mass. The **Unit of Length** in the metric system is the meter, a length very nearly equal to the one ten-millionth of the distance between the equator and the pole. The original meter was a platinum bar constructed and deposited in the Archives of the French Republic in 1799. At the same time a platinum weight was constructed which was made as nearly as possible equal to the mass of a cube of pure water at 4° C., the sides of the cube being one-tenth the length of the meter. This weight, which is equal to one thousand units in the metric system, is called the kilogram.

The use of the meter as the basis of geodetic surveys had become so general throughout Europe that a conference was called in Paris, France, in 1870, for the purpose of establishing a central bureau where the standards of the different countries could be intercompared. As a result of this conference an International Bureau of Weights and Measures was established near Paris in 1875, by the concurrent action of the principal nations of the world. One of the first tasks undertaken by the Bureau was the construction of exact copies of the meter and kilogram deposited in the Archives. Thirty-one standard meters of iridio-platinum and forty kilograms of the same alloy were constructed and carefully compared with the standards of the Archives and with one another. This great work was completed in 1889, and the meter and kilogram which agreed most nearly with the original standards were called international prototypes, and were deposited at the International Bureau, where they are maintained to-day subject to the authority of the International Committee on Weights and Measures. The remaining meters and kilograms were distributed by lot to the different nations which contributed to the support of the Bureau. The United States secured two copies of the meter and two copies of the kilogram, which are in the custody of the Bureau of Standards at Washington. One of the meters, known as No. 27, and one kilogram, No. 20, were selected as the United States standards, while the other meter and kilogram are used as secondary standards. It was the declared intention of the International Committee that the various national prototypes should be returned to the International Bureau at regular intervals for the purpose of recomparing them with the international standards and with one another. In this way all measurements based upon metric standards throughout the world are ultimately referred to the international meter and kilogram.

The Unit of Capacity in the metric system is the liter, which is defined as the volume of one kilogram of pure water at the temperature of maximum density (4° C.) under a pressure of 76 cm. of mercury. For all practical purposes the cubic decimeter and the kilogram of water may be regarded as identical, the difference between them being less than three parts in one hundred thousand, the kilogram of water having the larger volume.

26. The English System

Units of Length and Mass. While it is the common impression that the customary system of weights and measures in use in the United States is identical with the system in everyday use in Great Britain, there are important differences in some of the units. For all practical purposes the units of length and mass are the same, although the fundamental standards are quite different in the two countries. In Great Britain the primary standard of length is the yard, a bronze bar in the custody of the Board of Trade, and preserved in the Standards Office, Westminster. In the United States the primary standard of length is the National prototype meter, the length of which is known in terms of the International prototype meter. The United States yard is defined in terms of the meter. In terms of the International meter, in England, one yard equals 36/39.370113 meters. In the United States the yard is defined as 3600/3937 meters. The difference amounts to only a little more than one part in 400 000 which is about the difference found in comparing the Imperial yard with its authentic copies at different periods. A similar condition exists with respect to the avoirdupois pound; in England a certain platinum cylinder deposited in the Standards Office is regarded as the standard pound, the legal equivalent of which is 453.59243 grams, whereas in the United States the pound is defined as 453.5924277 grams.

The Capacity Measures of the two countries are, however, quite different. The United States gallon of 231 cu. in. and the Winchester bushel of 2150.42 cu. in., the United States Standards, have not been legal measures in Great Britain since 1825, having been superseded by the present Imperial gallon, which is defined as the volume of 10 lb. of pure water at 62° F., weighed against brass weights in air at the same temperature as the water, and with the barometer at 30 in., and by the Imperial bushel which is defined as the volume of 80 lb. of water weighed under the same conditions as the gallon. The bushel of Great Britain is, therefore, exactly equal to eight gallons. The volume of the Imperial gallon, according to the most reliable data available at this time, is 277.420 cu. in. and the bushel 2219.36 cu. in., the first being larger than the United States gallon by approximately 20% and the latter larger than the United States bushel by 3.2%.

27. Chinese and Other Foreign Weights and Measures

In China in 1915 a new weights and measures law was promulgated, making the meter and kilogram the fundamental standards of length and mass, and recognizing two systems of weights and measures, namely, a native system and the metric system. Of the native system, the Ying Chao Ch'ih (builder's foot) is the unit of length, and the Kuping tael (or liang) is the unit of weight. The Ministry of Agriculture and Commerce is charged with the enforcement of the law and has authority to restrict the use of the native system whenever necessary.

Measures of length

Chinese		Metric	
1 Hao	=	0.0032	Centimeter
1 Li	=	0.032	Centimeter
1 Fen	=	0.32	Centimeter
1 Ts'un	=	3.2	Centimeters
1 Ch'ih	=	0.32	Meter
1 Pu	=	1.6	Meters
1 Chang	=	3.2	Meters
1 Li	=	576.	Meters

1 Fen	=	0.37301	Gram
1 Ch'ien	=	3.7301	Grams
1 Liang	=	37.301	Grams
1 Chin	=	596.816	Grams

Note. A common commercial unit in the foreign trade of China is the catty, equivalent to 1-1/3 pounds, avoirdupois.

In Japan. The metric system was adopted by Japan in 1921. The law is to be put into force by Imperial Ordinances, and it appears that this is being done gradually.

Following are equivalents of the native units of weights and measures:

The Kwan, equal to 3.75 kg. or 8.267 lb. avoirdupois, is the unit of mass. It is divided into 1000 mommes, the momme into 10 funs and the fun into 10 rins, the rin into 10 mos, and the mo into 10 shis.

The Shaku is the unit of length, equal to 10/33 (0.30303) meter, or 0.994 U. S. ft. The shaku is decimally divided into sun, bu, rin, mo, shi. Multiples of the shaku are the ken, equal to 6 shaku; the cho equal to 60 ken, and the ri, equal to 36 cho, or 12 960 shaku.

The shaku (land measure) is equal to 1/3025 are or 0.3558 sq. ft. One bu. or tsubu is equivalent to 100/3025 are or 35.583 sq. ft. Thirty bu. equal one sé, ten sé equal one tan and ten tan equal one cho.

The shaku (capacity measure) equals 0.01804 liter, or 0.01924 U. S. liquid quart, ten shaku equal one go, ten go one sho, ten sho one to, and ten to one koku.

In Russia the metric system has been adopted and is gradually being put into force.

Following are equivalents of the native units of weights and measures:

The Funt, equal to 0.4095 kg., or 0.9028 lb. avoirdupois, is the basis of Russian weights. The funt is divided into 96 zolotniks or 32 loths, and the zolotnik is divided into 96 dolias; 40 funts equal one pood.

The Archine, equal to 28 in. or 0.71120 meter, is the basis of the length measure. The archine contains 16 verskops; three archines equal one sagene and 500 sagenes equal one verst.

The dessiatine, equal to 2400 square sagenes or 2.6997 acres, is the unit for land measure.

The tchetvert, equal to 2.099 hectoliters, or 5.9568 U. S. bushels, is the unit for dry measure. The tchetvert is divided into 8 tchetveriks, and the tchetverik into 8 garnetz. Twelve tchetverts equal one last.

The vedro, equal to 12.2994 liters, or 3.2492 U. S. gallons, is used for liquids.

28. Special Commercial Units

For Logs the Doyle rule, known in some sections as the Connecticut River Rule, the St. Croix Rule, the Thurber Rule, the Moore and Beeman Rule, and the Scribner Rule, is more generally employed than any other: Deduct 4 in. from the diameter of the log, as an allowance for slab; square one-quarter of the remainder and multiply the result by the length of the log in feet. It is the usual custom to measure the diameter inside the bark at the small end.

The Miner's Inch is defined as the quantity of water that will pass through an orifice one square inch in cross-section under a given head. The head has been fixed in various localities as from 4 to 6-1/2 in. to the center of the orifice.

Bushel (dry measure) = 4 pecks = 32 quarts, 1 struck bushel = 1.24446 cu. ft. = 2150.42 cu. in.

Barrel. The crude oil barrel is 42 gallons; while the refined product is bought and sold on the basis of 50 gallons to the barrel. The large lime barrel contains 280 lb.; the small one 180 lb. Legal net weight of a barrel of flour = 196 lb. For natural cement barrels contain 150 lb. to 400 lb., for portland cement 376 lb. or 4 sacks of 94 lb. each.

A legal standard barrel for fruits, vegetables and other dry commodities, except cranberries, contains 7056 cu. in. Its outside dimensions are: Length of stave, 28-1/2 in.; distance between heads, 26 in.; diameter of head, 17-1/8 in.; circumference of bulge, 64 in.; outside measurement, and thickness of staves not greater than 0.4 in. For cranberries the corresponding dimensions of the barrel are 28-1/2 in., 25-1/4 in., 16-1/4 in., 58-1/2 in.

Firewood is mostly sold by the cord of 128 cu. ft.

Old Foreign Units, still sometimes used, with their U. S. equivalents, are as follows:

Central America: libra = 1.014 lb., arroba = 25.36 lb., quintal = 101.41 lb., vara = 32.87, 32.91, and 33 in.

Cuba: libra = 1.0143 lb., arroba = 25.36 lb., vara = 33.38 in.

Virgin Islands: pund = 1.023 lb., fod = 1.029 ft., tönde = 3.948 bu., pot = 0.2552 gal., mil = 4.68 miles.

Mexico: libra = 1.015 lb., arroba = 25.367 lb., vara = 32.992 in., quartillo = 1.999 liquid quarts.

South Africa: leaguer = 153.64 gal., muid = 3.095 bu., morgen = 2.116 acres.

South America: libra = 1.014 lb., arroba = 25.36 lb., quintal = 101.4 lb., vara = 32.91 and 33.38 in.

Spain: libra = 1.0143 lb., arroba = 25.36 lb., vara = 32 9096 in., fanega = 1.52 bu.

Turkey: old oke = 2.828 lb., old kilé = 1.135 bu., pic = about 27 in.

29. Equivalents of Units *

In the following tables the quantities in the same line are equivalents. For example, 1 kilogram equals 2.20462 pounds or 0.980665 megadynes.

Numbers in **boldface** type are exact values by definition. The notation 0.(³)1259 indicates that the (³) is to be replaced by three ciphers.

30. Conversion Tables

The following tables give multiples for transferring English to metric measures or metric to English measures. For example, to reduce 39.37 in. to centimeters, take two numbers from the table at foot of page 314 and add them together, thus 39 in. = 99.06 cm., and 0.37 in. = 0.94 cm.; then 39.37 in. = 99.06 + 0.94 = 100.00 cm.

SECTION 4

THERMODYNAMICS AND FUEL POWER GENERATION

The following outlines of fundamental principles and facts have been prepared, not for mechanical but for civil engineers whose knowledge of the subject is limited.—EDITOR-IN-CHIEF.

BY

GEORGE A. GOODENOUGH

LATE PROFESSOR OF THERMODYNAMICS IN UNIVERSITY OF ILLINOIS

THERMODYNAMICS

1. Preliminary Statements and Definitions

Heat Energy. The mechanical theory of heat asserts that heat is a form of energy due to the motion or configuration of the molecules of a body. Like mechanical energy, heat energy may of the kinetic or of the potential form. The summation $\Sigma\ 1/2\ mv^2$ extended to the moving molecules of a system gives the thermal kinetic energy of the system. Considerations derived from the kinetic theory of gases show that the temperature of a body is a measure of its thermal kinetic energy. When the temperature rises, it is inferred that the thermal kinetic energy is increased and vice versa. Thermal potential energy is due to the position or configuration of the molecules of a body. Thus when the volume of the body is increased, work is required to separate the molecules against their mutual attractions, and this work is stored as potential energy. Again, when the state of aggregation is changed, as in fusion or vaporization, work is required to break down the molecular structure, and this work is stored in the system as potential energy. In the case of gases, like air and nitrogen, the attractive forces between the molecules are so small that the thermal potential energy is practically zero. The internal energy of a gas is therefore assumed to be wholly of the kinetic form.

Units of Energy. The conventional units used in this chapter are: (1) for **mechanical energy,** the foot-pound and the horsepower-hour (**hp.-hr.**), which is equal to 1 980 000 ft.-lb.; (2) for **heat energy,** the British thermal unit (**B.t.u.**), which is defined as the heat required to raise the temperature of one pound of water from 63° to 64° F.

Mechanical Equivalent of Heat. The numerical relation between the unit of heat and the unit of work has been determined very accurately from experiments. The accepted relations are

$$1 \text{ B.t.u.} = 777.64 \text{ ft.-lb.} \qquad 1 \text{ hp.-hr.} = 2546.2 \text{ B.t.u.}$$

In ordinary calculations the **integral values 778 and 2546** are sufficiently accurate. The mechanical equivalent is denoted by the symbol J and the reciprocal of it by A; thus, $J = 778$ and $A = 1/J = 1/778$.

State of a System. A thermodynamic system is defined as a body or group of bodies capable of receiving and giving out heat or other forms of energy. Examples of such systems are the media used in heat engines, as water vapor, air, ammonia, etc. In order that a system may receive or give up energy, its state must change; hence the magnitudes that determine the state must change. It is assumed ordinarily that the system is homogeneous and of uniform density and temperature throughout, also that it is subjected to uniform pressure. Then the magnitudes that describe the state of a unit mass are: the **pressure** p, the **temperature** t, and the **volume** v. In the case of a homogeneous mixture of vapor and liquid, as wet steam, a fourth variable is required; this is the **ratio** x of the **weight of vapor** to the **weight of the mixture.** These magnitudes, p v t and x are called the **coordinates** of the system.

Absolute Temperature. Many of the equations of thermodynamics are simplified by taking the temperatures from absolute zero instead of from the zero of the F. or C. scale. The position of the absolute zero, as determined by experiments on actual gases, is about 273.1° below zero C., or 459.6° below zero F. Hence, denoting ordinary temperatures by t and absolute temperatures by T,

$$T = t + 273.1 \text{ for the C. scale,}$$
$$T = t + 459.6 \text{ for the F. scale.}$$

Characteristic Equations. Of the three coordinates, p, v, T, any two may be, in general, taken as independent and the third is then a function of these two. Thus in the case of a confined gas, the pressure p may be kept at any desired value and by the addition of heat the temperature T may be raised to any predetermined point. The volume v must, however, depend upon the values given to p and T; that is, v is a function of p and T, as $\mathbf{v} = \mathbf{f}\ (\mathbf{pT})$. Likewise, taking v and T as independent, a functional relation $\mathbf{p} = \phi(\mathbf{v}, \mathbf{T})$ must exist. For any substance there is such a functional relation between the coordinates; this relation is called the characteristic equation of the substance. The simplest characteristic equation is that which applies to an ideal perfect gas, namely.

$$\mathbf{pv} = \mathbf{BT}$$

For certain imperfect gases van der Waal's equation

$$\mathbf{p} = \frac{\mathbf{BT}}{\mathbf{v} - \mathbf{b}} - \frac{\mathbf{a}}{\mathbf{v}^2}$$

represents the relation between p, v, and T. The behavior of superheated steam is, within certain limits, represented accurately by the empirical equation

$$\mathbf{p}(\mathbf{v} - \mathbf{c}) = \mathbf{BT} - \mathbf{p}(1 + \mathbf{a}\mathbf{p}^{1/2})\frac{\mathbf{m}}{\mathbf{T}^{\mathbf{n}}}.$$

The characteristic equation $\phi(\mathbf{p}, \mathbf{v}, \mathbf{T}) = 0$ having three variables may be represented geometrically by a surface. Any possible state of the substance is represented by a point on the surface and a change of state is represented by a path lying in the surface. In the case of a mixture of liquid and vapor (as wet steam), the pressure is a function of the temperature only, and the volume depends upon the temperature and the ratio $\mathbf{x}$. The characteristic surface of such a mixture is a cylindrical surface cutting the pt-plane in the curve $\mathbf{p} = \mathbf{f}(\mathbf{t})$.

Changes of State. Certain changes of state of a thermodynamic system are of special importance.

1. **Constant Volume.** The volume remaining constant, the pressure varies with the temperature and, in general, heat is absorbed or rejected by the system.

2. **Constant pressure.** A change of volume involves a change of temperature. Heat is absorbed or rejected.

3. **Isothermal.** If the temperature remains constant during a change of state, the change is said to be isothermal. In general, heat is absorbed or rejected.

4. **Adiabatic.** An adiabatic change is one in which the system neither receives nor gives out heat.

5. **Isodynamic.** In an isodynamic change of state the internal energy of the system remains constant.

Specific Heat. The heat required to raise the temperature of a unit weight of a body one degree under given external conditions is called the **thermal capacity** of the body. The ratio of the thermal capacity of a substance at the temperature **t** to the thermal capacity of water at a chosen standard temperature (17.5° C. or 63.5° F.) is the specific heat of the substance. Since at 63.5° F. the thermal capacity of water is 1 B.t.u., it follows that the specific heat of a substance at temperature t is numerically equal to the thermal capacity at the same temperature. In the case of gaseous substances two specific heats are of special importance: the specific heat at constant volume denoted by $\mathbf{c_v}$, and that at constant pressure denoted by $\mathbf{c_p}$. For solids and liquids, these specific heats are practically identical, but for gases they are considerably different; thus in the case of air, $c_p = 1.4\ c_v$.

Latent Heat. During a change of state of aggregation the heat added to a substance is expended in performing work of disgregation, and none of it is used in raising temperature; that is, the heat absorbed goes to increase the potential energy of the system. Heat thus absorbed during fusion or vaporization is called latent heat. The heat required to vaporize a unit weight of a liquid depends upon the pressure under which the vapor is formed. The following are latent heats of fusion for various substances in British thermal units per pound:

Ice	144	Cast iron, grey	41.4
Lead	9.66	Cast iron, white	59.4
Tin	25.65	Zinc	50.6
Silver	37.93	Sulfur	16.86

2. Fundamental Laws of Thermodynamics

Transformations of Energy. All transformations of energy are subject to two far-reaching general laws: (1) The law of **conservation of energy,** of which the following is a statement: The total energy of an isolated system remains constant and cannot be increased or diminished by any physical process whatever. (2) The law of **degradation of energy.** According to this law, the result of any transformation of energy is to reduce the quantity of energy that may be usefully transformed into mechanical work.

Examples of the law of degradation are abundant. Work is transformed into heat through friction, and only a small part can be recovered; electrical energy is rendered unavailable when transformed into heat in the conducting system; heat flows from a body of higher temperature to one of lower temperature and as a result a smaller fraction of it becomes available for transformation into work; in the transformation of work into electrical energy or of electrical energy into work, some of the high-grade energy is transformed into heat and is rendered unavailable. The term thermodynamic degeneration is sometimes applied to the inevitable loss of available energy in any transformation of energy; and the law of degradation may be stated as follows: Every natural process is accompanied by thermodynamic degeneration.

The First Law of Thermodynamics is merely the law of conservation applied to the transformation of heat into work. It may be stated as follows:

> When work is expended in producing heat the quantity of heat generated is equivalent to the work done; and conversely, when heat is employed to do work, a quantity of heat precisely equivalent to the work done disappears.

Denoting by **Q** the heat converted into work, and by **W** the work thus obtained, the first law is expressed symbolically by the equations $\mathbf{W} = \mathbf{JQ}$ and $\mathbf{Q} = \mathbf{AW}$.

The Energy Equation. Let heat be absorbed by a body, at a given mass of gas or a saturated vapor. If the volume of the body remains constant, the energy absorbed must be added to the intrinsic energy of the system; as a result the temperature will rise, or, in the case of a liquid, vaporization will ensue. If, however, the volume of the system changes, external work will be done, and the heat absorbed will in part be used in doing this work, whereas the remainder will increase the intrinsic energy. In general, therefore,

heat absorbed = increase of energy + external work.

The change of energy depends upon the initial and final states of the system only. The external work depends, however, on the relation between p and v

during the change of state, that is, upon the path; hence the heat absorbed also depends upon the path.

If a system passes through a closed cycle of processes and returns to its initial state, the change of energy for the cycle is zero; hence for a closed cycle the heat absorbed by the system is the equivalent of the external work. If the change of state is adiabatic, the heat absorbed is zero and the external work is gained at the expense of the intrinsic energy of the system.

The Second Law of Thermodynamics is essentially the law of degradation of energy. Whereas the first law gives a relation that must be satisfied in any transformation of energy, it is the second law that gives information regarding the possibility of transformation and the availability of a given form of energy for transformation into work. A general statement of the second law is

> No change in a system of bodies that takes place of itself can increase the available energy of the system.

A more concrete statement is that of Kelvin: It is impossible by means of inanimate material agency to derive mechanical effect from any portion of matter by cooling it below the temperature of surrounding objects. In effect, Kelvin's statement denies the possibility of deriving work directly from the heat contained in the atmosphere.

Carnot's Cycle. The availability of a given quantity of heat energy for transformation into work is given by the efficiency of the ideal Carnot engine. In the ideal cycle described by Carnot, the medium is subjected to four processes: (1) It is placed in contact with a source of heat at a higher temperature T_1 and expands isothermally while absorbing heat Q_1 from the source. (2) It is removed from the source and expands adiabatically until the temperature reaches the lower value T_2. (3) It is placed in contact with a refrigerator at temperature T_2, is compressed isothermally, and rejects to the refrigerator the heat Q_2. (4) It is compressed adiabatically and arrives at the initial state. The heat $Q_1 - Q_2$ is transformed into work, and the efficiency of the cycle is therefore the fraction $e = \frac{Q_1 - Q_2}{Q_1}$. According to Carnot's principle, which may be proved by the second law, all ideal reversible engines working between the same temperature limits T_1 and T_2 have the same efficiency; that is, the efficiency is independent of the working medium and depends upon T_1 and T_2 only. Hence $e = f(T_1, T_2)$. Kelvin proposed as a definition of temperature the relation $\frac{Q_2}{Q_1} = \frac{T_2}{T_1}$. From this definition, $e = \frac{T_1 - T_2}{T_1} = 1 - \frac{T_2}{T_1}$. Assume a quantity of heat Q in a body having the temperature T, and let T_0 denote the lowest available temperature (e.g., the temperature of the atmosphere). No device can transform a greater part of Q into work than the ideal Carnot engine; hence the available part of Q is $Q\left(1 - \frac{T_0}{T}\right)$ and the remainder $\frac{QT_0}{T}$ must inevitably be wasted. For example, if the absolute temperature of the source is 900° and that of the atmosphere is 540°, the available energy is $1 - \frac{540}{900} = 0.4$ of the total energy; therefore of 1000 B.t.u. taken from the source not more than 400 B.t.u. can by any possible means be transformed into work and at least 600 B.t.u. is unavailable.

Entropy. Experience shows that any actual physical process, as the change of state of a system, is irreversible and is accompanied by frictional effects. A strictly reversible frictionless process is an ideal that may be approached but never attained. In the case of the ideal reversible process, there is no change in the quantity of available energy; but an actual irreversible process is always accompanied by a decrease of the amount of energy available for transformation, or, what is the same thing, an increase of unavailable energy. An investigation of special cases shows that the increase of unavailable energy is the product of two factors: one is T_0, the lowest absolute temperature available in a refrigerator, the other is a term of the form $\frac{Q}{T}$ or $\int T^{-1} dQ$. This second factor is called the increase of entropy of the system under consideration.

When the conception of increase of entropy is applied to the system composed of all the bodies involved in a change, that is, to an isolated system, it appears that the increase of entropy is a measure of the thermodynamic degeneration produced by the change. According to the law of degradation every natural change is accompanied by thermodynamic degeneration, therefore it is accompanied by an increase of entropy. The following important principle is evident: The direction of a process, physical or chemical, that occurs of itself is such as will bring about an increase of entropy of the system. This principle is the foundation of the application of thermodynamics to chemistry.

The Change of Entropy of a body which is in thermal communication with other bodies (as a pound of air, or the steam in an engine cylinder) is illustrated as follows: Let the ordinate $A_1 A$ (Fig. 1) represent the absolute temperature T_1 of the body in its initial state. Suppose the body to receive heat from external sources while its state changes reversibly; and let the ordinate A_1A increase in length so as to represent the successive values of T during the heating and at the same time move horizontally in such a way that the area swept over represents the heat absorbed. The end of the ordinate must move in a definite path, as AB. The horizontal distance A_1B_1 through which the ordinate moves represents the increase of entropy. If OA_1 is chosen arbitrarily to represent the entropy S_1 of the body in the initial state, then OB_1 represents the entropy S_2 in the final state. The area A_1ABB_1 represents the heat Q absorbed (provided the process is reversible), and the following relations between Q and the change of entropy exist:

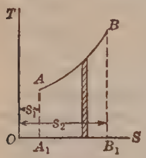

Fig. 1

$$Q = \int_{S_1}^{S_2} T\, dS, \qquad S_2 - S_1 = \int_{T_1}^{T_2} \frac{dQ}{T}.$$

The entropy of a system, as thus defined, depends upon the state only; hence S may be used with p, v, and T as a coordinate. Graphical representations on the TS-plane are specially advantageous, as the areas involved represent heat entering or leaving the system. If the process in question is not reversible (for example, as in the case of the flow of steam in a nozzle), this graphical representation fails. The area in this case does not represent the heat entering the system.

An isothermal process is represented on the TS-plane by a straight line parallel to the S-axis, as AB and CD, Fig. 2; reversible adiabatic processes by lines parallel to the T-axis, as BC and DA. The closed cycle $ABCD$ is the ideal Carnot cycle. Area A_1ABB_1 represents the heat Q_1 absorbed from the source during the isothermal expansion AB, area B_1CDA_1 represents the heat Q_2 rejected to the refrigerator during the isothermal compression CD, and the cycle area $ABCD$ represents the heat $Q_1 - Q_2$ transformed into work. The expression for efficiency $e = \frac{Q_1 - Q_2}{Q_1} = \frac{T_1 - T_2}{T_1}$.

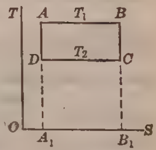

Fig. 2

follows from the geometry of the figure. When the order of events in the cycle of Fig. 2 is reversed, the cycle represents the operation of a refrigerating machine under ideal conditions. During the isothermal expansion DC heat Q_2 is absorbed from the cold body, and during the isothermal compression heat Q_1 is rejected to a body at temperature T_1. The cycle area represents the equivalent of the work W that must be furnished from external sources; and $Q_1 = Q_2 + AW$.

Heat Content. The functions $u + pv$ plays an important part in many technical applications of thermodynamics. The energy u is measured in mechanical units (foot-pounds) and the product pv has necessarily the same unit. The heat equivalent $A(u + pv)$ is denoted by i and is called the heat content of the system (per unit weight). Evidently i, like u and s is a function of the state only. The heat absorbed by a unit weight of a substance at constant pressure is the change in heat content $i_2 - i_1$. It is frequently convenient to represent changes of state on a plane having i and s as coordinates. In this scheme of representation, quantities of heat are represented by segments of lines instead of by areas.

3. Properties of Gases

Experimental Laws. The so-called permanent gases obey quite closely the laws of Boyle, Charles, and Joule, namely:

Boyle's Law. At constant temperature, the volume of a given mass of gas varies inversely as the pressure. That is, the product pv is constant when T is constant.

Charles's Law. At constant pressure, the change of volume of a gas is proportional to the change of temperature. That is, $(\Delta v/\Delta t)\,p = \text{constant}$.

Joule's Law. The intrinsic energy of a gas is independent of the volume of the gas and depends upon the temperature only. Denoting the energy of unit weight of gas by u, Joule's law is expressed symbolically by the relations: $u = f(t)$, $\partial u/\partial v = 0$.

Characteristic Equation. By a combination of the laws of Boyle and Charles the relation $pv = BT$ is obtained as the characteristic equation of a gas that strictly obeys those laws. Here v denotes the volume of unit weight. If V is used to denote the volume of M pounds of gas, the equation takes the useful form $pV = MBT$. The homogeneous form $p_1V_1/T_1 = p_2V_2/T_2$ is advantageous in the solution of problems that involve two states of the gas. The numerical value of the constant B is determined from the equation by inserting known values of p, v, and T corresponding to some assumed standard state. The following are the values of B for certain gases (English units):

Air	53.34	Hydrogen	765.86
Oxygen	48.25	Carbon dioxide	35.09
Nitrogen	55.10	Carbon monoxide	55.14

The gas equation may be written in the form $p = B\gamma T$ where $\gamma = 1/v$ denotes the weight of unit volume. For a chosen pressure and temperature, the product $B\gamma$ is the same for all gases to which the equation applies; and since γ is directly proportional to the molecular weight m, the product Bm is likewise the same for such gases. This product is denoted by R and it is called the universal gas constant. For English units the numerical value of $R = 1544$; hence the gas equation may be written in the form $pv = \left(\frac{1544}{m}\right)T$.

It is frequently desirable to refer the specific volume or the specific weight of a gas to a standard state, namely, atmospheric pressure and a temperature of 32° C. In this state v and γ are expressed in terms of the molecular weight m of the gas by the relations $v_0 = 358.65/m$ and $\gamma_0 = 0.002788\ m$.

Specific Heat of Gases. The specific heat of a gas that obeys the law $pv = BT$ must be independent of the volume and also of the pressure, but it may vary with the temperature. For moderate ranges of temperature the specific heats c_p and c_v may be assumed constant without serious error. The following are mean values for the range 0° to 200° C. (32° to 392° F.):

	c_p	c_v	$k = c_p/c_v$
Air	0.242	0.173	1.4
Hydrogen	3.424	2.446	1.4
Nitrogen	0.2438	0.174	1.4
Oxygen	0.2175	0.155	1.4
Carbon monoxide	0.2426	0.162	1.3
Ammonia	0.5106	0.387	1.32

When the temperature range is large, as exemplified in the internal combustion engine, the assumption of constant specific heat is no longer justified. The experiments of Mallard and Le Chatelier, Langen, and others, show that both c_p and c_v increase with the temperature according to a law that is expressed sufficiently well by the linear relation $c = a + bt$. The variation of specific heat with temperature is represented by the following equations, temperatures being Fahrenheit and m being the molecular weight of the gas:

1. **Diatonic Gases** N_2, O_2, H_2, CO, and **air**.

$$c_p = \frac{1}{m}\left[6.93 + 0.12\left(\frac{T}{1000}\right)^2\right]$$

$$c_v = \frac{1}{m}\left[4.945 + 0.12\left(\frac{T}{1000}\right)^2\right]$$

T = absolute temperature fahr.

m = molecular weight.

2. **Carbon Dioxide** CO_2

For $T < 2900$

$$c_p = 0.1625 + 0.0866\frac{T}{1000} - 0.01364\left(\frac{T}{1000}\right)^2$$

$$c_v = 0.1174 + 0.0866\frac{T}{1000} - 0.01364\left(\frac{T}{1000}\right)^2$$

For $T > 2900$

$$c_p = 0.2772 + 0.0955\frac{T}{1000}$$

$$c_v = 0.2321 + 0.0955\frac{T}{1000}$$

3. **Water Vapor** H_2O

$$c_p = 0.4628 - 0.01533\frac{T}{1000} + 0.0235\left(\frac{T}{1000}\right)^2$$

$$c_v = 0.3525 - 0.01533\frac{T}{1000} + 0.0235\left(\frac{T}{1000}\right)^2$$

Changes of State. For any change of state of a permanent gas the following relations hold. Denoting by M the weight of gas under consideration, the change of energy is

$$U_2 - U_1 = JMc_v(T_2 - T_1) = (p_2V_2 - p_1V_1)/(k - 1).$$

the change of heat content is

$$I_2 - I_1 = Mc_p(T_2 - T_1) = A\,(p_2V_2 - p_1V_1)k/(k-1),$$

and the change of entropy per unit weight is

$$s_2 - s_1 = c_p \log_\epsilon \frac{v_2}{v_1} + c_v \log_\epsilon \frac{p_2}{p_1}.$$

For certain important special changes of state the following relations exist: (W = external work, Q = heat absorbed.)

(a) **Constant Volume:**

$$\frac{p_2}{p_1} = \frac{T_2}{T_1}. \qquad W = 0. \qquad Q = Mc_v(T_2 - T_1) = (U_2 - U_1)A.$$

$$S_2 - S_1 = Mc_v \log_\epsilon \frac{T_2}{T_1}.$$

(b) **Constant Pressure:**

$$\frac{V_2}{V_1} = \frac{T_2}{T_1}. \qquad W = p(V_2 - V_1) = MB(T_2 - T_1).$$

$$U_2 - U_1 = \frac{p(V_2 - V_1)}{k-1} = \frac{W}{k-1}. \quad Q = Mc_p(T_2 - T_1) = I_2 - I_1.$$

$$S_2 - S_1 = Mc_p \log_\epsilon \frac{T_2}{T_1}.$$

(c) **Isothermal Change of State:**

$$p_1V_1 = p_2V_2. \quad U_2 - U_1 = 0. \quad W = MBT \log_\epsilon \frac{V_2}{V_1} = p_1V_1 \log_\epsilon \frac{V_2}{V_1}.$$

$$Q = AW. \qquad S_2 - S_1 = \frac{Q}{T} = ABM \log_\epsilon \frac{V_2}{V_1}.$$

(d) **Adiabatic Change of State:** In the adiabatic change, the equation of the expansion curve is pv^k = const. Combining this with the equation $pv = BT$,

$$Tv^{k-1} = \text{const., or } \left(\frac{V_2}{V_1}\right)^{k-1} = \frac{T_1}{T_2}; \quad \frac{p^{\frac{k-1}{k}}}{T} = \text{const., or } \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} = \frac{T_2}{T_1}.$$

$$Q = 0. \quad W = U_1 - U_2 = JMc_v\,(T_1 - T_2) = \frac{p_1V_1 - p_2V_2}{k-1}. \quad S = \text{const.}$$

(e) **Polytropic Change of State:** This change is defined by the relation pv^n = **a constant** in which n is a constant.

$$\left(\frac{V_2}{V_1}\right)^{n-1} = \frac{T_1}{T_2}. \quad \left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}} = \frac{T_2}{T_1}.$$

$$W = \int_{v_1}^{v_2} p\,dV = p_1V_1{}^n \int_{v_1}^{v_2} V^{-n}\,dV = \frac{p_2V_2 - p_1V_1}{1-n}. \quad U_2 - U_1 = \frac{p_2V_2 - p_1V_1}{k-1}.$$

$$JQ = U_2 - U_1 + W = \frac{k-n}{(k-1)(1-n)}\,p_2V_2 - p_1V_1).$$

$$W : U_2 - U_1 : JQ = k-1 : 1-n : k-n.$$

For example, let air be compressed according to the law $pV^{1.3}$ = a constant. Taking $k = 1.4$, $W : U_2 - U_1 : JQ = 0.4 : -0.3 : 0.1$. That is, three-fourths of the work of compression is stored in the air and is manifested by a rise of temperature and one-fourth of it is taken away by the water jacket.

The specific heat corresponding to the polytropic change is constant and is given by the relation $c_n = c_v(k - n/(1 - n)$. For values of n lying between 1 and k, c_n is negative. The work W and heat absorbed may be expressed in terms of c_n; thus

$$\mathbf{W} = \mathbf{JM}\,(\mathbf{c_n} - \mathbf{c_v})(\mathbf{T_2} - \mathbf{T_1}) = \frac{\mathbf{MB}}{\mathbf{n} - 1}(\mathbf{T_2} - \mathbf{T_1}). \quad \mathbf{Q} = \mathbf{Mc_n}(\mathbf{T_2} - \mathbf{T_1}).$$

Also

$$\mathbf{S_2} - \mathbf{S_1} = \mathbf{Mc_n} \log_\epsilon \frac{\mathbf{T_2}}{\mathbf{T_1}}.$$

To determine the value of n for an experimental curve, which is assumed to follow the law pV^n = const., measure to any convenient scale p_1, V_1 and p_2, V_2 at two assumed points A and B. Then compute $n = \dfrac{\log P_2 - \log P_1}{\log V_1 - \log V_2}$.

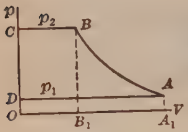

Fig. 3

Air Compression. The ideal indicator diagram of an air compressor without clearance is shown in Fig. 3. The curve AB represents the change of state of the air during compression. Without a water jacket, curve AB may be taken as an adiabatic. If a water jacket is used, AB is represented by an equation pV^n = a constant, and the value of n lies between 1.4 and 1.0. In practice, n is usually about 1.3.

The work represented by area $ABCD$ is given by the expression $W = \dfrac{n(p_1V_1 - p_2V_2)}{n - 1}$, in which V_1 and V_2 denote the volumes at points A_1 and B_1 respectively. The heat absorbed by the water in the jacket during the compression AB is given by $Q = \dfrac{AW(k - n)}{k - 1}$. The work of compression is reduced: (a) by water-jacketing; (b) by compression in two or more stages with cooling between the stages.

4. Saturated and Superheated Vapors

Characteristics of Vapors. When sufficient heat is applied to a liquid the state of aggregation is changed from the liquid to the gaseous. The process is called vaporization, and the resulting gaseous product is called a vapor. As long as the vapor is in contact with the liquid from which it is formed it is said to be saturated. The leading characteristic of a saturated vapor is that its temperature depends upon the pressure only, that is, $\mathbf{t} = \mathbf{f}(\mathbf{p})$. If the vapor is removed from the liquid and is further heated at constant pressure, the temperature rises above the saturation temperature given by $\mathbf{t} = \mathbf{f}(\mathbf{p})$, and the specific volume increases. The vapor is then said to be superheated, and the difference between the temperature of the vapor and the saturation temperature is the degree of **superheat.** In the case of saturated vapor, the volume of one pound is a function of the pressure only ($\mathbf{v} = \phi(\mathbf{p})$), while in the case of a superheated vapor the volume is a function of pressure and temperature ($\mathbf{v} = \mathbf{F}(\mathbf{p}, \mathbf{t})$). The so-called permanent gases, air, nitrogen, etc., are in reality superheated vapors far removed from the saturation state.

Vapor and Liquid Mixtures. The process of vaporization and superheating is shown graphically on the TS-plane in Fig. 4. Liquid at 32° F. represented by point A ($OA = 491.6$) is heated under constant pressure. The process is represented by AB. At B the saturation temperature is reached, vaporization begins and proceeds till all the liquid is changed to vapor, as indicated by point C. Further application of heat superheats the vapor, as indicated by CD. Point B represents liquid at the boiling temperature, point C, saturated vapor, and point D, superheated vapor. For different pressures, points B and C will move along curves s' and s'', called the liquid and saturation curves, respectively. In raising the temperature from 32° to the boiling point, heat represented by area $OABB_1$ is absorbed; this is the heat of the liquid (q'). To vaporize the liquid, heat represented by area B_1BCC_1 is required; this is the heat of vaporization (r). The sum of these is the total heat of the vapor (q''). The area C_1CDD_1 represents the heat absorbed during the superheating. OB_1 represents the increase of entropy (s') during the heating of the liquid, and B_1C_1 the further increase of entropy during vaporization. A point M between B and C represents a mixture of vapor and liquid, the ratio **BM/BC** being the ratio of the weight of vapor to the weight of the mixture. This ratio is denoted by x and is called the **quality** of the mixture.

The latent heat of vaporization r is separable into two parts: (1) the external latent heat, that is, the heat equivalent of the work done during the vaporization process; (2) the internal latent heat ρ, which is the heat required to break up the molecular structure and is stored in the steam in the form of potential energy. The total heat of steam q'' is practically equal to the heat content i'', and in recent steam tables i'' rather than q'' is given.

For a mixture having the quality x (as indicated by point M, Fig. 4) the total heat is $q' + xr$ B.t.u. per lb., and the energy above that of water at 32° is $q' + x\rho$ B.t.u. per lb. The entropy of the mixture per pound is $s' + xr/T$.

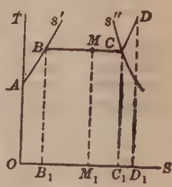

Fig. 4

Thermal Properties of Saturated and Superheated Steam. The magnitudes i', i'', r, ρ, v'', s', and s'', defined in the preceding articles, are dependent on the temperature of vaporization. For several vapors of technical importance these properties have been determined experimentally with more or less accuracy, and empirical formulas have been deduced by means of which the properties are expressed as functions of the temperature. In the case of water vapor, the older tables based on Regnault's experiments are now known to be inaccurate.

The relation between pressure and temperature of saturated steam is given very accurately by the formula

$$\log p = 10.5688080 - \frac{4876.643}{T} - 0.0155 \log T - 0.00406258\, T$$
$$+ 0.00000140055\, T^2 - 0.00002\left[10 - 10\left(\frac{t-370}{100}\right)^2 + \left(\frac{t-370}{100}\right)^4\right].$$

The relation between the volume, pressure and temperature of superheated steam is given by the equation

$$v - 0.017 = 0.59495\,\frac{T}{p} - (1 + 0.05129\, p^{1/2})\frac{66834 \times 10^6}{T^4},$$

in which p is in pounds per square inch.

The following formulas give the heat content and entropy of superheated steam.

$$i = 0.320\,T + 0.000063\,T^2 - \frac{23583}{T} - p(1 + 0.0342\,p^{1/2})\,\frac{6188 \times 10^7}{T^4} + 948.5,$$

$$s = 0.73683 \log T + 0.000126\,T - \frac{11792}{T^2}$$

$$- 0.254 \log p - (1 + 0.03420\,p^{1/2})\,\frac{49504 \times 10^6}{T^5} - 0.0811.$$

With **p** in pounds per square inch the energy **u** is obtained from the relation

$$u = i - 0.1852\,pv.$$

If in the preceding formulas corresponding values of **p** and **T** at the saturation state are inserted, the volume, heat content, and entropy (v'', i'', s'') of saturated steam are obtained.

Properties of Saturated Steam

(Condensed from Goodenough's "Properties of Steam and Ammonia")

* The number in brackets is the saturation temperature corresponding to the pressure.

Example 1. Let a mixture of steam and water having a quality $x = 0.96$ expand adiabatically from a pressure of 120 lb. per sq. in. absolute to atmospheric pressure. Required the properties of the mixture in the initial and final states and the work of expansion.

In the initial state the heat content is $i_1' + x_1 r = 311.9 + 0.96 \times 879.5 = 1156.2$ B.t.u., and the energy of the mixture is $i_1' + x_1 \rho_1 = 311.9 + 0.96 \times 796.9 = 1076.8$ B.t.u. The entropy is $s_1' + x_1 r_1/T_1 = 0.4911 + 0.96 \times 1.0982 = 1.5454$. The volume of 1 lb. of dry steam at 120-lb. pressure is 3.735 cu. ft., and the volume of a pound of the mixture is $3.735 \times 0.96 = 3.586$ cu. ft.

In the adiabatic expansion the entropy remains constant, and in the final state, therefore, $s_2' + x_2 r_2/T_2 = 1.5454$, whence $x_2 = 0.852$; that is at the end of the expansion the mixture contains nearly 15% water. The heat content in the second state is $180 + 0.852 \times 971.7 = 1007.9$ B.t.u., the energy is $180 + 0.852 \times 898.9 = 945.9$ B.t.u., and the volume of 1 lb. is $26.81 \times 0.852 = 22.84$ cu. ft. The external work is the equivalent of the decrease in energy, or $778\ (1076.8 - 945.9) = 101\ 840$ ft.-lb. per pound of mixture. The difference $i_1 - i_2 = 1156.2 - 1007.9 = 148.3$ B.t.u., is the available heat, that is, the heat that may be transformed into work in an ideal engine working between the pressure limits under consideration. It is also the equivalent of the kinetic energy $w^2/2\,g$ of a jet flowing from a region of 120 lb. pressure into a region of atmospheric pressure.

Example 2. Let steam at 200 lb. per sq. in. absolute pressure superheated to 560° expand adiabatically to a pressure of 3 in. of mercury. Required the final quality, the change in heat content, and the change of energy.

By interpolation the following values are obtained for the steam in the initial state: $i = 1300.9$, $s = 1.7562$, $v = 2.95$. Consequently the energy per pound is $1300.9 - 0.1852 \times 200 \times 2.95 = 1191.6$ B.t.u. $s_2 = 1.6562 = s_2' + x_2 r_2/T_2 = 0.1561 + 1.7893 x_2$, whence $x_2 = 0.838$, the final quality. $i_2 = 83 + 0.838 \times 1028.3 = 945.1$, $u_2 = 83 + 0.838 \times 965.2 = 892.2$ B.t.u. The change in energy is therefore $1191.6 - 892.2 = 299.4$ B.t.u., and the change in heat content is $1300.9 - 945.1 = 355.8$ B.t.u.

Adiabatic Changes. An adiabatic expansion of a saturated or superheated vapor may be represented approximately by the equation $\mathbf{pv^m} =$ **const.** For saturated steam m depends upon the initial quality and pressure and is given by the equation $m = 1.059 + 0.000315\,p + 0(0.0706 + 0.000376\,p)x$. For superheated steam m may be taken as 1.31, for superheated ammonia at 1.333, and for superheated sulfur dioxide as 1.282. The final volume V_2 is given by the relation $\mathbf{V_2 = V_1(p_1/p_2)^{\frac{1}{m}}}$ and the external work is then approximately $\mathbf{W = (p_1V_1 - p_2V_2)/(m - 1)}$.

5. Flow of Elastic Fluids

General Equation of Flow. Let an elastic fluid, as air or steam, flow along a horizontal tube, Fig. 5. At an assumed cross-section $\mathbf{F_1}$ the pressure of the fluid is $\mathbf{p_1}$ and the mean velocity is $\mathbf{w_1}$; at a second section $\mathbf{F_2}$ the pressure is $\mathbf{p_2}$ and the velocity is $\mathbf{w_2}$. The principal equation of flow is $\mathbf{(w_2^2 - w_1^2)/2\,g = J\,(i_1 - i_2)}$, in which $\mathbf{i_1}$ and $\mathbf{i_2}$ denote, respectively, the heat content per pound of fluid at sections F_1 and F_2. If section F_1 is taken in the boiler or reservoir from which the fluid is flowing, then $w_1 = 0$, and the equation becomes

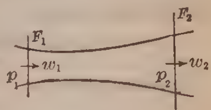

Fig. 5

$$\mathbf{w^2/2\,g = J\,(i_1 - i_2) \quad \text{or} \quad w_2 = 223.7\sqrt{i_1 - i_2}.}$$

In the flow of elastic fluids, the heat content i plays the same part as the head h in the flow of liquids.

Example. Steam at 120 lb. per sq. in., quality 0.96, flows into the atmosphere through a properly proportioned nozzle. Required the velocity of flow. The heat content i_1 is 1156.2 B.t.u. per lb., and if the flow is adiabatic and frictionless the final heat content i_2 is 1007.9 B.t.u. Hence $w = 223.7\sqrt{1156.2 - 1007.9} = 2724$ ft. per sec.

Formulas of Discharge. The weight M of fluid flowing past a cross-section per second is given by the equation of continuity $Fw = Mv$ in which F denotes the area of the section and v the specific volume of the fluid at this section. If the flow is through an orifice or short tube, it is found that the pressure in the plane of the orifice never falls below a certain value p_m called the **critical pressure.** The ratio p_m/p_1 (p_1 being the pressure in the boiler or reservoir) is called the **critical ratio.** For air its value is about 0.53; for saturated steam, about 0.57. If the pressure p_2 of the region into which the fluid is flowing is greater than p_m, the pressure at the orifice is p_2, but if p_2 is less than p_m, then the pressure at the orifice is p_m and the discharge M is the same whatever the value of p_2. The following formulas for discharge are in current use:

(a) **Fliegner's equations for air.**

When $\quad p_2 < 0.53\, p_1 \qquad M = 0.53\, F \dfrac{p_1}{\sqrt{T_1}}.$

When $\quad p_2 > 0.53\, p_1 \qquad M = 1.06\, F \sqrt{\dfrac{p_2(p_1 - p_2)}{T_1}}.$

(b) **Grashof's Equation for Steam.** Taking the area of the orifice in square inches and the pressure p_1 in lb. per sq. in.,

$$M = 0.0165\, F p_1^{0.97}. \qquad p_2 < 0.57\, p_1.$$

(c) **Rateau's Equation.** This equation is empirical and is based on experimental data.

$$M = \frac{F p_1}{1000}(16.367 - 0.96 \log p_1). \quad p_2 < 0.57\, p_1.$$

(d) **Napier's Equations.** These are also empirical and rather inaccurate.

When $\quad p_1 > \dfrac{5}{3} p_2, \quad M = \dfrac{F p_1}{70}.$

When $\quad p_1 < \dfrac{5}{3} p_2, \quad M = \dfrac{F p_2}{42}\sqrt{\dfrac{3(p_1 - p_2)}{2\, p_2}}.$

Example. Required the discharge in pounds per minute of saturated steam at 100 lb. pressure (absolute) through an orifice having an area of 0.4 sq. in. The back pressure is less than the critical pressure, 57 lb. per sq. in.

By Grashof's formula:

$$M = 60 \times 0.0165 \times 0.4 \times 100^{0.97} = 34.493 \text{ lb.}$$

By Rateau's formula:

$$M = \frac{60 \times 0.4 \times 100}{1000}(16.367 - 0.96 \times 2) = 34.673 \text{ lb.}$$

By Napier's formula:

$$M = \frac{0.4 \times 100}{70} \times 60 = 34.286 \text{ lb.}$$

The discharge may be found from the two fundamental formulas:

$$w = 223.7\sqrt{i_1 - i_2}, \text{ and } M = Fw/v.$$

The critical pressure p_m is 57 lb. per sq. in. From the steam table, i_1 (for 100 lb.) = 1188.4 B.t.u.; i_m (for 57 lb.) = 1144.1 B.t.u.; $x_m = 0.963$; $v_m = 7.26$ cu. ft. Then $w = 223.7\sqrt{1188.4 - 1144.1} = 1490$ ft. per sec., and $M = 60 \times \dfrac{0.4}{144} \times \dfrac{1490}{7.26} =$ 34.18 lb.

Flow in Nozzles. When the pressure p_2 of the region into which a jet is flowing is less than the critical pressure p_m, which is the pressure existing in the emerging fluid, the difference $p_m - p_2$ gives rise to a lateral spreading of the jet. This spreading may be prevented by the addition of a properly proportioned tube (Fig. 6). The tube must diverge so as to permit the expansion of the fluid required by the drop in pressure from p_m at the smallest section a to the external pressure p_2 at the end section b. The effect of the diverging nozzle is to cause a solid jet to emerge with a velocity w_2 given by the fundamental relation $w_2 = \sqrt{2\,gJ\,(i_1 - i_2)} = 223.7\sqrt{i_1 - i_2}$. If the external pressure p_2 is greater than p_m the diverging tube is unnecessary and a simple orifice is used. In the Rateau turbine, for example, the drop in pressure from cell to cell is so arranged that $p_2/p_1 > 0.57$ and the steam flows through orifices rather than nozzles.

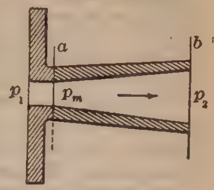

Fig. 6

On account of the length of a nozzle there is necessarily some loss of energy due to frictional resistances. The work of friction is converted into heat, which enters the flowing fluid and increases the final heat content i_2 to a larger value i_2'. It is customary to take as a friction coefficient the ratio of the loss of energy to the kinetic energy of the jet without friction. Denoting the coefficient by y, its formula is

$$y = \frac{i_2' - i_2}{i_1 - i_2}$$

and the actual velocity of exit w_2' is given by the relation

$$w_2' = \sqrt{2\,gJ\,(1 - y)\,(i_1 - i_2)} = 223.7\sqrt{(1 - y)\,(i_1 - i_2)}.$$

The quality of the steam at exit is increased by the heat generated through friction and is given by the equation

$$x_2' = x_2 + \frac{(i_1 - i_2)y}{r_2},$$

in which x_2 denotes the quality on the assumption of frictionless adiabatic expansion and is given by $s_1' + \frac{x_1 r_1}{T_1} = s_2' + \frac{x_2 r_2}{T_2}$. Experiments indicate that y may vary from 0.08 to 0.20, depending on the size of nozzle.

Throttling. The throttling or wiredrawing of a fluid is merely a special case of flow, in which the loss by friction is excessive. The fluid in the region of higher pressure p_1 passes through a valve or constricted passage into a region of lower pressure p_2. The velocity is increased from w_1 to w_2, but the increased kinetic energy is dissipated as the fluid passing the orifice enters and mixes with the fluid in the second region. Ultimately the velocity w_2 is sensibly equal to the original velocity w_1, and therefore $i_2 = i_1$. For a mixture of saturated vapor and liquid, the equation of throttling is $i_1' + x_1 r_1 = i_2' + x_2 r_2$. From this equation the value of x_2 is found, and having x_2, the increase of entropy is determined; and the increase of entropy multiplied by T_0 gives the loss of available energy resulting from the throttling.

If steam at the higher pressure p_1 is nearly dry, it becomes superheated when throttled to a much lower pressure. The equation, in this case, becomes $i_1' + x_1 r_1 = i_2'' + c_p(t_2' - t_2)$, in which t_2 denotes the saturation temperature for the pressure p_2, t_2' the temperature of the superheated steam, and c_p the mean specific heat for the range $t_2' - t_2$. By means of this equation the initial quality x_1 may be determined from observed values of p_2 and t_2'.

6. Steam Boilers

Types of Boilers. Steam boilers may be divided into two general classes: (1) **fire tube boilers,** in which the hot gases from the furnace pass through the tubes and the water surrounds the tubes; (2) **water-tube boilers,** in which the water flows through the tubes. A second classification takes account of the location of the furnace. In an **externally fired** boiler, the furnace is placed in a brick chamber external to the boiler. The **internally fired** boiler has its furnace enclosed in the steel shell of the boiler itself. Marine and locomotive boilers are examples of the latter type.

Horsepower. The capacity of a boiler for the generation of steam is measured in terms of an arbitrary unit called horsepower. As defined by the American Society of Mechanical Engineers, a **boiler horsepower** is the equivalent of the evaporation of 34.5 lb. of water per hour from and at 212° F. The latent heat of steam at 212° F. and atmospheric pressure is 971.7 B.t.u.; hence a horsepower is equivalent to the development of **33 523 B.t.u. per hour.**

Let **M** denote the weight of feed water actually evaporated per hour. Also let i_1' denote the heat content of the feed water at the temperature at which it enters the boiler, and i_2 the heat content of the steam in its final condition (wet, saturated, or superheated). Then the boiler horsepower is given by the formula

$$\text{Boiler hp.} = \frac{M\,(i_2 - i_1')}{33\,523}$$

Boiler Capacity. The **rated** boiler horsepower depends upon the heating surface, which is the total surface of the shell and tubes that is exposed to hot gases and has water on the opposite side. According to recent practice stationary boilers are rated on the basis of 10 sq. ft. of heating surface per boiler horsepower. By this system of rating, boilers having the same heating surface are rated at the same horsepower. The actual capacity of one boiler may, however, be greater than that of another boiler of the same horsepower due to a more advantageous arrangement of heating surface. Most power plant boilers can develop from 200% to 400% of their normal rating, and many are operating for long periods at 200% rating. However, the efficiency of the boiler may be decreased when it is forced to develop much more than its rated capacity. The decrease in efficiency is not significant until the overload reaches 25% (for fire tube) to 100% (for water tube).

Boiler Performance. In estimating boiler performance the following items may receive consideration: 1. Efficiency. 2. Rate of combustion. 3. Evaporation per pound of fuel. 4. Heat absorbed per square foot of grate surface per hour. 5. Percentage of rated horsepower developed.

The overall **boiler efficiency** is the ratio of the heat absorbed to that supplied: thus

$$E_b = \frac{M\,(i_2 - i_2')}{M_c\,H}$$

in which E_b = efficiency of boiler, furnace, and grate;
M_c = total weight of coal fired per hour;
H = heat of combustion of 1 lb. of coal.

The **rate of combustion** may be expressed as the weight of fuel burned per hour (*a*) per square foot of projected gate surface, or (*b*) per cubic feet of furnace volume. The boiler horsepower that can be developed is dependent on the rate of combustion; that is, upon the kind of fuel, size and kind of grate, and the quantity of air supplied. Rates of expansion as high as 200 lb. per hour per square feet of grade surface have been obtained in locomotive boilers, the high capacity accompanied by a lowered efficiency. With ordinary chimney draft the grate area should be 1/4 sq. ft. or more per rated horsepower. With forced draft, the area may be considerably smaller. The rate of combustion is ordinarily 10 to 20 lb. of coal per hour per square foot of grate for anthracite coal and 20 to 30 lb. for bituminous coal. With forced draft these rates may be largely exceeded.

Small **hand-fired** boilers may show overall efficiencies varying from 0.40 to 0.65; **stoker-fired** boilers may show efficiencies from 0.60 to 0.80, depending on the size of the plant, and the amount of heat saving equipment in operation. Large **pulverized coal installations** have given efficiencies of 80 to 85%. With **superheaters, air pre-heaters,** and **economizers** in operation the efficiency of a large installation with mechanical stokers, or with pulverized coal may be pushed up to nearly 90%. It may be noted that the average all-year boiler efficiency is well below the high value obtained for short periods under test conditions.

Heat Losses. The principal losses of heat incurred in the combustion of fuel in the boiler furnace are:

1. Heat carried away by the dry chimney gases.
2. Heat required to evaporate moisture in coal.
3. Heat required to evaporate moisture formed by burning hydrogen in fuel.
4. Heat required to superheat water vapor in air supplied.
5. Loss of heat due to incomplete combustion of fuel.
6. Heating value of unconsumed carbon in ash and refuse.
7. Heat radiated; also heat not accounted for.

A tabulation of the various heat losses, along with the heat absorbed by the boiler constitutes a **heat balance** for the boiler and furnace. From such a heat balance a comparison of the various losses may be made.

The **data required** for the determination of the various losses are: Chemical analysis of fuel, of chimney gases, and of ash; heat of combustion of fuel; relative humidity of air supplied; temperature of air supplied and temperature of chimney gases.

An indication of the boiler operating conditions as regards economy is furnished by the composition of the **chimney gases.** With insufficient air supply some of the carbon content of the fuel may be burned to CO instead of to CO_2. The result will be a loss of heat developed amounting to about 10 150 B.t.u. per pound of carbon. The CO_2 content of the chimney gases is of special significance. Under good conditions of operation the CO_2 content will vary from 9 to 13% by volume. A value lower than 9% usually indicates either excessive air supply to the fuel bed or leakage of air through the furnace walls. More than 13% of CO_2 may indicate an insufficient supply of air, and a small amount of CO may be present in the gases. Many boiler plants are provided with automatic CO_2 recorders.

Boiler Tests. The object of a boiler test may be:

1. To determine the capacity and efficiency of the boiler.
2. To compare different kinds of fuels.
3. To compare different conditions and methods of operation.

Boiler tests should be conducted in accordance with the boiler test code prepared by the Power Test Code Committee of the American Society of Mechanical Engineers.

7. Steam Engines

Types of Steam Engines. Reciprocating steam engines may be grouped in classes in several ways. The type of valve gear furnishes one basis of division; thus engines may be classed as slide-valve, Corliss, four-valve, etc. Slide-valve engines may be either throttling or automatic, according as the governor regulates the work in the cylinder by throttling the steam or by changing the point of cutoff. Engines in which the complete expansion of steam takes place in one cylinder are **simple engines**; if the expansion requires two, three, or four cylinders, the engines are termed **compound, triple,** and **quadruple,** respectively. Engines are **condensing** when the exhaust steam passes into a condenser, **non-condensing** when it passes directly into the atmosphere. Most steam engines are **double-acting,** that is, work is done during both strokes of the piston.

Ideal Cycle. The ideal cycle of a steam engine without clearance may be represented most advantageously on the temperature-entropy plane. The point A (Fig. 7) represents the state of one pound of water entering the boiler; curve AB represents the heating of the water to the boiling temperature T_1, BC represents vaporization, CD adiabatic expansion in the engine cylinder, and DA condensation of the exhaust steam. The cycle area $ABCD$ represents the available heat, that is, the part of the total heat supplied that may be transformed into work. Denoting by i_1 the heat content of the steam in state C and by i_2 the heat content after adiabatic expansion to D, the available heat is the difference $i_1 - i_2$. The **weight of steam consumed** per horsepower-hour is **$2546/(i_1 - i_2)$**.

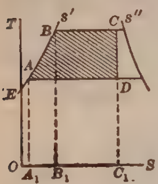

Fig. 7

Example. Referring to the examples on p. 341, it was shown that in the case of an engine using steam at 120-lb. pressure, quality 0.96, and exhausting at atmospheric pressure, the available heat was 148.3 B.t.u. per lb. For an engine using steam at 200-lb. pressure superheated to 560° and with a condenser pressure of 3 in. of mercury, the available heat was 355.8 B.t.u. per lb. In the first case the ideal steam consumption is 2546/148.3 = 17.2 lb., and in the second case it is 2546/355.8 = 7.16 lb. per hp. hr.

This ideal cycle is called the **Rankine cycle** and is used as a standard by which to measure engine performance. With given limiting pressures p_1 and p_2 and initial quality x_C, the available heat is the maximum amount of heat that can be transformed into work under these conditions, and the ratio of the heat actually transformed to the available heat indicates the real efficiency of the engine from the point of view of thermodynamics.

Indicator Diagram. The actual cycle of the steam engine differs from the ideal Rankine cycle in several particulars: (1) The metal of the cylinder walls and piston conducts heat, and there is thus an active interchange of heat between the metal and steam, which makes adiabatic expansion impossible. (2) The valves do not act instantly and there is wiredrawing of steam in passing through the ports. (3) The cylinder must have clearance. The result of these modifications is a cycle having a smaller area than the ideal Rankine cycle.

On the pv-plane the actual cycle of the engine is the diagram drawn by the indicator (Fig. 8). In this diagram, OV represents the line of **zero pressure,** XX the atmospheric line, OX representing atmospheric pressure and YY the line of boiler pressure. The length GH represents the volume swept through by the piston, and XG the clearance volume V_c. AB is the **steam line,** B the point of cutoff, BC the **expansion curve**, C the **point of release**, CD the **exhaust line**, DE the **back-pressure line**, E the **point of exhaust closure**, EF the **compression curve**, and FA the **admission line.** A single indicator diagram shows graphically the pressures exerted by the steam on one side of the piston during two strokes. To determine the net steam pressure transmitted to the piston rod, diagrams taken simultaneously from opposite ends of the cylinder must be superimposed.

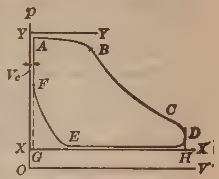

Fig. 8

The expansion curve BC of the actual diagram may be represented by an equation of the form $pV^n =$ a constant. The usual statement is that the curve is an equilateral hyperbola, in other words, that $n = 1$, has no foundation. Experiments show that the value of n depends upon the quality of the mixture in the cylinder at cut off; if there is a large percentage of water in the mixture, n falls as low as 0.85 or 0.9, whereas if there is little or no water present, due to use of superheated steam, n may rise to 1.2.

The indicator diagram has **two principal uses:** (1) It shows the distribution of the steam to the cylinder, and reveals errors in the setting of the valves. (2) It gives the horsepower developed in the cylinder, the so-called indicated horsepower (i.hp.).

Indicated Horsepower. The **area** of the indicator diagram is the integral $\int pdV$ taken around the closed cycle; hence it represents the **work of the cycle.** The mean ordinate of the diagram (see Fig. 8) is found by any convenient method. Ordinarily the area is determined by a planimeter, and this area divided by the length GH gives the mean ordinate. Multiplying by the scale of the indicator spring (30, 40, or 60 lb. per sq. in.), the resulting product is the **mean effective pressure** (m.e.p.) in pounds per square inch.

Let **p** denote the mean effective pressure, **a** the area of piston in square inches, **l** the length of stroke in feet, and **n** the revolutions per minute. Then the indicated horsepower is

$$\text{hp.} = \frac{2\ \mathbf{plan}}{33\,000}$$

For a **single-acting engine,** the factor 2 is dropped. For accurate calculations, the area a should be reduced by one-half of the cross-section area of the piston rod if the rod passes through one head and by the whole area if the rod passes through two heads. The piston speed S, is given by $2\,ln$; hence i.h.p. $= paS/33\,000$.

Brake Horsepower is the horse-power of the engine delivered at the flywheel. The difference between the i.hp. and b.hp. is the **friction horsepower,** and the ratio $\frac{\text{b.hp.}}{\text{i.hp.}}$ the **mechanical efficiency** of the engine. The brake horsepower is determined experimentally by the use of a band brake or an absorption dynamometer.

Losses in the Steam Engine. The following are the principal sources of loss of available heat in the operation of the engine: (1) Wiredrawing in ports and valves, and friction in pipes. (2) Leakage past the piston and valves. (3) Loss due to clearance. (4) Radiation and conduction from the cylinder. (5) Initial condensation.

The losses indicated in the first four items may be reduced to a minimum by careful design and construction. The most serious loss is due to the interchange of heat between steam and metal, resulting in initial condensation and subsequent evaporation. The magnitude of this loss depends upon the conditions of operation. It is greater the slower the rotative speed of the engine, the earlier the cutoff, the greater the temperature range in the cylinder, and the greater the ratio of cylinder-wall surface to cylinder volume. The following are the means used to reduce the loss due to initial condensation.

(a) **Steam Jackets.** The cylinder is surrounded by an annular space containing steam at boiler pressure. The condensation takes place in this jacket instead of in the cylinder. The jacket is most effective in slow-speed engines having large ratios of expansion.

(b) **Compounding.** The large temperature range that accompanies a large ratio of expansion may be divided between 2, 3, or 4 cylinders, thus giving a relatively small range in each cylinder. The total loss from condensation in all the cylinders is less than the loss would be if the steam were expanded in a single counter-flow cylinder. The use of two or more cylinders is also advantageous mechanically; the pressures on cranks, shafts, etc., are reduced, and by setting the cranks at proper angles a more uniform turning moment on the shaft is obtained.

(c) **Superheating.** The most effective means of reducing initial condensation is the use of steam initially superheated. By a sufficient degree of superheat dry steam at cutoff may be insured, and as the rate of absorption of heat by a gas is small, the activity of heat interchange between steam and metal is greatly reduced.

(d) **Uni-directional Flow.** Steam flows directly from the inlet to the exhaust. The engine piston serves as a valve at the exhaust ports, which are located in the cylinder walls midway between the heads. The inlet ports are not chilled by the low temperature exhaust steam; and the cushion steam is compressed to a pressure and temperature nearly equal to those of the supply steam. The expansion of the steam through a wide temperature range in a single cylinder with reduced cylinder condensation results in excellent economy under all conditions of load.

Efficiency Standards. The term efficiency when applied to the steam engine may mean any one of several ratios. Let q = heat supplied to an engine per pound of steam, q_a = available heat, the maximum quantity of heat that can be transformed into work in the ideal Rankine cycle, q_e = heat transformed into work in actual engine, $W_e = Jq_e$ the indicated work per lb. of steam, W_b = the work obtained at the brake per pound of steam. Then $e_a = q_a/q$ = thermal efficiency of Rankine engine,

$$e_e = \frac{q_e}{q} = \text{thermal efficiency of actual engine,}$$

$$e_i = \frac{e_e}{e_a} = \frac{q_e}{q_a} = \text{efficiency ratio (sometimes called potential efficiency),}$$

$$e_b = \frac{W_b}{Jq_e} = \text{brake efficiency ratio (based on work at break),}$$

$$e_m = \frac{W_b}{W_a} = \text{mechanical efficiency.}$$

Two other standards are coming into use. These are B.t.u. consumed per indicated horsepower-hour and B.t.u. per brake horsepower-hour. Since 1 hp.-hr. = 2546 B.t.u., the first ratio is equal to 2546 divided by the indicated thermal efficiency; thus if the thermal efficiency is 0.20, the engine consumes 2546/0.20 = 12 730 B.t.u. per hour per indicated horsepower.

The really useful criterion of engine performance is the ratio e_b which is equal to the product $e_t \times e_m$. The ratio e_t is a measure of the extent to which the engine transforms into work the heat q_a that is available for transformation, and the ratio e_m measures the mechanical perfection of the engine. The product $e_t \times e_m$, therefore, is an indication of the quality of the engine both thermodynamically and mechanically.

The Rankine efficiency e_a depends upon the pressure limits used and may vary from 0.08 to 0.30. The thermal efficiency of the actual engine varies from 0.03 to as high as 0.25. The efficiency ratio e_e usually lies between 0.60 and 0.75, but in exceptional cases the extremely high value 0.88 has been attained. At full load the mechanical efficiency e_m should lie between 0.80 and 0.95. Since the engine friction remains nearly constant at all loads, e_m may fall as low as 0.50 at light loads.

Performance of Steam Engines. The following gives approximate values of steam consumption of various classes of steam engines (Allen and Bursley's Heat Engines, third edition, p. 246):

Steam consumption.	Pounds per indicated horsepower-hour
Simple throttling engine, non-condensing	33–49
Simple automatic engine, non-condensing	27–34
Simple Corliss engine, non-condensing	21.5–26
Simple automatic engine, condensing	17–20
Simple Corliss engine, condensing	19.3–21.7
Compound automatic engine, non-condensing	25–30
Compound automatic engine, condensing	18–20
Compound Corliss engine, condensing	12–15
Triple Corliss engine, condensing	12-1/4–13
Uniflow engine, simple, condensing, superheat	11-1/4–12

The Economy of Pumping Engines is usually expressed in terms of **duty**, which is defined as follows: The duty is the number of foot-pounds of work obtained from the pump cylinders per million B.t.u. furnished to the engine by the boilers. The duty is sometimes expressed as the foot-pounds of work per 1000 lb. of dry steam or per 100 lb. of coal. The energy supplied by 1000 lb. of dry steam is somewhat indefinite, but, roughly, the work done by 1000 lb. of dry steam is 10 to 25% greater than the work done per million B.t.u. In view of the difference in quality and heat of combustion of different coals, duty expressed in 100 lb. of coal is practically meaningless. The duty that may be expected of various forms of pumping engines is as follows (Allen and Bursley's Heat Engines, p. 248, third edition):

Small duplex non-condensing pumps	10 000 000
Large duplex non-condensing pumps	25 000 000
Small simple flywheel pumps, condensing	50 000 000
Large simple flywheel pumps, condensing	65 000 000
Small compound flywheel pumps, condensing	85 000 000
Large compound flywheel pumps, condensing	120 000 000
Large triple-expansion flywheel pumps, condensing	165 000 000
Large triple-expansion flywheel pumps, condensing, of exceptional economy	180 000 000

The efficiency ratio of a good steam engine should lie between 0.62 and 0.75. Under exceptional conditions it may rise to 0.80. In general, the steam consumption per horsepower-hour and the efficiency ratio vary with the load. At light loads the efficiency decreases rapidly as the load is decreased; for loads in excess of the engine's rating, the efficiency also decreases but at a slower rate.

Steam Engine Testing. The object of the test is to determine the steam consumption of the engine and the efficiency ratio. If a surface condenser is used the steam consumption is determined by weighing the steam condensed;

otherwise, the water fed to the boilers must be measured, care being taken that all the steam produced from the feed water goes to the engine. The length of the engine test should be at least 5 hours, and if the test includes the boilers, it should continue 24 hours. The indicated horsepower is determined from indicator diagrams taken at intervals of 10 or 15 minutes; and the brake horsepower is obtained by the use of a brake or dynamometer. The weight of water reduced in pounds per hour is divided by the average indicated horsepower, and the quotient is the steam consumption in pounds per horsepower-hour. The steam consumption for the ideal Rankine engine is readily found for the same conditions and the ratio of these gives the efficiency ratio.

A code of rules for conducting steam-engine tests is contained in the Transactions of the A. S. M. E., vol. xxiv. The following are extracts from the report of the committee:

From Introduction to Report. The heat consumption of a steam engine plant is ascertained by measuring the quantity of steam consumed by the plant, calculating the total heat of the entire quantity, and crediting this total with that portion of the heat rejected by the plant which is utilized and returned to the boiler. The term engine plant as here used should include the entire equipment of the steam plant which is concerned in the production of the power, embracing the main cylinder or cylinders; the jackets and reheaters; the air, circulating, and boiler-feed pumps, if steam driven; and any other steam-driven mechanism or auxiliaries necessary to the working of the engine.

X. Measurement of Feed Water. The method of determining the steam consumption applicable to all plants is to measure all the feed water supplied to the boilers, and deduct therefrom the water discharged by separators and drips, as also the water and steam which escape on account of leakage of the steam main and branches connecting the boiler and engine. In plants where the engine exhausts into a surface condenser the steam consumption can be measured by determining the quantity of water discharged by the air pump, corrected for any leakage of the condenser, and adding thereto the steam used by jackets, reheaters, and auxiliaries as determined independently.

XIII. Indicated Horsepower. The indicated horsepower should be determined from the average m.e.p. of diagrams taken at intervals of 20 minutes, and at more frequent intervals if the nature of the test makes this necessary, for each end of the cylinder.

XXI. Standards of Economy and Efficiency. The hourly consumption of heat . . . divided by the indicated and brake horsepower, that is, the number of heat units consumed per i.hp. and per b.hp. per hour, are the standards of engine efficiency recommended by the committee.

XXIV. Ratio of Economy of an Engine to That of an Ideal Engine. The ideal engine recommended for obtaining this ratio is . . . one which follows the Rankine cycle, where steam at constant pressure is admitted into the cylinder with no clearance, and after the point of cutoff is expanded adiabatically to the back pressure. In obtaining the economy of this engine the feed water is assumed to be returned to the boiler at exhaust temperature.

8. Steam Turbines

Types of Steam Turbines. Steam turbines may be divided into two general classes: (1) The **impulse** or **velocity** turbine, which is analogous to the Pelton water wheel. Steam expands in a nozzle until the pressure drops to the pressure in the region in which the turbine wheel rotates, and the jet issuing with relatively high velocity is directed against the blades of the wheel. (2) The **reaction** or **pressure** turbine, which is analogous to the water turbine. In this type of turbine the steam flows through alternate guide blades and moving blades and the pressure gradually falls through both sets of blades. The essential differences between the two types are shown by the following comparison:

Impulse or Velocity	Reaction or Pressure
1. Drop of pressure in nozzles only.	1. Drop of pressure continuous in guides and moving blades.
2. Jet may fill only part of wheel circumference.	2. Turbine runs full.
3. Blades may be symmetrical.	3. Blades necessarily unsymmetrical.
4. Jet velocity high, 1000 to 3500 ft. per sec.	4. Steam velocities low, 300 to 900 ft. per sec.
5. Speed of blade nearly one-half of jet velocity for highest efficiency.	5. Speed of blade nearly equal to velocity of steam.

Compounding. The high velocity of the steam jet resulting from a considerable drop of pressure renders desirable some methods of compounding in order that the peripheral speed of the turbine wheels may be kept within reasonable limits. In most turbines pressure compounding is used. The total drop of pressure $p_1 - p_2$ is divided among several wheels, thus reducing the velocity of the jet at each wheel. The arrangement is shown in Fig. 9. Steam passes through orifices m_1, m_2, etc., in the partition which divide the interior of the turbine into wheel chambers. The pressure drops from p_1 to p_2 in passing through the first orifices, then from p_2 to p_3, etc. The curves p and w show roughly the pressure and velocity changes. The principle of velocity compounding is shown in Fig. 10. The steam is expanded in a nozzle to the back pressure p_2, thus giving a jet of relatively high velocity. The jet passes into the first moving wheel, then through a fixed guide, where its direction is reversed, then into a second moving wheel. A second guide and a third wheel are sometimes added. The curves p and w show the changes of pressure and velocity.

Leading Commercial Turbines. The **De Laval turbine** is a velocity turbine having a single stage. The steam expands in a diverging nozzle to the final pressure and the jet passes through a single wheel.

The **Rateau turbine** is a velocity turbine with pressure compounding, Fig. 9. The ratio of pressures between successive stages is kept above the critical ratio, so that diverging nozzles are not necessary. The number of pressure stages is relatively large. The larger turbines constructed by the General Electric Co. are of the Rateau type.

The **Parsons turbine** is a reaction or pressure turbine. The moving blades are mounted on a drum or rotor and the rows of moving blades alternate with rows of stationary blades attached to the casing. The entire annular space between rotor and casing is filled with steam and the pressure drops continuously as the steam passes through the stages. The radial length of the blades is increased from stage to stage to provide for the increasing specific volume of the steam. The Parsons turbine is made in the United States by the Westinghouse Company and by the Allis-Chalmers Company.

The **Westinghouse double-flow turbine** is a combination of a velocity and pressure turbine. The steam at boiler pressure is expanded in a nozzle to a much lower pressure and the jet at high velocity is passed through two sets of moving blades with intermediate guide blades (see Fig. 10). The steam is then led to two rotors on opposite ends of the shaft, and the remainder of the expansion is the same as in the Parsons turbine.

Performance of Steam Turbines. The economy of a steam turbine measured in steam consumption per horsepower-hour is not much different from the economy of a reciprocating engine under the same conditions. With a good vacuum (28 to 29 in. of mercury) and with superheated steam the consumption per brake horsepower-hour should lie between 10.5 and 14 lb. The efficiency ratios shown by numerous tests lie between 0.60 and 0.78.

Steam Turbine Speeds. Turbines of practically equal efficiency may be designed within wide limits of rotative speed. The peripheral velocity is the controlling condition so that a lower rotative speed requires an impeller of correspondingly larger diameter and results in greater cost. Formerly units having rotative speeds up to 20 000 r.p.m. were used in small turbines, whereas large units direct connected to electric generators were designed for speeds as low as 750 r.p.m. The tendency during recent years has been toward greatly

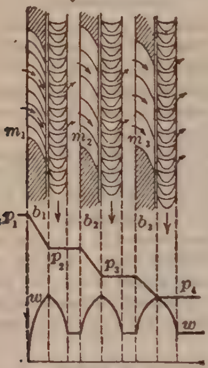

Fig. 9

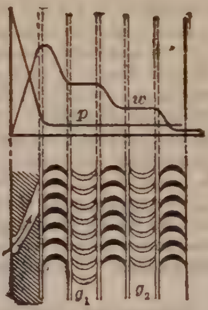

Fig. 10

increased rotative speeds in the larger units which are being designed with speeds up to 3600 in this country and considerably higher in foreign countries. Units of ordinary size up to about 2500 hp. are commonly built with speeds of 4500 to 6000 according to manufacture. Peripheral velocities now range from about 200 ft. per sec. for smaller units up to 750 or more for larger units. Foreign practice is considerably in advance of American practice in the use of these high velocities, but American designers are following rapidly.

Because of high speeds, the turbine is often used with **reduction gears.** The **double helical** type is used for reduction ratios up to about 15 to 1 and **worm** gears for higher ratios. Reductions up to 100 to 1 may be obtained by single worm gear reductions and a ratio of about 900 has been used in at least one case by a **compound worm** gear reduction. Obviously this ratio could have been increased up to 10 000 if conditions demanded. These gears have been developed to a high degree of efficiency, durability and freedom from noise. The better helical gears absorb less than 2% of the power transmitted and the worm gears less than 10%. The considerable cost and the space occupied by these reduction gears are the main drawbacks to their use.

When the steam turbine is used for driving **centrifugal pumps** direct drive or gear drive is used according to circumstances, more often direct for the smaller units, though at sacrifice of efficiency. The general prevalence of alternating current power has caused paramount development of centrifugal pumps at the various **synchronous electric motor speeds** particularly in 60-cycle current, namely, approximately 900, 1100, 1400, 1800 and 3300 r.p.m., the latter being rarely used on account of lesser pump efficiency. For use with pumps of about 900 to 1400 r.p.m. steam turbine must be geared. For pumps of about 1800 r.p.m. the turbine is not infrequently used direct connected for simplicity and cheapness, but at a considerable sacrifice of steam economy, as illustrated in Fig. 11. In this figure curves A and B, Fig. 11, represent approximate performance of two commercial makes, one having normal speed of 6000 and the other of 4500 r.p.m.

EFFECT OF SPEED ON STEAM ECONOMY USING COMMERCIAL TYPES OF TURBINES, SIZES UP TO ABOUT 2500 H. P.

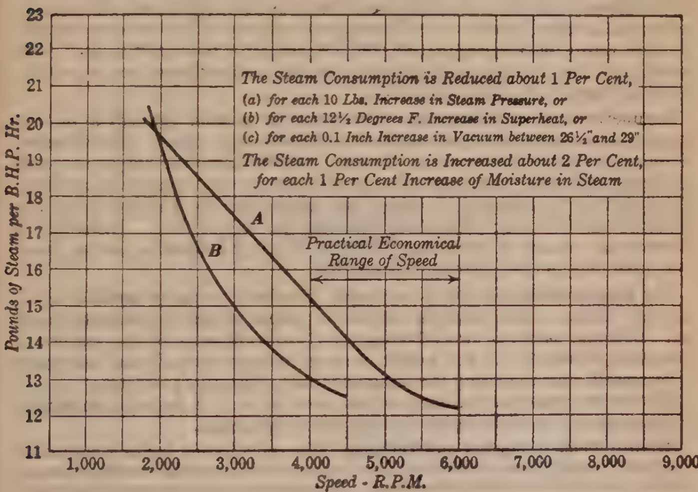

Fig. 11

Higher Steam Pressure and Superheat. Modern tendencies are toward greatly increased steam pressures. Plants of ordinary size are being designed for pressures of about 400 lb., medium sized utility plants for pressures of about 600 lb., and the largest plants for pressure up to 1300 lb. Super-heat of from 100° to 150° F. is being used for plants of ordinary size and 200° for the high pressure installations. For pressures up to about 400 lb. steam use by turbines is decreased roughly 10% for every 100 lb. increase in pressure and 8% for every 100 degrees of superheat. The increase in efficiency at higher pressures is at a lesser rate.

In recent installations steam at a pressure of 1200 lb. is passed through a turbine and is discharged at a pressure of about 450 lb. into the steam main. The high-pressure turbine thus acts as a reducing valve and adds 5000 to 7000 kw. to the capacity of the plant.

The initial temperature of the steam has been increased along with the pressure. At present about 750° Fahr. is the upper limit.

Low-pressure Steam Turbines. Because of the limitation of cylinder volume, the reciprocating engine is unable to make effective use of an extremely high vacuum. No such restriction applies to the steam turbine, as the buckets in the final stages may be made long enough to pass the required volume of steam at the lowest pressures obtainable. In general, the reciprocating engine is more economical than the turbine at high pressures, but the reverse is true at low pressures; hence a combination of reciprocating engine, to work between boiler pressure and atmospheric pressure, and a turbine to take steam from the engine and expand it to condenser pressure, is more efficient than the engine alone or turbine alone. Such combinations have found favor in marine engineering. In many cases low-pressure turbines have been installed with excellent results in existing reciprocating engine plants (see paper by Stott and Pigott, Trans. A. S. M. E., 1910). Rateau has applied the low-pressure turbine in cases where the steam supply is intermittent, as in rolling mills, mine hoists, etc. The engine exhausts at about atmospheric pressure into a heat accumulator, which is simply a tank partly filled with water, and the turbine is supplied from this accumulator (see paper by Rateau, Trans. A. S. M. E., vol. 25).

Resuperheating and Bleeding. The steam in passing through a turbine loses its superheat and begins to condense in the later stages. The presence of water is detrimental to stage efficiency and therefore the stages near the condenser end suffer more and more as the water in the steam accumulates. This loss may be obviated by taking the steam from the turbine before the saturation point is reached and superheating it a second time. Reheating is effective as a means of increasing efficiency, but it is expensive and is, therefore, used only in the larger central stations.

The **regenerative** principle is employed effectively in many turbine installations. Steam is bled from the turbine at various stages to feed-water heaters. Bleeding presents two advantages: (1) the efficiency of the turbine is somewhat increased; (2) the weight of steam passing through the last stages is decreased, thus rendering the design of those stages more effective.

Bleeder or extraction turbines are also used where it is desirable to extract low pressure steam from the turbine for various processes.

Relative Fields of Engines and Turbines. The reciprocating engine is most effective in any service of an irregular character, where varying speed is required, or where the direction of rotation must be reversed. The moderate rotative speed of the engine is also a decided advantage in many classes of service. The field in which the turbine is preëminent is in central power-station service. The high rotative speed of the turbine facilitates direct connection to electric generators. The turbine requires small floor space and comparatively inexpensive foundations. For these reasons, as well as low first cost, the turbine has been more generally adopted than the reciprocating engine in central-station service. The turbine has also been applied successfully to marine service both alone and in combination with reciprocating engines.

9. Internal Combustion Engines

Heating by Internal Combustion. An air engine is one that uses air as the working fluid. The term hot-air engine is usually applied, however, to an engine in which the air is separated from the furnace by a metal wall. Such engines have been failures for the reason that the air absorbs heat slowly and it is impossible to maintain a high temperature in the working fluid. By the method of heating by internal combustion the rapid chemical action supported by the medium itself permits the rapid heating of large quantities of air to a very high temperature. The medium and the furnace being within the cylinder, the metal walls can be kept at a sufficiently low temperature by a water jacket, and the inner surface may be exposed to high temperature without danger of destruction. Engines that make use of the principle of internal combustion are in reality air engines, since the working medium is principally air, but they are generally known as gas engines and oil engines.

Types of Gas Engines. Internal combustion engines fall under two chief classes: (1) The **explosion** type, in which the mixture of fuel and air is drawn into the cylinder and ignited, thus producing an explosion and a sudden rise of pressure at nearly constant volume. (2) The **slow-burning** type, in which the fuel is introduced gradually and burned quietly without increase of pressure. The Otto engine is a representative of the first type, the Diesel engine of the second type.

Another classification is based on the number of strokes of the piston required for the completion of the cycle. In the **four-cycle** engine four strokes are required, in the **two-cycle** engine, two strokes. Engines of small power are usually **single-acting; large engines, are, however, usually double-acting.**

According to the class of service, internal combustion engines may be grouped as follows: (1) Small gas and gasoline engines for miscellaneous service. (2) Automotive engines for automobiles and aviation. (3) Large gas and oil engines for power plants. For descriptions of various types, see Streeter's "Internal Combustion Engines."

The Otto Cycle. In Fig. 12 is shown the ideal indicator diagram of the four-cycle Otto engine. The operations are as follows: The explosive mixture is drawn into the cylinder, as represented by *ED*, and compressed adiabatically (*DA*). The mixture is ignited, causing a rise of pressure, as shown by *AB*. The gases in the cylinder, which are products of combustion with an excess of air, expand adiabatically, as shown by *BC*. Finally, the burned gases are in part expelled from the cylinder, as indicated by *DE*. As a first approximation it is assumed that the medium throughout the cycle has the properties of air, that the specific heat is constant, and that the medium during the process *AB* receives a quantity of heat equal to that developed by the combustion of the fuel in the actual cycle. With this assumption, the ideal efficiency of the engine is

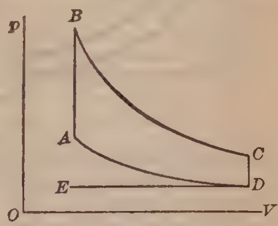

Fig. 12

$$e = 1 - \frac{T_d}{T_a} = 1 - \left(\frac{V_a}{V_d}\right)^{k-1} = 1 - \left(\frac{p_d}{p_a}\right)^{\frac{k-1}{k}}.$$

It is seen that the higher the compression pressure p_a, the greater the ideal efficiency.

For the ideal case the temperature and pressure at the point *B* are determined as follows: If q_1 is the heat absorbed per pound of air during the process *AB*,

$$q_1 = c_v(T_b - T_a), \quad \text{whence} \quad \frac{T_b}{T_a} = \frac{q_1}{c_v T_a} + 1;$$

and since $V_a = V_b$,

$$\frac{p_b}{p_a} = \frac{T_b}{T_a}, \qquad \text{or} \qquad p_b = p_a\left(\frac{q_1}{c_v T_a} + 1\right).$$

The temperature and pressure as thus calculated are never realized in practice. In the first place, part of the heat q_1 is absorbed by the water jacket; secondly, the properties of the actual fluid in the cylinder are not the same as the properties of air, and the specific heat of the fluid is not constant but increases with the temperature. The efficiency of the cycle when the calculation is made with the actual contents of the cylinder taken into consideration is not more than 0.8 of the efficiency deduced for the cycle with air as the medium; and the efficiency of the actual engine is still smaller.

Diesel Cycle. In the Diesel oil engine, air without fuel is compressed to a pressure of about 500 lb. per sq. in. The fuel is introduced into this air by the aid of a separate small air compressor, or by spraying under high pressure and burns without explosion. No igniting device is required, as the temperature of the air is raised by compression above the temperature of ignition. The fuel may be cut off early or late, depending on the load.

In Fig. 13 is shown the ideal indicator diagram of the Diesel engine in which air is compressed adiabatically from D to A, fuel is introduced and burns from A to B, with constant pressure maintained and, after cutoff at B at from one-

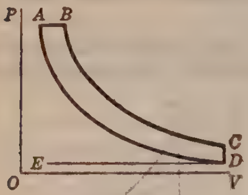

Fig. 13

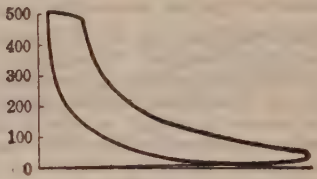

Fig. 14

tenth to one-sixth of the effective stroke, the gases of the combustion expand adiabatically from B to C, followed by their release at D with drop in pressure and rejection along DE. With the same assumptions as for the Otto Cycle, the heat added during the combustion of the fuel from A to B is $q_1 = c_p(T_b - T_a)$; that rejected from C to D is $q_2 = c_v(T_c - T_d)$. The ideal efficiency then is

$$e = \frac{q_1 - q_2}{q_1} = 1 - \frac{1}{k}\,\frac{(T_c - T_d)}{(T_b - T_a)},$$

where $k = \frac{C_p}{C_v}$. The work obtainable per pound of combustible is

$$W = J\,[c_p(T_b - T_a) - c_v(T_c - T_d)]$$

Fig. 14 is a typical diagram from a 4-cycle Diesel engine. The compression of the air to 500 lb. per sq. in. more or less raises it to a temperature sufficient to ignite the atomized fuel and the cycle is completed as indicated.

In the Diesel engine the pressure during combustion is limited, whereas in gas engines (Otto cycle) the combustibles enter the cylinder already mixed, under a limited pressure to prevent precombustion; then when the electric spark is discharged, combustion is practically instantaneous without change in volume and is accompanied by an enormous pressure before expansion can begin. The Diesel is more efficient than the gas engine at both full and fractional loads, uses less and cheaper fuel and lubricating oil, and has a longer life due to freedom from explosive shocks.

Semi-Diesel Engines. In the so-called semi-Diesel engine compression is brought only to about 250-lb. pressure, the ignition of the fuel depending on a "hot-bulb" heated from an external source. This type of engine is now practically obsolete and may be dismissed from further consideration.

The two prevalent methods of introducing the fuel into the combustion space are **air-injection** and **solid-injection.** The former requires a multistage air compressor, built as an integral part of the engine, which delivers air at from 800 to 1300 lb. pressure, depending on the load. A metered amount of fuel delivered to the fuel nozzle is atomized by the high pressure air blown through the nozzle at the proper time, and is carried into the combustion space. In the solid-injection method, fine atomization into the cylinder is obtained by forcing oil under 4000 to 4500 lb. through fine spiral grooves or through very small holes about .016 in. in diameter. Mean effective pressures are less with solid than with air injection. Solid injection engines are somewhat cheaper to build than those requiring compressor equipment. They do not require as high compression—only 450 lb.—for ignition temperature, because there is no cooling effect due to injection air.

Diesel engines are either **two-cycle** or **four-cycle.** The former have exhaust ports in the cylinder bore, which are uncovered near the end of the power stroke, and either scavenging air ports still lower down in the cylinder bore or else scavenging valves in the cylinder head. The scavenging air pressure, ranging from 3 to 6 lb., is supplied usually by casting a compression chamber in the crank case, the main piston also functioning as a compression piston on the down stroke, but in a few makes there is a separate scavenging pump. Four-cycle engines, on the other hand, require air and exhaust valves in the cylinder head, and the four strokes are for suction, compression, power and exhaust respectively, so that only one stroke in each two revolutions is effective. Scavenging, however, is more complete, compression is effective throughout the full stroke, and cylinder heating is more readily controlled. The air and exhaust valves and their operating mechanism, together with the larger cylinder required for a given output, make the four-cycle engine more expensive to build. The **Busch-Sulzer** engine, for example, is designed for four cycles up to 600 b.hp., with trunk pistons. Above 600 b.hp. this company makes the two-cycle type with cross-head and guides and having a capacity up to 4000 b.hp. Most makers employ one type exclusively. **The McIntosh & Seymour** engine, for example, is made only in the four-cycle type, up to 8000 b.hp. in 8 cylinders. Three to six cylinders are usually assembled in one unit.

Efficiency. The Diesel engine is the most efficient of all prime movers depending on the combustion of fuel, and its efficiency is nearly as high in a small unit as in a large one (which does not hold true of other prime movers), efficiencies ranging from 30% to 35% at full load; that of a two-cycle engine is slightly less than that of a four-cycle. The efficiency is expressed in terms of weight of fuel per brake horsepower per hour at full and fractional loads, the one shown in Fig. 15 being characteristic. The efficiency throughout fractional loads is better maintained than for any other prime mover. Manufacturers of Diesel engines generally rate them at or only a little below full load capacity, a 10% overload being a not uncommon limit. Lost heat appears in the cooling water rejected at from 100° to 140° F., 20% to 34%; in the exhaust gases, at from 425° to 700° F., 32% to 28%; in friction and radiation, 7% to 14%. The first two are recoverable in part for heating or for generating low-pressure steam. Ratings are based on sea level, capacity decreasing 1.5%, 5% and 14.5% at elevation of 1000, 2000 and 5000 ft. above sea level. **Lubrication** of Diesel engines of best make is based on one gallon of oil per 2500 b. hp.-hr. for small engines to 3000 or even more for large ones. The engine maker's guarantee should be imperatively required. **Cooling water** required depends on its initial and discharge temperatures, 6 to 10 g.p.m. being ordinarily provided (up to 30 g.p.m. in the tropics) for full load with 3000 B.t.u. per horsepower per hour assumed as the heat to be carried off by the water. The discharge temperature limit of the water ranges from 110° F. for brackish water to 125° F. for water of 12 deg. relative hardness, and to 150° F. for soft water. The amount of water is thus one-sixth to one-tenth that required by a condensing steam plant under similar load conditions.

Fuel Oils most suitable for Diesel engines are topped crude oils from which benzene, gasoline and other light oils have been distilled, if made reasonably free from sulfur, dirt and water. Run of oil from the still and not "compounded" from heavy residue and lighter oils is preferable. Oils with a

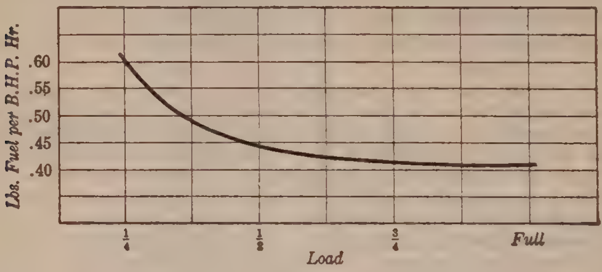

Fig. 15

specific gravity between 24° and 34° Baumé can be used; lighter than 34° oils are not satisfactory, very light ones introducing fire risk; also, light oils contain appreciably less B.t.u's per gallon, which increase the fuel cost. Oils of 20° Baumé and heavier do not flow readily and even those up to 24° may require heating in winter to reduce viscosity if kept in exposed storage tanks. A lighter oil is generally used for half an hour at the beginning and end of each run where Mexican crudes and bunker oils are used. One pound of fuel oil contains 18 000 to 19 500 B.t.u's per pound, 18 500 being assumed as the average value.

Fuel oil is quoted by either the gallon or the barrel of 42 gal. Oil with s. g. .8998, or 26° Baumé (nearly), weighs 7.5 lb. per gal., and 0.5 lb. per brake horsepower, 1 gal. = 15 b.hp.

With cost of fuel at	**3**	**4**	**5**	**6**	**7**	**8**	**cents per gal.**
the equivalent cost is	**\$1.26**	**\$1.68**	**\$2.10**	**\$2.52**	**\$2.94**	**\$3.36**	**per bbl.**

Costs. Diesel engines are heavy due to the high pressures generated in the cylinders, and they are high in first cost compared with a steam engine or a steam turbine; but in establishing comparative costs, boilers, condensers, and other auxiliary apparatus including piping and pump drives, coal storage and handling and the much larger buildings required, increase the cost of steam plants to such an amount that the investment, for example in a reciprocating triple expansion condensing pumping plant, is considerably more than for a Diesel engine plant; but the latter will cost more than a turbine-driven centrifugal pumping station and still more than an electric-motor-driven centrifugal pumping plant. The type of equipment is governed by the relative cost of fuel oil, coal and electric power in the locality of the plant.

Life and Maintenance. Experience shows the **life of Diesel engines** to be at least 25 years.

The brake horsepower capacity of a Diesel engine should be chosen to take the station peak load without exceeding its rated capacity. It has been found that by relieving the engine by from one-eighth to one-sixth of its rated full load, the maintenance charge has been materially reduced. In well managed plants, regular inspections are scheduled. One shut-down of several hours only per year is necessary for pulling pistons and cleaning rings and adjusting piston rods; three very short ones, four months apart, are advisable for inspection of air, exhaust and fuel valves; provided good oil is used and engine is not overloaded, they run continuously.

Maintenance of a Diesel engine is often based on a percentage of its cost, say 2% per annum. It is, however, higher for small engines and it is higher under continuous 24-hour operation than under daily shut-down conditions, where $1.00 per 2500 and 5000 b.hp.-hr. will cover small and large engines respectively. It should not exceed $5.00 per 5000 b.hp.-hr. under continuous full-load conditions. A skilled chief engineer is as good an investment for a Diesel as for a steam plant to keep maintenance at a minimum.

The comparative pumping costs for a city pumping plant requiring an average of 10 m.g.d. pumped against a head of 360 ft. with Diesel-driven triplex pumps, vertical triple-expansion steam pumps, turbine-driven centrifugal pumps, and electric-motor-driven centrifugal pumps, are indicated in an extract from "Power," shown in the accompanying table.

Horsepower of Gas Engines. The indicated horsepower of a gas engine is given by the formula i.hp. = $plan/33\,000$, in which n denotes the number of explosions per minute. The mean effective pressure that may be obtained depends upon the kind of fuel. It may vary from 60 to 70 lb. per sq. in. for producer and blast-furnace gas, 85 to 95 lb. for natural gas and gasoline, and 95 to 110 lb. for alcohol. The brake horsepower of automobile engines is given approximately by the rule of the Association of Automobile Manufacturers, namely: b.hp. = $d_2N/2.5$, in which d denotes the cylinder diameter in inches and N the number of cylinders.

Performance of Gas Engines. The internal-combustion engine has intrinsically a higher thermal efficiency than the steam engine. Based on coal used, the consumption of a gas engine with producer gas is about 30% less than the consumption of a steam engine. This result is obtained under most favorable conditions for both engines.

A large number of tests of a gas engine and gas producer were made by the U. S. Geological Survey at the St. Louis exhibition. The producer was rated at 250 hp. capacity and the engine at 235 hp. at 200 r.p.m. Tests were made with a large number of coals. With high-grade bituminous coal the weight of coal consumed by the producer per brake horsepower delivered by the engine ranged from 0.95 lb. to 1.32 lb. A steam engine of the same power would consume about double the weight of coal.

The following are the results of tests of gas and oil engines of the larger sizes:

Engine	Fuel	Brake hp.	Thermal efficiency	
			Per i.hp.	Per b.hp.
Westinghouse	Natural gas	606	28.6	25.5
Snow	Natural gas	595	29.4	23.7
Borsig-Oechelhaeuser	Coke-oven gas	628	33.0	27.5
Premier	Producer gas	368	33.7	25.6
Koerting	Producer gas	341	34.0	24.1
Westinghouse	Producer gas	500	30.1	25.2
Cockerill	Blast-furnace gas	725	31.5	26.0
Nürnberg	Blast-furnace gas	1186	33.9	28.2
Diesel	Oil	297	45.8	32.2

Comparison of Municipal Pumping Costs, Oil, Steam, and Electricity

Comparative plant and operating costs for a station pumping an average of 10 m.g.d. against 350-ft. total head, with oil, steam and electric equipment as indicated.

(From "Power," Dec. 18, 1923, Vol. 58, pp. 984-987)

Plant equipped with	Deisel engines, triplex pumps		Triple-expansion steam pumps	
Building:				
Pumproom (basement to eaves), ft	66 × 86 × 42		54 × 88 × 52

Fuel storage, ft	30 × 50 × 12		25 × 58 × 12	
Cost of above items		$ 69 000		$100 000
Equipment installed:	3-750 b.hp. Diesels	$213 600	1 12-m.g.d. unit	$160 000
	3-10 m.g.d. pumps	123 750	1-10 m.g.d. unit	140 000
			1 8-m.g.d. unit	125 000
			3 300-hp. boilers	33 000
Foundations for pump sets		11 250		4 000
Suction and discharge piping		50 000		51 000
Total investment		$467 600		$613 000
Yearly operating costs:				
Labor:	1 chief engineer	$3 000	1 chief engineer	$3 000
	3 assistant engineers	5 400	3 assistant engineers	5 400
	3 oilers	4 500	3 oilers	4 500
			3 firemen	4 500
Fuel:				
Oil at $1.70 per bbl.*	9010 bbl. oil	15 317	22 163 bbl. oil or 5700 tons coal	37 678
Coal at $6.75 per ton				
Lubricating oil and waste		1 000		300
Maintenance and repairs:				
Building, foundations, piping	$130 250 at 0.5%	652	$155 000 at 0.5%	775
Machinery and equipment	$337 350 at 2.0%	6 747	$458 000 at 1.5%	6 870
Total		$36 616		$63 023
Fixed charges:				
Interest at 5% on sinking fund	$467 600 or	$23 380	$613 000 or	$30 650
Building (assumed life 50 years)	0.5% on $69 000	345	0.5% on $100 000	500
Equipment	25 year life or 2.1% on $398 600	8 371	35 year life or 1.1% on $513 000	5 643
Total		$32 096		$36 793
Total yearly expense		$68 712		$99 816

* **Note by Author.** Oil at $1.70 per bbl. or 4.05 cents per gal. is low for small eastern plants at present (1929). An increase to 6-1/2 cents would increase Diesel engine costs from $68 712 to $78 000. A reduction to $5.00 per ton for coal and to 1 cent per kilowatt-hour for electric current would reduce the cost of triple-expansion steam pumping to $90 000, steam turbine centrifugal pumping to $82 800, and electric pumping to $80 000.

Comparison of Municipal Pumping Costs, Oil, Steam, and Electricity

Building:				
Pumproom (basement to eaves), ft.	50 × 84 × 42		50 × 60 × 32	
Boiler room, ft.	44 × 58 × 30		....	
Fuel storage, ft.	25 × 58 × 12		....	
Cost of above items		$83 000		$48 000
Equipment installed:	1 12-m.g.d. unit	$44 500	1 12-m.g.d. unit	$23 200
	1 10-m.g.d. unit	40 500	1 10-m.g.d. unit	20 200
	1 8-m.g.d. unit	37 500	1 8-m.g.d. unit	13 200
	3 350 hp. boilers	38 500	Switch and wiring	400
			Transformers	6 500
Foundations for pump sets	....	1 400		1 400
Suction and discharge piping	....	50 000		50 000
Total investment	....	$295 400		$162 900
Yearly operating costs:				
Labor:	1 chief engineer	$3 000	1 chief engineer	$3 000
	3 assistant engineers	5 400	3 assistant engineers	5 400
	3 oilers	4 500	3 operators	4 500
	3 firemen	4 500		
Fuel:				
Oil at $1.70 per bbl.*	33 204 bbl. oil or	56 447	Electric energy at 1-1/4 cents per kwh.	$68 219
Coal at $6.75 per ton	8 360 tons coal			
Lubricating oil and waste	....	600		200
Maintenance and repairs:				
Building, foundations, piping	$134 400 at 0.5%	672	$99 400 at 0.5%	497
Machinery and equipment	$161 000 at 1.7%	2 737	$63 500 at 1.7%	1 080
Total	....	$77 856		$82 896
Fixed charges:				
Interest at 5% on sinking fund	$295 400 or	$14 770	$162 900 or	$8 145
Building (assumed life 50 years)	0.5% on $83 000	415	0.5% on $48 000	240
Equipment	25 year life or 2.1% on $212 000	4 460	25 year life or 2.1% on $114 900	2 413
Total	....	$19 645		$10 798
Total yearly expense	....	$97 501		$93 694

* **Note by Author.** Oil at $1.70 per bbl. or 4.05 cents per gal. is low for small eastern plants at present (1929). An increase to 6-1/2 cents would increase Diesel engine costs from $68 712 to $78 000. A reduction to $5.00 per ton for coal and to 1 cent per kilowatt-hour for electric current would reduce the cost of triple-expansion steam pumping to $90 000, steam turbine centrifugal pumping to $82 800, and electric pumping to $80 000.

Comparative Costs of Pumping by Various Methods. An engineering company having charge of a number of water-works has worked out the following comparison of pumping costs. The unit cost of pumping including cost of labor, maintenance, depreciation and fixed charges is about the same when:

(a) For electric pumping, electric power costs.......	\$0.01 per kw. hr.
(b) For steam pumping by triple-expansion engines or steam turbines, coal of 14 000 B.t.u. costs.....	\$5.00 per ton
(c) For Diesel engine pumping, fuel oil of 19 000 B.t.u. costs..............................	\$0.06-1/2 per gal.
(d) For gas engines, natural gas of 1150 B.t.u. costs..	\$0.40 per 1000 cu. ft.
(e) For gasoline engines, gasoline of 20 100 B.t.u. costs..................................	\$0.08 per gal.

Note. The above unit prices are for comparative purposes only and do not represent the market values of the fuels mentioned. The high cost of operation for a gasoline unit makes it uneconomical except for standby service.

The above comparisons are respectively based on:

(a) Combined pump and motor efficiency of 73.5%.
(b) Pump duty of 130 million ft.-lb. per 1000 lb. of steam for triple-expansion steam pumps, a water rate of 12.8 lb. of steam per brake horsepower per hour for steam turbine, and a boiler efficiency of 72%.
(c) 0.066 gal. of fuel oil per brake horsepower per hour.
(d) 10.9 cu. ft. of natural gas per brake horsepower per hour.
(e) 0.1 gal. of gasoline per brake horsepower per hour.

SECTION 5

ELECTRICAL ENGINEERING

The following outlines of fundamental principles have been prepared not for electrical engineers but for civil engineers whose knowledge of the subject is limited.—EDITOR-IN-CHIEF.

BY

F. MALCOLM FARMER

CHIEF ENGINEER, ELECTRICAL TESTING LABORATORIES, NEW YORK CITY

ELECTRICITY

1. Definitions, Units, Fundamental Laws

Systems of Units. There are two systems of electrical units, both of which are derived from the fundamental or centimeter-gram-second (**C. G. S.**) system. The **electrostatic system** is based on the force exerted between two charges of electricity; the **electromagnetic system** is based on the force exerted between a magnetic field and a conductor carrying a current placed in that field. Many of these units are inconvenient to use in practice, and certain modifications, known as practical units, have been adopted and legalized in a number of countries by international agreement. These practical units are used in all engineering work; **C. G. S.** units are frequently used in physical and research work.

Electromotive Force (symbols **E, e,** and **e. m. f.**) is that which causes electricity to flow or tend to flow, and is analogous to hydrostatic head. The practical unit is the **Volt**, that electromotive force which, when applied to a circuit of one ohm resistance, will cause a current of one ampere to flow. The standard volt is represented by the Clark and Weston standard cells. The legal value of the **Clark cell**, when made according to certain prescribed directions, is **1.434** volts at 15° C. The value of the **Weston cell**, adopted by the U. S. Bureau of Standards, Jan. 1, 1911, is **1.0183** volts at 20° C.

The **Volt** is equal to 10^8 **C. G. S. units.** When very small electromotive forces or potentials are to be measured, the unit millivolt, one thousandth of a volt, is frequently used. High potentials are often expressed in kilovolts or thousands of volts. **Difference of Potential** is the difference in electrical pressure between two points in an electric circuit and is measured in volts. This term is often incorrectly used instead of electromotive force.

Current (**I, i**) is the rate of flow of electricity. The practical unit is the **Ampere,** which is the current flowing in a circuit of one ohm resistance when an electromotive force of one volt is impressed on it. The legal standard ampere is that steady current which will deposit **0.001118 gram of silver per second** when passed through a silver nitrate solution under certain prescribed conditions.

The **Ampere** is equal to 10^{-1} **C. G. S. units.** A **milliampere** is one thousandth part of an ampere.

Resistance (**R, r**) is that property of a material that opposes the flow of electricity through it. It varies directly with the length and inversely with the cross-sectional area. The practical unit is the **Ohm,** which is the resistance of a circuit in which a current of one ampere flows when subjected to an electromotive force of one volt. The legal standard ohm is the resistance of a column of mercury 106.3 cm. long and 14.4521 grams mass at 0° C. Working standard resistances are made of resistance wire or ribbon carefully adjusted and standardized by comparison with the legal standard. Manganin, a copper alloy, is most extensively used because of its permanency. The usual sizes range from 100 000 ohms to 0.00001 ohm, and always in powers of 10.

The **Ohm** is equal to 10^9 **C. G. S. units.** Insulation resistances are usually expressed in terms of the **megohm** or **one million ohms** and very small resistances in **microhms,** or **millionths of an ohm.** **Resistivity** (ρ) or specific resistance of a material is the resistance between opposite faces of a centimeter cube or an inch cube. **Conductance** is the reciprocal of resistance, and **conductivity** (γ) is the reciprocal of resistivity. **Relative conductivity** (usually incorrectly abbreviated to "**conductivity**") is the term most used in engineering. It is the percentage ratio of the true conductivity (i.e., reciprocal of resistivity) of the material to that of copper of a certain specific gravity and specific resistance known as the International Annealed Copper Standard. Materials are classed as conductors or insulators according as they are of low or high resistivity, respectively. **Insulation resistance** refers to the resistance of insulating material measured in megohms. The **dielectric strength** of an insulating material is the high-potential voltage which ruptures that material and is usually expressed in **volts per mil or per millimeter.**

Quantity of Electricity (Q, q) is the product of current and time. The practical unit is the **Coulomb,** which is one ampere flowing in a circuit for one second.

The Coulomb is equal to 10^{-1} **C. G. S. units.** The unit in more common use commercially is the ampere-hour, equal to 3600 ampere-seconds or coulombs.

Electrical Energy (W) is the work done in a circuit or an apparatus by current flowing through it. The practical unit is the **Joule** or **Watt-second,** which is the work done when one ampere flows through a resistance of one ohm for one second.

The commercial unit is the **watt-hour,** equal to **3600 joules;** also the **kilowatt-hour** equal to 1000 watt-hours.

Electrical Power (P) is the rate of expending electrical energy or the rate of doing work per unit of time. The practical unit is the **Watt,** which is the work done in one second when one ampere flows in a circuit under a pressure of one volt, or $\mathbf{P = I \times E = I^2R}$.

The commercial unit is the **kilowatt** (one thousand watts). **One horsepower is equal to 746 watts.**

Capacitance or **Electrostatic Capacity** (C, c) of a circuit or apparatus is the property by virtue of which it can hold a charge of electricity. The practical unit is the **Farad,** which is the capacity of a circuit or apparatus that will be charged to a potential of one volt by one coulomb of electricity.

The farad is so large a quantity that commercially the **microfarad** is generally used. The farad is equal to 10^{-9} **C. G. S. units;** the microfarad to 10^{-15} **C. G. S. units.**

Self-induction of a circuit is that property which opposes any change in the value of the current flowing through it. It is analogous to inertia and is due to the magnetic field which surrounds a conductor carrying current. When the current is established or changes, the field increases or decreases and the lines of force cut the conductor, inducing a counter e. m. f. which opposes the change in the current.

Inductance (L, l), or coefficient of self-induction, of a circuit is the constant by which the time rate of change of the current in the circuit must be multiplied to give the e. m. f. induced in the circuit by such change. The practical unit is the **Henry,** which is the inductance of a circuit where a change of one ampere per second will induce one volt e. m. f.

A henry is equal to 10^9 **C. G. S. units.** The unit ordinarily used is the **millihenry** (one-thousandth of a henry).

Impedance (Z) of a circuit is the resistance offered to the passage of alternating current. It depends on the frequency of the current and the resistance, inductance, and capacity of the circuit. It is measured in ohms and is equal to $\sqrt{\mathbf{R}^2 + \mathbf{X}^2}$.

Reactance (X) of a circuit is that part of the resistance offered to the passage of alternating current which is due to the inductance and capacity of the circuit. It is measured in ohms and is equal to $2\,\pi \mathbf{n} L - \frac{1}{2\,\pi \mathbf{n} C}$.

Frequency (n) of an alternating-current circuit is the number of complete reversals, or cycles, of the current per second. It is equal to the product of half the number of poles on the generator and the revolutions per second. An alternation is half a cycle.

The standard frequencies in this country are 25 and 60 cycles, although 40-cycle systems are in operation. A very few of the early 133-cycle systems are also to be found, and 15 cycles has been advocated for alternating current railways.

Phase refers to the time relation between the current and potential in an alternating-current circuit, or to the time relation between the potentials in two ro more circuits.

Thus, if the current and potential in a circuit reverse at the same instant, they are in phase. When the current reverses after the potential, it is said to be out of phase, and a lagging current; when it reverses before the potential, it is out of phase, and a leading current. A two-phase generator has two circuits in its armature and the e. m. f.'s generated are 1/4 cycle or 90 electrical degrees apart. Similarly, a three-phase generator has three circuits and the e. m. f.'s are 1/3 of a cycle or 120° apart.

Power Factor of a circuit is the ratio of the true power passing through it to the product of the volts and amperes. It is equal to the cosine of the time angle at any instant between the potential and current.

When the time angle is zero, that is, when the potential and current are in phase, the power factor is 1.00 (cosine 0°), often expressed 100%. If they are out of phase by 90°, the power factor will be zero (cosine 90°).

Load Factor. The daily or yearly (or other period) load factor of a machine, plant or system is the ratio of the average power to the maximum power during the period indicated.

The **demand factor** of an installation is the ratio of the maximum load actually taken by the installation to the total connected load (that is, the sum of the ratings of all apparatus in the installation).

The **diversity factor** of an installation is the ratio of the sum of the maximum demands of the various loads in the installation to the maximum demand of the whole installation.

Hysteresis is that property of magnetic material which causes the induction corresponding to a given magnetizing force to be greater when the latter is decreasing than when it is increasing.

Hysteresis loss is the energy expended in the material because of hysteresis when the magnetizing force is changed from one direction to the other and back again. It appears in the form of heat.

Eddy Currents are stray local currents induced in those metal parts of electrical apparatus which are in rapidly changing magnetic fields.

Eddy-current loss which appears in the form of heat, is the power expended by eddy currents flowing in these metal parts, and is equal to the product of the square of the current and the resistance. It is one of the largest losses in alternating current apparatus, and therefore parts in which this loss occurs are laminated in order to reduce the length of the current paths, thereby increasing the resistance and decreasing the currents.

A Series Circuit is one in which the total current passes through each part of the circuit. A **Parallel** or **Multiple Circuit** is one in which the total current is divided among the various parts of the circuit.

FUNDAMENTAL LAWS. The following are the more important laws and principles of electricity and magnetism underlying the practical applications of electricity.

Ohm's Law. The current in a circuit containing no source of **e. m. f.** is equal to the potential applied at the terminals of the circuit divided by the resistance, or $I = \frac{E}{R}$. This law applies to alternating current circuits only when they are non-inductive, that is, contain resistance only. Otherwise the current is equal to the potential divided by the impedance, or $I = \frac{E}{Z}$.

Laws of Series and Parallel Circuits Carrying Direct Current. In a series circuit the total resistance is equal to the sum of the resistances of its component parts. In a parallel circuit the current in each circuit is inversely proportional to the resistance of each branch of the circuit, and the reciprocal of the total resistance of the circuit is equal to the sum of the reciprocals of the branch resistances.

Capacitances. When two or more capacitances (condensers) are connected in series, the reciprocal of the total capacitance is equal to the sum of the reciprocals of the capacitances. If they are connected in parallel, the total capacitance is equal to the sum of the capacitances. It is to be noted that the law is just the reverse of that for resistances.

Conductor in a Magnetic Field. When a free conductor is placed in a magnetic field and current is passed through it, the conductor will move. The force exerted will be proportional to the field strength and the current. This is the fundamental principle of **motors.**

Electromagnetic Induction. When a conductor is moved through a magnetic field or a magnetic field is moved through a conductor, an e. m. f. will be induced in it which will be proportional to the field strength, the rate of motion, and the length of conductor cutting the field. This is the fundamental principle of **generators.**

Fundamental Equation for the Generation of an E. M. F. The following is the equation for the e. m. f. generated in (*a*) a coil rotating in a magnetic field at a uniform speed or (*b*) a coil which incloses an alternating magnetic flux varying in such a manner that a sine wave e. m. f. is generated (see Art. 2).

$$E = 4.44\frac{n\phi f}{10^8}$$

where E = e. m. f., mean effective value (see Art. 2) in volts;
n = number of complete turns in coil;
ϕ = total magnetic flux (maximum instantaneous value if produced by alternating current) inclosed by the circuit. If the magnetic flux density is uniform (the usual case) throughout the space occupied by the coil, $\phi = BA$ where B = flux density in lines per square centimeter and A = area inclosed by coil in square centimeters;
f = revolutions of coil per second or frequency in cycles per second of magnetizing current.

Law of Magnetic Circuits. In a magnetic circuit the total magnetic flux is equal to the magnetomotive force divided by the reluctance of the circuit, the relation being similar to Ohm's law. The **total magnetic flux** (**lines of force**) corresponds to **current** (**amperes**), the **magnetomotive force** (**gilberts**) to **electromotive force** (**volts**), and **magnetic reluctance** (**oersteds**) to **resistance** (**ohms**). In practice it is customary to deal with the magnetizing force per unit length of magnetic circuit, which, when the magnetic circuit is of non-magnetic material, is equal to $H = 4\,\phi NI/10\,l$, where H = **field strength** (**gausses**) NI = **ampere turns** and l = **length.** When the material is magnetic, **the magnetic induction** (**gausses**) is $B = kH$, where k = **permeability,** a quantity which varies with the material and with B.

Galvanic Electricity. If two unlike metals are immersed in an acid or salt solution an electromotive force will be generated between them. The magnitude of the e. m. f. will depend upon the metals and the solution used. This phenomenon is the basis of all electric batteries.

Electrolysis. When electric current (direct) is passed through a solution (called electrolyte), it is decomposed. According to **Faraday's law,** the amount of decomposition is directly proportional to the quantity of electricity (product of current and time) passed through the solution.

Thermoelectric Effect. When a circuit is made up of two dissimilar metals and the two junctions are maintained at different temperatures, an e. m. f. will be established which will be very nearly proportional to the difference in temperature between the two junctions. Conversely if current is passed through a circuit consisting of two dissimilar metals, heat will be developed at one junction and absorbed at the other junction. This is known as Peltier effect.

Heating Effect. When an electric current is passed through a solid conductor, the electric energy expended in the conductor is entirely converted to heat energy. The amount of heat developed is proportional to the resistance, the square of the resistance and the time (Joule's law). That is,

$$H = 0.2928\, I^2RT,$$

where H = heat in British thermal units;
I = current in amperes;
R = resistance in ohms;
T = time in hours.

2. Commercial Electrical Measurements

Commercial and Ordinary Engineering Measurements are made with various indicating instruments which are calibrated by various more or less direct methods against the primary standard or standards representing the quantity indicated by the instrument.

Direct Current and Potential are measured with ammeters and voltmeters respectively. They are almost universally of the D'Arsonval type, in which a small fine wire coil is free to move in the field of a permanent magnet. In ammeters this coil is connected to a specially made low resistance called a "shunt." Its deflections are proportional to the fall of potential across this shunt and therefore to the current flowing through it. Voltmeters differ from ammeters only in that the moving coil is connected in series with a high resistance and across the circuit to be measured instead of in parallel to a low resistance which is in series with the circuit.

For moderate currents (25 amperes and less) the shunt is contained in the instrument case, but for larger currents it is external to the instrument and connected to the latter by small flexible wires. Thus, shunts as high as 25 000 amperes capacity can be placed in the circuit at the most convenient point. Instruments permanently located on switchboards are called switchboard or station instruments, as distinguished from portable instruments used for testing purposes.

Alternating Current is measured with ammeters of several types, the more usual being the iron-disk, inclined-coil dynamometer, and hot-wire types. The principle of iron-disk instruments is the repulsion between the eddy currents induced in a very small iron disk, and the field which produces them. The principle of the inclined-coil and dynamometer instruments is the attraction and repulsion between two coils carrying current. In hot-wire instruments the expansion of a taut wire, when heated by the passage of a current, is utilized to measure the current. Some of the types are made self-contained up to 300 amperes, but current transformers are usually used with larger currents. In all high-tension circuits (over 440 volts) current transformers are used irrespective of the size of the current in order to insulate the instrument from the circuit.

The several **values of an alternating current** (and e. m. f.) are (*a*) **instantaneous value** or value at any instant during a cycle, (*b*) **mean effective value,** which is the square root of the sum of the squares of the instantaneous values during one cycle (also called effective value and root-mean-square value), (*c*) **average value**, which is the arithmetical average of the instantaneous values during one alternation or half cycle, (*d*) **maximum value**, which is the maximum of the instantaneous values during one cycle. When the wave form is a sine curve (that is, when the variation of the instantaneous values during one cycle with respect to time follows the sine law) the relations between these various values are as follows:

Maximum value = $\sqrt{2}$ × effective value;

$$\text{Maximum value} = \frac{\pi}{2} \times \text{average value;}$$

$$\text{Average value} = \frac{2\sqrt{2}}{\pi} \times \text{effective value;}$$

$$\frac{\text{Effective value}}{\text{Average value}} = \frac{\pi}{2\sqrt{2}} = 1.11 \text{ (= form factor);}$$

$$\frac{\text{Maximum value}}{\text{Effective value}} = \sqrt{2} = 1.414 \text{ (= crest, peak or amplitude factor).}$$

All of these values are employed in electrical engineering but the **effective value** is the one ordinarily measured and used. This particular value is used because it is the value which will produce the same heating effect as a direct current of the same magnitude, and it is the value indicated by all alternating-current instruments used in all ordinary measurements.

Alternating Potentials are measured with voltmeters of the same types as the ammeters, being wound with many turns of small wire instead of a few turns of relatively large wire. Voltage transformers which step-down the voltage to the standard value of 110 volts are used when measuring high voltages.

The secondaries of current transformers are usually 5 amperes capacity, but the instrument scales are marked to read the primary current. Similarly, the scale of the voltmeter may be marked to indicate the line potential although the voltage on the instrument is usually about 110 volts.

Power in direct current circuits is usually measured with an ammeter and a voltmeter, the power in watts being the product of the amperes and the volts. In alternating current circuits, however, power is usually measured with a **wattmeter**. It is a two-circuit instrument, one circuit being a fixed coil of a relatively few turns of relatively large wire, connected in series with the circuit to be measured. The other circuit consists of a coil of many turns of fine wire so mounted as to be free to move within the magnetic field produced by the fixed coil. It is connected in series with a certain amount of resistance and across the circuit to be measured.

In a single-phase alternating-current circuit, having a power factor of 1.00 (which is practically the case where the load is incandescent lamps), the power may be measured with an ammeter and a voltmeter because in that case the power is equal to the product of the amperes and the volts. If, however, the power factor is less than 1.00 (which is always the case where the load is all or partially motors, arc lamps, etc.), the power is equal to the product of amperes, volts and power factor, and a wattmeter is used. (The power may be measured by the less convenient "three-ammeter" or "three-voltmeter" method indicated in Figs. 2 and 3).

Wattmeter Connections. The following paragraphs show the methods of connecting wattmeters in various kinds of alternating current circuits. Current and potential transformers are used with wattmeters where necessary, the same set of transformers being often used for all three instruments (wattmeter, ammeter and voltmeter) at the same time.

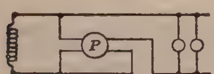

Fig. 1

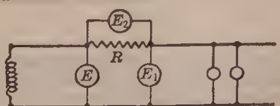

Fig. 2

Single-phase Circuit. One wattmeter connected as shown in Fig. 1 will read true watts. The power may also be measured with three voltmeters or three ammeters.

In the three volt-meter method, a known non-inductive resistance, R, is connected in series with the load as shown in Fig. 2, where E, E_1, and E_2 are points where volt-meter readings are to be taken. The power in watts is

$$\mathbf{W} = \frac{\mathbf{E}^2 - \mathbf{E}_1^2 - \mathbf{E}_2^2}{2\,\mathbf{R}} \qquad \text{(watts)}$$

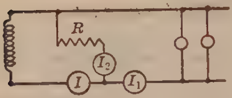

Fig. 3

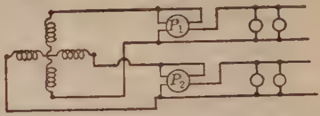

Fig. 4

Similarly, in the three-ammeter method, Fig. 3, the power in watts is

$$\mathbf{W} = \mathbf{R}\left(\frac{\mathbf{I}^2 - \mathbf{I}_1^2 - \mathbf{I}_2^2}{2}\right) \qquad \text{(watts)}$$

Two-phase Four-wire Circuit (**not interconnected**). Two wattmeters, connected as shown in Fig. 4, are sufficient, these conditions being equivalent to two single-phase circuits. The total power is obviously the arithmetical sum of the readings of the two instruments.

Two-phase Three-wire Circuit. Two wattmeters should be connected as shown in Fig. 5, the total power being the algebraic sum of the two readings. This connection

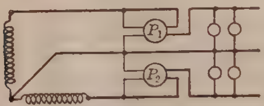

Fig. 5

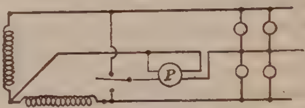

Fig. 6

is correct for all conditions of load, balance and power factor. One wattmeter may be used as in Fig. 6, provided there is no load across the outer conductors and the phases are balanced as to load and power factor.

Two-phase Four-wire Interconnected Circuit. Three wattmeters should be used, connected as in Fig. 7, the total power being the algebraic sum of the three readings. This connection is correct for all conditions of load, balance and power factor. Two wattmeters, one in each phase, will give the true power only when the load is balanced.

Three-phase Three-wire Circuits. Two wattmeters should be used, connected as

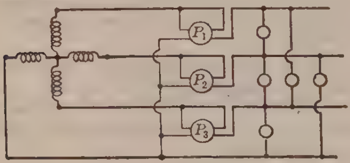

Fig. 7

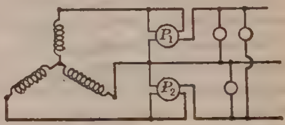

Fig. 8

indicated in Fig. 8, the total power being the algebraic sum of the two readings. With a balanced load, each instrument will indicate half the total power at unity power factor, and at 50% power factor one instrument will indicate the total power, the other instrument indicating zero. At less than 50% power factor, one instrument will read negative.

Three-phase Three-wire Circuits Balanced Load. When the load is balanced, the power may be measured with one wattmeter by the following methods:

(a) With "star" box or artificial neutral as shown in Fig. 9. The total power is three times the reading of the wattmeter. The resistance in each leg of the star box should be non-inductive and small compared with that of the potential circuit of the wattmeter, so that the current taken by the latter will not disturb the potential at the neutral point.

(b) With "Y" box as shown in Fig. 10. The total power is three times the wattmeter reading. This arrangement is similar to (a), one leg of the star box being replaced

Fig. 9

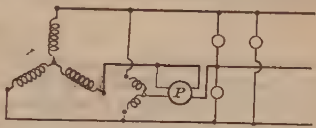

Fig. 10

with the potential circuit of the wattmeter itself. The other two legs have the same resistance as the potential circuit of the wattmeter.

(c) With a "T" reactance coil as shown in Fig. 11. The total power is twice the wattmeter reading. The impedance of the reactance coil must be small compared with that of the potential circuit of the wattmeter, so that the current taken by the potential circuit will not disturb the potential at *O*.

Three-phase Four-wire Circuits. Three wattmeters are used as shown in Fig. 12. The total power is the algebraic sum of the three readings. This method is correct

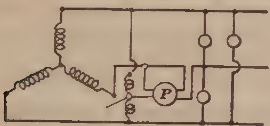

Fig. 11

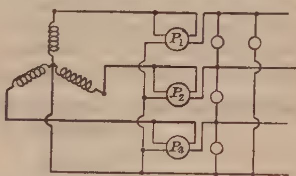

Fig. 12

for all conditions of load, balance and power factor. A three-phase "star" system with a grounded neutral is virtually a four-wire system and the power should be measured with three wattmeters. Obviously, if the load is balanced, one wattmeter can be used, the total power being the indication of the wattmeter multiplied by three. In that case, the current coil should be connected in series with one conductor or phase wire and the potential coil between that conductor and the neutral.

The Power Factor of a single-phase circuit and of each phase of a two-phase circuit is the ratio of the watts, indicated by a wattmeter, to the product of the volts and amperes. In a three-phase circuit it is the ratio of the total watts to the product of the average volts across the three phases, the average current in the three conductors and **1.73** ($\sqrt{3}$).

Electrical Energy is measured with watt-hour meters. They are essentially small motors in which the speed is proportional to the power and the total revolutions is proportional to the energy being consumed. The moving element is geared to a suitable registering mechanism (similar to that of gas and water meters) which indicates the kilowatt-hours of energy passed through the meter. On direct-current circuits the whole current usually passes through the instrument. Alternating current meters can be used with potential and current transformers, and in such cases the meter readings are multiplied by the product of the ratios of these transformers. Single-phase energy is measured with one meter, two-phase with one meter in each phase, or with a polyphase meter, and three-phase energy is measured either with two meters connected in the same manner as two indicating wattmeters or with a polyphase watt-hour meter which consists essentially of two single-phase meters with a common shaft.

Watt-hour meters are connected into the circuit just the same as wattmeters, as indicated in Figs. 1 to 12 inclusive. A polyphase meter has separate terminals for each element and is connected just as two wattmeters would be connected.

3. Conductors

Electrical Conductors are materials of comparatively low resistance, through which electricity will flow in appreciable quantities, as distinguished from high-resistance materials called **insulators,** through which electricity will not pass except in minute quantities. There is no sharp distinction between the two, there being good and poor conductors, and good and poor insulators. Most metals are conductors, but only a few are used commercially. Silver is the best conductor, but copper is very nearly as good, and being comparatively plentiful, cheap, and otherwise very suitable, it is by far the most generally used metal for conductors. Aluminum, which has about 62% of the conductivity of copper, is being used to some extent in high-voltage transmission and on heavy current switchboards where minimum weight is desirable. Iron and steel have 10 to 20% of the conductivity of copper and are used in telephone and telegraph lines and in special cases where the current is small and low cost or greater strength is important. A bimetallic conductor consisting of steel wire with a shell of copper welded on the outside is used to a considerable extent. This material has a conductivity of 30 to 40% of that of copper alone, and a much greater tensile strength. Poor conductors, such

* Down to an including No. 7 B. & S. is stranded; No. 8 B. & S. and smaller is solid. The mass and resistance of stranded wire are assumed to be 2% greater than those of the equivalent solid wire.

These data apply to bare copper wire of 100% relative conductivity (International Annealed Copper Standard). The resistance of hard-drawn wire may be considered as about 2.5% higher than these values. The corresponding data for aluminum wire of 61% conductivity may be obtained by multiplying weights by 0.304, feet per pound by 3.29 and resistance by 1.64.

The data for sizes larger than No. 0000 B. & S. refer to stranded cable and are approximate. They may be in error from 1% to 3%.

as nickel, nickel alloys of various kinds, and platinum, are used to a great extent where the comparativly high resistance is desirable, as in rheostats and heating devices. Wire made of these materials is known as resistance wire.

The cross-section of electrical conductors is usually measured in circular mils. A circular mil is the area of a circle of 0.001 in. diameter. The specific resistance is often expressed in terms of a mil-foot, which is the resistance of a wire one circular mil in cross-section and one foot long. Telephone and telegraph engineers use the term pounds per mile-ohm, which is the weight in pounds of a conductor one mile long and having a resistance of one ohm. The resistance of conductors varies with the temperature, usually increasing in direct proportion to the temperature up to at least 100° C. The increase in resistance per ohm per degree increase in temperature above a given standard (0° or 20° C.) is the resistance temperature coefficient. The preceding tables give data for the more common conductor materials and copper wire of standard sizes.

Resistance Wires. The following materials are representative of this class of conductors:

German Silver is one of the first materials used for resistance purposes. Alloy of copper, nickel, and zinc (the percentage in the table refers to percentage of nickel). Tends to become brittle if repeatedly heated and cooled and has comparatively high temperature coefficient (0.0002 to 0.0004 per degree C.). Resistance per mil-foot, 195 and 290 ohms, respectively.

Manganin. Alloy of copper, nickel, and manganese. Very low temperature coefficient (order of 0.00001 per degree C.). Permanent if not heated excessively. Used extensively for precision instruments. Resistance per mil-foot, 270 ohms at 20° C. Thermal e. m. f., nil.

"**Nichrome.**" Trade name for a nickel-chromium alloy. Practically non-corrosive and has extremely high melting point (2800° F.). Used extensively in heating appliances and small electric furnaces. Resistance per mil-foot, 660 ohms at 20° C.

"**Advance.**" Trade name for a copper-nickel alloy. Temperature coefficient practically nil. Durable at moderate temperatures. Used extensively in electrical instruments and temperature measuring instruments because of high thermal e. m. f. Resistance per mil-foot, 295 ohms at 20° C. Thermal e. m. f., 0.043 mv. per degree C.

Pure Nickel. High temperature resistance coefficient. Suitable for moderately high temperatures. Used extensively for resistance type pyrometers. Resistance per mil-foot, 60 ohms at 20° C. Temperature coefficient, 0.0048 average in range 0–100° C.

4. Direct-current Generators and Motors

Definitions. A **Generator** is a machine for converting mechanical power into electrical power, and a **Motor** is a machine which converts electrical power into mechanical power. A direct-current generator can also be operated as a motor, but commercially it is not customary to make motors and generators interchangeable because there are minor differences in design.

When a loop of wire is revolved in a magnetic field, an electromotive force is induced, the value of which, at any instant, depends upon the speed of rotation, the strength of the magnetic field, and the size of the loop. The direction of the e. m. f. in such a loop will reverse twice each revolution, hence to obtain direct current a **commutator** is used to reverse the connection between the external circuit and this coil at the proper moment, thus keeping the polarity of the potential at the terminals the same. A number of such loops wound on an iron or steel **core** together with a suitable commutator constitute the **armature** of a generator. The magnetic field is produced by two, or any multiple of two, electromagnets, called **poles**, which surround the armature. These poles and the supporting frame which completes the magnetic circuit constitute the **field** of the machine.

Types of Generators. The various types of direct-current generators may be classified according to the method of exciting the field. **Series Generators** have the field windings connected in series with the armature, and hence the voltage depends upon the load. This type can be designed to give potentials of 2000 to 6000 volts, and a special form was formerly used extensively for series arc-lighting systems. **Shunt generators** have their field windings connected in parallel with the armature. The field contains many turns of relatively small wire and requires only a small current. The voltage is regulated independently of the load by increasing or decreasing the field current by means of a variable resistance (rheostat) which is in series with the field This type is little used, the **compound generator** being the standard type. In this, both a shunt field and a series field are provided, one winding being placed over the other.

In the plain shunt generator the voltage decreases somewhat as the load increases unless the field current is increased. By winding a few turns of heavy conductor on the poles and passing the load current through them, the field is automatically increased so that the voltage can be not only kept automatically constant but even raised to compensate for the drop in voltage in the feeders and mains. This form of compound generator is said to be over-compounded. The compound generator is universally used for lighting and power at 125 and 250 volts, and for railway purposes at 550 to 1200 volts. Any number of compound generators can be operated in parallel, but a special connection between the series fields of the several machines, called an **equalizer** is necessary to obtain satisfactory operation.

A Separately Excited Generator is a generator in which the field current is obtained from a source other than the generator itself. It is used only in special cases, such as low-voltage generators for electroplating and for storage-battery charging. **Boosters** are separately excited low-voltage generators in which the armature is connected in series with a circuit in which it is desired to raise the voltage. They are frequently used on circuits where the voltage is below normal on account of the excessive drop due to heavy loads or long length. **Magneto generators** have permanent magnets and are only built in small sizes for telephone signals, gas-egnine ignition, and similar purposes.

Types of Motors. There are three general classes of motors,—**series, shunt,** and **compound**; like generators, they are distinguished by the method of exciting the field. The field of the **series motor** is in series with the armature and the characteristic feature is a large torque at low speed, which makes it particularly adapted for railways, hoists, and cranes where a high torque is required at starting. **Shunt motors** have the fields in parallel with the armature and are essentially shunt generators operated as motors. This is the type in most common use for general power purposes, as its speed decreases only a few per cent from no load to full load. Fig. 13 shows the characteristic relation between speed and torque, also between current and torque for both series and shunt motors. **Compound motors** have both shunt and series fields, and are either accumulative or differential, according as the series field strengthens or weakens the total field when the load increases. The accumulative form is ordinarily used, for it combines the high-starting-torque feature of the series motor with the constant-speed feature of the shunt motor. Where very uniform speed or an increase in speed is desired, the differential form is used.

To prevent excessive sparking in motors subject to rapidly changing loads over wide ranges, interpoles are provided. These are small poles placed between the regular poles and provided with a winding which is in series with the armature.

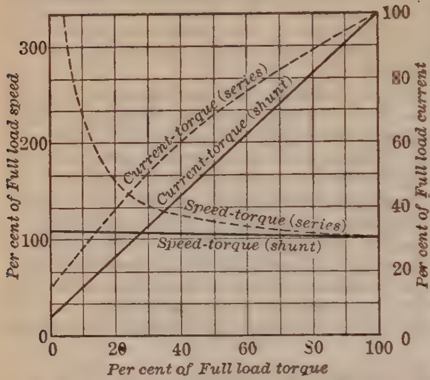

Fig. 13

Speed Regulation can be effected by changing the voltage applied to the armature or the amount of magnetic flux passing through it. The former is done either with a regulating rheostat in series with the armature or by having several different voltages available to which the armature can be connected. The usual method of changing the magnetic flux is to change the field current by means of a rheostat. There are also in commercial use, in small motors, methods in which the distance between the pole pieces and the armature can be readily changed with a hand wheel thus altering the field strength.

Starting. Motors are not connected directly to the line when starting because the resistance is so low that an excessive current would flow which would injure the motor. When the motor is running, a generator or **counter e. m. f.** is produced which opposes the line voltage, and limits the current to the amount required by the load. A motor is started by reducing the line voltage to a low value by inserting resistance (starting rheostat) in series with the armature, the resistance being gradually cut out as the motor comes up to speed. These rheostats are usually provided with attachments which automatically cause the lever to return to the starting position whenever the voltage is cut off the line.

Motor Starters, Controllers and Switches. Shunt motors up to 1/4 hp. and series motors up to 4 or 5 hp. may be started by connecting directly to the line. For larger sizes, starting resistance must be used as stated above.

Shunt and compound motors up to 50 hp. which are started infrequently (i.e., two or three times an hour or less often) and without load use the face-plate type of starting rheostat rated for " starting duty " only. If the motor must start with a load, a heavier duty size must be used. Where the speed is to be regulated, a similar style of rheostat is used for moderate size motors designated as " starting and speed-control " rheostat. For frequent starting and frequent adjustment of speed as in crane, hoisting, and elevator service and many industrial machines, the drum-controller type of rheostat is preferable because it is of more substantial construction which is necessary for this more severe use and reversing the direction of rotation motor is more easily accomplished. Large motors are started with multiple-switch starters where the resistance is cut out of circuit in successive steps by separate switches manipulated individually but interlocked so that the proper sequence must be observed. In the case of very large motors, these switches are operated electrically by means of magnets. Provision can be made for remote control of starting or for automatic starting controlled by any ordinary condition met with in industry such as water level in a tank, pressure, temperature, etc.

It is customary to install a knife switch (double-pole) with each motor by means of which the motor is totally connected to and disconnected from the supply circuit even though all starting rheostats, on the first step, automatically disconnect the motor. Above about 50 hp. it is desirable to use oil switches where the circuit is broken under oil instead of in the open air as in the ordinary knife switch.

In addition to the switch and starting device, automatic protection of the motor against overloads which would burn out the motor must be provided. Fuses, consisting of short pieces of fusible alloy wire or ribbon which melt and open the circuit at a given current, are used for small and moderate size motors. Above 50 hp. circuit breakers are preferable. These are quick-opening switches which operate automatically when a predetermined current is reached.

Note. The Board of Fire Underwriters has an elaborate code of rules with which electric installations, including motors, must comply where the property is insured by fire insurance companies.

The Capacity of generators and motors is practically always determined by the temperature that their insulation will withstand continuously without injury. The rating of such machines is therefore more or less indefinite, but the American Institute of Electrical Engineers prescribes in its Standardization Rules that, at rated load and with a room temperature not exceeding 40° C., the maximum rise in temperature above the room of any part of the insulation shall not exceed certain stipulated values for the various types of insulation in general use. These range from 55° to 85° C.

It is obvious that since temperature is the usual limiting factor which determines the capacity and therefore the rating of a motor, ventilation has a great influence on the rating. Ordinary applications permit the use of motors designed to provide maximum ventilation (known as open-type) but there are many industrial applications where the motor must be screened or partly enclosed for mechanical protection (semi-enclosed type) or entirely enclosed on account of dust, etc. (totally-enclosed type). A semi-enclosed motor will have approximately three-quarters and a totally-enclosed motor approximately one-half of the capacity of an open-type motor of the same weight. In other words, for the same load, semi-enclosed and totally-enclosed motors must be larger and therefore are more expensive than the open-type motors.

Selection of Motors. (See discussion of alternating current motors under this caption.) Each application of an electric motor must be considered by itself with due regard to the many factors which govern the best selection of type and size for the particular application. In general, as in the application of other engineering equipment, the best choice is that which will result in the lowest total annual cost for the life desired. Too large a motor results in a high investment cost and, because of low efficiency, a high operating cost. On the other hand, too small a motor means a high depreciation cost because of shortened life and a high maintenance cost because of repairs and frequent attention required.

Among the many factors that must be considered are:

(a) Character of Load. The torque and speed characteristics of the load dictate the class of motor best suited. Thus, series motors having a large starting torque which decreases as speed increases and are suited to railway, crane, hoisting and similar applications. Shunt motors are substantially constant-speed and are suitable for the great majority of ordinary applications. Cumulative compound motors are most suitable for applications requiring heavy starting torque but also a more constant speed with variations in load than the series motor such as elevators, large metal-working tools like power hammers, punch presses, etc.

The character of the load as to fluctuation influences the size. If the load is constant in magnitude, the rating of a motor which accurately fits the load is easily selected. If the load varies, the best selection will depend upon the load cycle, i.e., magnitude of the maximum load and its duration, the magnitude of the minimum load and its duration, regularity of the cycles, etc. Sparking at the brushes (with resulting rapid wear of commutator and brushes) may be the limiting factor rather than temperature. In well designed standard motors this may be taken as about one-third above the normal rating. In other words with an intermittent load, the normal rating of the motor may be 75% of the maximum load provided the load cycle is such that the prescribed temperature limit is not exceeded. Interpole motors can withstand higher overloads so that a still smaller rating can be used.

In general, the manufacturer of the device, machine or apparatus to which a motor is to be applied can recommend the most suitable class, type and size of motor or at least furnish the power characteristic. In driving groups of machines or apparatus, the diversity of use should be considered, because this may mean a motor as small as only one-third the sum of the powers required by the individual units. However, allowance usually has to be made for line shafts, counter shafts, etc. In installations of any considerable size, it is always best, where at all possible, to determine the actual power requirements by a test with a temporarily-installed motor.

(b) **General Conditions** as to danger of foreign objects getting into the motor and prevalence of dust, moisture, gas, acid fumes, etc. Standard lines of motors are manufactured for each of these general conditions being designated, for example, as dust-proof where an accumulation of dust will not interfere with successful operation, or dust-tight where dust is totally excluded, weather-proof, water-proof, gas-proof, gas-tight, etc. Obviously, the open-type motor being the cheapest, should be used if possible.

(c) **Ambient Temperature.** Where the temperature of the surrounding air is generally higher than the standard at which motors are rated (40° C.) a motor must be used which has a higher normal rating than that corresponding to the load to be carried. An approximate allowance would be about 2% increase in rating for one degree Centigrade increase in temperature above 40° C. In very high temperature situations a motor with so-called class "B"

Average Efficiency and Cost of Direct-current Generators and Motors

Generators			Motors		
Size, kw.	Efficiency at full load, per cent	Cost, dollars per kw.	Size, hp.	Efficiency at full load, per cent	Cost, dollars per hp.
5	83	60	1	75	90
10	85	45	2	80	70
25	87	35	3	81	60
50	89	25	5	82.5	50
100	91	20	7.5	84	45
200	92	17	10	85	40
500	93	15	15	86.5	35
1000	94	14	20	87.5	30
1500	95	13.5	50	90	25
2000	95	13	100	91	20

For a standard starting rheostat, add for example about 10% for a 1-hp. motor and about 5% for a 100-hp. motor.

insulation (heat-resistant) or the ordinary type with forced ventilation should be considered.

Specifications for generators should state the class of service on which the machine is to operate; type of machine; kind of prime mover; and whether direct-connected or belted; kilowatt capacity; voltage; speed; allowable temperature rise of commutator, field, and armature under continuous operation at full load and two hours at 25% overload; that no sparking should occur at any load from no load to full load with brushes stationary; that the machine should carry 50% overload two hours without injury or serious sparking; efficiency at 25, 50, 75, 100, and 125% loads; and change in voltage from no load to full load. Specifications for motors include similar clauses, except that speed regulation replaces voltage regulation.

Cost and Efficiency of generators and motors will vary with the type and conditions of use. In the table on p. 378 are given approximate figures for standard high-speed machines for ordinary service.

The cost of motors and generators varies greatly with the speed. Standard slow-speed machines are 30 or 40% more expensive than standard high-speed machines of the same capacity. The efficiency falls off, with decrease in load, about 1% at 75% load, 2 to 3% at 50% load, and 7 to 15% at 25% load.

5. Alternating-current Generators and Motors

Alternating-current Generators, frequently called alternators, are essentially direct-current machines without commutators, the armature circuit being connected directly to the outside circuit. The connection between the armature and the outside circuit is not reversed every time the winding passes from a north pole to a south pole, and vice versa, as in a direct-current generator. Thus an e. m. f. is produced at the machine terminals which rises from zero to a maximum value in one direction, decreases to zero, reverses, increases to a maximum in the other direction, and again decreases to zero in the time that the winding passes under one north pole and one south pole. Such a cyclic period is called a **cycle,** and the **frequency** of the current is the number of cycles per second.

Types of Generators. The most common forms of alternating-current generators may be divided into two types. In the **revolving-armature** type, the armature is the moving member and the field is stationary, current being delivered to the circuit by means of **brushes** resting on the revolving collector rings. In the **revolving-field** type, the field is the moving member, while the armature is stationary. It is wound in the frame which surrounds the field.

The revolving-armature type is confined to generators of less than 200 or 300 kw. capacity. The stationary-armature type permits the direct generation of potentials up to 15 000 volts and higher, and the economical construction and operation of large capacity generators for a wide range of speeds, from that of the low-head water-wheel to that of the steam turbine.

Windings. There are three kinds of alternators, based on the number of circuits in the armature. A **single-phase** generator has only one circuit in its armature and two terminals. In a **two-phase** generator there are two circuits which generate e.m.f.'s 90 electrical degrees apart. When each circuit or phase is brought out separately there are four terminals, for connection to a two-phase four-wire circuit. Frequently, the two phases are connected to each other and to the middle one of three terminals, for connection to a two-phase three-wire circuit. In a **three-phase** generator there are three circuits or phases in which three e. m. f.'s 120 electrical degrees apart are generated. These circuits are interconnected with either a delta or a star connection requiring three or four terminals respectively.

The accompanying diagrams indicate the relation between the currents and voltages in these various forms of generators and the circuits to which they are ordinarily connected. **I** and **i** are the amperes per phase, and **E** and **e** the volts per phase in armature and circuit respectively.

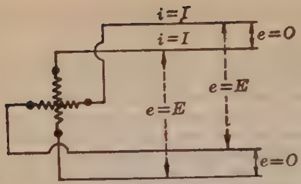

Fig. 14. Two-phase, Four-wire Circuit

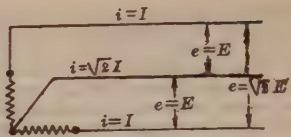

Fig. 15. Two-phase, Three-wire Circuit

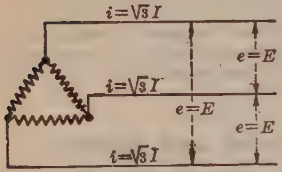

Fig. 16. Three-phase, Three-wire Circuit, Delta Connected

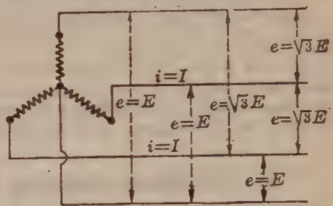

Fig. 17. Three-phase, Four-wire Circuit, Star Connected

Field Excitation. Alternators are usually separately excited. Small machines are sometimes provided with a commutator device by means of which sufficient current is rectified to excite the field. A common practice is to provide a separate generator or exciter for each alternator. This machine is driven from the alternator shaft by a belt or by direct mechanical connection. In large stations, a source of excitation common to all the generators is often provided.

Efficiency and Cost. The following table gives average conservative figures for the efficiency and cost of polyphase alternators. The cost figures, in particular, are necessarily approximate. Slow-speed machines cost more than high-speed machines, and high-voltage more than low-voltage machines. Hence there may be a difference of at least 25% in the cost of generators of the same capacity.

Efficiency and Cost of Polyphase Alternators

Size, kw. *	Efficiency			Cost, dollars per kw.
	50% load	75% load	100% load	
50	83	86	87	35
100	87	89	90	25

20 000	93.5	95.5	96.5	6

* Ratings are in kilowatts at 0.8 power factor. The capacity at a power factor of 1.0 is 25% greater. The power factor of commercial and industrial loads is nearer 0.8, hence ratings on that basis are more in accord with usual practical conditions.

Types of Motors. There are two general types of alternating-current motors—the synchronous and the induction. The **synchronous motor** is essentially an alternator operated as a motor. It has to be brought up to synchronous speed (the speed at which it would run if operated as a generator at the line frequency) by external means before it can be connected to the line. It will operate only at synchronous speed.

Synchronous motors are used as a rule only in large sizes (200 hp. and over) and where it is not necessary to stop the machine frequently. Such cases are in substations where power is converted from one frequency to another or from alternating current to direct current, and in large factories.

Induction Motors are, theoretically, transformers in which the core and the secondary winding are free to move, and the force which the windings of a static transformer exert on each other is utilized to produce mechanical power. When the rotating member (rotor) runs at synchronous speed, no magnetic flux from the stationary member (stator), which is connected to the line, cuts the conductors, and hence no torque is exerted. When a load is applied to the motor, the speed falls below synchronism (called slip), and a current is induced in the rotor conductors which will produce the necessary torque to carry the load. Fig. 18 shows the characteristic relation between speed and torque, also between current and torque, of a polyphase induction motor.

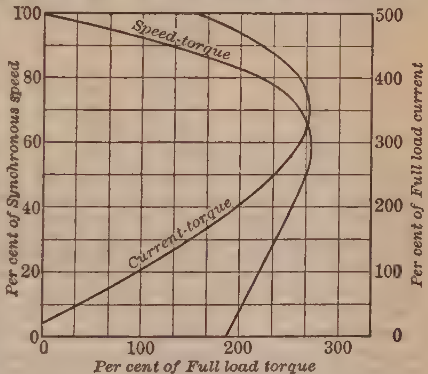

Fig. 18

Polyphase Induction Motors (both two- and three-phases) are the most commonly used type. Their characteristics are similar to those of the shunt motor, in that they have a comparatively low starting torque and operate at approximately constant speed. Polyphase motors are built in all sizes from fan motors to 1000 hp. and over, and are used for all power purposes. There are two forms—the **squirrel cage** in which the winding of the rotor consists of heavy copper bars short-circuited on each other, and with no external connections; and the **slip-ring** form, in which the rotor has a regular polyphase distributed winding, into the phases of which an external variable resistance is connected through collector rings on the shaft. The slip-ring form has a larger torque at starting than the squirrel-cage form, but its efficiency is somewhat lower. When induction motors are overloaded a certain definite amount they will stop. This load is called the maximum torque, or " stalling " load and is two or three times normal load.

Single-phase Induction Motors are infrequently used (and then only in small sizes) because special devices are necessary to make them self-starting. They are more expensive and less efficient than polyphase motors and they unbalance the supply system, which is usually polyphase.

The Series Alternating-current Motor is essentially a direct-current series motor with certain modifications which are necessary for operation on alternating current. It is a single-phase motor and is used in traction work where variable speed and variable torque are required. The repulsion motor is one of several forms of the series alternating-current motor.

Operating Data and Cost. In the following table are given approximate average values for the slip, power factor, efficiency, and cost of standard 60-cycle polyphase motors of the squirrel-cage type. The efficiency and cost of 25-cycle motors are slightly higher. As with all rotating electrical apparatus, the cost varies greatly with the speed—as much as 50% in some cases.

Polyphase Induction Motor Data

(Squirrel-cage type)

Standard sizes, hp.	Slip, per cent	Power factor, per cent	Efficiency, per cent	Cost, dollars per hp.
1	10	80	80	70
2	8	85	82	55
5	6	88	85	40
10	6	89	87	30
20	5.5	90	89	20
50	4.5	90	89	12
100	3.5	90	90	11
200	3.0	91	91	9
500	3.0	91	91	8

Starting. If an induction motor is connected directly to the line when starting it will take a current two to four times the normal full-load running current. To avoid the disturbance which this produces in the system, it is customary to start at a reduced voltage. This is obtained by means of a **compensator**, a single-winding transformer with several taps on it to which the motor is successively connected. The slip-ring type is started with full-line voltage on the motor but with resistance in the rotor circuits. This resistance is gradually cut out as the motor speed increases.

Speed Variation. The inherent characteristics of induction motors are such that the speed is practically constant at a value depending on the frequency and the number of poles in the stator winding. Certain fixed changes in speed are sometimes obtained by providing a special winding by means of which the number of poles can be changed. Change in speed may also be obtained with a variable resistance in the rotor circuits of a slip-ring motor, but the efficiency is materially decreased.

Rating. Alternating-current apparatus, like direct-current apparatus, is rated on the basis of the load which it will carry without overheating. In alternators, this rating is the output in kilovolt-amperes, and in motors it is horsepower. The recommendations of the American Institute of Electrical Engineers for the limiting temperature rise above a room temperature not exceeding 40° C., vary from 55° C. to 85° C., depending upon the class of insulation used.

The discussion of the capacity of direct-current motors (p. 377) applies also to alternating-current motors.

Selection of Motors. The discussion of selection of direct-current motors (p. 377) applies also to alternating-current motors.

Induction motors of the squirrel-cage type have essentially constant speed much like shunt-type direct-current motors and like them are the most generally used type of alternating-current motor. Where higher starting torques and variable speeds are required as with elevators, cranes, etc., the slip-ring type is more suitable. Synchronous motors are preferable only in large sizes where constant speed is required.

As far as surrounding conditions such as dust, dampness, fumes, etc., are concerned, it is obvious that the induction motor of the squirrel-cage type is applicable to a much wider range of conditions than direct-current motors because of the absence of the commutator and sparking. The open-type is therefore very generally used with perhaps special treatment of the insulation for conditions where moisture, acid fumes, oil, etc., are present in unusual amounts.

Specifications for alternators should include, in addition to a description of the type of machine desired and the class of service in which it is to be used, certain performance requirements as follows: Efficiency at various loads from 50% to 125% normal load; voltage regulation (per cent rise in voltage when the load is reduced from normal value to zero) at 100% and 80% power factor; maximum voltage required to excite the field with 125% normal load at 80% power factor; temperature rise of the various parts after continuous operation at full load and 25% overload; ability to withstand 50% overload for one hour without injury; and ability to withstand running at 100% overspeed without injury. Specifications for **induction motors** should include: description of type of motor desired; purpose for which they are to be used; efficiency; power factor and slip at various loads up to 25% overload; maximum torque at starting when connected directly to the line; maximum current required when starting; maximum torque and maximum load which motor will carry without stopping; temperature rise after continuous operation at full load and after two hours at 25% overload; and ability to carry 50% overload one hour without injury.

6. Power Plants

The term Central Station usually refers to a plant operating under a franchise for the manufacture and sale of electricity to the general public. It is therefore a semipublic enterprise as distinguished from a private plant, in which electricity is generated for private purposes. Central stations vary in size from 50-kw. plants in small villages to the large stations in New York and Chicago of several hundred thousand kilowatts capacity. Private plants range from single-unit plants for small office buildings and industrial establishments to the large traction and industrial plants of over 50 000 kw. capacity.

Location. The location of **hydraulic plants** is obviously at the source of water power. Many conditions govern the location of a **steam-driven** central station. The more important are: kind of service to be rendered, whether alternating or direct current; concentrated or scattered area of distribution; size of plant; coast of real estate; and transportation facilities. Large steam plants must be located where an ample supply of condensing water is available (100 to 500 gal. per kw-hr. required). Where a waterway is not available, cheap land, railroad facilities, and water free from scale-forming impurities are the more important considerations. On the other hand, it might be more economical for a smaller plant to be located as near the center of distribution as possible, regardless of other disadvantages. **Gas-driven** plants are usually private plants, and hence are located on the same premises as the load. Private plants in buildings primarily used for other purposes should be located with due regard to the following points: effect of vibration and noise, ventilating facilities, facilities for handling coal and ashes, value of the space for other purposes, and coal storage facilities.

Prime Movers. The prime movers in common use for electric power generation are reciprocating steam engines, high- and low-pressure steam turbines, internal-combustion engines, and hydraulic turbines.

The Reciprocating Steam Engine is the most commonly used small and moderate size steam-driven prime mover. The principal types used for electric power generation are the simple and compound high-speed engines. Small single-cylinder engines receive steam at 75 to 100 lb. pressure per sq. in., and exhaust it at about atmospheric pressure. Larger engines operate condensing; receiving steam at 100 to 200 lb. pressure and discharging it into a vacuum at 2 to 4 lb. absolute pressure.

Steam Turbines are rapidly superseding reciprocating engines above a few hundred horsepower because they are simpler, occupy much less space, cost less per kilowatt, are more efficient, can be used with steam at higher pressures and with a much higher degree of superheat than is permissible with reciprocating engines, and can be built in much larger units—machines up to 150 000 kw. capacity are now in daily operation. Furthermore, high-speed generators, which are cheaper than low-speed generators, can be used.

Low-pressure turbines receive steam at about atmospheric pressure and discharge it into a vacuum. A much greater percentage of the energy in steam below atmospheric pressure can be utilized in a turbine than in the low-pressure cylinder of a reciprocating engine. The capacity of existing plants using condensing engines can be increased 10 to 30% by exhausting from the engines at atmospheric pressure into low-pressure turbines. This additional capacity is obtained without additional fuel consumption. At the same time the range of loads at which maximum economy is obtained is greatly increased.

Internal-Combustion Engines are operated with natural, illuminating, producer, and blast-furnace gases, with crude petroleum, kerosene oil and with gasoline. Where liquid fuels are used, an auxiliary device vaporizes the liquid before it is admitted to the cylinders. This very efficient class of prime movers has been handicapped for electric power plant work because of non-uniform angular velocity, unreliability of operation, limited overload capacity, and high maintenance cost. These faults are rapidly being overcome and gas engines are being used quite extensively, particularly where very cheap fuel is available, such as the waste gases from blast furnaces. Engines of several thousand horsepower are in successful operation on this fuel. The thermal efficiency of the gas engine is from 20 to 30% and is the highest of all heat engines. The cost of power is therefore very low even in small sizes, especially in connection with producer-gas plants, where cheap grades of coal can be utilized.

Hydraulic Turbines in power plants where the head is less than 150 ft. are usually of the pressure type. The turbines in the older plants are of the vertical type, but the lower cost and more reliable operation of horizontal generators has led to the general use of horizontal turbines. Where the head is high the impulse type of turbine is used.

Approximate Steam and Fuel Consumption of Prime Movers

	Pounds of steam per kw-hr.	Pounds of coal per kw-hr.
Steam Reciprocating Engines:		
Simple, non-condensing, 25 to 200 hp........	100 to 40	25 to 8

Gasoline, 10 to 75 hp......................	....	2.0 to 1.2 pints
Oil Engines:		
100 to 500 hp..............................	....	1.5 to 1.0 lb. oil

* Complete plant

Boilers for the production of steam are built in several different types, the most commonly used for power-plant purposes being the water-tube and fire-tube. The **water-tube boiler** is the safest, most efficient, and can be operated at the highest pressure. The small **fire-tube boiler** is cheaper and easier to operate than the small water-tube boiler, and hence is preferable for small plants. Boilers are arranged to reduce the piping to a minimum and make firing as convenient as possible. They are usually placed side by side in one row or in two rows facing each other. All are piped to a common pipe or header, but in such a way that each boiler and group of boilers can be cut off by conveniently located valves.

Rating. Boilers are rated in horsepower, an arbitrary unit equal to the evaporation of 34.5 lb. of water per hour from water at 212° F. to steam at 212° F. Boilers properly rated should develop their rated horsepower when fired by an ordinary fireman and with ordinary steam coal but boilers in modern power plants are regularly operated at two to four times their rating.

Steam Piping should be well lagged and free from pockets where condensed steam can collect. All valves should be easily accessible. The following table gives the approximate size of piping required to deliver any quantity of steam at any distance from the boiler. This table is based on Babcock's formula, which is as follows:

$$p = 0.0001321 \left(1 + \frac{36}{d}\right) \frac{M^2L}{Dd^5}$$

where p = difference in pressure between the two ends of the pipe, pounds per square inch;
d = internal diameter of pipe, inches;
M = amount of steam, pounds per minute;
L = length of pipe, feet;
D = mean density of steam, pounds per cubic foot.

It is to be noted that authorities do not agree on what is the correct formula for steam flow so that for exact calculations reference should be made to the more extensive discussions of the subject in Lucke's "Engineering Thermodynamics," Marks' "Mechanical Engineer's Handbook" (p. 360), etc.

Flow of Steam through Pipes (Babcock)

Pounds per minute with 1 lb. loss of pressure

Initial gage pressure, lb. per sq. in.	Diameter of pipe, inches. Length, 240 diameters								
	1	1-1/2	2	3	4	5	6	8	10
50	4.04	11.2	20.01	49.48	91.34	150.8	226.0	412.2	665.0
60	4.32	11.9	21.38	52.87	97.60	161.1	241.5	440.5	710.6
70	4.58	12.6	22.65	56.00	103.37	170.7	255.8	466.5	752.7
80	4.82	13.3	23.82	58.91	108.74	179.5	269.0	490.7	791.7
90	5.04	13.9	24.92	61.62	113.74	187.8	281.4	513.3	828.1
100	5.25	14.5	25.96	64.18	118.47	195.6	293.1	534.6	862.6
120	5.63	15.5	27.85	68.87	127.12	209.9	314.5	573.7	925.6
150	6.14	17.0	30.37	75.09	138.61	228.8	343.0	625.5	1009.2

For any other loss of pressure, multiply by the square root of the proposed loss. For any other length of pipe, divide 240 by the given length expressed in diameters, and multiply the table figures by the square root of this quotient to get the flow for one pound loss of pressure.

The resistance due to steam entering pipe = 60 diameters additional length; to a globe valve = 60; to an elbow = 40, or two-thirds of a globe valve.

Furnaces are designed for the particular class of fuel to be used. The object of a furnace is to transfer the heat in the fuel to the water in the boiler with the least loss; hence there is a certain kind of grate and arrangement of fire-walls, baffles, flues, etc., best suited for each fuel, i.e., lump coal, powdered coal, fuel oil or gas. The average grate surface provided per boiler horsepower is about 1/4 to 1/2 sq. ft. Furnaces for oil, gas fuel, and powdered coal are the same as coal-burning furnaces, except that special burners are substituted for grates.

Great progress has recently been made in improving furnace efficiencies through the use of water-cooled walls, preheated air, higher combustion temperatures, etc.

Combustion. The sources of inefficiency in a furnace are radiation and conduction losses, coal passing through the grates unburnt (in lump coal furnaces), and incomplete combustion. The unburnt coal in the ashes should not exceed 2 or 3%. Complete combustion means that the carbon—the source of heat in the fuel—is completely oxidized to carbon dioxide. If oxidized only to the monoxide, about two-thirds of the available heat is wasted. Incomplete combustion is usually caused by insufficient air supply. Too much air, on the other hand, not only lowers the temperature of the furnace but absorbs heat which is carried up the chimney. Frequent analysis of the flue gases and ash is necessary to insure that the furnace is being properly operated.

Draft. Air is supplied to the furnaces by natural draft through chimneys or by forced draft. **Natural draft** is more commonly used and various formulas have been developed to express the relation between the internal area and height of chimney required per horsepower of boilers. Kent's formula, based on the rather liberal allowance of 5 lb. of coal per boiler hp., is $\mathbf{HP = 3.33\,(A - 0.6\sqrt{A})H}$, where HP = horsepower of boiler plant, A = inside area in square feet, and H = height in feet. Self-supporting steel chimneys cost about one-third as much as brick chimneys, and are therefore replacing brick for plants of 100-hp. capacity and less. **Forced draft**, either by pressure in the ash pit made air-tight or by suction in the flues, is used to a considerable extent in large power plants. The maximum capacity of the plant can be greatly increased with forced draft, and greater economy, under fluctuating load conditions, is obtained.

Mechanical Stokers are devices for automatically carrying the coal under the boilers, properly burning it, and depositing the ashes in the ash pit. The principal forms are the **rocking grate**, **endless chain grate**, and the **screw feed**. The many advantages in large plants include economy in labor, economy in fuel because cheaper fuels may be used, and more uniform fires. Their use is not advisable in comparatively small plants where the total load varies through wide ranges, hand firing under such conditions being more flexible and economical.

Approximate Cost and Heating Value of Fuels (1928)*

Fuel	Cost, dollars	B.t.u.	B.t.u. per dollar
Anthracite (rice size)	5.50 per ton	13 000 per lb.	4 750 000
Bituminous	4.00 per ton	14 000 per lb.	7 000 000
Coke	8.00 per ton	13 100 per lb.	3 300 000
Wood, hard, dry	15.00 per cord	6 250 per lb.	1 850 000
Crude petroleum	0.03 per gal.	19 000 per lb.	4 700 000
Kerosene	0.15 per gal.	17 000 per lb.	880 000
Illuminating gas	1.25 per M. cu. ft.	750 per cu. ft.	600 000
Natural gas	0.35 per M. cu. ft.	1 000 per cu. ft.	2 900 000
Gasoline	0.20 per gal.	18 000 per lb.	475 000

* Prices are obviously greatly affected by market conditions, distance from source of supply, quantities purchased, etc.

Generators. The type of generator used in a power plant varies with the conditions. Where the load is concentrated, near at hand, and mixed lighting and power, direct-current generators are used. Since, however, the cost of power production decreases with the size of the units and the size of the plant, the trend of modern engineering is toward the concentration of power production in large stations with large alternating-current generator units (single units of over 150 000 kw. capacity of the compound type are in service), the power being distributed at high tension to distributing centers called substations. The selection of the size and number of units for a plant requires careful consideration. Both prime movers and generators decrease rapidly in efficiency below 50 or 60% load, hence the sizes should be such that those in use will always be well loaded. There should be enough units to carry the maximum load, with one as a reserve. For example, a 200-kw. plant ought to have three 100-kw. units, a 600-kw. plant four 200-kw. units, and a 1000-kw. plant three 500-kw. units.

The Foundations for all apparatus should be separate from that of the building. They should be of ample dimensions and never less than those recommended by the manufacturer. Direct-connected generators, motor generators, and rotary converters, although self-contained, should have substantial foundations in order to reduce the vibration and consequent wear on the bearings and insulation. Concrete foundations are the best and cheapest: they will safely carry loads of 7500 lb. per sq. ft. The safe bearing loads of various soils are as follows: clay 4000 lb., coarse gravel and sand 2500 to 3500 lb., rock 10 000 to 30 000 lb.

Switchboards are designed to provide not only independent, easy and quick control of each generator, exciter, and feeder, but to show by means of instruments mounted on them the amount and character of the load. They are made up in panels of slate, marble, and artificial stone placed side by side, one panel for each machine and feeder. The board is usually installed along one side of the generator room with ample space in the front and rear. In low-tension alternating-current and direct-current plants, all circuits are brought to the switches and instruments on the board. **Buses** or heavy copper bars are mounted on the back of the board (often in duplicate) and connected to the various panels so that any number of generators and feeders may be connected in parallel. The circuits of high-tension plants are not brought to the switchboard but are controlled by switches under oil which are operated mechanically or electrically from the switchboard, the instruments being connected in the secondary circuits of instrument transformers.

The very large modern stations generate high-tension alternating current and all generators and feeders are controlled from a miniature remote-control switchboard. The main switches are operated by motors controlled by small switches on this control board. One operator can thus handle all of the outgoing power of a very large plant.

Direct-current generator and feeder panels are usually provided with knife switches, an automatic overload circuit breaker, a voltmeter and ammeter. Low-tension alternating-current panels are similarly equipped, with the addition of a wattmeter and a power-factor meter.

Cost of Power Plants. The cost of power plants depends upon location, type of plant, class of service, size, etc. **Hydraulic plants** formerly, on the whole, cost less than steam plants, but now the reverse is generally the case because the after-war increase in costs has been compensated by marked improvements in efficiency and economy of steam plants, whereas no such improvement has been made in hydraulic power machinery. The average investment per kilowatt of hydraulic plant will range from $125 to $250 per kilowatt, but some plants cost $400 per kilowatt. This is divided, in a typical case, about as follows: hydraulic works 60%, wheels and fittings 12%, building 5%, generators, exciters, and switchboard 15%, and step-up transformers 10%. **Steam plants** cost from $75 to $125 per kilowatt, and an average approximate division of the cost is: boilers and piping 15%, engines and condensers 25%, The following distribution of items which make up the cost of power in various kinds of plants was made by H. G. Stott (Power-Plant Economies, vol. xxv, Trans. A. I. E. E., 1906). This analysis was prepared nearly 25 years ago and obviously does not accurately apply to present day conditions. No more recent figures are available, but these are retained because they give a general "picture" of the relative distribution of power costs.

Relative Cost of Power

Items	Reciprocating engines	Steam turbines	Reciprocating engines and steam turbines combined	Gas-engine plants	* Gas engines and steam turbines combined
Maintenance:					
1. Engine, room, mechanical	2.57	0.51	1.54	2.57	1.54

15. Electrical labor	2.52	2.52	2.52	2.52	2.52
Relative cost of maintenance and operation	100.00	79.64	75.72	50.67	46.32
Relative investment	100.00	82.50	77.00	100.00	91.20

* A proposed combination where the exhaust gases from the gas engine would be used to generate low-pressure steam for low-pressure turbines. Both of these machines have a high efficiency and each would be used under the most favorable conditions.

pumps and other auxiliaries 5%, generators and switchboard 20%, building, foundations, and smoke-stack 25%, coal-handling plant 5%, and engineering 5%.

The cost of Producing Energy depends upon a great many factors, principal among which are the kind and size of plant, the cost of fuel, labor, and supplies, and the load factor. In hydraulic plants it will range from 0.4 to 1.0 cent per kilowatt-hour delivered to the transmission line. An average division of cost will be about as follows: interest, taxes and depreciation 65%; labor 15%; maintenance and supplies 20%. The average cost per kilowatt-hour at the bus-bars in steam plants may be taken at about 3 cents for 250-kw. plants, 1.75 cents for 500-kw. plants, 1.5 cents for 1000-kw. plants, and 1.25 for 2000-kw. plants. Very large plants of 50 000 kw. and over probably produce power for less than 0.5 cent per kilowatt-hour. The cost in gas-engine plants will be less than in steam plants of the same size. This is particularly true of the smaller sizes. Producer-gas plants of 400 or 500 kw. can produce energy at a cost of 1 cent per kilowatt-hour.

7. Transmission of Power

Losses of Electrical Power occur in transmission, the principal one of which is that due to the resistance of the conductors. The amount of loss which may be economically allowed will depend upon several factors such as cost of producing the power, the line investment, size of the load, load factor and the value of the power at the point of delivery. Much greater losses may be allowable and much larger distances covered under certain conditions that would be financially permissible under others.

When current flows through a conductor, a loss occurs which is equal to the product of the current and the fall in potential between the ends of the conductor. From Ohm's law it follows that with a given percentage loss the distance that power may be transmitted will be proportional to the square of the voltage. High-voltage direct current is not commercially practicable, for although a moderately high voltage may be produced by connecting generators in series, it cannot be readily reduced to low voltage for general distribution. On the other hand, alternating current can be transformed from low to very high voltage and vice versa with very simple and efficient apparatus called transformers.

It is now standard practice in large concentrated systems to generate all of the power in one station and transmit it (usually underground) at 2200 to 25 000 volts to various sub-stations from which it is distributed at low potentials. The distance in such cases is, however, comparatively short. Where the electricity is generated by water power, it is usually necessary to transmit long distances to reach a sufficiently large market. In such systems it is customary to generate at 2200 to 15 000 volts and transform to 6600 to 220 000 volts, depending upon the distance. About 220 000 volts is at present the highest voltage in commercial use and about 500 miles the greatest distance of transmission.

Transformers are essentially large induction coils without interrupters. Two coils are wound on a common core built up of laminated steel. They are thoroughly insulated from the core and from each other with varnished cambric and similar materials. When alternating voltage is applied to one coil, the primary winding, an alternating flux is produced in the core. This flux induces an e. m. f. in the other coil, the secondary winding. The ratio of the voltages will be practically the same as the ratio of the number of turns of wire in the two coils.

Classification. Transformers may be classified according to their application, whether for power purposes or for use with instruments. Power transformers may be either constant potential or constant current. The **constant-potential** transformer is the most usual form and is used for all general power transmission at constant potential. Power from two-phase generators is transmitted with two transformers, one in each phase. Power from three-phase generators is transmitted with three transformers connected delta or star and with three-phase transformers in which three transformers are combined by placing three sets of windings on three parts of a common magnetic circuit. The three-phase transformer is cheaper than three single transformers, but the latter method is more flexible and permits operation with only two transformers if one burns out. **Constant current** transformers convert power from low-voltage constant potential to constant current at variable high voltage. They are used for series lighting systems. **Instrument transformers** are used only to insulate instruments from the line and have only 10 to 200 watts power capacity. **Voltage transformers** are connected to voltmeters and wattmeters. They transform the high voltage of the line to about 110 volts. **Current transformers** are connected to ammeters and wattmeters. They insulate the instrument from the line, and also transform the current to a small value, usually 5 amperes.

Rating. The capacity of transformers is determined by the maximum temperature reached in operation. This is fixed at values which will not cause deterioration of the insulating materials. The American Institute of Electrical Engineers recommends a temperature limit corresponding to 55° to 85° C. rise above a standard room temperature of not exceeding 40° C. after continuous operation, the limit of permissible rise depending upon the class of insulation employed. Various methods are used to dissipate the heat and thus increase the capacity. In **self-cooled** transformers the case is filled with oil. The oil, in addition to increasing the insulation, carries the heat by natural circulation from the core and coils to the sides of the tanks, from which it is dissipated by radiation and convection. The surface of the tank is made as large as possible by corrugating and by the addition of external pipes or reservoirs connected to the tank at the top and bottom. The **water-cooled type** is the same as the oil-cooled type, with the addition of coils of pipe at the top through which water flows and carries off the heat. Transformers up to 500 or 600 kw. capacity are usually self-cooled; larger transformers may be either self-cooled or water-cooled.

Losses and Efficiency. The losses in transformers are of two kinds: **Copper loss** is due to the resistance of the windings and varies with the square of the load. The **core loss** is due to the rapid reversal of the magnetic flux in the steel core and is constant at all loads. In well-designed transformers these losses are about equal, except in distribution transformers (50 kw. and under) where the iron loss is usually not over half the copper loss. The iron loss in a transformer is constant irrespective of the load and consequently is made a smaller proportion in distribution transformers for light and power (see Art. 8) where the load is on only a few hours a day but the iron loss is constant for 24 hours. In other words, the "all-day" efficiency becomes more important. The efficiency of transformers is comparatively high, as indicated by the following table:

Efficiency of Power Transformers

Size, kw.	Per cent of normal load				
	125	100	75	50	25
5	95	95.5	96	95.5	93.5
50	97	97.5	98	98.0	97.25
100	97.5	98.0	98.25	98.25	97.5
500	97.75	98.25	98.5	98.25	97.5
1000	98.25	98.75	99.0	98.75	98.0
3000	98.5	99.0	99.25	99.25	98.5
5000	98.5	99.0	99.25	99.25	98.5

These are approximate average values for three-phase, 2200-volt distribution transformers up to 500 kw. and single-phase, 44 000-volt transmission transformers over 500 kw. The efficiency is slightly lower for 25 cycles than for 60 cycles. Also the efficiency is lower for high voltages than for low voltages.

Regulation. With a constant primary voltage, the secondary voltage of a transformer will increase as the load decreases due to the resistance and inductance of the windings. The ratio of this increase to the voltage at full load is the **regulation** of the transformer. In designing, the aim is to keep the regulation as small and the efficiency as high as possible. The regulation at 100% power factor of well-designed transformers will range from 3% for a 5-kw. transformer to 1.5% for a 1000-kw. It will increase very rapidly as the power factor decreases.

Specifications usually include the following: purpose for which the transformer is to be used, capacity, voltage, kind of cooling, efficiency at various 100% power-factor loads, regulation at 100% and 80% power factor, temperature after continuous operation at full load and after 2 hours at 25% overload, high-potential test of insulation at double normal voltage and an over-potential test by operating at double voltage for 5 minutes.

Cost. The cost of transformers of a given rating will depend upon the high-tension voltage, the frequency and the method of cooling. For example, the approximate cost of 5-kw., 2200-volt distribution transformers is of the order of $15 per kw. but for 22 000 volts the cost is $50 or $60. The cost of a 5000-kw. water-cooled, three-phase transformer will vary from about $1.50 per kw. at 22 000 volts to the order of $2.00 at 66 000 volts. Self-cooled transformers cost 25 to 50% more than water-cooled. Sixty-cycle transformers are slightly cheaper than 25-cycle.

The Transmission Line is the weakest part of a transmission system, and therefore, where continuity of service is at all important, requires great care in designing. It is essential to have ample insulation under all weather conditions; ample factor of safety in poles, conductors and insulators under all temperature, wind, and sleet conditions; effective protection against lightning.

Moderate voltage lines are run on wood poles with wood cross-arms. They are set 100 to 200 ft. apart and the conductors are carried on rigid porcelain pin-type insulators. High-voltage lines, also important heavily loaded moderate voltage lines, are carried on towers built up of steel shapes throughout and set 400 to 800 ft. apart. The conductors are suspended from the cross-arms by insulators made up of 3 to 12 or 15 porcelain disks fastened together with flexible joints. On large systems these towers are either rectangular, square, or triangular in shape and are very substantially built. The base will occupy a space 10 to 15 ft. square, the height will vary from 40 to 60 ft., and they will withstand loads of 10 000 to 15 000 lb., applied at the top of the tower. A two-legged flexible steel tower is being extensively used on transmission lines where a low investment charge is essential.

A very high voltage transmission line is usually run over a private right-of-way 50 to 100 ft. wide with all tall and dead trees cut away on each side. To guard against complete shut-down due to an accident to the line, large systems are frequently provided with a duplicate line. This line may be run beside the other, but is preferably run through a different part of the country so that both lines would not ordinarily be subjected to a lightning storm at the same time.

The kind of material to be used for the conductors depends upon various factors such as topography (rough country may require some long spans where the strength of the conductors would be unusually important), climate (excessive wind and sleet storms would require high-strength conductors), importance of continuity of service, length of line and the economics of the proposition. Copper, aluminum, steel, iron, and copper-clad steel are used, but hard-drawn copper is by far the most generally employed.

Size of Conductor. The size of the conductors will depend upon many conditions including most economical energy loss, load factor, character of the installation (that is, whether temporary or permanent), strength required and voltage regulation necessary. With very high voltage, especially at high altitudes, loss due to corona (which is greater with smaller conductors) must also be considered. So far as the energy loss is concerned, Lord Kelvin propounded the law that "the most economical area of conductor will be that for which the annual interest on capital outley equals the annual cost of energy wasted."

Line Drop, Efficiency and Regulation. The **line drop** is the difference between the voltage at the sending end of the line and that at the receiver end under prescribed load conditions. It will depend upon the resistance and reactance of the line. The **line efficiency** is the ratio of the power delivered by the line (that is, receiver load) to the power input at the sending end under prescribed conditions at the receiver end. **Line regulation** is the change in voltage at the receiver end where the prescribed load changes from no load to full load, voltage being maintained constant at the generator or sending end. It will depend upon, in addition to the resistance, the inductive reactance and capacitance reactance, which will vary with the frequency, and with the size and spacing of the conductors.

For calculations of these quantities for long lines and very high voltages, reference should be made to the numerous reference books on the subject. The following formulas will, however, be approximately correct for short lines of moderate voltage where capacitance reactance and capacitance current is negligible. E_S = voltage, sending end; E_r = voltage, receiver end; θ = angle of lag between current and voltage, receiver end; I = current in one conductor in amperes; R = total resistance of one conductor in ohms, x = total reactance of one conductor in ohms.

$$E_s = \sqrt{(E_r \cos\theta + IR)^2 + (E_r \sin\theta + IX)^2} \text{ (volts)}$$

$$\text{Line drop} = E_s - E_r \text{ (volts)}$$

$$\text{Regulation} = \frac{E_s - E_r}{E_r} \times 100\ (\%)$$

$$\text{Power, receiver end} = E_r I \cos\theta \text{ (kw.)}$$

$$\text{Power, sending end} = E_r I \cos\theta + I^2R \text{ (kw.)}$$

$$\text{Power factor, sending end} = \frac{E_r \cos\theta + IR}{E_s} \times 100\ (\%)$$

$$\text{Efficiency} = \frac{E_r I \cos\theta}{E_r I \cos\theta + I^2R} \times 100\ (\%)$$

In application, it is more convenient to use conductor-to-neutral rather than conductor-to-conductor voltage and the power in one wire only, converting back again in the final results. In a single-phase circuit this means 1/2 line voltage and 1/2 total power respectively, and in three-phase circuits, $\frac{1}{\sqrt{3}}$ line voltage and 1/3 power respectively. Resistance and reactance tables will be found in various handbooks.

Conductor Spacings are fixed by experience, but for moderate voltages the distance between conductors in inches may be made 20+ voltage in kilovolts between conductors.

Conductor Stresses. The general formula usually applied to the spans assumes that the conductor takes the shape of a parabolic curve. It is ordinarily approximately true. This formula is

$$T = \frac{L^2w}{8\,d}$$

where T = total tension at center of span in pounds;
L = distance between supports (assumed same height) in feet;
w = weight of conductor in pounds per foot;
d = sag at center of span in feet.

The tension at the point of support is:

$$T' = T + wd.$$

The length of the conductor between supports is approximately

$$L' = L + \frac{8\,D^2}{3\,L}.$$

The important factor of added load due to wind, sleet, snow and temperature changes depends of course upon the climate, and for data, reference should be made to electrical engineering handbooks. This added load is taken as high as 0.75 in. of ice plus 11 lb. wind pressure per square foot of projected area (including ice).

Lightning Storms are the cause of most interruptions to the service on high-tension transmission lines. The poles, conductors, and insulators are often struck by direct discharges. The potential of the conductors may be raised an excessive amount above that of the earth by electrostatic induction from the thunder cloud. This may break down insulators, cause arcing over and grounding of the circuit, or set up waves of high potential which travel along the conductors to the power station or substation and seriously damage apparatus. **Lightning arresters** are devices for allowing excessive voltages to be quietly dissipated without interfering with the service. A common, but not universal, form of protection for a transmission line is a steel wire along the topmost points of the poles or towers and connected to the gound at frequent intervals. This is supplemented with special arresters wherever apparatus is connected to the line.

The voltage at the receiver end of the line will depend upon the inherent regulation of the line as mentioned above and the character of the load. With a low-power-factor load, it is customary to connect either a static or a synchronous condenser (a form of synchronous motor operated without load and with a field current above the normal value) to the receiver end of the line, thus neutralizing the lagging current and improving the voltage regulation by raising the power factor.

Substations are stations at the various centers of distribution where the high-tension power is transformed by "step-down" transformers to low-tension power. It is then distributed either as alternating or direct current, by any of the methods described in Art. 8.

With alternating-current distribution, the substation contains only the transformers which lower the voltage to the required value, and switchboards controlling the incoming and outgoing lines. For direct-current distribution, the alternating current is transformed to direct current either by **synchronous** converters or motor generators. A **synchronous converter** is essentially a double-current generator, a machine which, when driven as a generator, will give direct current at one end and alternating current at the other end. If the alternating-current end is connected to an alternating-current supply and operated as a motor, the machine becomes a rotary converter and direct current will be produced at the other end. The relation between the impressed alternating-current voltage and the direct-current voltage is fixed. Variation of the direct-current voltage must therefore be made with auxiliary apparatus which will alter the alternating-current voltage. The principal devices of this kind are the **synchronous booster,** a generator in series with the alternating-current supply; the **induction regulator,** a single-winding transformer with a movable secondary coil by means of which the supply of voltage can be raised or lowered in small steps; and the **split-pole field** by means of which the wave form of the machine and therefore the alternating-current voltage can be altered. A **motor generator** is a synchronous or induction motor mechanically connected directly to a direct-current generator. This method gives complete electrical separation of the direct-current from the alternating-current system, and complete control of the direct-current supply. The rotary converter, on the other hand, has a higher efficiency, especially at loads less than full load, occupies less floor space, and is somewhat lower in cost. The switchboards in substations, like those in central stations, are designed to give control over each machine and outgoing feeder. Control of the incoming high-tension current is provided by means of remote-control oil switches.

Rectifiers. Alternating currents of relatively small magnitudes are transformed to unidirectional current by several other methods. In the **mercury-arc rectifier** the operation depends upon the fact that if a glass (or steel) tube is exhausted to a low pressure, filled with mercury vapor and has a pool of mercury at one end with a metallic electrode at the other, the resistance to the flow of current is low in one direction and high in the other. Thus a valve action is obtained which in the simple case and with alternating current, would permit current to flow only every other half cycle. It is necessary to start the action by first producing a momentary arc between the mercury and the other electrode, which is usually accomplished by tipping the tube for an instant. In commercial rectifiers there are two positive electrodes (the mercury being the negative electrode) which are so connected to a transformer, suitable reactances and the direct-current load, that both halves of the wave are utilized and a continuous but pulsating unidirectional current is obtained. They are built for use on two- and three-phase circuits as well as single-phase.

Mercury-arc rectifiers are available having current capacities up to 40 or 50 amperes with glass tubes and order of 1000 kw. with steel tubes. The most common application of the smaller sizes is for charging storage batteries in electric vehicles, operating moving picture arc lamps, etc. The larger rectifiers are used in electric railway work, and high-voltage rectifiers are employed in conjunction with constant-current transformers to operate series, direct-current arc-lighting circuits (see Art. 9).

The "**Tungar rectifier**" employs the principle of the thermionic valve which is as follows: If one of two electrodes in a vacuum tube is heated to a red heat, current will flow between the electrodes if they are connected to an e.m.f. and the hot electrode is negative. When the hot electrode is positive, no current will flow. These rectifiers are limited to about 5 or 6 amperes capacity at voltages from 7.5 to 75.

Mechanical rectifiers of various types have been developed in which the connection between the alternating-current circuit and the direct-current load is reversed each half cycle by means of a commutator driven by a synchronous motor having the same number of poles as the commutator has segments, or by means of alternating-current electro-magnets and a pivoted, contact-making, polarized magnet which changes the connection every half cycle. The former type is used with X-ray apparatus and the latter for charging automobile ignition batteries which require small currents at low voltages.

Auxiliary Steam Plants. Many water-power transmission systems have auxiliary steam plants connected to the system. These plants, in addition to assisting the water-power plant at times of low water, are kept under a low head of steam, so that they will be available on short notice in case of failure of the transmission line.

8. Power Distribution

Distribution Systems. Electrical power is distributed to consumers in two forms, direct current and alternating current. **Direct current** systems have been considered the most suitable for general public service purposes in closely settled districts where the distances involved are short. Direct current motors are somewhat more flexible in application because of the more convenient speed control. With a direct current system, continuity of service to customers in case of accidental interruption of the supply for short periods can be more readily maintained because of the applicability of large "stand-by" storage batteries which can be kept constantly connected to the system and automatically discharge into the system in case of failure of the supply. But the great increase in the use of electricity in recent years, and the development of equipment and methods for the distribution and utilization of alternating current power as effectively as direct current power, together with development of applications of electricity where alternating current is the more suitable, are resulting in direct current being gradually supplanted by **alternating current** even in congested districts because of the great economy and flexibility of distribution of the latter. Even in congested districts of the largest cities, electricity is being furnished in the alternating current form — being distributed at 2200 to 6600 volts by means of underground cables in the streets and stepped down to 110 or 220 volts at convenient points for service to consumers. **Alternating-current** systems are always used where scattered districts are served because the distribution can be made at a higher voltage and thus greatly reduce the investment in copper. The power is usually distributed at 2200 to 6600 volts and reduced to a lower voltage at the consumers' premises by small transformers called distribution transformers at each building or group of buildings. Direct current is distributed by series two-wire and three-wire systems. Alternating current is distributed by the series single-phase; two- and three-wire single-phase; three- and four-wire two-phase; and three- and four-wire three-phase systems.

Series Systems. In both direct- and alternating-current systems all apparatus is connected in series and the same current passes through all. This system is used only for street lighting, where the smaller investment in copper required is a great advantage. The current is kept constant by automatic apparatus in the station and the voltage varies with the number of lamps in the circuit. Open-arc lamps require 45 to 50 volts each, inclosed-arc lamps 75 to 80 volts each, and series incandescent lamps 15 to 30 volts each. Forty to one hundred lamps may be burned on one circuit, requiring a total of 2000 to 6000 volts. Provision is made in each lamp for automatically keeping the circuit closed when the electrodes of an arc lamp become too short or the filament of an incandescent lamp breaks. Incandescent lamps of different current ratings (and therefore different candlepower ratings) are used on the same alternating-current circuit by employing specially designed individual current transformers.

Two- and Three-wire Systems. The series system is not feasible for general distribution because lamps cannot be turned on and off individually without affecting the others on the circuit, series motors are not suitable for general use, and the high voltage of the series system would be dangerous to life and property if carried into buildings. Distribution to and within buildings is therefore made with constant-potential multiple circuits, either two-wire or three-wire.

In a Two-wire Direct-current System, pairs of cables (feeders) radiate from the central station, each pair dividing and subdividing into other pairs (mains) running to the premises of the consumers. The voltage varies from 100 to 125 volts and each lamp and motor is connected directly across these lines, each being independent of the others. **Single-phase alternating current** is similarly distributed at high voltage to transformers just outside of the consumers' premises and from the transformers secondary distribution is furnished at 100 to 125 volts. The two-wire system requires a large copper investment to keep the potential drop within reasonable limits. Excessive drop in potential due to too high resistance in the circuit means not only lost power but flickering of incandescent lamps, since the candlepower of the latter changes 4 to 6% with 1% change in voltage.

The Three-wire System was developed to decrease the amount of copper required. Two direct-current generators are connected in series and feeders are run from each outer terminal of the two machines and the common connection between them. The distribution to the consumers' premises is made with three instead of two feeders and mains. The lighting load is divided, half being connected between each outer wire and the middle or neutral wire. Motors are connected to the outer wires in order to decrease the flickering of lamps which fluctuating motor loads produce. Furthermore, 250-volt motors are somewhat cheaper than 125-volt motors. In the three-wire system the advantages of the two-wire system are retained and at the same time only 38% as much copper is required for the same percentage loss. By keeping the load fairly evenly divided, the neutral feeders and mains may be made smaller and an additional saving effected.

Secondary distribution on single-phase alternating-current systems is made by the same method by winding the secondary of transformers for 200 to 250 volts, and connecting the third wire to the center of the winding.

Two-phase Systems. The two-phases system of distributing alternating current is very generally used where the load is both lamps and motors, the lamps being connected across each phase separately and motors across both phases together. Single-phase motors are not practicable except in small sizes, hence the two-phase system combines the advantages of a polyphase system for motors with those of the two- and three-wire systems for lamps. The current is generated with two-phase alternators and is distributed over four or three wires. In the four-wire system, each phase is distributed independently through two wires. In the three-wire system, one wire of each phase is common.

Three-phase Systems of distribution are used only where the load is principally motors and where the power has to be transmitted considerable distances. About 25% less copper is required than for two-phase, four-wire, systems under the same conditions. The current is generated in three-phase alternators, usually at 25 or 60 cycles, and may be distributed directly to consumers up to 440 volts or transformed to a higher voltage for transmission to distributing centers, or directly to the consumer's premises, where it is transformed to a low voltage. The primary distribution is always three-wire, but the secondary distribution may be made with four wires where there is a considerable lighting load. In such cases, lamps are connected between each of the three main wires and the neutral, while motors are connected to the three main wires.

Distribution Methods. The power is delivered to the consumers' premises from the power plant or substation through feeders and mains carried on poles or placed underground. The former method is very much cheaper and is the general practice outside of large cities. In congested districts, the crowded conditions of the streets, the unsightly appearance of pole lines, and the handicapping of firemen have caused the development of the underground method.

Overhead Distribution is made on wood, built-up steel, cast-iron, or reinforced-concrete poles 30 to 60 ft. high and spaced 50 to 200 ft. apart, depending upon the local conditions. The wires are carried on insulators attached to wood cross-arms. Glass insulators are used for low-voltage circuits and glass or porcelain insulators for high-voltage circuits. Wire with weather-proof covering is commonly used. The cost of overhead distribution depends upon the kind, quality, height, and spacing of the poles, upon the number of circuits, condition of the streets, and so forth. It varies from $750 to $2000 per mile exclusive of the cost of the wire.

Underground Distribution is largely carried out in this country by the conduit system—that is, tubes of various kinds, 3 to 5 in. diameter, are laid in the ground and insulated conductors (cables) are pulled into them. In some special cases such as park and parkway lighting, armored cable is laid directly in the ground.

Conduits are made of wood impregnated with creosote, sheet-iron pipe lined with cement, fiber, and vitrified clay. Wood conduit and sometimes fiber conduit is laid directly in the soil, but the other conduits mentioned are usually encased in concrete or cement mortar, a number of conduits being laid side by side. The conduit materials most in use are vitrified clay and fiber tubing. Clay conduits are made in single-duct pieces about 18 in. long, and in multiduct pieces, with any number of round or square holes (from two to sixteen), about 30 in. long. Fiber conduits are made up in pipes about 5 ft. long of treated wood pulp. Where used for multiple-duct conduits they are embedded in and surrounded by a casing of concrete. On account of the greater strength and smaller number of joints, the multiduct clay conduit is frequently laid directly in the ground without cement encasement, the joints being wrapped in burlap, and well asphalted. Manholes built of brick or concrete are provided every 100 to 500 ft. where service connections may be made, cables pulled in and out for repairs, and splices made. If distribution is made at high voltage, the step-down distribution transformers are installed in these manholes.

Interior Wiring. The system used for the distribution is usually continued through the building. The materials and methods used in wiring buildings on which insurance is carried must conform to the rules of the National Board of Fire Underwriters. The building departments of all large cities also have rules which must be observed. The standard methods are open or cleat work, molding, rigid steel conduit, flexible steel conduit, non-metallic tubing and armored cable.

In Cleat Work, the wires are exposed and supported on walls and ceilings by porcelain cleats or knobs. Porcelain tubes are used where the wires pass through walls or ceilings. This class of wiring is the cheapest but is entirely satisfactory when the work is properly done and appearance is of secondary importance.

In Molding Work the wires are embedded in grooved strips of wood or metal, and covered with a thin strip of the same material. Special porcelain fittings are used where apparatus is connected. (Wood molding is no longer allowed in some of the larger cities.)

Rigid Steel Conduit Work consists of special soft-steel pipe run throughout the building and through which the wires are pulled. Steel junction boxes are provided through which the wires are pulled into the pipe and defective ones pulled out. This is the most expensive form of wiring, in first cost, but it completely protects the wires from mechanical injury, reduces the fire risk on the building to a minimum, and the maintenance cost is small, for old and defective wires can be readily replaced without injury to the conduit.

Flexible Steel Conduit is a tubing of steel ribbon wound spirally in such a manner as to produce a very flexible steel tubing which is reasonably tight but not water-tight. Steel outlet boxes and junction boxes are used as with the rigid conduit. Although this is a cheaper construction than the rigid pipe system it eliminates the unsafe features of molding work. It is particularly applicable in wiring old buildings.

Non-Metallic Tubing is a stiff though sufficiently flexible hose of fiber composition which is a cheap substitute for the metal conduit. It is obviously not waterproof.

Armored Cable is similar to flexible steel conduit with the conductors included. The conductors are covered with suitable insulation and the steel ribbon wound directly over this insulation. This form of wiring is rapidly replacing the flexible conduit method for old buildings because conduit and wire are installed together.

Wires and Cables. There are three general classes of wires and cables used in electrical work: weatherproof, rubber insulated, and lead-covered.

Weather-proof Wire is insulated with two or three layers of cotton braid impregnated with insulating compounds. It is used only for exterior wiring, principally for overhead distribution. It is the cheapest form of insulation, but also the least efficient. Although sufficient protection is provided for pole-line purposes where the wires are supported on insulators, it is entirely inadequate for interior wiring.

Rubber-covered Wire forms the greatest percentage of wire used for electrical purposes. It is used almost exclusively for wiring buildings and extensively for high-tension cables. There are three principal grades of rubber insulation: National Electric Code Standard, 30% Para, and Navy Standard All grades consist of rubber, ground and mixed with various kinds of powdered mineral matter together with a certain amount of sulfur. After being applied to the wire by running through dies, it is vulcanized by subjection to a high temperature. The principal difference in the grades is in the quality and amount of rubber used. National electric Code insulation is made with various kinds of old and reclaimed rubber and rubber substitutes but must contain about 20% Para rubber. Before it can be used, it must be approved by the National Board of Fire Underwriters. Thirty per cent Para insulation contains at least 30% of new Para rubber gum. It is more durable than the National Electric Code wire and is used in all first-class interior-wiring work. Navy Standard insulation contains not less than 40% of new Para gum. It is used by the government on all battleships and is the highest grade of wire regularly manufactured.

Lead-covered Wires and Cables include various forms of insulation and are made up in a great variety of ways to suit any requirement for insulation and mechanical protection. Lead-covered cables are used where protection from mechanical or chemical injury is essential, as in underground distribution and under water. One, two, or three conductors may be in one cable. The conductors in two- or three-conductor cables may be side by side or one inside the other (concentric). The standard insulations are 30% rubber, paper, and varnished cambric. Paper insulation is applied in a narrow strip wound spirally on the copper to any desired thickness and saturated with suitable oil to increase the insulation and render the cable flexible. Varnished-cambric insulation is applied in the same manner. The capacity of wires and cables is fixed by the temperature at which the life of the insulation will be affected

The accompanying table shows the carrying capacity of various kinds of wires and cables based on safe temperature limits. The second column of this table gives capacity for wire in still air, at 125° F. The third and fifth columns give the capacities allowed by the Fire Insurance Underwriters (National Electric Code). The limits given for rubber are those beyond which deterioration (when exposed to air) may begin. The seventh column gives capacity at 125° F.; the eighth column gives capacity at 175° F. for still air at about 70° F. These data apply substantially to the conditions existing in a standard single-duct, underground conduit. If the conduit is multiduct with a loaded cable in each duct, the capacity of each cable will be reduced from 5 to 25 or 30%, depending on the number and arrangement of ducts and cables.

The temperature of paper cables will be about 10% higher than that of rubber cables for the same current and thickness of coverings. Paper cables should not be operated over 190° F. and rubber cables over 160° F. Cables immersed in water will carry, for the same temperature rise, 40 to 50% more current than indicated in the table, and if buried in moist earth, 10 to 25% more current.

The capacity of each conductor in a two-conductor, non-concentric cable is about 85% of that of a single-conductor cable; in a two-conductor, concentric cable, 80%; in a three-conductor, non-concentric cable, 75%; and in a three-conductor, concentric cable, 60%.

The voltage drops given in the table are per 1000 ft. of wire (500 ft. of two-wire cir-

* Solid wire assumed up to and including No. 0000 although in practice stranded wire is usually used in sizes over No. 6. Sizes above No. 0000 are assumed stranded and are expressed in circular mils. Stranded wire has about 2% greater resistance than same size solid wire.

cuit) and are calculated from the resistance at 25° C. The copper temperature will be actually higher than 25° C. by an amount which will depend upon conditions so that the actual drop may be as much as 5% greater than these figures.

Choice of Wiring. The selection of the type of wiring is largely a matter of cost from among those allowed by the Underwriters for a particular type of building (certain types are not permitted under certain conditions). The rigid-conduit, flexible-conduit and armored-cable types offer about equal protection from fire due to an accidental arc in circuits of moderate size. In the larger sizes where an arc would be heavier, the rigid conduit is preferable. The relative cost varies, of course, with the conditions but the following gives a general idea of the range for new buildings * :

Rigid steel conduit, exposed 125%
Rigid steel conduit, concealed (i.e., installed during construction of building) 100%
Armored cable 65%
Open wiring 50%
Knob or tube wiring 40%

Before the size of wire can be decided the current loads must be determined. In lighting systems all branch circuits are limited to 660 watts by the Under-

* "Interior Wiring," A. L. Cook, p. 244. John Wiley & Sons, Inc.

writers. Feeders and mains are calculated on a basis of 600 watts for each branch circuit—the corresponding current being the total watts in each case divided by the nominal voltage (usually 120 volts). In the case of power systems, each motor over one-quarter horsepower is supplied by a separate branch circuit, the current being taken as the full load running current as marked on the nameplate. The diversity in the use of the several motors (over 5 or 6) may be taken advantage of in estimating feeder and main currents and may be taken as low as 50% of the total of the nameplate currents where there are more than 10 or 12 motors.

The best size of wire is determined for each part of the circuit between the source of supply (entrance to building if from public utility service or switchboard if private plant) and the consuming equipment (lamps, motors, etc.), i.e., feeders, mains and branches, respectively. There are two limitations on the minimum size: temperature rise and voltage drop. The former is automatically provided for by the Underwriters' rules which limit the current for each size of wire (see interior wiring section of table on p. 398) and the latter is determined by calculation (see wiring table, p. 399). The voltage drop is usually limited to about 5% at the lamp in the case of lighting systems and 10% at the motor in power systems (about one-quarter of this in branches, one-quarter in mains and one-half in feeders). If the size which would be allowed by voltage drop is less than that allowed by the Underwriters for that current, the latter size should be used.

The Sale of Power. Systems of selling power are based on the direct cost of manufacturing; on the investment in power-station and distribution equipment; and on the reserve capacity of the plant required to meet unusual demands of the consumer. Among the numerous systems in use, the principal ones are **flat rate, straight meter basis**, and **maximum demand**. In the **flat-rate** method a fixed price, depending

Wiring Table

Distances in feet which power at 100 volts may be transmitted with various sizes of wire at various percentages of loss.

upon the size of the installation, is charged per month, irrespective of the hours of use. This is used only where power is cheap or the loads small. The **meter system** is the usual system employed by central stations. Various discount methods, based on the total kilowatt-hour consumption per month and on the size of the installation, are used. The **maximum demand** system makes the price paid depend upon the maximum power taken during any given period, as for instance during any 5-minute period in 24 hours. This system is extensively used where large quantities of energy are being consumed and is designed to take care of the investment in equipment not used except for a short time during each day.

Meters. Where the charge for electricity is based on the energy consumed, the energy is measured with watt-hour meters (see p. 371). If the maximum demand is involved in the charge it may be estimated or actually measured. The former practice is used extensively for small consumers because the expense of metering the maximum demand is not justifiable. Various systems are used, such as total number of active rooms, floor area or number of outlets in the case of a residence and total connected load (from nameplate data of connected motors, etc.) or trial test in the case of an industrial plant.

Maximum-demand meters are, however, used for large customers. They function with the watt-hour meter and may be combined with the latter or in a separate case but electrically connected with the watt-hour meter. Some types merely indicate, by means of a pointer, the largest amount of energy which has been used in the fixed interval agreed upon (usually 15 or 30 minutes) since the pointer was previously set back. When the watt-hour meter is read, this indication is also noted and the pointer reset at zero. Other types show a graphic record on a continuous tape or chart on which the demand is shown continuously for successive intervals and from which the maximum is determined by observation.

In the rate for a large industrial plant, there is sometimes included a factor which depends upon the power factor since low power factor is objectionable to the supply company because generation and transmission capacity is used without a corresponding increase in energy consumption. Meters which record the volt-amperes (as distinguished from watts) are used for this purpose. Sometimes special rates for certain applications are made by the power company if the energy is taken during certain " off-peak " hours when the plant equipment is not loaded—the " off-peak " energy being measured by a separate watt-hour meter which is cut in and out of circuit by means of a clock.

9. Electric Lighting and Illumination

Lighting by electricity is accomplished by three methods: by the arc between two carbon pencils automatically kept a short distance apart, by the passage of current through rarefied gases, and by the heating of a refractory material to incandescence.

The intensity of a source of light is measured in terms of a unit source called a **candlepower.** The four principal standard sources of light are (a) the British standard candle, a spermaceti candle, (b) the English Harcourt lamp, which burns pentane vapor mixed with air in an Argand burner, (c) the French Carcel lamp, which burns colza oil with a wick, and (d) the German amylacetate lamp, which burns amylacetate with a wick. The British candle is nominally the standard in this country but the amylacetate lamp is probably the most generally used standard lamp. All of these standards are of course arbitrary, and are made and used in strict accordance with very detailed specifications in order to insure reliable and reproducible results.

Illuminants are measured with a **photometer,** an instrument which gives the value of the unknown source in terms of a standard lamp. Because of the much greater convenience in commercial work, this standard is usually an electric incandescent lamp that has been carefully standardized against one or more of the above primary standards.

Rating of Illuminants. The theoretical standard of intensity of light, the candlepower, is a point of light giving a candlepower in each direction. **Mean horizontal candlepower** is the average candlepower in all directions in a horizontal plane through the center of the source. **Mean spherical candlepower** is the average candlepower in all directions from the center of the source. **Mean hemispherical candlepower** is the average candlepower in all directions in a hemisphere with the source as the center.

Illuminants are now being rated in terms of the lumen which is the unit of light radiation. A **lumen** is equal to the light flux emitted by a source of one candlepower in unit solid angle. A source of one candlepower emits a total light flux of 4π lumens.

All commercial illuminants have a more or less irregular distribution curve, that is, the candlepower is greater in some directions than in others, and in making comparisons between different illuminants it is therefore necessary to be specific. Formerly, it was customary to rate electric lamps on a basis of the maximum candlepower obtainable. Later incandescent lamps were rated on a mean horizontal candlepower basis and other illuminants on a mean spherical or mean hemispherical candlepower basis. The present practice, however, is to rate all electric illuminants on the basis of the nominal watts consumed. This applies particularly to incandescent lamps which are all labeled and described on this basis, the candlepower (or lumens) being omitted. This practice is the result of the wide use of reflectors, each form of which gives a different apparent candlepower.

Arc Lamps are used for lighting streets, large interiors, and similar places where the illumination must be general but not necessarily high. Arc lamps are, however, being rapidly superseded by large incandenscent lamps even for these applications.

In the **open arc,** the earliest form of electric light, an arc is maintained between solid carbon rods in the open air. They are usually operated 40 to 100 in series, on both direct and alternating constant-current circuits. The standard sizes are 6.6- and 9.6-ampere lamps, requiring 45 to 50 volts. Although this type is relatively very efficient as a source of light, it has been largely superseded by the **enclosed-arc** lamp, a lamp which is less efficient but also much less expensive to operate and gives a much better distribution of light. The arc is surrounded by a small, close-fitting glass globe which excludes the air and retards the consumption of the carbons, thereby increasing their life eight to ten times. These lamps are operated on both direct and alternating current, but more often on multiple circuits at 110 volts than on series circuits. The voltage per lamp is 75 to 80 and the current varies from 3.5 to 7.5 amperes. The **magnetite-arc** lamp is a direct-current open arc in which the electrodes are metallic copper and an oxide of iron. Its special features are long life of electrodes (about 150 hours), high efficiency, and light distribution particularly suited for street lighting. The **flaming-arc** lamp is an alternating and direct-current open arc with small-diameter carbons impregnated with sodium or other similar salts which enormously increase the light emitted. They are the highest candlepower units in general use, 2500 to 4000 cp. being given in the maximum direction, and are extensively used for spectacular and show purpose.

Lamps with Luminous Rarefied Gases are not used for general illumination but only where the special characteristics of the light are advantageous.

The Cooper Hewitt lamp consists of an arc in a tube 2 to 4 ft. long, in which the cathode is metallic mercury and the arc passes through rarefied mercury vapor. The light is not due to the temperature of the arc, as in the ordinary arc lamps, but to the luminescence of the vapor. The light is therefore green in color, red and yellow being almost entirely absent from the spectrum. The actinic value of the light is high, hence it is used for photographing and blueprinting. It is also said to be less fatiguing to the eyes than white light, and is therefore desirable in drafting rooms. On account of the unnatural greenish tint of the light it is not suitable for general use. When a quartz tube is used instead of glass, the lamp can be operated at a much higher current density, and a higher efficiency as well as a whiter light is obtained. The Cooper Hewitt lamp operates on either direct or alternating current.

The various forms of tube light employ the principle of the Geissler tube, that is, a continuous and silent electrical discharge takes place through gas at a low pressure in a sealed glass tube. The tubes are operated from small high-tension transformers. The color depends upon the kind of gas, neon giving the familiar pink light and nitrogen, a white light.

Incandescent Lamps are almost exclusively used for interior illumination where relatively high and uniformly distributed illumination is required.

An Incandescent Lamp is an illuminant in which a refractory material in the form of a long thin wire in a glass bulb is heated to incandescence by the passage of electric current. The types are distinguished by the material of which the filament is made, the carbon filament being the oldest. The others in the order of development are metallized (specially treated) carbon, tantalum, and tungsten. The essential difference between these is in the temperature at which the materials may be operated, the temperature of carbon being the lowest and that of tungsten the highest. For the same amount of light, thinner filaments may be used as the permissible temperature increases, and therefore less power is required. Where the power required per candle-power in carbon lamps is about 3.1 watts, that for gas-filled tungsten lamps is 1 watt. or less.

The tungsten lamp has now about completely supplanted the other kinds. It is made in two types. In one type (known commercially as type " B ") the filament operates in a vacuum while in the other type the bulb is filled with nitrogen, argon or other inert gas at about atmospheric pressure (" type C "). The latter is operated at a slightly higher temperature and therefore a slightly higher efficiency than the vacuum type. The gas-filled type is made principally in the larger sizes where the increase in efficiency is most pronounced.

The accompanying table shows the approximate lumens, power consumption in watts per lumen, and cost of tungsten lamps. The sizes given are those most commonly used. The prices are approximate for not less than 5000 lamps purchased per year.

Luminous Output, Efficiency, and Cost of Tungsten (Mazda) Lamps

Nominal watts	Vacuum (Type B)			Gas-filled (Type C)		
	Nominal lumens	Lumens per watt	Approximate cost	Nominal lumens	Lumens per watt	Approximate cost
15	126	8.4	$0.20	....	....	....
25	235	9.4	0.20	....	....	....
40	396	9.9	0.20	....	....	....
50	....	....	....	515	10.3	$0.22
60	....	....	....	666	11.1	0.22
100	....	....	....	1320	13.2	0.35

Operation of Incandescent Lamps. Incandescent lamps are used on series as well as multiple circuits, but series lamps are a small per cent of the total. Series lamps have short thick filaments, requiring 15 to 30 volts, and are often connected in the same series circuit with arc lamps and placed in side streets, alleys, and similar places where high illumination is not required. Lamps of different sizes, that is, different current ratings, can be operated from the same series circuit by employing a special type of current transformer. The continuity of the series circuit is maintained when a filament burns out by means of an automatic short-circuiting device in the lamp socket.

The life and candle-hours of incandescent lamps are seriously affected by changes in voltage for although raising the voltage on a lamp increases its efficiency, the life is reduced at a much greater rate. The most economical operating voltage is therefore that where a balance is obtained between the decreased cost of energy consumption and the increased cost of lamp replacements. Fluctuating voltage also produces disagreeable flickering, consequently it is essential that the system be well regulated if satisfactory service is to be obtained. The following table shows the effect of change in voltage on the candlepower and life of tungsten lamps (vacuum type).

Effect of Voltage Variation on Tungsten Incandescent Lamps

Per cent normal voltage	Per cent normal lumens	Per cent normal life *

* scp. = mean spherical candlepower.
† Manufacturers claim several thousand hours.

The Relative Cost of Lighting depends not only on the amount of light produced per watt of power consumed, but also upon the cost of power, hours of burning, initial investment, repairs, life, and cost of maintenance (cleaning glassware, replacing incandescent lamps, renewing carbons, glowers, and so forth). Hence the relative standing of the various illuminants will vary with conditions applying to each case, and no general statement can be made that will be universally applicable. For instance, where the cost of energy is low or the lamps are burned only a small fraction of the time, it might cost less to use lamps of relatively low efficiency.

Illumination. Illumination is expressed in terms of the **foot-candle**, which is the illumination produced on a surface normal to, and one foot from, a source of one candlepower. The intensity of illumination varies inversely as the square of the distance from the source.

Illumination of Interiors is usually effected by direct lighting, indirect, and semi-indirect lighting. In direct lighting the illumination is received directly from the light sources; in the indirect method the light sources are concealed from direct view and the light is reflected into the room from a highly reflecting surface, usually the ceiling. In the semi-indirect method, a part of the illumination is obtained by reflection and part by direct lighting usually by means of an inverted, translucent reflector or bowl. The two latter methods have the physiological advantage of removing the light sources from the field of vision of the eye, but they usually require somewhat more energy for the same amount of illumination. In direct lighting, the intrinsic brilliancy of the sources is (or should be) reduced by enclosing the lamp or by some other means. This entails a loss of the order of 15%.

The amount of illumination which is considered desirable in various applications is steadily increasing as the value of better artificial lighting becomes more appreciated. The following tabulation lists the values of the illumination considered desirable at the present time in a few typical applications.* The ranges given provide for the different conditions, such as the kind of room in the case of a building or the kind of work in the case of a factory. For example, in a residence the minimum value given is sufficient for halls and similar places but the highest value is for rooms where plenty of light is desirable, such as the living room. The Illuminating Engineering Society has prepared complete, detailed codes for lighting factories and school buildings,

The candlepower required in the lamps can be readily computed for a given case if the distance to the lamps and the curve of distribution of light around the lamps are known together with the approximate reflection factors of the ceiling and walls.

Typical Illumination Values

Class of service	Illumination, foot-candles	Class of service	Illumination, foot-candles
Auditoriums	2–4	Stores, miscellaneous	4–8
Theatres	3–10	Stores, clothing	6–12
Churches	3–6	Drafting	10–20
Reading rooms	3–10	Engraving	10–50
Residences	0.5–8	Machine shops	4–50
Desk lighting	8–10	Foundries	3–12

Street Lighting. The best method of illuminating streets is that which will produce the most uniform illumination for the same average illumination. This lies between the two extremes, large units placed far apart and smaller units placed close together. Cost considerations have dictated the very general use of the former method, the lamps being of such a size and so spaced that the minimum illumination midway between lamps will be at least that of average moonlight or about 0.02 foot-candle. Obviously, the amount of illumination may be as much greater than this minimum as cost considerations will permit. The prices obtained for street lighting by electric companies vary from $50 to $125 per lamp per year, and the cost per mile of street will range from $500 per year in villages to $5000 for the important avenues in cities. The cost varies greatly even for the same illumination because of the varying conditions such as hours of burning, whether all night or only a part, and whether every night or on a "moonlight schedule"; type of construction, whether ornamental iron poles or wood poles, and overhead or underground distribution; cost of producing energy and so forth.

Reflectors. Efficient artificial illumination requires that as much as possible of the light emitted from the source fall upon the surface or objects to be

* From "Light, Photometry and Illuminating Engineering," W. E. Barrows, McGraw-Hill Book Co., pp. 168–177, where nearly 300 applications are listed.

illuminated. Care should be exercised to select the proper type and size of lamps for the particular case and to locate them where they will be most effective. Reflectors placed back of the lamps can be advantageously used to reflect the light from directions where it is useless to the object to be illuminated. Reflectors are now scientifically designed according to the laws of reflection and refraction. They may be obtained with various forms of distribution curves, either extreme concentration, moderate concentration, or wide diffusion.

10. Batteries

Primary Batteries. If two metals are placed in a liquid, an **e. m. f.** is generated at the plates, the value of which will depend upon the metals and the liquid. Such a combination constitutes a **voltaic couple.** Those couples which produce the greatest potentials are used to a large extent as sources of electricity for telegraphing, signals, telephones, call-bell systems, and other purposes where very small amounts of power are required. They are called **primary cells,** and a number connected together form a primary battery. The various kinds may be divided into two classes: closed circuit and open circuit. Batteries in the first class always use a fluid electrolyte. Those in the second class use either fluid or nonfluid electrolyte.

Closed-circuit Batteries are those which can be discharged continuously. The most common battery of this class is the gravity battery, with electrodes of copper and zinc and a copper-sulfate electrolyte. Its construction is such that it operates best when kept connected to a closed circuit. The voltage of the gravity battery and the similar Daniell battery is about 1 volt per cell, but the current capacity is only a few hundredths of an ampere. The gravity battery is used extensively for telegraph and railway signal work. **Potassium-bichromate** batteries use carbon and zinc electrodes with a solution of bichromate of potash. These cells have a potential of about 2 volts each and a comparatively large current capacity. Frequent renewal of the elements and electrolyte is necessary. The **Edison-Lelande** battery consists of zinc and copper electrodes and caustic-soda electrolyte. Its potential is about 1 volt per cell and the largest size will deliver about 7 amperes for nearly 100 hours on one charge of material.

Open-circuit Batteries are intended to be used only on intermittent service, such as call bells and short telephone lines. Very large quantities are used for pocket flash lamps and radio sets. Practically all batteries in this class are carbon and zinc in a sal-ammoniac solution. The **e. m. f.** per cell is about 1.5 volts. **Dry batteries** are carbon-zinc-sal-ammoniac batteries made nonspillable by filling the space between the electrodes with sawdust or similar material which has been saturated with sal-ammoniac solution. They cannot be renewed when exhausted.

Standard Cells are cells used as standards of **e. m. f.** The two types in most general use are the Clark cell and the Weston cell. The **Clark cell** is made with zinc and mercury electrodes and a solution of zinc and mercurous sulfate. Its potential when made up in accordance with certain conditions is 1.434 volts at 15° C. The **Weston cell** is made with cadmium instead of zinc and the potential is 1.0183 volts at 20° C. Both will remain constant for years if no appreciable current is drawn. The Weston cell has a much lower temperature coefficient and a longer life than the Clark cell.

Storage Batteries are those in which the chemical process is reversible, and which, after being discharged, can be restored to the original chemical condition by sending current through them in the opposite direction. In the best-known class, the elements or electrodes are metallic sponge lead (negative plate) and lead peroxide (positive plate) in a sulfuric-acid electrolyte. While discharging, both elements partially change to lead sulfate and when current is passed through the cell in the opposite direction (charging) they are converted back again to the original state. The two important methods of making the plates are the Planté method and the pasted or Faure method. In the

Planté process the lead peroxide and the sponge lead are formed by chemical or electrochemical means directly on lead plates from the plates themselves. In the **Faure process** various oxides of lead are mechanically applied to the plates and then reduced electrochemically to sponge lead and lead peroxide, respectively. The Planté type batteries are usually used for stationary work where weight and volume are relatively unimportant. For motor vehicles, train lighting, and similar purposes where the maximum capacity per unit of weight and volume is essential, the pasted or Faure type is used.

The Capacity of a battery is measured in ampere-hours. A capacity of one ampere-hour means the ability to deliver one ampere continuously for one hour. The capacity of a battery depends upon the amount of active material; the area of the plates; the amount, temperature, and specific gravity of the electrolyte; and the current at which discharge is taking place. In order to get as great capacity as possible per unit volume, the effective surface of the plates is increased by cutting or casting grooves and ridges in the plates and by laminating. Batteries of any capacity are obtained by putting additional plates in the same cells and connecting all positive plates together and all negative plates together. The volts per cell, however, are the same irrespective of the size of the plates or the number connected in parallel, the total voltage required being obtained by connecting cells in series.

The capacity of a battery will vary with the temperature, increasing as the temperature of the electrolyte rises. The change per degree varies with the type of battery. The capacity is greater with currents below the normal rate and smaller with currents above the normal rate. Lyndon gives the following approximate figures for the capacity of lead batteries at high rates: 200% normal rate, 75% normal capacity; 300% normal rate, 58% normal capacity; 400% normal rate, 50% normal capacity.

Rating. The standard method of rating a storage battery is the current which it will give continuously during 8 hours for stationary batteries, and 5 hours for vehicle batteries. Automobile lighting and starting batteries are rated on two bases. One, the lighting rating, is the ampere-hour capacity obtained when discharging at 5 amperes; the other, the starting rating, is the current the battery will deliver continuously for 20 minutes.

Voltage. During discharge at normal rate the voltage of a lead battery falls rapidly at first from about 2.10 or 2.15 to 2.0 volts per cell, and then drops slowly to 1.90 or 1.85 volts. Beyond this point the voltage drops rapidly. In order to maintain constant voltage on a load being supplied by a battery **end cell switches** are often used by means of which an additional cell is cut in when the total voltage drops 2 volts.

Efficiency. There are two efficiencies of storage batteries, the watt-hour and the ampere-hour. **Watt-hour efficiency** is the ratio of the total energy delivered during discharge to the total energy received during charge. **Ampere-hour efficiency** is the ratio of the product of amperes and hours during discharge to that of amperes and hours during charge. The watt-hour efficiency of lead batteries averages 75 to 80% and the ampere-hour efficiency about 85 to 90%.

Application. Storage batteries are used extensively in a great variety of applications—railway and other signalling purposes, automobile propulsion, automobile starting and lighting, railway train lighting, emergency lighting, etc. All modern power plants use storage batteries as a source of power for operating switches which is independent of the system power.

They are used in connection with the power supply developed in power plants of all sizes. In small, isolated, or private plants, a battery is often used to carry the load during parts of the day when the load is too small to warrant running a generator. In the largest direct-current central stations and substations, large batteries are often installed for the sole purpose of carrying the load in case of an accident necessitating the shutting down of the regular source of power. Such a battery is designed to deliver very large currents for short periods of time. It is often connected across the buses all the time, so that it will deliver current automatically when the bus voltage falls below the normal value.

Care. Storage batteries require intelligent care and use if reasonable life is to be obtained. High rates of charge and discharge, repeated discharging to voltage below 1.70 volts per cell, and charging longer than necessary will rapidly disintegrate the active material and decrease the life. The specific gravity should be kept within the proper limits, the battery should be charged immediately after discharge, and should be charged at occasional intervals when not in regular use.

The most reliable indication of the state of charge or discharge is the specific gravity. hence in large plants readings of the specific gravity are taken at frequent intervals on certain representative cells called pilot cells. Autographic hydrometers have been devised which indicate and record the specific gravity at a point some distance from the cells, as for instance the switchboard.

Cost and Depreciation. The cost of stationary type storage batteries, installed, depends on the size and particularly the kind of service. For continuous service involving frequent discharging, a long life battery with heavier plates and therefore more expensive may be the most economical. On the other hand for infrequent demands, the lighter plate battery with high discharge capacity and shorter life, but cheaper, may be the more economical. Costs will range from about $1.25 per ampere per cell for small batteries of 5 amperes capacity to order of $1.00 for 500-ampere batteries. The cost will decrease slightly with larger capacities. Small portable batteries cost from $4 or $5 to $1.00 per ampere per cell. The depreciation of batteries varies enormously with the care and amount of use which they receive. The rate of depreciation for stationary batteries varies from 8 to 15% and for vehicle batteries from 20 to 50% per year.

The Edison Battery is an alkaline storage battery quite extensively used for vehicle and other purposes where weight is specially important. The elements are nickel and iron, and the electrolyte is sodium hydrate. It is considerably lighter than a lead battery and, according to the manufacturers, requires less care and attention and has a considerably larger life. On the other hand it is considerably more expensive. The output per pound of cell is about 2.5 watts and 16 watt-hours, compared with about 1.25 watts and 12 watt-hours respectively for the vehicle-type lead battery. The efficiency of the Edison battery is, however, lower than that of the lead battery by about 15 to 20%.

SECTION 6

SURVEYING, GEODESY, RAILROAD LOCATION

BY

CHARLES B. BREED

PROFESSOR OF RAILWAY AND HIGHWAY ENGINEERING IN MASSACHUSETTS INSTITUTE OF TECHNOLOGY

* By George L. Hosmer, Professor of Geodesy in Massachusetts Institute of Technology.

INSTRUMENTS and MAPS

1. Chains and Tapes

The Engineer's Chain has 100 links, each one foot long. Gunter's chain, formerly much used in land surveys, is 66 ft. in length and has 100 links, each 7.92 in. long. The metric chain is 20 meters in length and has 100 links, each 20 cm. long.

Each end link is provided with a handle, the outside edge of which is the zero point. Every tenth link counting from either end is marked by a brass tag having one, two, three or four points on the tag corresponding to the number of tens of links it marks; the middle of the chain is marked by a round tag. The long links are connected by two short links for flexibility. This introduces about 600 wearing surfaces which causes the chain to lengthen with use. All chains should therefore be frequently compared with a Standard; the length is adjusted by means of a screw and nut in one handle which allows the length of the end link to be changed, thus putting all of the error in length into the end link. Chains have been quite generally displaced by the heavy steel tapes, which will stand rough usage and are not subject to change of length from wearing.

Cloth, Metallic, and Steel Tapes are in common use. Cloth tapes stretch so readily that they are useless for surveying. Metallic tapes are cloth tapes with fine brass wires woven into them to prevent stretching. They are usually graduated into feet, tenths, and half-tenths and are made in lengths of from 25 ft. to 100 ft. It is not uncommon for metallic tapes when subjected to rough usage and to alternate wetting and drying to become 0.2 to 0.5 ft. in error in a length of 50 ft. Metallic tapes should not be used except for measurement of short lines where great precision is not required.

Steel Tapes may be obtained in lengths up to 500 ft., but the most common lengths are 50 ft., 100 ft., 200 ft. and 300 ft. The shorter tapes are usually made of thin ribbons of steel; the longer tapes are made heavier in cross-section so that they will withstand rougher usage and will not become kinked so readily. The light tapes are graduated throughout their length into feet, tenths, and hundredths; the heavier tapes are generally marked only at every foot, the first and last foot being divided into tenths; sometimes it is an additional foot beyond the zero point that is divided into tenths. In most tapes the zero point is at the outer edge of the ring attached to the end of the ribbon of steel; some tapes are graduated so that the zero point comes on the tape 0.2 or 0.3 ft. from the end ring. Light tapes are not conveniently handled in rough work; they become easily kinked and broken, but can be mended by riveting to the back of the tape a piece of an old tape of the same width. A new tape is considered to be ot standard length by the U. S. Bureau of Standards at 68° F. with a pull of 10 lb. and supported throughout its length. Although the steel tape varies in length slightly with variations in temperature and pull, still in much of the work of surveying it is accurate enough to use it without regard to its change in length, and for surveys which require great accuracy the change in length can be determined and proper corrections applied to measured distances.

Special steel tapes fitted with a thermometer and with a spring-balance handle for registering the amount of pull can be obtained from the manufacturers, also tapes graduated in feet and inches for use in building construction. Pocket Steel Tapes from 3 ft. up are very useful in the field.

Tapes made of nickel steel, called "Invar" tapes, change in length only slightly with change in temperature. See Art. 13.

Steel tapes are broken usually by jerking them when they are looped or kinked or by stepping on them or allowing a vehicle to pass over them in soft ground. A tape properly cared for to prevent rusting and kept intact will last until the graduations are worn off.

To change measurements recorded in tenths and hundredths of a foot into inches and fractions, the following equivalents may be used:

Decimal of Foot =	.01	.08	.17	.25	.50	.75
Inches =	1/8−	1−	2+	3	6	9

If these values are memorized, decimals of a foot may be quickly transposed into inches as follows: 0.44 ft. = 0.50 ft. − 0.06 ft. = 6 in. − 3/4 in. = 5-1/4 in.

The Odometer is an instrument attached to a wheel of a vehicle which records the number of revolutions the wheel makes in traversing between two given points. If the circumference of the wheel is known the approximate distance can be computed. Since the wheel travels on sloping roads in hilly country the distances recorded may be slightly larger than horizontal distances.

The Pedometer is an instrument which records the number of steps of a walker carrying it. A modern form records the distance traversed by a person carrying the pedometer, after it has been adjusted for the length of pace of the walker.

2. Verniers

The Vernier is a device for determining the subdivision of the smallest division of a scale more accurately than can be done by simply estimating the fractional part. Its accuracy depends upon the fact that one can judge more accurately when two lines coincide than he can estimate a fractional part of a space. The simplest form of vernier (Fig. 1) is used on some kinds of leveling rods. It is constructed by making the entire length of the vernier equal the length of 9 divisions on the scale, and subdividing this vernier length into 10 equal parts. In this way one division on the vernier equals 9/10 of a division on the scale, so that *ab* is 1/10 and *cd* is 2/10 of a scale division. If the vernier is raised until *a* becomes opposite *b* then the reading will be 701; if raised until *c* comes opposite *d* the reading is 702. The number of the line on the vernier that coincides with some line on the scale is the number of tenths of the smallest division on the scale that the index point lies above the scale division just below it.

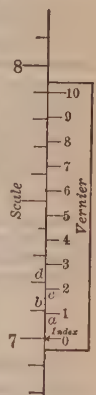

Fig. 1

Transit Verniers are usually made double, one on each side of each index, so that angles can be read in either direction. For transits reading to minutes the vernier scale is made by dividing a space equal to 29 half-degrees of arc into 30 parts, so that the difference in length of one division of the circle and one division of the vernier is equal to one minute of arc. If the vernier is placed so that its zero point (or the index) coincides with the 0° mark on the circle, then the first lines on either side of the zero of the vernier will fail to coincide with the corresponding lines on the circle by just one minute, the second lines on each side of the zero of the vernier will fail to coincide with their corresponding marks on the circle by just 2 minutes, and so on. If the vernier is moved along the circle so that the first line next to the zero of the vernier exactly coincides with its corresponding line on the circle the reading will be 0° 01′; and if the vernier is moved one minute more the second lines will coincide and the reading will be 0° 02′. Therefore in reading an angle on a transit, read the position of the vernier index on the circle, reading the angle in the same direction that the telescope has moved and estimate roughly the number of minutes the index has passed over from the graduation next back of it on the circle, then follow along the vernier in the same direction and find the vernier line which coincides with some line on the circle and add the number of this line to the circle reading. Thus, Fig. 2 represents a one-minute transit circle with double vernier which reads, if the telescope (which always moves with the vernier) has moved clockwise, 274° 23′. If it has moved anticlockwise it reads 85° 37′. For a one-minute instrument the circle is divided into 30′ spaces and there are 30 divisions on the vernier; a 30-second instrument has the circle divided into 20′ spaces with 40 divisions on the vernier; a 20-second instrument has the circle divided usually into 20′ spaces with 60 divisions on the vernier;

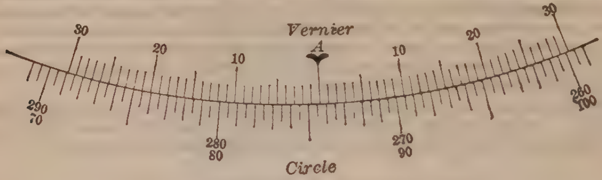

Fig. 2. Transit Circle with Double Vernier

and a 10-second instrument has the circle divided into 10′ spaces with 60 divisions on the verniers.

Single Verniers which are to be read in either direction must be numbered from both ends, and the index at either one end or the other is set at 0° on the circle depending upon which direction the angle is to be measured. These single verniers are used on transits reading to 10 seconds or 20 seconds where a double vernier would be so long as to interfere with the standards. Another type of single vernier called the **folded vernier** is sometimes used on the vertical circle of transits and on alidades of plane tables. It is like any single vernier except that the index is the middle division of the vernier. In reading it, if a coincidence is not reached by passing along the vernier in the proper direction, it is necessary to pass to the other end of the vernier and continue in the same direction, toward the center, until the coincidence is found.

Retrograde Vernier. The verniers described above are all **direct** verniers in which the smallest division of the vernier is smaller than the smallest division of the circle. The **retrograde** vernier is one in which the smallest division of the vernier is larger than the smallest division of the circle. It is seldom used on surveying instruments.

3. The Compass

The Surveyor's Compass is an instrument for determining the difference in direction between any horizontal line and a magnetic needle. The needle is balanced on a pivot in the center of a compass-box so that it can swing free in a horizontal plane, the pivot being the center of a circle which is graduated usually to half-degrees and numbered from 0° to 90° in both directions from the N and S end of the compass-box. The pivot and the circle are secured to a brass frame on which are two vertical sights placed on the line passing through the pivot and the N and S points of the compass-box. When not in use the needle should be kept raised from the pivot by the screw and the lever provided for that purpose so as not to dull the pivot-point. The compass is connected to the tripod by a ball-and-socket joint which is clamped in position after the instrument has been leveled by means of two spirit levels attached to the frame at right angles to each other. The frame has a spindle which fits into the ball-and-socket joint so that after the instrument has been leveled it can be swung around in a horizontal plane. Since in the northern hemisphere the N end of the needle if not counterbalanced would dip downward, a little counterweight is attached to the S end of the needle.

To Use the Compass it is first set up over the proper point and leveled, and then sighted along the line whose direction is desired. Since the needle stands still and the box turns under it, the letters E and W on the box have been reversed from their natural position so that the reading of the needle will give the proper quadrant. To obtain the **bearing** of the line in the direction it is sighted it is important to follow this rule: When the N point of the compass-box is toward the station whose bearing is desired, read the N end of the needle (the end to which the counterbalance is not attached in northern hemisphere). When the S point of the box is toward the station, read the south end of the needle. The term " station " as here used means any point on the survey line. Bearings are usually read to the nearest quarter of a degree. The bearing looking in the opposite direction along the line is called the **reverse bearing.** To avoid a parallax error the needle should be read by looking along the needle, not across it.

Precautions. Before the bearing is read the glass should be tapped lightly over the end of the needle to be sure that it is not touching the under side of the glass. If the needle appears to cling to the glass it probably indicates that the glass has become electrified, and this difficulty can be removed by placing the moistened finger on the glass.

In the use of the compass great care should be taken that no iron or steel is near the instrument to attract the needle from its true position. The chain, pins, ax, pocket knife, iron wire in a stiff hat are fruitful sources of errors. Electric currents affect the needle so seriously that it is of little use in cities for obtaining even an approximate magnetic meridian. It is customary to take the forward and reverse bearing of lines so that any local attraction of the needle may be detected. If the bearing of AB taken from Station A and the bearing of BA from Station B do not agree it indicates that at either A or B there is local attraction. To determine at which station it exists, take the bearing of BC with the compass at B, and then with the compass at C determine the bearing of CB. If these agree it indicates that there is no local attraction at B.

Adjustments of the Compass. (1) The bubbles are adjusted like those on the horizontal plate of a transit (Art. 4). (2) Straightening needle and centering pivot-point: Bent needle may be detected by reading both N and S ends when N end is held opposite a given graduation, and then by reading both ends again when S end is held opposite same graduation; take needle out and bend it with pliers at the middle until the end reads the same in either position. Pivot may be centered by finding (by trial) position of maximum difference between end readings on different parts of the circle, and then bending pivot so that end readings agree. (3) Remagnetizing needle: rub with a bar magnet from center toward ends, using N end of magnet for S end of needle, and vice versa.

The Pocket Compass is a hand instrument for obtaining roughly the bearing of a line. There are two kinds, the **plain** and the **prismatic**. The former is much like the the surveyor's compass, except that it has no sights. In the prismatic compass the graduations, instead of being on the compass-box, are on a card which is fastened to the needle (like a mariner's compass) and which moves with it. This compass is generally provided with sights. The bearing can be read, by means of a prism, at the same instant that the compass is sighted along the line.

4. The Transit and Its Adjustments

The Engineer's Transit, a view of which is shown in Fig. 3, has two spindles one inside the other, to each of which is attached a horizontal circular plate, the outer spindle being attached to the lower plate and the inner one to the upper plate. Attached to this upper plate are two standards supporting the horizontal axis of the telescope. The motion of this horizontal axis and of the two spindles is controlled by clamps and slow-motion (tangent) screws.

On the upper plate are two spirit-levels, which are used in leveling the instrument. Most transits have four leveling screws; but those made for triangulation work usually have only three. When the instrument is provided with a telescope bubble and a vertical arc it is called an **Engineer's** (or **Surveyor's**) **transit**; if it does not have these attachments it is called a **plain transit.**

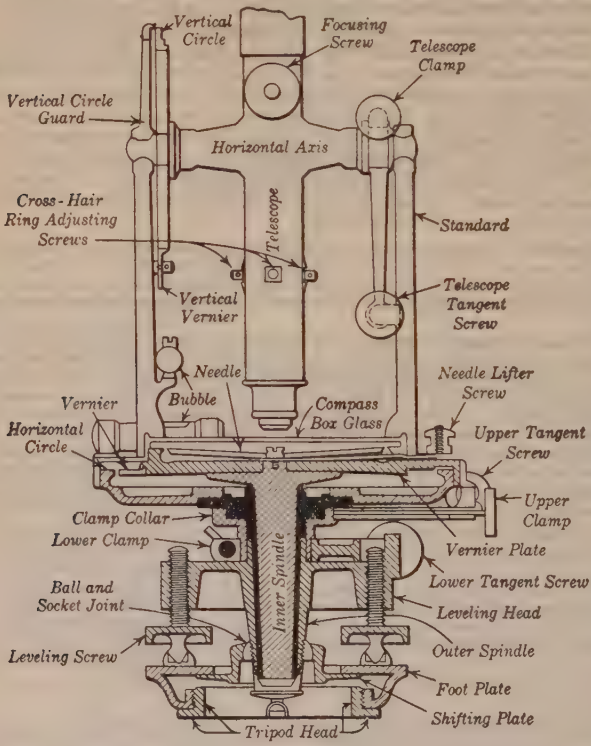

Fig. 3

The **Telescope** has two lenses cemented together for its objective, and an eyepiece of four lenses if the instrument is an erecting transit, two lenses if inverting. An inverting instrument gives a much more illuminated field. Between the objective and the eyepiece is the cross-hair ring. The objective is moved away from or toward the cross-hair to focus. There is a growing tendency (prevalent in Europe) toward the use of an interior system of focusing, which was introduced as "Porro's Telescope." This has a movable lens or lenses between the object glass and cross-hair, thus making the telescope barrel dust-proof; the stadia constant is zero. Its disadvantage lies in the fact that the additional lenses cut out light and the adjustment is not so completely in the hands of the operator. The **line of sight,** or **line of collima-**

tion, is the straight line drawn through the optical center of the objective and the point of intersection of the cross-hairs. **Focusing** is the adjustment of the eyepiece and of the objective so that the cross-hairs and image of the object can be clearly seen at the same time. The **magnifying power** of a telescope is the amount by which an object is increased in apparent size. It is equal to tan $1/2\ A$/tan $1/2\ a$ (or nearly A/a), A being the angle subtended by the object as seen through the telescope and a the angle as seen by the unaided eye. It may be found approximately as follows: Hold a rod a short distance from the instrument and view it through the telescope with one eye; at the same time look at it directly with the other eye. It will be noticed that one space as viewed through the telescope will appear to cover several spaces as seen with the naked eye. This number is approximately the magnifying power of the telescope.

Common Special Attachments are: (1) Diagonal or prismatic eyepiece for sighting high altitudes. (2) A reflector attached to the telescope for illuminating the cross-hairs when working in the dark. (3) A gradienter screw for measuring rates of grades directly. (4) Stadia hairs, which are two extra horizontal cross-hairs used in measuring distances by stadia. (5) Solar attachment, for determining a meridian by observation on the sun.

By Observing a Few Important Precautions much of the wear of instruments and accidents to them can be avoided. Neither the tripod legs nor the shoes should be allowed to become loose. In taking the instrument out of its box always lift it by placing the hands beneath the leveling base. When about to move the transit from one point to another be sure that the four leveling screws are properly bearing, that the needle is lifted, and that the clamps are set just firmly enough so that any slight shock will allow motion. A waterproof bag should be carried at all times to cover the instrument if it rains or when the instrument is exposed to dust. When the transit must stand out in the rain the cap should be put over the object glass; if water should get into the telescope, take out the eyepiece, cover the open end of telescope tube with cloth, and allow it to dry out. Any parts of the instrument that have been wet should be wiped dry, especially the vertical arc, but be careful not to touch the edges of the arcs. One should always avoid placing the hands on exposed graduations, as it will tarnish the metal. In cleaning the lenses use a fine camel-hair brush, and for screw threads use a stiff tooth brush and apply a very little watch oil after cleaning, but do not apply oil to exposed screws.

Important Adjustments of the Transit are: (1) to make the plane of the plate bubbles perpendicular to the vertical axis of the instrument. (2) To make the line of sight perpendicular to the horizontal axis. (3) To make the horizontal axis perpendicular to the vertical axis of the instrument. These three adjustments are made to depend on the principle of reversion, the effect of an error being doubled by a reversal of the instrument. Each adjustment should be repeated to test its accuracy.

(1) **Adjustment of the Bubble Tubes.** Bring plate bubbles in center of respective tubes by means of leveling screws. Turn 180° in azimuth; half the apparent error in bubbles is the rear error; so bring bubble half-way back by screws on the bubble tubes. Adjust each bubble independently.

(2) **Adjustment of the Line of Sight.** First adjust the vertical cross-hair so it will lie in a plane perpendicular to the horizontal axis. Set up and level the instrument. Leveling the instrument is not necessary for this part of the adjustment, but as it is an essential part of the second portion of this adjustment it is well to level at this time. Sight the vertical hair on a well-defined point, clamp both plates, rotate telescope about horizontal axis. If point does not appear to travel along the vertical cross-hair, loosen screws holding cross-hair ring, and by tapping lightly on one screw, rotate ring until

above condition is fulfilled. Then tighten screws and proceed with the second part of the adjustment as follows: sight telescope at point A (200 to 300 ft. away), and clamp vertical axis; revolve telescope on horizontal axis and set a point B in line of sight and same distance approximately from instrument as A but in the opposite direction. Points A and B should be at about the same elevation. Loosen clamp, turn in azimuth and sight A again, clamp, revolve telescope on horizontal axis and set point C in line of sight beside point B. Mark or note a point D one-fourth the distance between C and B measured from C. To adjust, move the cross-hair ring until D is sighted by loosening the screw on one side of the telescope and tightening that opposite. If the transit has an erecting eyepiece move the ring in the direction D to C; if an inverting eyepiece, move ring in the same direction C to D.

(3) **Adjustment of the Standards.** Set up and level the transit. Sight on some high point A and clamp vertical axis. Lower telescope and set point B in line of sight about level with telescope. Reverse telescope and turn in azimuth 180° and sight on B and clamp. Raise telescope until point A is visible and note point C in line of sight and at same height at A. If C does not fall on A, loosen pivot cap screws at adjustable end of horizontal axis and raise or lower the end of the axis by means of capstan-headed screw under axis. The adjusting screw should be brought into position by a right-hand turn, otherwise the block on which the horizontal axis rests may stick and not follow the screw. The cap screws should then be tightened just enough to avoid looseness of the bearing.

If the instrument is badly out of adjustment it is better to bring it as a whole gradually into adjustment rather than to attempt complete adjustment of one part at a time. In this way the adjustment of any part will not disturb the preceding adjustments, the parts are not subjected to strains, and the instrument will remain in adjustment longer.

To Adjust the Vernier of the Vertical Circle so it will read 0° when the telescope bubble is in the center, loosen the screws holding the vernier, and tap lightly until the zeros coincide. This adjustment eliminates index correction in measuring vertical angles, provided the line of sight is parallel to the bubble tube.

To Adjust the Objective Slide so it will move parallel to the line of sight. Adjust the line of sight as described under (2) above, but use very distant objects, then repeat this same adjustment using points very near by, and if in this last test there is an apparent error, it indicates that the objective slide does not move parallel to the line of sight. The adjustment is made by moving the adjusting screws of the objective slide so as apparently to increase the error by one-quarter of the apparent error. Then test adjustment of line of sight again by using distant points. The adjustments of the objective slide—centering the eyepiece tube, centering the circles—are usually done by the instrument makers.

To Eliminate Effects of Errors in Adjustment and still obtain accurate results the instrument must be used as follows. To avoid errors in the plate bubble, level up, turn 180° in azimuth and bring bubbles half-way back by means of leveling screws. This makes the vertical axis truly vertical, and the bubbles should remain in the same parts of their respective tubes as the instrument is turned about the vertical axis. Errors in light of sight and horizontal axis are avoided by using the instrument with telescope in its direct and then in its reversed position and taking the mean of the results, whether the work is running lines or measuring angles. Errors of eccentricity are eliminated by taking the mean of the readings of the two opposite verniers, and errors of graduation of the circle are nearly eliminated by reading the angle in different parts of the circle or by measuring the angle by repetition. Where only one vernier is read in determining an angle always read the one that was set.

5. The Solar Attachment

The Solar Attachment is a small instrument which is sometimes attached to a transit and with which a true meridian can be established by observation on the sun. The commonest form of solar attachment (**Saegmuller's**) consists of a small axis called the polar axis attached at right angles to the telescope and to its horizontal axis; on this axis is mounted a small telescope. Another form of solar attachment (**Burt's**) has the small telescope replaced by a lens and a screen on which the sun's image can be thrown. This instrument is provided with a special arc for setting off the sun's declination.

Astronomic Terms. In Fig. 4, which represents half of a celestial sphere, the circle $NWSE$ is the observer's horizon, $SZPN$ is the observer's meridian

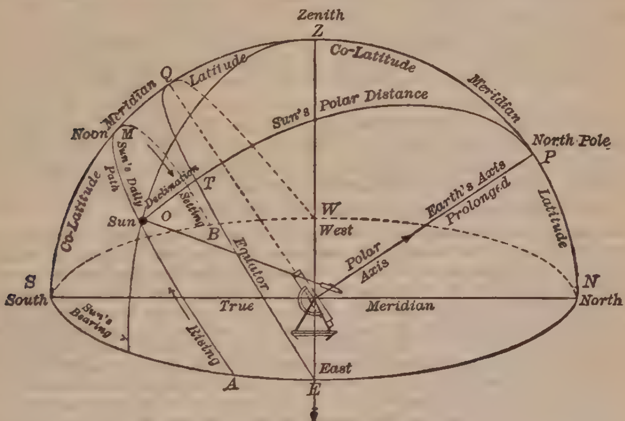

Fig. 4. Celestial Sphere

(a vertical circle through the pole, P). The circle EQW is the celestial equator, and AMB, parallel to the equator, is a parallel of declination, or the path of the sun on a certain day. The sun's **declination** is its angular distance north or south of the equator, or arc OT; it is + when north and − when south. The **polar distance** of the sun is the complement of the declination, the arc OP; when the declination is minus (in winter) the polar distance is more than 90°. If the polar axis points toward the pole, the small telescope can be made to following the sun's daily path by giving it an inclination to the polar axis equal to the sun's polar distance and then revolving it about the polar axis.

To Find the True Meridian by an observation on the sun with a Saegmuller solar: (1) Make the angle between the polar axis and the solar telescope equal to the sun's polar distance at the time of the observation. This is done by turning the solar telescope into the same plane as the main telescope by sighting both on some distant object, and then making the angle between the two telescopes equal to the sun's declination. Incline the main telescope until the reading of the vertical circle equals the declination, and clamp; then level the solar telescope by means of the attached level. The angle between the polar axis and the solar telescope is then 90° plus or minus the reading of the vertical circle.

(2) By means of the vertical circle of the transit incline the polar axis to the vertical by an angle equal to the colatitude of the place, which is 90° minus the latitude. The polar axis will then have the same angle of elevation as the celestial pole.

(3) If the observation is in the forenoon, place the solar telescope on the left of the main telescope (on the right if in the afternoon); then, by moving the whole instrument about the vertical axis and the solar telescope about the polar axis, point the solar telescope at the sun. The sun's image is brought to the center of the square which is formed by four cross-hairs in the solar telescope. The final setting is made by the tangent screw controlling the horizontal motion of the transit and the one controlling the motion of the solar about the polar axis. Only one position can be found where the solar telescope will point to the sun. In this position the vertical axis points to the zenith, the polar axis to the pole, and the solar telescope to the sun. Since the solar telescope is pointing to the sun the main telescope must be in the plane of the meridian. If all of the work has been correctly done it will be observed that the sun's image will remain between the cross-hairs set parallel to the equator, and therefore the sun can be followed in its path by a motion of the solar telescope alone revolving about the polar axis. If it is necessary to move the instrument about the vertical axis to point the solar telescope again at the sun, this shows that the main telescope was not truly in the meridian. For good results observations should not be made near noon, or near sunrise or sunset when the altitude is less than 10°.

The Sun's Polar Distance may be obtained from the "American Ephemeris and Nautical Almanac," published by the Government. The polar distance is not given directly, but its complement, the sun's "apparent declination," is given for each day and for the instant of 0^h or Greenwich mean midnight. The rate of change of the declination, that is, variation per hour, is also given. In order to use these data for any given locality, it is first necessary to find the local or the standard time corresponding to midnight (0^h) at Greenwich. In the United States, where standard time is in use, the relation to Greenwich time is simple. In the Eastern time belt the time is exactly 5 hours earlier than at Greenwich; in the Central belt, 6 hours earlier; in the Mountain belt, 7 hours earlier; and in the Pacific belt, 8 hours earlier. If a certain declination corresponds to 0^h Greenwich time, the same declination corresponds to 7^h p.m. in the Eastern belt, 6^h p.m. in the Central, etc., of the preceding date. The declination for any other hour in the day may be found by applying the "variation per hour" multiplied by the number of hours from 7^h p.m. (or 6 p.m., etc.). Declinations marked North must be regarded as positive and those marked South as negative. An examination of the values of the declination for successive days will show which way the correction is to be applied. It will be useful to remember that the declination is 0° about March 21, and increases to about June 22, when it is approximately 23° 27′ North; it then decreases, passing the 0° point about September 22, until about December 21, when it is approximately 23° 27′ South; it then goes North and is again 0° on March 21.

Atmospheric Refraction. After the correct declination is found it has still to be corrected for refraction of the atmosphere. The effect of refraction is to make the sun appear higher up in the sky than it actually is. In the northern hemisphere, when the declination is North this correction must be added, when South, subtracted; or algebraically it is always added. The amount of refraction can readily be found by **Comstock's method** as follows. Set the vertical hair on one edge (or limb) of the sun and note the instant by a watch. Set the vernier of plate 10′ ahead and note the time when the same edge meets the cross-hair. If n is the number of seconds of time between the observations and h is the altitude in degrees, then the refraction in minutes equals $2000/hn$ approximately.

The Colatitude which must be set off on the vertical circle may be obtained from a map, or may be determined by an observation as follows. Set off the sun's declination for noon, as for any other observation, the two telescopes being in the same vertical plane, and point the small telescope at the sun. By varying the angle of elevation of the main telescope, keep the solar telescope pointing at the sun until the maximum altitude is reached. The angle read on the vertical circle is the colatitude. This observation necessarily comes near noon, but in order to be sure of the maximum altitude it is necessary to begin the observation some time before noon, for the maximum does not occur at exactly apparent noon because the declination is continually changing, the interval between apparent and Standard noon may not be known, and the watch may not be exactly right.

6. The Level and Its Adjustments

A Level Instrument is a telescope with a delicate spirit-level attached to it so that when the bubble is in the center the line of sight is horizontal, or tangent to a level surface, which is a curve every point of which is perpendicular to the direction of gravity. The two common types are the **wye** and the **dumpy** levels. In both of these instruments the telescope is mounted on a vertical axis about which the telescope can swing, and is leveled by means of four leveling screws.

In the Wye Level the spirit-level is attached to the telescope which rests in two Y-shaped supports, which in turn are fastened to a horizontal bar to which the vertical axis is attached. The telescope can be taken out of the Y's, turned end for end and replaced, when testing the bubble for adjustment.

The Dumpy Level has its vertical axis, the horizontal bar and the supports of the telescope all in one piece, to which the spirit-level is attached. The dumpy level will stand much rougher usage than the wye level, has fewer wearing parts and allows fully as precise work. Practically the only advantage the wye level has over the dumpy is that the adjustment of the line of sight can be a little more conveniently tested. The precautions in use of the level and its care are similar to those described for the transit in Art. 4.

The Locke Hand Level is simply a metal tube with plain glass covers at its ends and with a small spirit-level on top. When looking through the tube the bubble is seen on one side of the tube in a mirror through a lens; on the other side the landscape is viewed. When the bubble is in the center of the tube the observer can note where the horizontal line which appears in the center of the bubble tube cuts a rod and in this way do approximate leveling (see Art. 28).

Principal Adjustments of the Wye Level are: (1) to make the line of sight coincide with the axis of the pivots, or parallel to it. (2) To make the line of sight and axis of bubble tube parallel. (3) To make the axis of the bubble tube perpendicular to the vertical axis. As in the transit instrument, most of the adjustments depend upon the principle of reversion.

(1) **Adjustment of Line of Sight.** First make the horizontal cross-hair truly horizontal when the instrument is level. This adjustment is tested by sighting, after leveling, on a point and noting if the cross-hair appears to remain on the point as the telescope is revolved about its vertical axis. If an adjustment is necessary it is done by rotating the cross-hair ring as described in the case of the second adjustment of the transit. After this adjustment is made loosen the clips which hold the telescope in the wyes. Sight the intersection of the cross-hairs at a point and clamp. Rotate the telescope 180° in wyes. If the cross-hairs do not remain on the point they must be moved half-way back to the point by means of screws on the cross-hair ring, each cross-hair being adjusted separately by means of its proper ring screws.

(2) **Adjustment of Bubble by Indirect Method.** Bring the bubble in the center of its tube and clamp in that position. Rotate telescope in wyes a few degrees around its horizontal axis; if the bubble moves, correct the entire

error by means of the horizontal capstan screws at one end of the bubble tube. Then clamp the telescope over the pair of leveling screws and bring the bubble into the center of the tube, lift the telescope from the wyes, turn it end for end, and replace in the wyes without jarring the instrument. Correct half the apparent error by the vertical adjusting screw of the bubble tube.

(3) **Adjustment of the Wyes.** Level the instrument, then bring the bubble exactly to the middle over a pair of leveling screws. Then turn the telescope 180° about its vertical axis and correct half the apparent error by means of the adjusting screw of the wye support. Since the bubble is brought to the center of the tube at each rod-reading this last adjustment in no way affects the accuracy of the leveling work but is a convenience.

The Adjustments of the Dumpy Level are the same in purpose as for the wye level, but are, owing to the construction of the instrument, done in a different order and by a different procedure in some cases. They are: (1) To make the horizontal cross-hair truly horizontal when the instrument is level. (2) To make the axis of the bubble tube perpendicular to the vertical axis. (3) To make the line of sight parallel to the axis of the bubble.

(1) **The Adjustment of the Cross-hairs** is done as described under the first adjustment of the wye level.

(2) **Adjustment of Bubble Tube.** Level the instrument and carefully center the bubble over a pair of leveling screws. Turn the telescope 180° in azimuth and correct half the apparent error in the bubble by means of the adjusting screws of the level tube.

(3) **Adjustment of Line of Sight by Direct or "Peg" Method.** Select points A and B 200 ft. or more apart. Set up the level beside A so that when a rod is held on A the eyepiece will swing and just clear the rod. Look through the telescope wrong end to at the rod and find the reading opposite the center of the field. Turn the telescope toward B and take a rod-reading in the usual manner, being sure that the bubble is in the middle of the tube. Then set up the level at B and repeat the above operation. These two sets of observations give two independent determinations of the difference in elevation between the two points. The true difference in elevation is the mean of these two results. Leaving the instrument at B, set the rod at A so that it will read the height the instrument is above B plus or minus the true difference in elevation between A and B. Then if the level is sighted on the target of the rod it will define a level line. While the bubble is in the center of its tube the line of sight should be brought to coincide with the target by moving the cross-hair ring by means of its adjusting screws. The following example illustrates the method:

Instrument at Sta. A		Instrument on Sta. B	
Rod-reading on Sta. A	= 3.971	Rod-reading on Sta. B	= 5.064
Rod-reading on Sta. B	= 4.937	Rod-reading on Sta. A	= 4.036
Diff. in elev. of A and B	= 0.966	Diff. in elev. of B and A	= 1.028

Mean of two diff. in elev. = 1/2 (0.966 + 1.028) = 0.997, true diff. in elev.
Instrument is now 5.064 above Sta. B.
Rod-reading on Sta. A should be 5.064 − 0.997 = 4.067 to give a level sight.

This "peg" adjustment may be used for adjusting the line of sight of the wye level except that in the wye level after the target at A has been set at the correct elevation to define a level line the line of sight is made to coincide with the target by means of the leveling screws and then the bubble is brought to its mid position by means of its adjusting screws. This "peg" adjustment is also used for the hand level. In using the "peg" method for transits the adjustment may be made either by moving the cross-hair ring or by moving one end of the level tube. If the cross-hair is moved the adjustment of the line of collimation must be tested; if the bubble tube is moved the vertical arc must be adjusted.

To eliminate the effect of errors in adjustment of the line of sight, of the bubble tube or the wyes the observer must be sure that the bubble is in the center of the tube at the instant that the rod is read, and the length of the backsights and foresights should be made equal.

7. Leveling Rods

Two General Types of Rods, target and self-reading, are in common use. The **target** rods are read only by the rodman, while the **self-reading** rods are read directly by the level man. The commonest forms of target rod are the Boston, the New York and the Philadelphia rods; the latter may be used also as a self-reading rod.

The Boston Rod is an extension target rod made of two strips one of which slides in a groove in the other, and provided with clamps to hold the two parts in any desired position. There is a scale on each side of the rod graduated to hundredths of a foot, each scale being provided with a vernier for reading to thousandths of a foot. The target is fastened to one of the strips, the other one is held on the ground and the target strip raised to the proper reading, the highest reading being 5.8 ft.; these are called "short rod-readings." For "long rod-readings" the rod is turned end for end and the target strip is raised, its highest reading being 11.4 ft. A serious objection to this kind of rod is that in reversing it any error in the position of the target with reference to the zero of the scale is doubled.

The New York Rod has two strips arranged similarly to those of the Boston rod, but the circular target is movable and for short rod the target is moved up and down on the rod, the scale graduated to hundredths being in the face of the rod; it is read by means of a vernier on the target. The scale for long rod is on the side of one of the strips and the vernier is on the other strip. When used as a long rod the target is clamped to the face of the rod at the reading corresponding to the lowest reading on the side scale; then the target is raised just as in the Boston rod.

The Philadelphia Rod is marked on its face throughout its entire length (extended) with red numbers to designate the feet and black numbers for the tenths so that it can be used as a self-reading rod. The red figures are 0.1 ft. high and the black figures 0.06 ft. When it is used as a target rod, it is operated just as the New York rod; the only difference being that the short scales at the center of the metal target and on the back of the rod (for long rod-readings) are not verniers, but these scales are graduated to 0.005 ft. and are used in estimating the readings to thousandths of a foot.

Special Designs of self-reading rods are in use, the figures on the face being as a rule made of some definite height (0.06 or 0.08 ft.) and of a thickness of 0.01 or 0.02 ft. to aid in estimating the readings. Some of these rods are in three parts, giving an extended length of 16 ft. In nearly every respect self-reading rods are preferable to target rods.

The Tape-rod is a wooden rod made in one piece with a metal roller near each end around which is a continuous movable steel band 20 ft. long and about 0.1 ft. wide, on the outside of which the scale is painted so that it can be used as a self-reading rod; the band has a clamp to fasten it to the rod at any desired position. Unlike the ordinary rod the scale reads down instead of up. In using this rod the band is set so that the level sights the reading of the elevation of the bench-mark. For example, if the B.M. elevation is 142.36 the band is moved and clamped so that the level sights 12.36 on the scale. When the rod is held at any other point the rod-reading plus 130 gives the elevation of the point. Such a rod is of great convenience in cross-section work.

Self-reading rods for Precise Leveling are used by the U. S. Coast and Geodetic Survey and are made of single pieces of wood soaked in paraffin to prevent changes in length due to moisture; they are made in the form of a + or a T in cross-section. The graduations are marked in the metric system on a strip of invar metal attached to the face of the rod (Art. 25). For plumbing the rod in precise work special devices are used such as spirit-levels attached to brass angles or watch levels held on the corner of the rod.

8. Drafting Instruments and their Uses

It is assumed that the reader is familiar with the ordinary drafting instruments; only a few of the more uncommon will be described.

The Pantograph is a jointed framework of several pieces (or arms) of wood or metal so joined as to form a parallelogram; and used for enlarging or reducing maps. It rests upon three points, one of which, *A*, is fixed and the other two, *B* and *C*, are movable. There are other bearing points but they simply support the instrument and are not essential to its principle. The two movable points *B* and *C* are in such positions that they will trace exactly similar figures. The instrument is used for copying plans either to the same or different scales; the latter is accomplished by varying the positions of the points *B* and *C* on the arms. Thus two points *B* and *C* can be attached to their respective arms at any desired position, but the essential condition is that *A*, *B*, and *C* shall lie in a straight line and each of the three points must be attached to one of three different sides (or sides produced) of the parallelogram. Any one of the three points can be the fixed point. These instruments are usually provided with scales on the arms indicating the proper settings for various reductions or enlargements. Because of lost motion in the joints very accurate results cannot as a rule be reached, but the best metal pantographs are sufficiently accurate for most topographic maps.

The Planimeter is an instrument for determining the area of a figure by moving the tracing point of the instrument around the perimeter of the plotted area however irregular its shape. The most common form is the **Amsler polar planimeter,** which has two arms, one fixed in length, at the end of which is the anchor point which has a needle point to attach the instrument to the paper. The length of the other arm, the tracing arm, can be changed to give results in different units. At the end of the tracing arm is a point which is moved along the outline of the area to be measured. This arm passes through a collar to which the fixed arm is attached by a pivot. Connected with this collar is a graduated wheel which, together with a little disk which records the revolution of the wheel, gives the area in units depending upon the length of the movable arm. The planimeter rests on three points, the anchor, the tracing point and the periphery of the wheel. To measure an area, press the anchor point into the paper at a position outside of the perimeter of the figure, if it is not too large, and start the tracer from a definite point on the periphery of the area, preferably such as will bring the two arms approximately at right angles to each other. Read the disk, wheel and its vernier, giving four figures. The tracing point is then moved carefully around the outline of the area until the starting point is again reached, when the disk and the wheel area again read. The difference of the two readings gives the area in the unit depending upon the length of the movable arm. The setting of the scale marked on the movable arm for different units is given by the maker. If the area is so large that the anchor point cannot be set outside its limits it can be divided into smaller parcels and the area of each determined separately; or the anchor can be placed inside the area provided the area of a **correction circle** is added to the result, which value is also given by the maker. Results correct to within 1% may be easily obtained with this instrument.

The Rolling Planimeter is not anchored to the drawing. It has a tracing point at the end of an adjustable pivoted arm which is fastened to a frame supported on two rollers. The whole instrument is rolled forward and backward in a straight line while the tracing point traverses the outline of the area. Results correct to 0.01% are easily reached with this instrument. The rolling planimeter is much more expensive than the polar planimeter.

The Three-armed Protractor is used to solve the "three-point problem" graphically. It is similar to the ordinary protractor except that it has three arms, the middle one fixed at 0° of the circle and the other two movable. On either side of the 0° point angles can be laid off. If a point is located by two angles taken between signals *A* and *B* and between *B* and *C* this point sought can be located by laying off the two angles one on either side of the zero point of the protractor and then moving the instrument about on the plan until the plotted points *A*, *B*, and *C* lie on the beveled edges of their respective arms. When this position is found the center of the protractor locates the point sought.

9. Drawing Papers and Blueprinting

Drawing Papers for Working Plans are of all grades from manila detail paper, which costs from 6 to 20 cents per yard, to well-seasoned mounted paper, which will not change greatly with changes in moisture, and which costs from \$1.50 to \$4.00 per yard, depending upon the width and quality. Mounted paper comes in 10-, 20-, and 30-yd. rolls and in widths of 36, 42, 56, 58, 62 and 72 in. The best grades of drawing papers can also be obtained in sheets, either plain or mounted; the common sizes are Cap, 13 by 17; Demy, 15 by 20; Medium, 17 by 22; Royal, 19 by 24; Super Royal, 19 by 27; Imperial, 22 by 30; Atlas, 26 by 34; Double Elephant, 27 by 40; Antiquarian, 31 by 53 in.

Transparent Paper, similar to bond paper, is used largely for studies and for temporary copies of plans. But for more permanent copies tracing cloth is used. Tracing paper comes in sheets of the same standard sizes as mounted paper; it also comes in 20- and 50-yd. rolls and in widths 30, 36, 39, 42, 57 and 60 in., which cost from 7 to 30 cents per yard.

Tracing Cloth is a very uniform quality of fine linen coated with a preparation to make it transparent. This material is manufactured in 24-yd. rolls in widths, 24, 30, 36, 38, 42, 48 and 54 in., and costs from 75 cents to \$2.00 per yard. Most tracing cloth has to be rubbed with powdered chalk before it will take ink. It has a smooth and a rough side; draftsmen should work on the rough side because it will take pencil lines and will not show erasures as much as the smooth side when process prints are made from them. In making a tracing of another tracing place white paper under the under tracing. From one tracing any number of process prints can be made.

Cross-section and Profile Papers can be procured with colored lines, both on heavy paper and on transparent paper or cloth. Cross-section paper, divided into 4, 8, 10, 12 and 16 squares to the inch, is printed in orange, green, red, blue and black in sheets 16 by 20, 17 by 22 and 18 by 23 in., and also on smaller sheets called "coordinate paper." Cross-section papers can be procured in 20- and 50-yd. rolls with the engraving 20, 24 and 30 in. wide, and also in metric units 50 cm. and 75 cm. wide. Profile papers are printed in green, orange and red in three scales, called Plates A, B, and C. Plate A has 4 spaces horizontally to the inch and 20 vertically; Plate B has 4 horizontally and 30 vertically; and Plate C has 5 horizontally and 25 vertically. This material is mostly manufactured in 20- and 50-yd. rolls with the engraving 9, 10 and 20 in. wide and costs from 15 to 25 cents per yard on paper and \$1.00 to \$1.35 a yard on tracing cloth.

Blueprint Paper is the most common of the pcocess papers. It is a white paper coated on one side with a solution which is sensitive to light. When fresh it is a yellowish green color. The following is a formula for this solution: solution (*a*) citrate of iron and ammonia 1 part (by weight) to 5 parts of water; solution (*b*) red prussiate of potash (recrystallized), 1 part (by weight) to 5 parts of water. These two solutions should be mixed in equal parts in the dark or in subdued light. The mixed solution is applied to the paper by means of a flat brush or sponge in a dark room or in subdued light, care being taken to coat the paper uniformly. Then the paper is hung in a dark room to dry and is stored there until used. The above coating will require an exposure of about 5 minutes in bright sunlight; for quick printing paper use a larger proportion of citrate of iron and ammonia. Prepared blueprint paper and cloth can be procured in 10- and 50-yd. rolls in widths of 24, 30, 36, 42, and 54 in. The paper costs from 10 to 25 cents and the cloth 50 cents to $1.50 per yard. In making the print expose the tracing in a printing frame (with the blueprint paper under it) to the sunlight a proper length of time depending upon the sensitiveness of the paper and the brilliancy of the light. Then remove the paper and wash thoroughly in water. Great care should be exercised so that the tracing may not become wet, for it is impossible to eradicate such spots on tracing cloth.

Vandyke Paper is a sensitized paper which is printed in the same manner as blueprint paper, except that the tracing is put into the frame with the ink lines adjacent to the sensitive side of the paper. After an exposure of about 5 minutes in bright sunlight the print is washed for about 5 minutes in clear water and then put into a solution of half an ounce of hyposulphite of soda to a quart of water. It is left in this solution about 5 minutes and then put into clear water again for 20 minutes. This process gives a negative of the drawing, a dark brown paper with white transparent portions where the ink lines of the tracing covered the paper in printing. This Vandyke print can then be used like a tracing to make other positive prints on Vandyke paper, giving brown lines on white background, or to make blueprints with blue lines and white background. This paper can be obtained in 10 and 50-yd. rolls and in widths of 30, 36 and 42 in.; it costs from 15 to 30 cents a yard. **Blackprint papers** are used to some extent; they require a chemical developing bath, and give a blackline copy of the original.

Process-printing Machines, equipped with a brilliant artificial light, so that the prints may be made at any time of day or night, are common. In one of the best types several horizontal rollers are provided, with the light so arranged that as the tracing and process paper pass from one roller to another the exposure is made. The speed of the machine is controllable and the length of the tracing that can be printed is limited only by the length of the roll of paper; thus long plans or profiles can be printed without the necessity of frequent splicing which is required with other types of printing frame; furthermore the print is of uniform color throughout. These machines are provided with an apparatus for washing and drying the prints as fast as the come out.

Photostats are used to a large extent by engineering offices for copying, enlarging and reducing plans, government topographical maps, notes, deeds, and other records. They make a faithful copy. Even faint pencil lines of field notes can be reproduced by this process. Enlargements up to about twice the original size can usually be made in one step; but since enlargements of the enlargements can be made, a plan of any desired scale can be produced by this process. A photostat of a tracing will show white lines on a black background, but a positive of the same scale can be made by making a photostat of the negative photostat. Photostats of blue prints show black lines on white background. Since all photostats go through a fixing bath and a washing process they shrink unevenly, as do blueprints; it is therefore advisable to draw a graphical scale or scales on plans which are to be photostated.

Engineers can obtain excellent process prints, at lower cost than they can be privately made, from process print companies located in all large cities. The prevailing prices per square foot are: for blueprints, 4 cents; for Vandyke negatives, 12 cents; for blue lines from Vandykes, 7 cents; for brown lines from Vandykes, 12 cents; for red lines on white paper, called "direct process," "ozalid," or "red lines," 7 cents; for direct process copies of tracings on tracing cloth, called "lithoprints," 35 cents per square foot; for photostats, 9 × 14 in. and under, 25 cents, and 14 × 18 in., 75 cents, and 18 × 22 in., $1.00.

10. Methods of Plotting Traverses

The Precision of Plotting depends upon the purpose of the survey. If it has been made simply to produce a map the angles may be laid off by means of a protractor and the distances scaled, but it is advisable to plot the triangulation system or the traverses on which the entire survey is based by a more exact method, leaving the details only to be plotted with protractor and scale. A traverse that is closed in the field should close on the plan; any error of closure in the plot indicates an error in scaling some distance or in laying off an angle, one or both. The bearing of each line of the traverse can always be computed from the bearing of some one line, assumed to be correct, and then any line can be extended till it meets the plotted meridian and its direction checked independently. Such checks are absolutely necessary if the traverse is not closed; and also the scaling of each line of the traverse should be checked. In the case of a closed traverse, if it closes on the plan, it is a good indication that it has been accurately plotted.

Plotting by Rectangular Coordinates is a common method for accurate results. It consists in referring all the angle points in the traverse to a pair of coordinate axes; for convenience these axes are the same ones used in calculating the area if the latter is required. The advantages of this method are that each point is plotted independently of the others, that all plotting is done by means of the scale only and that the plotting can be readily checked. First, compute the ordinate and abscissa, called **total latitude** and **total departure**, of each angle point of the traverse (Art. 16). If a meridian through the most westerly point and a perpendicular through the most southerly point are chosen for axes there will be no negative ordinates or abscissas, for east departures and north latitudes are always regarded plus values. The total latitude of any point is the algebraic sum of all the latitudes of the intervening courses beginning with the most southerly point, and similarly for the total departure but beginning with the most westerly point. Construct a rectangle whose height equals the difference in latitude of the most northerly and southerly points and whose width equals the difference in departure of the most westerly and easterly points. This rectangle should be plotted very accurately by straight-edge and reliable triangles or by use of a beam compass, and checked by scaling the diagonals. To plot any point lay, off its total latitude on both the easterly and westerly sides of the rectangle from the southerly side. The point will lie on a line connecting these two points. Along this line scale off the total departure of the point, thus plotting the position of the point. Similarly all of the other points are plotted. To check a plot of this character scale the lengths of the traverse lines. This method is particularly useful in plotting closed traverses where the traverse encloses a field whose area is desired, for in this case the latitude and departure of the courses have to be computed in determining the area; but in the case of traverses that do not close the Tangent Method or the Chord Method is generally preferable.

The Tangent Method consists in laying off the angles by constructing at each vertex a right triangle whose base is 10 in., or any other unit, and whose other leg is the natural tangent of the angle laid off in the same unit as the base. The traverse should first be roughly plotted with protractor and scale so as to determine its extent and shape and so that the first line of the plot can be laid in its proper place on the paper. This first line, AB (Fig. 5), is then drawn to the proper scale. The forward end is extended, say 10 in., at which point f a perpendicular is erected by using triangles.

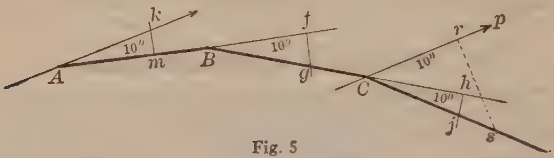

Fig. 5

On this perpendicular the natural tangent fg of the deflection angle is scaled off and line Bg is drawn. This gives the direction of the second line of the traverse on which the proper length BC is laid off, which is in turn extended 10 in. further to form the base of a new right triangle in which the acute angle hCj will be the deflection angle measured at that station. To check such a traverse, calculate the bearing of all the lines referred to any line as a meridian and draw such a meridian line accurately by plotting the bearing angle kAm from the first line by the tangent method. Then draw a line Cp parallel to this meridian line so that it will intersect the course Cj whose direction is to be checked, and measure the angle between this course and the meridian by laying off a 10-in base and erecting a perpendicular rs and scaling rs to determine the tangent of the angle pCj.

When the angle much exceeds 45° it is more accurate to plot the complement of the deflection angle rather than the angle itself, in which case a right angle is erected at the station point and this is used as the base of the right triangle; in such a case and throughout this method it is important that the triangles used shall be true.

In the Chord Method of plotting a traverse the angles are laid off by scaling off a chord across an arc so that it will subtend the required angle at the center of the arc. In detail, plot the first line AB to scale (Fig. 6). With B as a center swing an arc

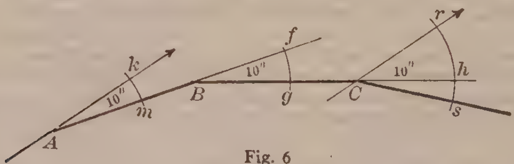

Fig. 6

with radius of say 10 in. Extend AB till it cuts the arc at f, from which point scale off the chord fg along the arc in the proper direction. Chords for different angles have been published, but any natural sine table is practically as convenient, since the chord distance equals twice the sine distance of half the angle. The necessity for multiplying by 20 can be avoided by plotting the natural sine of half the angle directly with a scale of 10 ft. to an inch, while the radius is scaled with a 20-ft. scale. The direction of any course Cs may be checked by calculating the bearings of all the lines and measuring the angle between a meridian line rC and the course in question Cs by drawing an arc rs as in plotting the angle, measuring the chord rs and finding the angle rCs corresponding.

For Maps of Large Areas, such as a state or portion of a country, it is not sufficiently accurate to draw the meridians and parallels of latitude as rectangles. The most common form of projection used is the **polyconic,** in which the surface of the sphere representing the earth is developed on a series of cones. In the U. S. Coast Survey Report for 1884, Appendix No. 6, p. 135, is a table giving coordinates of curvature for plotting the parallels of latitude and meridian lines for this projection.

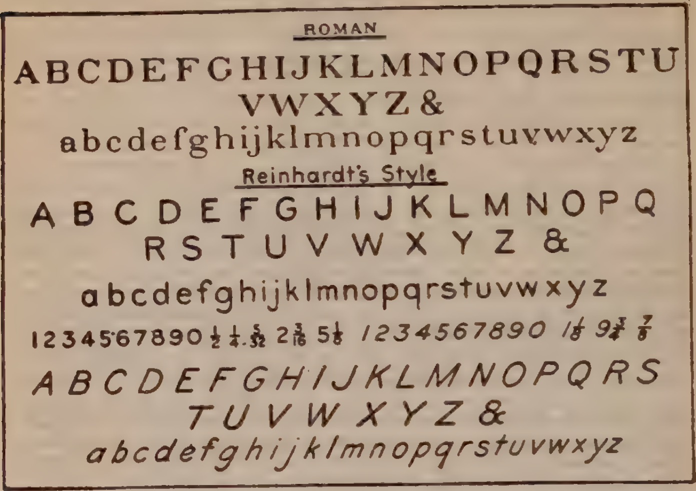
11. Finishing the Plan

The Style of a drawing and the data which it should give depend upon the use to which it is to be put. On every plan, however, there should be a complete title which should be a brief description of the drawing, the owner's name, the location of property, the scale, the date of the survey, the surveyor's name and address. Besides these, if the plan is a land plan, a meridian line should be drawn and some designation as to whether it is the true or magnetic meridian, the limits of abutting property and the names of their present owners. Notes are frequently added to give such further information as is necessary for a correct intepretation of the plan. All essential dimensions are lettered in their proper places. In the case of a land plan the area is usually expressed in square feet or acres and lettered in the middle of the parcel; the lengths of the sides are lettered in the middle of each line, and sometimes the bearings of each side or the angles between them are given, also any stone bounds, iron pipes or other physical boundaries which may exist are represented by abbreviations such as S.B. for stone bound, I.P. for iron pipe, sp. for spike, and stk. for stake. It is the practice of most surveyors to omit from the plan the calculated bearings of the lines or the angles. The bearings or angles are frequently of no use to the owner, but they are of great value to any other surveyor who may have occasion to rerun the lines of the property, and to fail to give them on the plan is in some instances at least withholding data for which the owner of the property has paid and to which he is rightfully entitled. Oftentimes the fact that the angles have been omitted from a drawing necessitates a resurvey which would have been unnecessary had the first surveyor given these data on his plan.

On Working Drawings and sometimes on finished plans the traverse line is drawn, usually as a colored full line, the angle points being shown either by very small circles the center of which marks the exact point or else by very short lines drawn through the angle points so as to bisect the angles. Triangulation stations are represented by small equilateral triangles with the point in the center, stadia stations by small squares, and other auxiliary stations by circles. The location of bench-marks is frequently represented by a small cross and figures thus, B.M. $\times$ 427.62.

The boundaries of the property and the physical features, such as streets or buildings, are usually drawn as full black ink lines. Shore lines are represented by black or by Prussian blue lines, and they should as a rule be the heaviest lines on the plan unless they are a very unimportant part of the plan. Whenever colors are used better results can always be obtained with water colors than with bottled inks. The following, burnt sienna, raw sienna, yellow ocher, scarlet, vermilion, carmine, sepia, cadmium yellow, gamboge, Hooker's green, Prussian blue and indigo, are the colors commonly used by surveyors. All of these except gamboge may be used on tracing linen without danger of running, but if sun process prints are to be made from the tracing it will be found that Prussian blue and indigo will not print well. Some colors which do not give good prints may be made to do so by adding a little of some color to give it body (such as Chinese white or cadmium yellow) but not in quantity enough to change the original color.

Lettering on a drawing should be plain so as to be easily read. Except in titles, the Reinhardt erect or inclined lettering is in general use. Gothic and Roman letters are appropriate for titles of published plans. All lettering should read from left to right when the plan lies with its title horizontal; lettering running perpendicular to the bottom should read from the bottom upward. Put title in lower right-hand corner of plan so that it can be read by turning up the corner of the sheets that lie above it in the drawer; put the number of the plan in the same corner. A rolled plan should have a brief title on the back at both ends. Put a graphical scale on all plans to be reproduced photographically.



Border lines are not as a rule used on construction drawings, but on finished land plans a single line drawn 3/4 in. to 2 in. from the edge of the drawing gives a good appearance if the line is not too heavy. A fine line just inside of a heavier one makes a good border line; it is the tendency of most draftsmen to make the border lines too heavy.

The Meridian should be represented on all land plans as a full arrow if it is a true meridian and as a half arrow if it represents the magnetic meridian, the half arrow head being on the side toward the declination. It should be of simple design, not too conspicuous in size or weight of lines. It is good practice to show both the true and the magnetic meridian and to letter on the magnetic the declination at the place and time the survey was made.

On Mounted Plans accurate scaling may be difficult on account of shrinkage of the paper. It is hence well to draw lines parallel to the borders, forming sides of 100 or 1000 ft., so that allowance may be made in scaling after the paper shrinks.

To Clean the Drawing use a soft pencil eraser, a sponge eraser or dry bread crumbs. For tracings, gasoline or benzine will remove pencil marks without affecting the ink lines.

12. Topographic Signs

Conventional Signs, which have come to be used so generally that they are practically accepted as standard, are used on topographic maps to show certain physical features. A sheet of standard topographic symbols adopted (1925) by the Board of Surveys and Maps of the federal government is on sale by the U. S. Geological Survey for 40 cents. A few of the most common are shown in Fig. 7. They are executed with a free-hand pen except that the horizontal lines on the " salt marsh " signs and the straight lines in " cultivated land " are ruled, also fences, railroads and buildings. In all cases the symbol for grass and marsh land should be parallel to the bottom of the map. In the

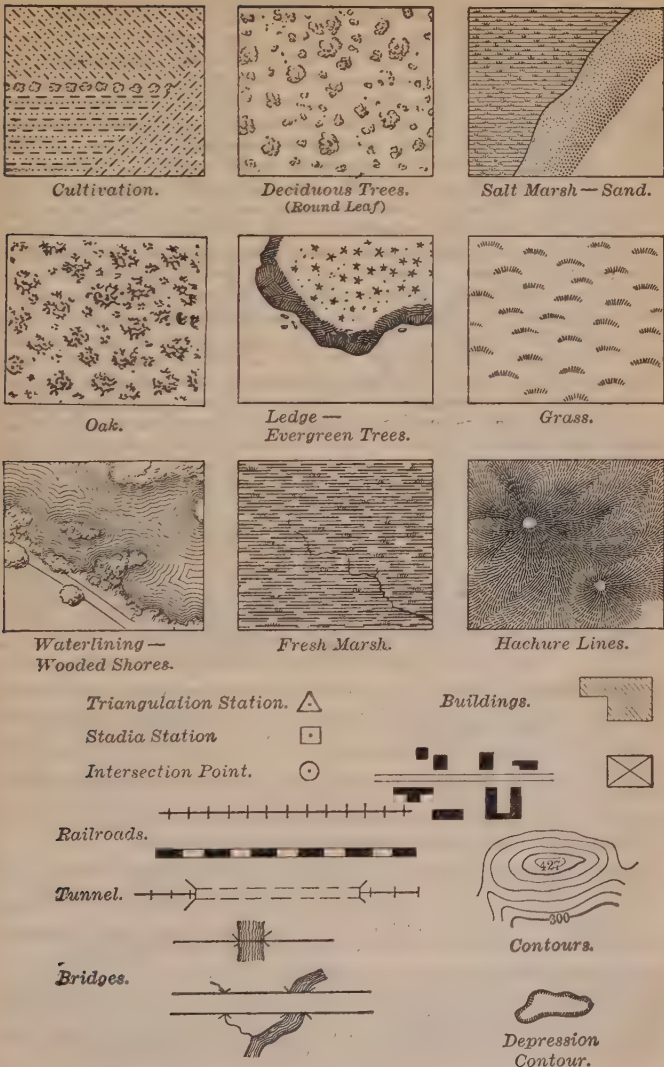


Fig. 7. Conventional Topographic Signs for Maps

grass symbol the little lines which represent a tuft of grass should all appear to radiate from some point below the base of the group. It is usually composed of five or seven short lines, the tops of the lines forming a curve. They are made beginning at the left-hand side with a short dash and increasing in length up to the middle line, which is vertical, and then diminishing and ending with a short dash or dot at the right-hand side. In executing "water-lining" the first line outside the shore line should be a light full line drawn just as close to the shore line as possible, and should follow very carefully every irregularity. The next line should be drawn parallel to the first but with a little more space between them than was left between the shore line and the first line. Then the third line should be spaced a little farther out and so on; five to ten lines are sufficient. The aim should be to change the spacing of the lines so gradually that no one place can be observed where the spacing suddenly increases. Water-lining, fresh marsh and salt marsh symbols are often represented in Prussian blue. A distinction is generally made between evergreen and deciduous trees by using different symbols, and a further distinction is made by using a special symbol for oak trees. The symbol for an evergreen tree is made up of five or six short free-hand radial lines of uniform weight, giving a star-like appearance to each individual symbol. They are made of different weight of lines, some much lighter than others. To avoid the tendency of making them in rows it is well to make irregular groups of the symbols in different parts of the area to be covered and to fill in between these groups with smaller or lighter symbols. In the symbol for deciduous trees it is attempted to represent the plan of a tree in foliage, with a slight shading toward the lower right-hand side. These little symbols are placed regularly over the area if they represent cultivated trees and are given a smoother outline than those representing wild growth, which are scattered irregularly over the area. On some topographic maps, such as the U. S. Geological Survey maps, most of the topographic signs are represented in colors, while the U. S. Coast and Geodetic maps are all produced in black. When colors are used the trees should be green; the grass, a light green tint (Hooker's green No. 2); water, a light Prussian blue tint; cultivated land, yellow ocher.

Contour Lines are almost always drawn in burnt sienna water-color. Every fifth or tenth contour is usually represented by a line slightly heavier and a little darker in color. These may be drawn either with a Gillott's No. 303 pen or with a contour pen. In numbering the contours just enough numbers should be marked so that the elevation of any contour can be found without difficulty. The numbers on the contours should be small figures in burnt sienna. A common mistake is to make the contours too heavy so that they subordinate some of the more important features on the map.

Hachure Lines instead of contours are sometimes used to represent the shape of the surface of the ground (Fig. 7). Contour lines are first sketched lightly in pencil as guides in drawing the hachure lines, which are drawn normal to the contours from the summit downward in rows, each row touching the next preceding; the steeper the slope the heavier and shorter the line. All of the lines are qually spaced.

Sub-aqueous Contours are usually represented on hydrographic maps by dot-and-dash black lines, the shallowest contour having one dot between the dashes, the next contour in depth having two dots between the dashes and so on. In some cases contours representing fathoms of water are shown as single dots for the first fathom, two dots and then a space for the second fathom, dots in threes for the next and so on.

LAND AND TOWN SURVEYING

13. Measurements of Length

Variations in Tape Measurements are due to erroneous length of tape, improper pull on the tape, careless plumbing, incorrect alignment, wind, changes in temperature, and sag of tape. The erroneous length of a tape can be discovered by comparing it with some standard; most cities have a standard which has been established with more or less care. The United States Bureau of Standards at Washington will, for a nominal charge, standardize tapes. The tape should be tested at intermediate points as well as for its total length; its temperature and pull should be noted, and whether it is suspended or supported. If the tape is too long the measurements made with it are recorded too short, and the proper corrections should be added.

The Amount of Pull on a tape will have a very appreciable effect upon its length; ordinary light 100-ft. tapes will stretch 0.01 to 0.02 ft. with an increase of 10 lb. over the ordinary pull. This increase will be different for different tapes; so it is well to investigate it by fastening the ring end of a tape to a nail in the floor, and with the tape supported on the floor to exert different amounts of tension on the tape and measure them with a spring balance. In this manner the variations in length due to different tensions can readily be determined for any tape.

Plumbing is the operation of transferring any point on a horizontal tape to the ground under the tape by means of a plumb-bob. Inaccuracies due to this process can only be avoided by using great care. It should be borne in mind, however, that if a line must be measured by plumbing, more accurate results can be obtained by measuring downhill than uphill. Even when great care is taking in plumbing, so much error is introduced that for accurate results it is better to measure the inclined distance from the horizontal axis of the instrument to the station mark ahead, measure with the vertical arc the angle of inclination of the tape, and compute the horizontal distances by means of the versine of the angle of inclination; horizontal distance = inclined distance minus (inclined distance × versine angle). This computation can usually be done with sufficient accuracy by means of a slide rule. This method requires a set-up of the transit at every other tape-length. Another way to measure these inclined distances is to tape directly from stake to stake in one tape-length; set the instrument up at every other stake and measure the vertical angle to a point above the two station points on either side of the instrument equal to the distance the horizontal axis is above the stake under the transit. This will give the inclination of the tape. Still another method is to measure the inclined distance from stake to stake and obtain the difference in elevation by leveling. When much of this inclined work is to be done it is more expeditious to use a 200-ft. or 300-ft. tape.

Alignment Errors are not likely to be large; lining in the tape by eye is for most measurements exact enough. If in measuring 100-ft. tape-lengths a point is 1 ft. out of line it will introduce an error of only 0.005 ft. in that tape-length. The error due to poor alignment may be computed by the formula $c - a = h^2/2\,c$, where c is the tape-length or fractional tape-length; h is the offset from the correct line; and a is the correct length. Thus, if one end of the tape is on line and the other 0.8 ft. off line the error in that one tape-length is $0.8^2/200 = 0.0032$ ft. Of course there will be a similar error in the next tape-length, making a total error of 0.0064 ft. The shorter the tape-length the greater is the error due to poor alignment.

Errors Due to Wind can be avoided only by making measurements in calm weather, because it is impossible to determine accurately the amount of these errors under such variable conditions as exist when the wind is blowing.

Temperature Changes of the ordinary 100-ft. steel tapes are about 0.01 ft. per 16° F. Tapes are usually made to be of standard lengths at 68° F. The coefficient of expansion of steel is about 0.00000645 for 1° F. Special tapes are made of alloys whose coefficient of expansion is very small; "Invar" tapes of nickel steel have been used in most government surveys and by many other engineers, the coefficient of expansion being about 1/25th that of ordinary steel tapes. By their use the temperature correction is eliminated except for very exact measurements. When ordinary steel tapes are used the temperature of the tape must be obtained and the temperature correction applied if exact results are desired. Small tape-thermometers are made for this purpose, but unless the thermometer is in contact with the tape and protected from the direct sunlight it will not register the tape temperature. Such an attachment is at best awkward. If the tape can be compared with a standard in sunlight and also in shade and the air temperature taken in the shade at both tests, then the correction to be made in measurements on account of temperature change can be readily determined if the air temperature in the shade is observed when the measurements are taken, for we have an empirical relation between the air temperatures and tape corrections. This is on the assumption, however, that the ratio between the tape temperature when lying in the sunlight and the air temperature in the shade is a constant.

Sag. Unless the tape is supported throughout its length, which is often impracticable, a correction must be applied for the sag of the tape due to its own weight, or, what is more commonly done, the pull is increased so as to stretch the tape an amount equal to the shortening due to sag. If supported at both ends it will hang in a curve of the form of a catenary, and the ends of the tape will therefore be less than its length apart, the amount of error depending upon the weight of the tape, the distance apart of the points of suspension, and the pull. With a 12-lb. pull on a 100-ft. ribbon steel tape supported at its ends the effect of sag will be about 0.01 ft. This may be found for any particular tape by the formula, Shortening due to Sag $= (L/24)\,(wl/t)^2$, where w = weight of tape in pounds per foot of length; t = tension in pounds; l = length of tape in feet between supports; and L = total length of tape in feet. The result will be in feet.

If a tape can be compared in a suspended condition with a standard, the shortening due to different amounts of sag may be determined, and then the proper approximate corrections applied to any measurements by judging the amount of sag.

With a steel tape, if ordinary care is taken in plumbing and in alignment and with rough corrections made for temperature, an accuracy of 1 in 5000 can easily be obtained. For accuracy greater than 1 in 10 000 it is necessary to apply corrections for pull, temperature, alignment, and sag.

In all measurements it is of utmost importance to distinguish between errors which tend to balance and those which continually accumulate, the latter being far more important. For those which tend to balance, the number of errors which will probably remain uncompensated, according to the Method of Least Squares, will be the square root of the total number of opportunities for error. For example, if a 100-ft. tape is 0.02 ft. too long an accumulative error of about 1 ft. will be made in measuring a line one mile long. If, on the other hand, the tape-lengths are not marked closer than 0.05 ft., the total error made by this compensating error of 0.05 will only be $\sqrt{52} \times 0.05 = 0.36$ ft.

14. Magnetic Variations

Surveys with Compass and Chain cannot be relied upon to be closer than about 1 part in 500, since the bearings are read only to the nearest quarter of a degree. This method is therefore adapted only to rough surveys of woodlands where the land is cheap and where there is little danger from local attraction of the needle.

For Transit and Tape Surveys it is desirable in some instances to determine the direction of the true meridian by observations on the sun or on Polaris (the "north star"), as described in Art. 44. In many cases exact bearings of the lines are not needed and it is sufficiently accurate to determine the magnetic bearings by reading the needle. The approximate true bearings may then be determined by applying the declination of the needle to the observed bearings; but in most transit and tape surveys in cities the magnetic bearings are so unreliable that when taken at all they are used merely for the purpose of plotting a needle on the map to show approximately the "points of the compass."

The Declination of the needle is the angle which it makes with the true meridian. The needle rarely points in the true meridian; if it points east of the true meridian it is called an east declination. The declination of the needle at places east of Ohio and the Carolinas is West (in 1925), being a maximum of 22-1/2° in Maine; in the western part of the country it is East, being a maximum of 25° in the state of Washington. The average declination in Alaska is 20-1/2° E; Porto Rico 4-1/2° W; Canal Zone 5° E; Hawaiian Islands 10-1/2° E; Philippine Islands 1° E. The declination continually changes; these changes are called variations.

The Secular Variation is a long slow swing, periodic in its character, and covering many years. In the United States all east declinations are now (1925) gradually decreasing and all west declinations are increasing at an average rate of 2 to 3 min. per year.

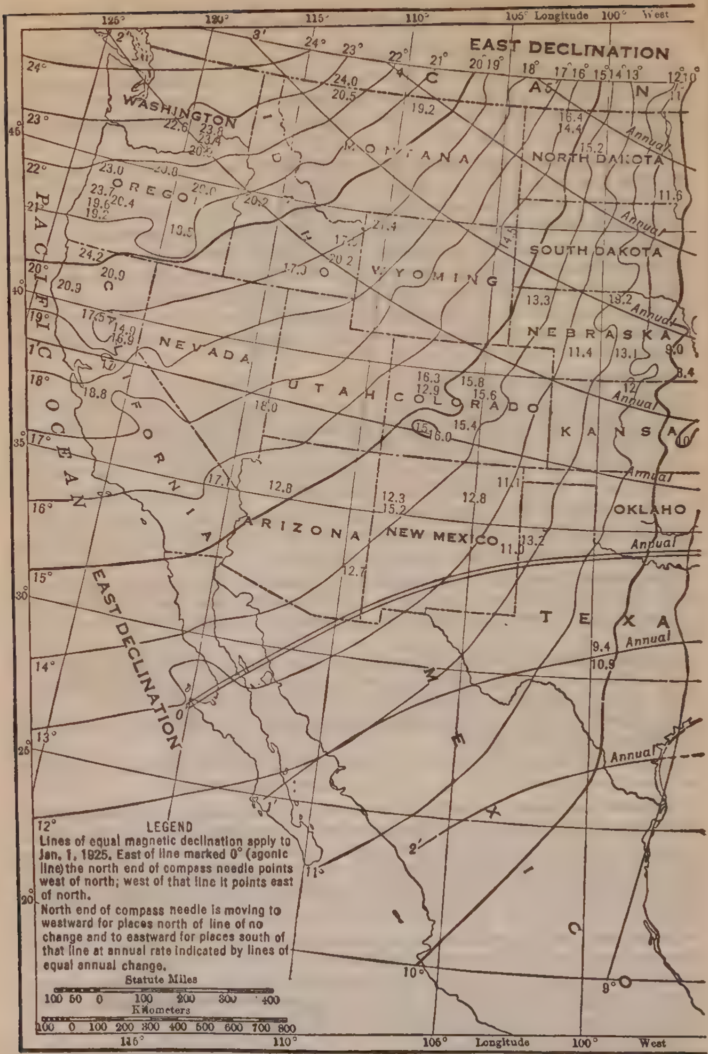
The Daily Variation consists of a swing from the extreme easterly position at about 8 a.m. to its most westerly position at about 1.30 p.m. It is in its mean position at about 10 a.m. and 5 p.m. This daily variation is from 5 to 15 min. of arc.

The Annual Variation (about one minute per year) is so small that it need not be considered in surveying work.

Irregular Variations, due to so-called magnetic storms, are uncertain in character and cannot be predicted. These variations are sometimes large.

Isogonic Lines are lines drawn on a map so as to connect all places where the declination of the needle is the same at a given time. The U. S. Coast and Geodetic Survey has constructed isogonic charts of the United States and these can be obtained from Washington. These charts do not give results with great precision, but are useful in finding approximate values of the declination. They are prepared by plotting upon the map the observed declination at magnetic stations located throughout the country and interpolating results at intermediate places. Observed declinations at these interpolated places frequently show results quite different from those given on these isogonic charts, so that it is necessary whenever the declination of the needle is desired with precision to make observations for finding the true meridian.

Changes in Declination make it necessary in rerunning old lines to modify the given bearings an amount equal to the change in declination which has taken place since the lines were first run. To determine the declination for some past date, records of the U. S. Coast Survey are of assistance provided they had a magnetic station in the vicinity of the place in question. A better way of finding the difference in declination is to take the magnetic bearing of any well-defined line of the old survey, such as be-



Isogonic Chart of United

States for 1925

tween two identified stone heaps, and compare the present bearing of this line with its original bearing.

An Isogonic Chart for Jan. 1, 1925, copied from one issued by the U. S. Coast and Geodetic Survey, will be found on pages 434 and 435. The full lines are the isogonic lines, or lines of equal magnetic declination, the heavy one marked 0° passing through the places in the United States where the north end of the magnetic needle points to the true north. East of the 0° line the north end of the magnetic needle points west of true north, west of that line it points east of true north. Thus, at Boston, Mass., the declination in 1925 was about 14-1/2° W, and at Helena, Mont., it was about 20-1/2° E.

These isogonic lines are constantly shifting; the 0° line is moving westward at a rate between 1′ and 2′ per year. On the chart a double line is seen marked "Annual Change 0"; at all places on that double line there was no change in declination in 1925, at all places east of it the west declination was increasing, at all places west of it the east declination was decreasing. Thus, near Denver, Colo., the east declination decreased nearly 2′ in 1925.

In 1926 the U. S. Coast and Geodetic Survey published a pamphlet (Serial No. 360) entitled "Magnetic Declination in the United States in 1925," which gives tables showing the magnetic declination as observed for many places since 1750. The following table, showing the secular change for eight places is taken from that publication.

Secular Change of the Magnetic Declination

Longitude Latitude..	70° 44°	72° 42°	74° 44°	76° 36°	84° 32°	84° 36°	84° 38°	84° 40°
State....	Maine	Conn.	New York	N. Car.	Ga.	Tenn.	Ky.	Ohio
	° ′	° ′	° ′	° ′	° ′	° ′	° ′	° ′
1750	9 34 W	6 46 W	8 00 W	1 18 W	3 04 E	1 11 E	....	....
1760	9 14	6 16	7 19	0 43	3 40	1 50	....	....
1770	9 02	5 55	6 46	0 13 W	4 15	2 28	....	....
1780	9 02	5 43	6 18	0 09 E	4 47	3 02	....	....
1790	9 09	5 40	6 05	0 23	5 12	3 29	....	....
1800	9 29	5 48	6 03	0 27	5 30	3 49	4 28 E	4 03 E
1810	9 56	6 04	6 11	0 24	5 40	3 59	4 39	4 15
1820	10 31	6 29	6 31	0 12 E	5 41	4 00	4 41	4 17
1830	11 12	7 02	7 01	0 09 W	5 35	3 53	4 34	4 09
1840	11 57	7 43	7 40	0 37	5 20	3 36	4 17	3 51
1850	12 44	8 26	8 21	1 12	4 58	3 12	3 53	3 26
1860	13 29	9 08	9 02	1 48	4 28	2 42	3 23	2 56
1870	14 00	9 43	9 41	2 28	3 55	2 07	2 48	2 21
1880	14 30	10 19	10 26	3 04	3 16	1 27	2 08	1 40
1890	14 50	10 45	10 54	3 37	2 37	0 46	1 26	0 57
1900	15 16	11 18	11 29	4 13	2 07	0 14	0 53	0 22
1905	15 33	11 37	11 47	4 31	2 01	0 04 E	0 42	0 09 E
1910	16 03	12 07	12 16	4 51	1 59	0 02 W	0 33	0 02 W
1915	16 33	12 35	12 45	5 10	1 59	0 09	0 25	0 14
1920	16 50	12 55	13 05	5 25	2 01	0 13	0 17	0 24
1925	17 15 W	13 20 W	13 30 W	5 40 W	2 00 E	0 20 W	0 05 E	0 40 W
Annual change in in 1925	5′.0 incr.	5′.0 incr.	5′.0 incr.	3′.0 incr.	0′.0	1′.5 incr.	2′.4 decr.	3′.2 incr.

These figures show that the variation in different decades is not the same and that the values of the declination are represented by a curve. The curve of sines approximately represents these values for a given place.

15. Traversing with Transit and Tape

The Transit and Tape Method is commonly used for running traverses. The instrument is set up at every angle point in the traverse and the angle measured with the transit. The distance between the angle points is measured with the tape. The distances are sometimes measured and recorded as separate distances from angle point to angle point, the angle points being designated by letters or by numbers. Another method is to measure the entire traverse from the first point, which is called " Station 0," continuously throughout the traverse, each 100-ft. point being called a station. If the second transit point is 672.43 ft. from Station 0 it is called " Sta. 6 + 72.43," if the next point is 350 ft. farther it would be recorded " 10 + 22.43 " and so on, so that the station of any point is its distance from the point of beginning of the traverse measured along the traverse.

The Precision with which the measurements should be taken will depend upon the object of the survey. If it is a city survey of valuable property the distances would be measured to the nearest hundredth of a foot, and the angles to 15 seconds; whereas in a farm survey the angles to the nearest minute and the distances to a tenth of a foot or in some cases even to a foot (by the stadia method) is exact enough. Transits used for general surveying work read to minutes or to half-minutes. It is therefore necessary in accurate surveys to measure the angles by repetition, as explained at the end of this article, to obtain results consistent with the accuracy of the tape measurements. A proper appreciation of the relation of distances and angles may be had if it is borne in mind that 0.03 ft. a hundred feet away subtends one minute.

The Angles Measured may be the deflection angle (the angle between the last course produced and the next course), the interior angle, or the azimuth angle. In measuring a deflection angle the telescope has to be inverted, and any error in the line of collimation will therefore be introduced into the deflection angle. This error may be eliminated if the angle is measured first with the telescope direct and then, without changing the circle reading, invert the telescope and " double " the angle; half the final angle is the correct angle. To avoid this necessity of reversing the telescope and repeating the angles some surveyors prefer to measure the interior angles directly.

For Azimuths the instrument is first set up at the point *A* with the circle set at 0°, and the lower clamp loose. The telescope is turned so as to point toward magnetic south or true south (true meridian is the better reference direction) and lower motion clamped. Then the upper plate is unclamped, *B* sighted, and the angle read in a clockwise direction. This gives the azimuth of the line *AB*, an azimuth angle being the total angle read in a clockwise direction from the south around to 360°. The instrument is then taken to *B* so as to obtain the azimuth of *BC*. Invert the telescope and backsight on *A*, the vernier remaining at the same reading it had when azimuth *AB* was read, clamp the lower motion, turn the telescope to its direct position, loosen the upper clamp and sight *C*. This will give the azimuth of *BC* referred to the same meridian as *AB*. Evidently this method does not eliminate any error in the line of collimation adjustment. By the azimuth method, when the survey is about to be closed the azimuth of the first line *AB* can be obtained by setting up again on *A* and using the last course as a backsight. The difference between the first determination of the azimuth of *AB* and its final determination gives directly the total error in the angular work.

As a check against large errors in the angles the magnetic bearing of each line should be read when practicable and compared with the calculated bearing. The calculated bearing of the first line is assumed to be its observed bearing; the calculated bearing of any line is obtained from the calculated bearing of the line next preceding combined with the measured angle between the two lines.

Deflection Angles should be recorded as R (right) or L (left). The algebraic sum of the deflection angles of a closed traverse should equal 360°. If the interior angles are read, the sum of all the interior angles of a closed traverse should be $(n - 2) \times 180°$, where n is the number of lines.

The Error of Closure of a traverse in which the angles are measured to the nearest minute and the distances to a tenth of a foot should not exceed 1/5000. But where the angles are measured to 15 seconds and the distances to hundredths of a foot, a closing error of not more than 1 in 20 000 to 40 000 may be obtained.

Checks on Traverses. In traverses which enclose an area there is a mathematical check on the distances provided the angles are correct, as shown in Art. 16. But in traverses which do not close there is no check on the distances other than by remeasurement of the lines (preferably in the opposite direction from the first measurement), except by cut-off lines which form closed traverses of portions of the survey. The angles can be checked by determining the true bearing of the first line of the traverse by solar or stellar observation, and whenever it is desired to check the angles the true bearing of any course can be determined by another meridian observation. The meridian can be determined to the nearest minute by solar observation and much closer by observation on the pole star.

To Measure an Angle by Repetition, set up the transit at A, set the verniers at 0°, sight B, and clamp lower clamp. Loosen upper clamp and sight C, read and record the angle. Leaving the two plates clamped together, unclamp the lower clamp, and sight B, unclamp upper clamp and sight C, and read and record the angle. Half this angle should check the first angle read, and the result obtained is more exact than the first angle. It is evident that by repeating this process with a one-minute instrument for six times and dividing by 6 an angle to ten seconds can be obtained. This method of repetition might be carried even further, but ordinary transits are not good for results much closer than ten seconds.

This method of repetition can be readily applied to laying off an angle. The angle is first laid off and a point set, and then the angle which has been laid off is measured by repetition as described in the previous paragraph. If it is found to be in error, say 20 sec., the point on the stake is moved in the proper direction a distance equal to the distance from the point set to the instrument $\times$ tan 20 sec.

16. Areas of Fields

Corrections of Field Notes are made before computation for area is begun. Errors in tape measurements due to erroneous length of tape are corrected. Errors in angles, provided they are not large enough to indicate mistakes, are eliminated by "balancing the angles," which means altering the value of those angles which were taken from short sights or those angles where the error is most likely to lie. The calculated bearing of each course is computed starting from one course whose bearing is either known or assumed.

The Double Meridian Distance Method of computing an area is as follows: The data are usually tabulated as shown in the computation below. The **latitude** of a course equals the distance times the cosine of the bearing; the **departure** is the distance times the sine of the bearing. North latitudes and East departures are regarded as positive values and South latitudes and West departures are negative. After these have been computed the error in latitude and in departure is found, which is the difference between the plus and the minus latitudes and the plus and minus departures. If these errors are not large enough to indicate a mistake in the measurements or computations then they are distributed among the latitudes and departures according to the following rule if it is a transit and tape survey. The correction applied to the $\left\{\begin{matrix}\text{latitude}\\ \text{departure}\end{matrix}\right\}$ of any course is to the total error in $\left\{\begin{matrix}\text{latitude}\\ \text{departure}\end{matrix}\right\}$ as the $\left\{\begin{matrix}\text{latitude}\\ \text{departure}\end{matrix}\right\}$ of that course is to the sum of all the $\left\{\begin{matrix}\text{latitudes}\\ \text{departures}\end{matrix}\right\}$ (without regard to algebraic signs). Any knowledge of difficulties met in the field which would lead the surveyor to suspect that the error lay in certain lines should take precedence over this rule. Furthermore it is more probable that on account of sag of the tape and small obstacles on the line the recorded distances are too long rather than too short, and therefore it is not good practice to apply the above rule when it lengthens any of the distances. In the example here given, however, the rule is rigidly followed in balancing this survey in order merely to show its application. The algebraic sum of balanced latitudes and the departures should be zero.

The next column to compute is the double meridian distance (D.M.D.) of each course. The D.M.D. of the first course equals the departure of the first course. The D.M.D. of any other course equals the D.M.D. of the course preceding plus the departure of the preceding course plus the departure of the course itself. The D.M.D. of the last course should be numerically equal to the departure of the last course but should have the opposite algebraic sign. The algebraic signs must be carefully observed not only in computing the D.M.D.'s but in all of this computation for area. If the D.M.D.'s are computed beginning at the most westerly point in the traverse all the D.M.D.'s will be plus. The last column of positive and negative double areas is found by multiplying each D.M.D. by its corresponding latitude. Half the algebraic sum of the double areas gives the area of the field.

Computation for Area by Double Meridan Distance Method

Station	Bearings	Distance, ft.	Latitudes	Departures	Balanced Latitudes	Balanced Departures	D.M.D.	Double areas
A	N 56° 25′ E	540.91	+ 299.20	+ 450.62	+299.19	+450.66	+ 450.66	+134 833
B	S 64° 27.5′ E	198.44	− 85.56	+ 179.05	− 85.56	+179.06	+1080.38	− 92 437
C	S 67° 50′ E	212.46	− 80.16	+ 196.76	− 80.16	+196.78	+1456.22	−116 731
D	S 68° 34′ E	98.13	− 35.86	+ 91.34	− 35.86	+ 91.35	+1744.35	− 62 553
E	S 29° 17′ E	186.75	− 162.89	+ 91.35	−162.90	+ 91.36	+1927.06	−313 918
F	S 61° 26.5′ E	651.70	− 311.55	+ 572.41	−311.57	+572.45	+2590.87	−807 234
G	S 66° 50′ W	910.92	− 358.37	− 837.46	−358.39	−837.40	+2325.92	−833 583
H	N 45° 21′ W	1046.25	+ 735.28	− 744.32	+735.25	−744.26	+ 744.26	+547 217
		3845.56	+1034.48 −1034.39 error +0.09	+1581.53 −1581.78 −0.25				2)1 544 406 772 203 sq. ft.

This result should be roughly checked by determining the area by use of the planimeter (Art. 8) or by dividing it into triangles, scaling the bases and altitudes and computing the area. The agreement between the sum of the + and − latitudes and + and − departures is a check on the multiplication of the distance by the cosine and sine of the bearing. The D.M.D.'s are checked as shown above. But there is no check on the double areas. A good exact check on the area is to compute from the latitudes the double parallel distances (D.P.D.) just as the D.M.D.'s were computed from the departures, and then obtain double areas by multiplying each D.P.D. by its departure. If l is the error in latitudes and d the error in departures, the error of closure of the survey equals $\sqrt{l^2 + d^2}$. Thus, the error of closure of the survey shown above is 0.266 ft., and

$$\frac{\sqrt{0.09^2 + 0.25^2}}{3845.56} = \frac{0.266}{3846} = \frac{1}{14\,500} = \text{relative error of closure}$$

Sometimes it is not possible to follow the perimeter of the field with the traverse, in which case the fractional areas to be added to or subtracted from the area of the traverse are computed by dividing them into triangles, rectangles or trapezoids.

Large mistakes made in the fieldwork will be detected in the computation by the D.M.D. method. If the latitudes and departures do not balance within reasonable limits, the error in departure divided by the error in latitude equals the tangent of the bearing of the line which would represent the error of closure, and if only one mistake has been made in measuring the distances it probably lies in a line having this angle for its bearing.

Compass Surveys should be balanced by the following rule, because the errors are more likely to be due to the rough results obtained in the angles than in the distances. **The correction to be applied to the $\left\{\begin{array}{l}\text{latitude}\\\text{departure}\end{array}\right\}$ of any course is to the total error in $\left\{\begin{array}{l}\text{latitude}\\\text{departure}\end{array}\right\}$ as the length of the course is to the perimeter of the field.**

Area of a Field by Rectangular Coordinates. Where the coordinates of the corners of a property are known the coordinate method of computing its area is more direct than the D.M.D. method. Let x_a, x_b, x_c, etc., and y_a, y_b, y_c, etc., represent the abscissas and ordinates of points A, B, C, etc., of the same area computed above by the D.M.D. method. By the rectangular coordinate method the area is found as follows: Every abscissa is multiplied by the difference between the following and preceding ordinates, always subtracting the following from the preceding. The algebraic sum of these products divided by 2 gives the area. Expressed as a formula, this rule is

$$\text{Area} = 1/2\left\{x_a(y_b - y_h) + x_b(y_c - y_a) + x_c(y_d - y_b) + x_d(y_e - y_c) + \ldots\right\}$$

Below is the computation by coordinates of the same area as that above. The origin of coordinates is 100 ft. W and 2 000 ft. S of the initial point.

Computation for Area by Coordinate Method

Station	x	y	Difference between adjacent y's	Double areas +	Double areas −
A	100.00	2000.00	−1034.44	....	103 444
B	550.66	2299.19	− 213.63	....	117 637
C	729.72	2213.63	+ 165.72	120 929	....
D	926.50	2133.47	+ 116.02	107 493	....
E	1017.85	2097.61	+ 198.76	202 308	....
F	1109.21	1934.71	+ 474.47	526 287	....
G	1681.66	1623.14	+ 669.96	1 126 645	....
H	844.26	1264.75	− 376.86	....	318 168
				2 083 662	539 249

Area = 1/2 (2 083 662 − 539 249) = 772 206 sq. ft.

17. Crooked Boundaries

Curved Boundaries, such as brooks, are often located by measuring the perpendicular offsets from the traverse line which has been run alongside of the brook. The curvature of the boundary may be so flat and uniform that it will be feasible to take the offsets at regular intervals, while in cases where the boundary changes in direction abruptly it is necessary to take the offsets only at the points where these changes occur. In either case there will be the areas of several trapezoids to compute to find the area between the traverse line and the boundary, but if the offsets are taken at equal intervals then the computation may be made by one of the following methods:

By the Trapezoidal Rule, Area $= 1/2\, d\,(h_e + 2\,\Sigma h + h_e')$, where d = common interval between offsets; h_e and h_e' = end offsets of the series of trapezoids; and Σh = sum of intermediate offsets. This rule assumes that the boundary is a straight line between adjacent offsets.

Simpson's One-third Rule assumes that between adjacent offsets the boundary is a curve (a parabola). By this rule **Area** $= \frac{d}{3}\,(h_e + 2\,\Sigma h_{odd} + 4\,\Sigma h_{even} + h_e')$, where d = common interval between offsets; h_e and h_e' = end offsets of the series; $2\,\Sigma h_{odd}$ = twice the sum of the odd offsets except the first and last (the 3rd, 5th, 7th, etc.); $4\,\Sigma h_{even}$ = four times the sum of the even offsets (the 2nd, 4th, 6th, etc.). For this rule to apply there must be an odd number of offsets; if there is an even number, compute the area of one end trapezoid separately.

To Straighten a Crooked Boundary is to run a straight line cutting the crooked boundary so as to make the lots on either side of the straight line have the same areas as they have with the crooked boundary for the division line. To do this, first run a trial line AB (Fig. 8), then measure proper offsets to the crooked boundary and compute the areas X, Y and Z on each side of AB between it and the crooked boundary. The sum of X and Z should equal Y, for $X + Z$ is the amount taken from Lot M, and Y is the amount taken from Lot N. If $X + Z$ does not equal Y the difference is the amount the trial line has taken from one lot more than it has taken from the other, so this whole difference must be returned. For example, suppose the original area of Lot M = 50 000 and Lot N = 40 000. When AB is run it is found that the area of $X = 300$, $Y = 1000$, and $Z = 500$, that is, the trial line AB has made Lot M = 50 000 − 800 + 1000 = 50 200, and Lot M = 40 000 − 1000 + 800 = 39 800. An area 1000 − (300 + 500) = 200 must therefore be taken from Lot M and added to Lot N by running the final line AD so as to make the area ADB equal to 200.

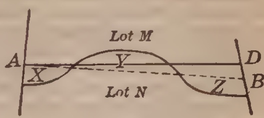


Fig. 8

18. Old Lines

In Rerunning Old Property Lines the surveyor must first determine where the original boundaries of the property lie and then survey those boundary lines. He should not attempt to correct the original lines even though he may be sure that errors exist in them. He must first of all find the physical evidence of the location of the boundaries, and failing in this he should base his judgment as to their location on such evidence as occupancy or dimensions given in deeds or the word of competent witnesses. It must not be assumed that a boundary is missing because it is not at once visible. Stone bounds are often buried two or three feet deep; the top of a stake soon rots off, but evidences of the existence of the stake are often found many years after the top has disappeared, and the supposed location should be carefully dug over to find traces of the old stake.

In Interpreting a Deed it is assumed that it was intended to convey property the boundaries of which will form a closed traverse. Therefore, if it is found that the omission of a whole chain-length or the reversing of the direction of a bearing will make a deed description close, this change in dimensions may be made, for it is assumed that the description is of a closed field. Where the record of the original survey does not close, the deeds of adjoining property may be of assistance. Where artificial features are mentioned as boundaries, these always take precedence over the recorded measurements or angles, but these marks must be mentioned in the deed in order to have the force or authority of monuments. When the area does not agree with the boundaries as described in the deed those boundaries control. All distances unless otherwise specified are to be taken as straight lines; but distances given as so many feet along a wall or highway are supposed to follow these lines even if they are not straight. When a deed refers to a plan the dimensions on this plan become a part of the description of the property.

Legal Boundaries. Where property is bounded by a highway the abutters own to the center line, but where it is an accepted street each abutter yields his portion of the street for public use; if, however, the street is abandoned the land reverts to the original owners. If a street has been opened and used for a long period, bounded by walls or fences, and there has been no protest regarding them, these lines usually hold as legal boundaries. In the case of a line between private owners acquiescence in the location of the boundary will, in general, make it the legal line; but if there is a mistake in its location and it has not been brought to the attention of the interested parties or the question of its position raised, then occupancy for many years does not make it a legal line.

Where property is bounded by a non-navigable stream it extends to the thread of the stream. If the property is described as running to the bank of the river it is interpreted to mean to the low-water mark unless otherwise stated. Where original ownership ran to the shore line of a navigable river and the water has subsequently receded, the proper sub-division is one that gives to each owner along the shore his proportional share of the channel of the river; these lines will therefore run, in general, perpendicular to the channel of the stream from the original intersection of division lines and shore lines.

A more complete statement of the principles mentioned above, particularly with reference to the U. S. Public Land Surveys, will be found in an address on "The Judicial Functions of Surveyors," by Chief-Justice Cooley of the Michigan Supreme Court. See Proceedings Mich. Association of Engineers and Surveyors, 1882, pp. 112–122.

Should all evidence of artificial boundaries of the property be missing the surveyor will have to use the deed description as the best evidence. Where the directions of the lines are given as magnetic bearings it is necessary first to determine the declination of the needle at the date of the survey. The declination should be stated in the deed or on the original plan, but it seldom does appear in either. If the date can be established the declination for that year and place may be obtained from the records of local surveyors or from past U. S. Coast Survey records. If one line can be identified as a boundary the difference between its present magnetic bearing and its original bearing gives the difference in declination directly, and all the rest of the deed lines can be run out by correcting all the bearings by this amount. The chain used in the original survey may have been of different length from the one now used; this can be readily determined by measuring the length of any of the well-defined lines of the property.

19. Obstacles and Inaccessible Distances

A Random Line is sometimes required on account of obstacles on line. If it be required to run the line AB (Fig. 9), neither point being visible from the other, a random line AX can be run. Measure the perpendicular distance BC and also AC. The length of AB may then be computed and any desired point may be set on the line AB as follows. Suppose a point D is to be set on AB and that a perpendicular from D meets AC at E, then $AE = AD \times AC/AB$, and $ED = BC \times AD/AB$. By this method, then, it may not be necessary to run out and actually measure the line AB. The angle CAB can be found from CB and AC.

If a straight line such as AX cannot be run, a traverse composed of several straight lines and angles may be made to connect A and B, and using AB as the closing side of a closed traverse, its length and direction may be computed (Art. 16), and also the coordinates of any point in the traverse may be found referred to AB so that distances may be laid off from the traverse which will define any desired points on AB. This traverse method, since it involves the measurement of angles, will not lend itself as readily to accurate results as the case first described where the random line is a straight line. In running a straight line where it is necessary to produce the line by reversing the telescope it should always be done by taking the mean result of a double reversal, the telescope being erect in taking the first backsight and inverted when taking the second backsight, so as to eliminate any error in the line of collimation.

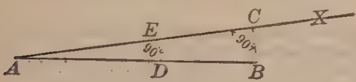

Fig. 9

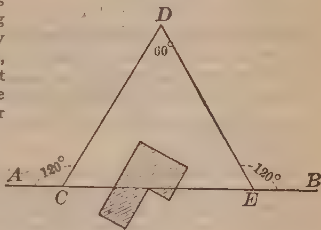

Fig. 10

An Equilateral Triangular Traverse about an obstacle is a special case of the above method. Let the obstacle be on the line AB (Fig. 10); the instrument is set up at C, an angle of 120° is laid off, and a stake set a sufficient distance away at D, and CD is measured. The transit is then set up at D and an interior angle of 60° laid off so as to run a line that will cut AB; this line is made equal to CD and stake E is set. With the instrument at E an angle DEB is laid off equal to 120° which should be sighting along AB if the work has been done accurately. Evidently $CD = ED = CE$. This method is weak in accuracy owing to its dependence upon angle measurements. A slight error in any angle will introduce an appreciable error in CE. If CD is short the error in CE is small, but the error in producing EB by an angle laid off from the short side ED is likely to be large.

Running Parallel Line Past Obstacle. One of the most exact ways of producing a straight line past an obstacle of limited size, such as a house, is to run an offset parallel transit line past the obstacle as follows. The instrument is set up at C (Fig. 11) and a right angle ACC' laid off with the transit.

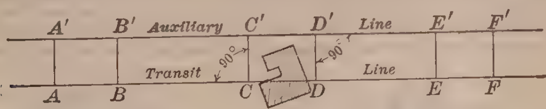

Fig. 11. Running Parallel Line past Obstacle

CC' is made any convenient distance which will bring the auxiliary line beyond the obstacle. Similarly, point A' is set opposite point A, and sometimes a second point B' opposite B. These points A' and B' need not be set by means of a transit set up at A and B if AA' is short. The instrument is then set up at C' and backsighted on A', the sight is checked on B', the telescope inverted, and points D', E' and F' set on line. Leaving the telescope inverted, another backsight is taken on A', and the process repeated to eliminate any error in the line of collimation. Then the transit is moved to point D', and a right angle turned off, and point D set, the distance $D'D$ being made equal to $C'C$. Then by setting up at D and sighting ahead on F ($FF' = DD'$), and checking on point E ($EE' = DD'$), the transit line is again run forward in its original location. The distance $C'D'$ is carefully measured, which gives the distance CD, and thus it appears why it is so necessary that the lines CC' and $D'D$ shall be laid off at right angles by means of the transit. The other offsets AA', BB', EE' and FF' are not in any way connected with the measurement along the line; they simply define the direction of the line, so that if convenient it is often only necessary to show these distances as swing offsets for the transitman to sight on. The swing offset is given by swinging a tape in a horizontal arc about A as a pivot. The zero point of the tape is held at A, and at the distance AA' out on the tape a pencil is held vertically on which the transitman sights when the pencil appears to be swung out farthest from A so that his line of sight will be tangent to the arc. The offsets BB' and EE' are not absolutely necessary, but they serve as desirable checks on the work, and in first-class surveying they should not be omitted. For obvious reasons the offsets AA' and FF' should be taken as far back from the obstacle as is practicable.

Should the house be in a hollow so that it is possible to see over it with the instrument at A, the point F, or a foresight of some sort, should be set on line beyond the house to be used as a foresight when the transit is set up again on the original line. The distance may be obtained by an offset line around the house. Sometimes it is possible to place exactly on line on the ridgepole of the house a nail, which gives an excellent backsight when extending the line on the other side of the building.

If the building has a flat roof and it is possible to set a point on the roof exactly on line, move the instrument to this point on the roof, and prolong the line in this way. Under these conditions the transitman will have to be extremely careful in the use of his instrument on account of its insecure foundation. If he walks around the transit he will find that it affects the level bubbles and the position of the line of sight; it is therefore well for him if possible to stand in the same tracks while he backsights and foresights. Sometimes two men, one in front and one behind the transit, can carry on the work under these conditions more accurately and conveniently. This method insures an accurate prolongation of the line, but the distance through the building must be found by an offset method, by plumbing from the edge of the flat roof, or by inclined measurements.

To Measure an Inaccessible Distance where the line is visible, as across a pond, several methods may be employed:

(1) Lay off from the transit line AC (Fig. 12) a line AB which passes by the end of the pond so that it can be taped and set stake B; then set up the instrument at B and lay off $ABC = 90°$, point C being obtained by intersecting the main transit line. Measure angle CAB and side AB, from which $AC = AB/\cos CAB$; or, better, $AC = AB + AB \operatorname{exsec} CAB$. The measurement of the angle at C and of CB will serve as checks.

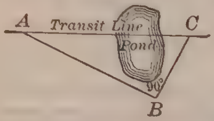

Fig. 12

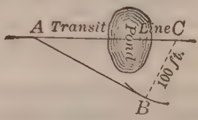

Fig. 13

(2) With the instrument at A (Fig. 13) and a swing offset of 100 ft. from C (some point on the main traverse line on the other side of the pond) measure the angle between CA and a tangent AB to the swing offset. $AC = 100/\sin CAB$.

(3) Any line AB (Fig. 14) may be laid off along the shore of a river, and a point C set on the main traverse line across the river, measure angles A and B, and C as a

check, and from AB as a base compute AC by trigonometry. If AB is run perpendicular to CA and made some number of hundred feet long the computation is greatly simplified.

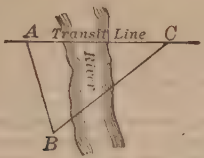

Fig. 14.

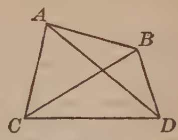

Fig. 15

To Obtain the Distance between Two Inaccessible Points A and B (Fig. 15) by observations from two accessible points C and D, measure DC and angles ADC, ADB, ACB and BCD. Compute CB in triangle CBD, AC in triangle ACD, and then in triangle ACB compute AB.

To Obtain the Inaccessible Distance AB (Fig. 15) between two accessible points by observation on two inaccessible points C and D when distance CD is known. Measure angles CAD, DAB, CBD and ABC. Assume $AB = 1$. Then compute CD by the process described in the above paragraph. This gives a ratio between AB and CD, and since CD is known, the actual length of AB may be computed.

20. City Surveying

Staking Out Line and Grade for streets, curbs, sewers, and pavements is constantly done by a city engineering department. This class of work as a rule calls for lines and grades to the nearest hundredth of a foot. For this reason it is customary to use transits with the horizontal arcs graduated so as to read 30″, 20″ or even 10″, and to use steel tapes graduated to hundredths of a foot. In some cases the spring balance and the thermometer should be used so as to make the proper tension and temperature corrections (Art. 13).

A Standard of Length is established as a rule by carefully transferring the length of some other standard by means of different tapes and under different weather conditions, or by means of tapes which have been standardized by the U. S. Bureau of Standards. This standard should be placed where it will not be exposed to the direct rays of the sun. When the tape is tested it should be stretched out at full length beside the standard and left there until it acquiries the same temperature as the standard before the comparison is made.

Street Lines are usually marked by monuments, but the best practice requires that besides these monuments, which may become misplaced, accurate offsets to the underpinning of buildings along the line shall be measured and recorded so that if the monuments become disturbed, due to building operations or paving of the sidewalks, they can readily be replaced in their exact location. These monuments are usually ordinary stone bounds 3 or 4 ft. long and 4 to 8 in. square on top. The bound should be long enough so as to rest on ground below frost. A drill-hole in the center of the top marks the point; a more exact method of marking is to fill this drill-hole with lead and drive a very small copper tack in the lead at the exact point. A copper bolt, with a punch hole marking the exact point, is sometimes inserted in the drill-hole.

To Set a Stone Bound in the place of a stake marking a corner, first drive four temporary stakes around the corner stake 3 or 4 ft. from it and in such a way that a line stretched from two opposite stakes will pass over the tack in the head of the corner stake. Then tacks are carefully set in the tops of these temporary stakes in such positions that a stretching line running from the tack on one stake to the tack on the opposite stake will pass exactly over the tack in the corner stake. Then the corner stake is removed and the hole dug for the stone bound. Care should be taken not to dig the hole any deeper than is necessary so that the bound may be set on firm earth. When the hole for the bound has been dug to the proper depth the monument is dropped into the hole in such a manner that it will be plumb. The fill around the bound should be placed with considerable care, the material being properly rammed as the filling proceeds and the bound kept in such a position that the drill-hole in the top of it shall be exactly under the intersection of the strings. It is sometimes desirable to put in a foundation of concrete and to fill with concrete around the monument to within a foot of the surface where a very substantial bound is required, or where the ground is so soft as to furnish an insecure foundation.

Curved Street Lines are as a rule composed of simple or compound circular curves and are laid out by the method of deflection angles as explained in Art. 56. But the lengths of these curves are the actual length of arcs; this calls for a slight modification in the computations and in measuring the lengths from that used in railroad practice. The length of the curve in city practice equals the radius × the circular measure of the central angle. Since the tape must be stretched along chords in making the measurements the station points to be set by the deflection angle method will be located by measuring the chord subtending the arc of say 50 or 100 ft. depending upon how frequently the points are to be located on the curve. A convenient formula for determining the difference in length between the arc and its chord is $\mathbf{L - C = L^3/24\,R^2}$, where L is the arc, C is the chord, and R the radius, all in the same units. This formula is correct to the nearest hundredths of a foot for chords of 50 ft. or less where the radius is 150 ft. or greater, or for chords of 25 ft. or less and radii 25 ft. or greater. It is sufficiently exact to compute the results by such a formula with the ordinary slide rule. The deflection angle to any point on the curve equals half the total central angle multiplied by the ratio of its distance from the instrument to the total length of curve (see Art. 56).

In Staking Out Street Grades for setting curbs, for pavement or sewer construction, self-reading rods, such as the Philadelphia rod, are the most practicable, although target rods are used to some extent. The target rod is particularly useful in taking an individual exact reading at any considerable distance from the instrument, which is required in city surveying more than in topographic surveying.

A target rod is also useful in "shooting in grades," for curbs or sewers as follows. If it is a straight grade from Sta. 0 to 5 and grade stakes have been set at 0 and 5 the instrument is set up just to one side of Sta. 0, the rod held on the grade stake at Sta. 0, and target clamped at the height of the telescope, then the rod is held on the grade stake at Sta. 5 and the telescope inclined so as to sight the target and clamped. The line of sight is then parallel to the grade line, and any intermediate stake may be set by driving it until the target coincides with the horizontal hair of the telescope when the rod is held on the stake.

It often happens that the pavement is so hard that stakes cannot be driven or that it is not advisable to use stakes on account of the danger to pedestrians, in which case the grades are marked on fences and buildings, and frequently a convenient place is not found at the grade height. In such cases the grade is marked one or two feet higher or lower than the grade height and marked on the building thus $\underline{\diagdown^{2'}\diagup}$ meaning that the correct grade is 2 ft. lower than this mark, or $\overline{\diagup_{1'}\diagdown}$ meaning that the grade is 1 ft. above this mark; the arrow points in the direction and the number gives the distance to measure to reach the proper elevation.

When the grades are marked in hard pavements it is customary to drive stout spikes flush with the ground and take the elevation of the tops of these spikes and make a record of the amount the several spikes are above or below grade to be given to the foreman.

Both curb and sewer grades are as a rule laid out as above described. The lines given for such construction are usually parallel lines, 3 to 6 ft. to one side of the center line, and marked by stakes or spikes.

Parabolic Vertical Curves are used to connect grades of different slope, the same system of computing elevations for points on the curve being used as explained in Art. 60.

A Rectangular Coordinate System based upon plane surveying, disregarding the effect of curvature of the earth, is used in the survey of some of the large cities, such as Baltimore and Boston. Two arbitrary lines at right angles to each other are chosen as axes of a coordinate system, and all important points, such as street corners, are located with reference to these coordinates. One of the chief advantages of this system is that any number of lost points can be easily replaced because their relation to the remaining located points in the city is known.

In laying out a system of this sort a base-line is measured and a triangulation scheme computed as a basis, secondary triangles being formed from the larger ones, and then traverses are run from these triangulation points and closed on other triangulation points. All of the triangles are considered to be plane triangles in the computation. The origin of the coordinate axes is either taken so as to lie outside of the city limits or else, if it is inside, it is given a value such as 20 000, 20 000, so that negative values for coordinates are avoided.

21. Special Problems

Setting Batter-boards for a Building. One of the most common tasks of the surveyor is to set the batter-boards for the excavation and construction of the cellar of a new building. For a brick or stone building the lines to be defined are the outside lines of the building, and the elevation desired is usually the top of the first floor. In the case of a wooden building the line usually given is the outside line of the brick or stone underpinning, and the elevation given is the top of this underpinning on which the sill of the house is to rest. Sometimes the outside line of the sill is desired instead of the outside line of the underpinning. There should be a definite understanding in regard to these points before the work of staking out is begun.

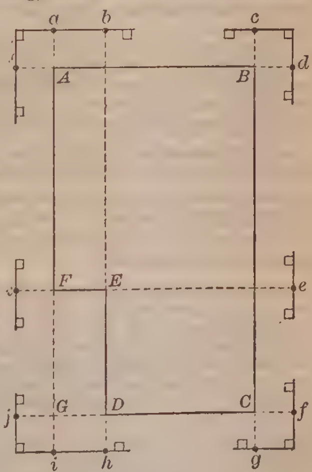

Fig. 16

The first work is to stake out the location of the building by accurately setting temporary stakes at all of the corners of the building—in Fig. 16, at A, B, C, D, E and F. A stake should be set at G also so that the entire work can be checked by measuring the diagonals AC and BG, and FD and EG. These checks should always be applied where possible. Then the posts for the batter-boards are driven into the ground 3 or 4 ft. outside the line of the cellar so that they will not be disturbed when the walls are being constructed. On these posts, which are usually of 2 × 4-in. scantling, 1-in. boards are nailed. These boards are set by the surveyor so that their top edges are level with the grade of the top of the underpinning or for whatever other part of the building the grades are required. After the batter-boards are all in place they should be checked roughly by sighting across them; they should all appear at the same level. Sometimes, however, on account of the slope of the ground some of them have to be set a definite number of feet above or below grade.

Then the lines are to be marked by nails driven in the top of these batter-boards. The transit is set up on one of the corner stakes of the house at *B* (Fig. 16), for example, and a sight is taken on *C*. This line is then marked on the batter-board beyond (at *g*) and on the one near the transit (at *c*). Then a sight is taken along *BA* and this line is produced both ways and nails set on the batter-boards at *l* and *d*. In a similar manner all of the lines are marked on the batters. These points should be marked with nails driven in the top-edges of the batter-boards, and there should be some lettering on the boards to make clear which lines have been given. It is well for the surveyor also to show these marks to the builder or inspector and have it clearly understood just what parts of the structure these lines and grades govern.

Supplying Closing Side of a Traverse. If the latitudes and departures of the several courses of a traverse which does not close are computed, the algebraic sum of the latitudes give the latitude of the closing side and the algebraic sum of the departures gives the departure of the closing side (Art. 16). The square root of the sum of the squares of these two elements gives the length of the closing side, and the tangent of its bearing is its departure divided by its latitude.

To Cut Off an Area by a straight line from a point on a side: Plot the field and the known point; draw a trial line from this point to an angle in the other side of the field so as to lay off approximately the required area. Then the sides and bearings of all the lines except the trial line across the field are known; and its length and bearing can be computed as explained in the previous article, and the area of the portion cut off computed by the D.M.D. method (Art. 16). The difference between this area and the area required is a triangle whose base is the trial line and whose altitude can be readily computed, from which the distance along the side of the field from the end of the trial line to the correct point can be computed. Then the closing side can again be calculated and the area cut off computed by the D.M.D. method, which should this time give the desired result.

To find the area cut off by a line in a given direction from a given point, let the cut-off line be *AC*. This problem may be readily solved by drawing a line from *A* in the traverse to the corner *B* which lies nearest the other extremity *C* of the cut-off line. The area of the portion of the traverse cut off by *AB* is then computed (Art. 16), and to this area is added or from it is subtracted the area of the triangle *ABC*.

Athletic Grounds. In the layout of athletic grounds the matter of orientation, so that the sun will not shine in the eyes of the players or in the eyes of the spectators, is of great importance. A baseball, football or tennis ground should therefore be laid out with its length running in a north and south direction, and with the grand-stand on the west side because most games are played in the afternoon.

Running Tracks should be as a rule one-eighth or one-quarter mile in length, because on tracks of these lengths a full number of laps (or half laps) are required for the ordinary dashes of 220 yd., 440 yd. and 880 yd., thus bringing both the start and the finish of the race in front of the grand-stand. A good running track should be 15 ft. wide on all portions except in front of the grand-stand, where it should be made 20 ft. wide for use in 100-yd. dashes, in which race the contestants are usually "bunched." For these short dashes the straightaway portion of the track is usually lengthened beyond the curve so as to allow at least 40 ft. beyond the finish line. The curves at the ends of an oval field-track should not be sharper than 100-ft. radius if it is possible to avoid it. The line for measurement of the length of a running track is 18 in. from the pole, and in a horse race-track it is 3 ft. from the pole. A good running track can be made in three layers: 8 in. of rock, 2 in. of cinders, and 2 in. of 3 parts screened cinders to 2 parts screened clay loam. A quarter-mile track with curves of 100-ft. radius at its ends will allow placing a football gridiron inside the oval with 20 ft. of turf between the side lines of the football field and the running track, which should be about the minimum distance. One of the best example of this arrangement is the quarter-mile track shown in Fig. 17. The Harvard Stadium is another example of this arrangement, but there the side lines of the football field are too near the running track.

Football Grounds should be 360 ft. × 160 ft., and on level ground; the goal lines are 300 ft. apart, but the goal posts are 360 ft. apart. Lines 5 yd. apart and parallel to the goal lines are laid out to aid in estimating distances made in the plays. The goals are placed in the center of the ends of the field; the goal poles are 18-1/2 ft. apart, and the horizontal cross-bar 10 ft. above the ground. It is of importance, if a good football field is to be made, to screen the surface material through a half-inch screen.

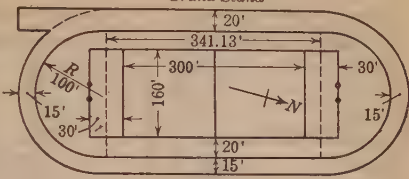

Fig. 17

A Baseball Diamond is laid out as shown in Fig. 18. The size of the field itself is limited only by the space available, except that the shortest distance from home plate to any fence between the foul lines should be 235 ft. The ground should be as near level as possible; there must not be more than 15 in. fall from the pitcher's box to the base lines or to home plate, and the base lines should be level. Where possible to obtain it, there should be 90 ft. behind the home plate, with a minimum of 50 ft. The official junior diamond for boys under 16 years is 82 ft. square and has a pitching distance of 50 ft.

Fig. 18

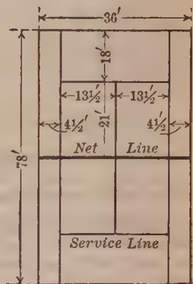

Fig. 19

A Tennis Court is laid out as shown in Fig. 19. An area of 120 ft. × 66 ft. is about the minimum for a good tennis court. It should have surface drainage by grading the court on a slight slope (about 6 in. per 100 ft.) from the center toward the sides. The net posts are placed 3 ft. outside the side lines, and are 3.5 ft. high; the net should be 3 ft. high at the center.

Field Hockey grounds are laid out as shown in Fig. 20. The length is always 300 ft., but the width must be not less than 165 ft., nor more than 180 ft.; always 180 ft., if possible.

In Lacrosse, the field is rectangular, 110 ft. long between goals which are set 6 ft. apart and 6 ft. high in the middle of the ends of the rectangle. The width should be not less than 210 ft. nor more than 255 ft.; there should be 60 to 100 ft. of level ground behind each goal. Each pair of goals is in the middle of a rectangle which measures

18 ft. crosswise of the field and 12 ft. lengthwise. In the center of the field is a circle of 10-ft. radius.

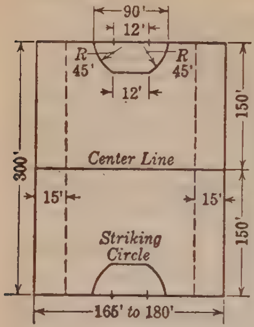

Fig. 20

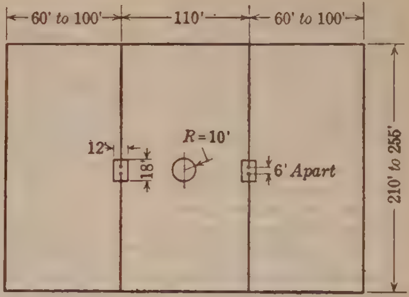

Fig. 20a

In Soccer the field is rectangular, not less than 165 ft. nor more than 195 ft. wide, and not less than 300 ft. nor more than 330 ft. long. The field is marked and goals located as in Fig. 21.

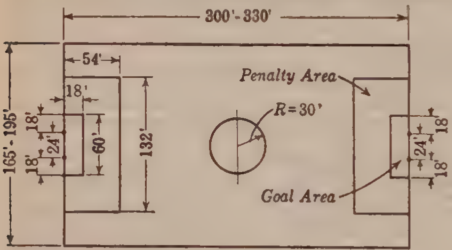

Fig. 21

In Basketball the rectangular court is not less than 35 ft. nor more than 50 ft. in width, and not less than 60 ft. nor more than 94 ft. in length. The field is marked and the goals located as in Fig. 22.

Badminton Courts courts are rectangular and are laid out as in Fig. 23. The net extends 8 ft. on each side of the central line of the courts and at right angles to it; it is 5 ft. high at the center and 5 ft. 1 in. at the posts.

In Quoits the rink should be about 80 ft. long and 25 ft. wide. The pitching distance is 54 ft. Stiff by sticky pottery clay should be used around each iron pin so that the quoit will stay where it lands.

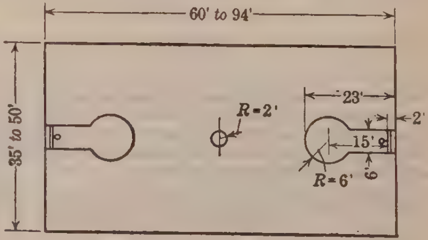

Fig. 22

22. United States Public Lands

The System. The United States system of surveying public lands, inaugurated in 1784 and since modified by various acts of Congress, requires that public lands "shall be divided by north and south lines run according to the true meridian, and by others crossing them at right angles so as to form townships six miles square," and that corners of townships thus surveyed "must be marked with progressive numbers from the beginning." Also, that townships shall be subdivided into 36 sections, each of which shall contain 640 acres, as nearly as may be, by a system of two sets of parallel lines, one governed by true meridians and the other by parallels of latitude, the latter intersecting the former at right angles, at intervals of a mile. Since meridians converge, it is evident that the requirement that the lines shall conform to true meridians, and also that townships shall be six miles square, is mathematically impossible.

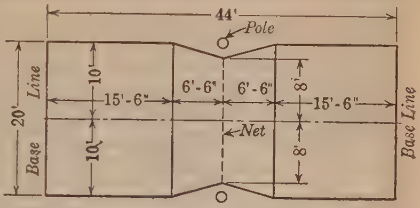

Fig. 23

A surveyor whose work lies in a district formerly a part of the U. S. public lands should procure from General Land Office, at Washington, a copy of "Manual of Surveying Instructions for Survey of the Public Lands of the United States." In this will be found all general and many specific instructions regarding the system, only the general scheme of which is described below.

Subdivision work is carried on as follows: First, the establishment of an **initial point**, a **principal meridian**, by astronomical observations, which is a true meridian through the initial point; and a **base-line** which is a true parallel of latitude through the intial point (Fig. 24).

These operations are performed in different localities as a basis for surveys in those regions. The principal meridian is a straight line and the base-line a curve, being at every point at right angles to the meridian through that point. The base-line is laid out by first running a straight line and measuring offsets from it to locate points on the parallel of latitude. Two methods are used for this, called the secant method and the tangent method, complete explanations of which, with tables, will be found in the manual issued by the General Land Office.

Second, the division of the area into tracts approximately 24 miles square, by establishment of **standard parallels,** sometimes called **correction lines,** which are true parallels of latitude extending east and west through 24-mile points on the principal meridian; and also establishment of **guide meridians,** which are true meridians through 24-mile points on base-line and on standard parallels, and extending north to the intersection of the next standard parallel or base-line.

Since these guide meridians converge, the tracts will be 24 miles on their southern and less on their northern boundaries (Fig. 24). The southerly end of these guide meridians, where they leave the standard parallel or base-line, are called **standard corners,** and points where they meet the next standard parallel to the north are called **closing corners.**

Third, the division of each 24-mile tract into **townships** (Fig. 24), each approximately 6 miles square, by establishment of **meridional lines,** or **range lines,** which are true meridians through standard township corners, established at intervals of 6 miles on the base-line and on the standard parallels, and extending north to an intersection with the next standard parallel or base-line; also establishment of **latitudinal lines,** or **township lines,** joining township corners previously established at intervals of 6 miles on principal meridian, guide meridians, and range lines.

Neglecting discrepancies in fieldwork, the east and west boundaries of all townships will be 6 miles in length, but the north and south will vary in length, being a maximum of 6 miles at standard parallel or base-line forming the southern limit of a 24-mile tract, and a minimum at that forming its northern limit. Townships are designated by numbering them in order north and south from the base-line and east and west from the principal meridian. Any series of contiguous townships or sections situated north and south of each other constitutes a **range,** while such a series in an east and west direction constitutes a **tier.** Thus "Township 2 North, range 4 west of the sixth principal meridian" locates its position; usually abbreviated to "T 2 N, R 4 W, 6th P M" (Fig. 24). The half-mile intervals on range lines are made full 40 chains for the entire 24 miles except the most northerly half-mile, into which all excess or deficiency due to irregularities of measurement is thrown. Similarly, corners on east and west lines are so marked that excess or deficiency of measurements is thrown into the most westerly half-mile of a 24-mile tract.

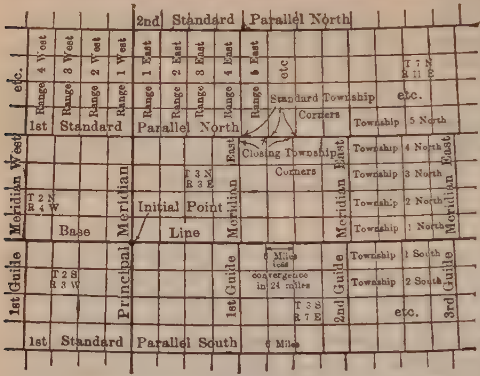

Fig. 24. Subdivision of 24-mile Tract into Townships

Fourth, the division of each township into **sections** (Fig. 25), each approximately 1 mile square (640 acres), by establishing **section lines,** both meridional and latitudinal, parallel to and at intervals of 1 mile from eastern and southern boundaries of township. The sections in all townships are numbered.

In staking out section corners, the surveyor sets up the instrument at the southeast corner of the township, observes the meridian, and retraces range line northward 1 mile, and township line westward the same distance. This is for comparing his own meridian and needle observations, and length of his chain with those of the surveyor who laid off township exteriors. Then from the southwest corner of section 36 he runs north on a line parallel with the east boundary of the township, setting a quarter-section corner at 40 chains and a section corner at 80 chains. Then from the section corner just set he runs east on a random line, parallel to the south boundary of the section, setting a temporary quarter-section corner at 40 chains. On intersecting the range line he notes the falling of his random line and also the distance it overruns or falls short of length of the south boundary of the section. If the falling is not more than 50 links (33 ft. representing an angular deviation of 21 min.) and if the distance overrun for falls short of length of the southern boundary of section 36 by not more than the same amount, a return course which will join the two section corners is calculated; this new line is then run toward the west, the permanent quarter-section corner being set at its middle point.

From the section corner just regained, the survey is now continued north between sections 25 and 26, the direction being changed slightly to east or west according to whether the latitudinal section line just completed exceeded or fell short of the desired length. At 40 and 80 chains on this line quarter-section and section corners, respectively, are set; from the section corner a random line is run across to the range line, a return course being calculated and run as before. This process is continued until 5 of the 6 sections in the series are enclosed. Then, if the north boundary of the township is not a correction line, from the section corner last established a random is run north to the township boundary, and from data thus secured a true line is calculated and run from section corner on township line back to initial corner. If the north boundary of township is a correction line, however, the point at which the random intersects this boundary is established as a **closing corner,** and its distance from the nearest **standard corner** is measured and recorded. In either case the permanent quarter-section corner is established at 40 chains north of the initial corner, the excess or deficiency being thrown into the most northerly half-mile.

In a similar manner the succeeding ranges of sections are enclosed, randoms being run eastward to section corners previously established, and true lines corrected back. But, from the fifth series of section corners thus established, random lines are projected to westward also, and are closed on corresponding section corners in the range line forming the western boundary of township. In correcting these lines back, however, the permanent quarter-section corners are established at points 40 chains from initial corners of the randoms, thereby throwing all fractional measurements into the most westerly half-miles. Reference to Fig. 25 will assist in understanding this method of subdivision.

Subdivision of Sections. When public lands were parceled out to settlers, the quarter-section was usually the unit area granted as a "homestead"; this required establishment of the quarter-section corner at the center of a section. Also, the subsequent division of original "quarters" into "eighties," "forties," or other minor subdivisions, has necessitated the location of numerous corners in addition to those originally established by the government.

The interior quarter-section corner of a section is always located at the intersection of straight lines joining quarter corners on opposite sides of the section. This holds wherever the section may be located within a township; that is, it applies to those in north and west sides as well as to other sections of township. A modification of this method is required in west and north sides of a township; in case of sections lying in west range the meridional line from the quarter corner on north or south boundary of section is run parallel to the east line of the section; similarly, in case of sections lying in the north tier, the latitudinal interior line initiated at the quarter corner on east or west boundary is run parallel to the south line of section. The reasons for this procedure in these special cases are apparent from consideration of methods previously described for establishment of original quarter-section corners in such sections. For subdivisions smaller than quarter-sections the same general methods are employed.

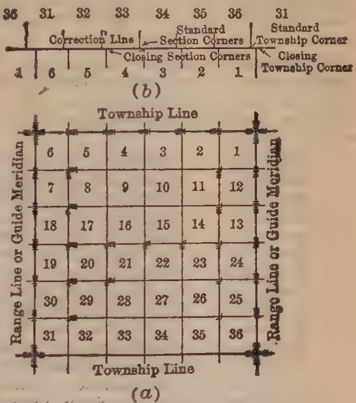

Fig. 25. Subdivision of Township into Sections and Method of Marking Corners

Corners are marked on the ground by various kinds of monuments, depending upon the character and importance of the corner to be perpetuated, the soil, the materials available, and upon other local and special conditions. Where stone is plentiful, stone monuments are usually set. In timbered districts, where suitable stones are difficult to obtain, posts are driven to mark the points. In prairie regions, where neither stone nor timber is available, a mound of earth may be raised over the corner, a small marked stone, a charred stake, a quart of charcoal, or some other permanent and distinguishable mark being deposited beneath it. Occasionally, in timber lands, the corner falls on a spot occupied by a tree, in which case the tree itself may stand as a monument.

Stones or posts are marked with horizontal notches, to indicate their respective positions in the township. Section corners on range lines, including under this term principal and guide meridians, are marked with notches on their north and south faces, the number of notches being equal to the number of miles to the next adjacent township corner north or south. Similarly, section corners on township lines, including baselines and standard parallels, are notched on their east and west faces. Township corners, being located on both range and township lines, are marked with six notches on each of the four sides. Besides being notched, corners on correction lines are marked SC on their northern or CC on their southern faces, depending upon whether they are standard or closing corners. Section corners in interior of a township are given notches on their east and south faces, corresponding to the number of miles to east and south boundaries of township. Thus, the corner common to sections 20, 21, 28, and 29 would have two notches on south and four on east face, as indicated in Fig. 25. Quarter-section corners are marked with the fraction "1/4," those on meridional lines on their west and those on latitudinal lines on their north faces. Wherever possible, a monument set at a corner is witnessed by several nearby objects which may easily be found, are not readily moved or obliterated, and are comparatively permanent. In timbered country the stone or post is usually witnessed by "bearing trees," situated near the corner.

Field Notes of public land surveys must be returned to the General Land Office, giving in narrative form complete data of alignment and topographic features crossed or near the lines. Original notes and plats of these surveys in the following states have been transferred to the state authorities, from whom may be obtained copies on request.

Alabama:	Secretary of State, Montgomery.
Arkansas:	Commissioner of State Lands, Little Rock.
Florida:	Commissioner of Agriculture, Tallahassee.
Illinois:	Auditor of State, Springfield.
Indiana:	Auditor of State, Indianapolis.
Iowa:	Secretary of State, Des Moines.
Kansas:	Auditor of State and Register of State Lands, Topeka.
Louisiana:	Register of the State Land Office, Baton Rouge.
Michigan:	Commissioner of State Land Office, Lansing.
Minnesota:	Secretary of State, St. Paul.
Mississippi:	Commissioner of State Lands, Jackson.
Missouri:	Secretary of State, Jefferson City.
Nebraska:	Commissioner of Public Lands and Buildings, Lincoln.
North Dakota:	State Engineer, Bismarck.
Ohio:	Auditor of State, Columbus.
Oklahoma:	Commissioner of General Land Office, Washington, D.C.
Wisconsin:	Commissioners of Public Lands, Madison.

In many, if not all, of the states named either the original records, or copies of them, have been distributed among the various counties of the state, and are kept for reference and inspection in the office of the County Register of Deeds, County Surveyor, or other official.

Photo-lithographic copies of township plats and field notes of surveys of the area covered by public lands surveys in the above states may also be obtained from the General Land Office, Washington, at nominal prices. In other public-land states, copies of records can be procured on application to the Surveyor General at the State Capitol, except in California and Oregon, whose Surveyors General are at San Francisco and Portland respectively.

Relocating Lost Corners. An act of Congress specifically provides that corners actually located in the field shall be established as proper corners of sections or quarter-sections which they were intended to designate, irrespective of whether or not they were properly located in the first place. A further provision is that "the boundary lines actually run and marked" (in the field) "shall be established as the proper boundary lines of the sections, or subdivisions for which they were intended, and the length of such lines as returned by . . . the surveyors aforesaid shall be held and considered as the true length thereof." The principles upon which present practice in relocating corners of original surveys are based are given in "Circular on the Restoration of Lost or Obliterated Corners and Subdivisions of Sections," published by the General Land Office, Washington.

23. Leveling for Profile

In Leveling to Determine a Profile the line is first stationed, every 100-ft. point, or such other interval as is desired, being distinctly marked. The level is set up and a rod-reading called a **backsight** (B.S., or +S) taken on a point called a **bench-mark** (B.M.) whose elevation is known. When this B.S. is added to the elevation of the B.M. it gives the **height of instrument** (H.I.). Rod-readings called **foresights** (F.S., or −S) are then read on as many station points on the line as can conveniently be seen from the instrument, and the elevation of the point on which the rod rests when a F.S. is taken is found by subtracting the F.S. from the H.I. Rod-readings are taken at all distinct changes in slope which occur on the line which is being profiled, whether these changes come at the full station points or not, and the intermediate stations are determined by tape measurements (sometimes by pacing) and are recorded as plus stations as shown in the sample notes below.

Field Notes in Running a Profile

Profile of Hudson St. Curb (West side). June 17, 1908. Brown, level. Jones, rod.

When it is necessary to move the level to a new position to proceed along the line to be profiled a **turning point** (T.P.) is selected and its elevation determined to use at the next set-up of the level in finding the new H.I. When this new H.I. is found, F.S. readings are taken at the proper stations on the line as far as is consistent with the precision required and then a new T.P. is established, and so on. The readings on the B.M.'s and T.P.'s should be taken to one more decimal place than those taken for the profile. In the notes shown, for example, the readings were taken on the curb to the nearest 0.01 ft., while those on the T.P.'s were read to 0.001 ft. The B.M.'s are all carefully described in the notes; as a rule T.P.'s are not described, but where they are taken on points easily identified it is well to describe them also. The distances from the level to the rod when held on the T.P. or B.M. should be about equal for a backsight and its corresponding foresight, so that any errors in the adjustment of the line of sight or wyes may be eliminated.

If possible the levels should form a circuit, returning to the original B.M. so as to check the intermediate work. A common method is to check the work by readings on other B.M.'s which are passed in progressing along the line. When this is done those B.M.'s should be used as T.P.'s.

The calculation of the level notes may be checked by finding the difference between the sum of the B.S.'s and F.S.'s which were taken on the first B.M., on all the intermediate T.P.'s, and the final B.M. This gives the difference in elevation.

In taking levels for a profile it is necessary to start from some datum to which to refer the levels, and a B.M. whose elevation above some datum plane (such as mean sea level) is used if one is near the locality of the work. Or a B.M. of assumed elevation may be used, in which case all of the levels will refer to an assumed datum. At a later period, if necessary, these levels may be connected to a sea-level datum by running an accurate line of levels between the assumed B.M. and some other B.M. whose elevation referred to sea level is known.

The Proper Length of Sights will depend upon the distance at which the rod appears distinct and upon the precision required. Under ordinary conditions sights should not exceed 300 ft. where elevations are required to the nearest 0.01 ft., and even at a much shorter distance the boiling of the air may prevent a precision of this degree.

Curvature and Refraction Correction. Since a level line is a curved line which at every point is perpendicular to the direction of gravity and the line of sight of a level is along a tangent to this curve it is necessary to take this into account in the more precise leveling work. This correction is usually combined with that due to the refraction of the atmosphere; and the combined correction, for sights of 300 ft., is about 0.002 ft.; for 500 ft., 0.005 ft.; for 1000 ft., 0.020 ft. These corrections are to be applied to any single rod-reading by subtracting from the reading; but if the rod is equally distant from the instrument on the foresight and backsight the effect of curvature and refraction is eliminated from the result.

To Establish a Datum from tidal observations, set up a vertical staff, graduated to feet and tenths, in such a manner that the high and low water can be read. Read the positions of high and low water for each day for as long a period as practicable. The mean value obtained from an equal number of high and low water observations will give the approximate value of mean sea level. If the observations extend over one lunar month the result will be fairly good; to determine this accurately will require observations extending over about eighteen years.

Double Rodded Lines are frequently used when it will be impracticable to run a circuit or when a profile is to be made through a new country where no intermediate B.M.'s have been previously established. Instead of taking a foresight on a single T.P., foresights are taken on two different T.P.'s near together and varying in elevation by a foot at least. When the level is set up again a backsight is taken on both T.P.'s and two H.I.'s computed, which should agree within whatever limits of error are allowable for the class of work at hand. This method of carrying on a check on the leveling is particularly applicable to such cases as running preliminary surveys for a railroad.

24. Leveling for Cross-sections

Cross-sections for Borrow-pits. When it is desired to determine the shape of the ground with a nicety such as is required for landscape architect studies or for computing the material taken from a borrow-pit, the area may be divided into squares (or rectangles) and elevations taken at the corners of these squares and at as many intermediate points as are necessary to determine the shape of the ground. These surface elevations are usually taken to the nearest tenth of a foot, and the squares, which are anywhere from 10 ft. to 100 ft. on a side, are laid out with transit and tape. The corners may be designated by a system of letters for the lines running in one direction and numbers for the system perpendicular to the lettered system; for example, point D 7 lies at the intersection of lines D and 7, and intermediate point $E + 8$, $6 + 4$ lies 8 ft. from line E toward F and 4 ft. from line 6 toward line 7. The notes are kept like profile notes (Art. 23) except that the stations are designated as just described. The tape-rod, described in Art. 7, is of particular use in work of this sort.

When cross-sections are taken to determine the amount of material taken out of a borrow-pit, readings are taken, as described above, before the excavation is started; after the excavation is completed the same system of cross-section lines is again run out and the new elevations at corners, and intermediate points if necessary, are determined. The quantity of material removed is computed as explained in Art. 68.

Road Cross-sections are taken as a basis for estimating the quantity of earthwork in railroad or highway construction, but by an entirely different method from the borrow-pit method. From the plan of the proposed road its alignment is staked out and a profile is taken along the center line, which is subsequently plotted. On this profile the grade line is drawn, which corresponds to the finished surface of the road. Roads are usually first finished to subgrade, which is below the computed surface by an amount equal to the thickness of the road covering, the pavement of a highway or the ballast in the case of a railroad. The width of the base of the road and the inclination of the side slopes are known. For ordinary gravel the slope is usually 1-1/2 ft. horizontal to 1 ft. vertical, called " a slope of 1-1/2 to 1."

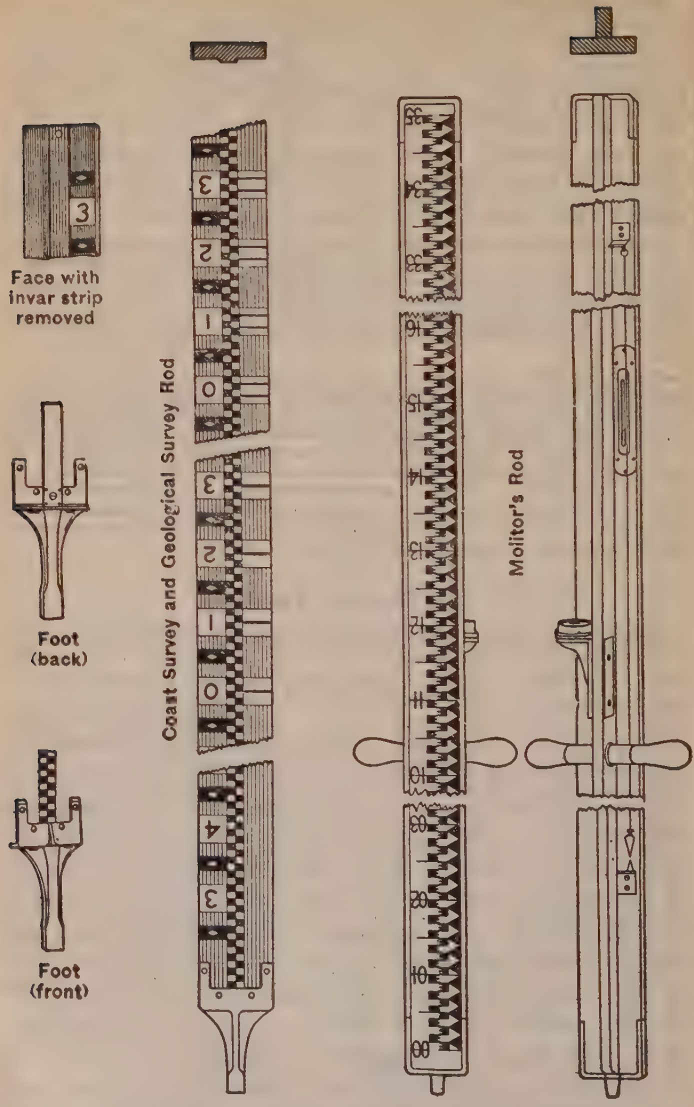
For construction work the engineer sets grade stakes at every full station or oftener on the center line and at both sides where the finished slope intersects the surface of the ground. All three of these stakes are marked, giving the amount of " cut " or " fill " to be made at these points. The cut or fill marked on the stakes where the slopes meet the original surface is the vertical distance from the base of the road to the surface of the ground at these points. The process of setting these slope stakes is described in Art. 64.

Cross-sections for dams, for canals and other engineering structures are common problems for the surveyor. This work consists of making a short profile at right angles to the line of the structure, at intervals of from 10 to 100 ft., depending upon various conditions, and extending far enough on either side to include the possible location of the structure. These cross-section lines representing the surface are plotted for each station, and on them are also plotted the proposed cross-sections of the structure at the respective stations. This gives a complete record of the conditions before the work is started; and as it progresses, by the use of different colored lines, a continual graphical record of the work may be kept from month to month, which is the customary interval for making estimates for partial payments to contractors.

25. Precise Leveling

Precise Spirit-leveling is like ordinary leveling except that certain refinements are introduced into the field methods and the construction and manipulation of the instrument. The characteristic features of a precise level are an inverting telescope of high power and good definition, provided with one vertical and three horizontal hairs, and a sensitive spirit-level of uniform curvature, and a mirror or a set of prisms so adjusted that the observer can see the bubble while he is looking at the rod. The instrument rests on three leveling screws. There is a box level (or two small levels at right angles to each other) for approximate leveling, and a micrometer screw by means of which one end of the telescope tube can be raised and lowered when centering the large bubble. Some of these instruments are of the wye and some of the dumpy type. The present Coast and Geodetic Survey level is a dumpy. This instrument differs from the earlier patterns in that it is made of nickel-iron alloy, which has a low coefficient of expansion; the bubble is placed close to the line of sight so that the adjustment will not be disturbed by local temperature variations; and the reflecting prisms are contained in a second tube at the left of the telescope, so that the observer can view the bubble with his left eye at the same instant that he observes the rod with the right eye. The level vial is provided with an air chamber for regulating the length of the bubble. With this instrument readings can be taken with great rapidity. (See Coast Survey Reports for 1900, p. 521, and 1903, p. 200.)

The Rods used in recent precise leveling work are of the non-extensible self-reading pattern. They are sometimes made in the form of a cross or a T, but the latest rods are flat, about 1 in. × 4 in. in section. The graduations



Precise Leveling Rods

are on a strip of invar fastened to the wood. The rods are usually graduated in the metric scale, the centimeter being the smallest division. The decimeter marks and the figures are painted on the wood at the side of the invar strip. Since the telescope is inverting the figures are for convenience painted upside-down. Sometimes rods are graduated to yards and hundredths. Such a rod is used by the U. S. Geological Survey. The foot of the rod carries a flat steel shoe instead of the rounded form previously used. These rods are provided with a spirit level and a thermometer.

The greater part of the **precise leveling** is done on railway lines. The turning point is ordinarily a nail driven into a tie; sometimes the top of a rail is used. For leveling on highways or whenever the ordinary turning points cannot be used steel pins are driven into the ground.

While being carried from one station to another the level should be protected from the sun's rays. The cam protecting the micrometer should be turned so that the point of the screw is not in contact with the telescope, the nuts at the top of the tripod should be loose, and the central clamp should be tight. The level should be held so that air will not escape into or from the air chamber and change the length of the bubble. When the level is set up the tripod nuts are tightened and the tension on the central clamp screw released so that the leveling screws are free. The instrument is first leveled approximately by means of the circular level and the leveling screws. The telescope is then turned toward the rod and the long bubble centered exactly by using the micrometer screw.

The observations are made in such a manner as to eliminate so far as possible the recognized common errors in leveling work, namely (1) settling of instrument or rod in soft ground; (2) unequal expansion and contraction of different parts of instrument due to temperature changes; (3) irregular refraction near surface of ground; (4) unequal length of foresights and backsights (faulty adjustment of instrument); (5) use of poor turning points; (6) rod not held plumb, and (7) bubble not centered in tube.

Errors due to settling of tripod or rod may be eliminated by taking two backsights and two foresights at each set-up, in the following order: 1, backsight; 2, foresight; 3, foresight; and 4, backsight. The same result is accomplished by taking the backsight first on one set-up and the foresight first on the next set-up. The latter is the method used by the Coast Survey. It is based upon the assumption that the rising or settling takes place at a uniform rate. Temperature errors are avoided by shading the level by an umbrella and by taking the readings in rapid succession. Rapidity also tends to eliminate error in the settling of tripod or turning point. Errors due to refraction may be partly avoided by using a high tripod, always keeping the line of sight away from the ground as much as possible. The lowest reading should be selected when the reading of the lower hair varies on account of refraction. Observations during the middle of the day are more likely to be free from such errors, but in practice leveling is carried on throughout the day. The lengths of backsights and foresights are balanced (nearly) on each sight by reading all three hairs and finding the stadia intervals from the upper and lower ones. The sums of the foresight intervals and the backsight intervals should be shown in the notes at each set-up. The rod is plumbed by use of the spirit-level and the temperature is read frequently.

On the U. S. Coast and Geodetic Survey leveling work two rods are used, the same rod being held on any T.P. first for a foresight and then for a backsight. This results in the same rod being read first at every set-up. The three hairs are read, and the mean and the difference computed, the latter being the stadia interval. The lines of levels are divided (roughly) into 1 kilometer sections, and each section is run forward and then backward, the allowable error of closure being that stated below. The longest sight allowable is 150 meters, which can be used only under exceptional conditions. The difference between foresight and backsight distances must not exceed 10 meters on any one sight, or 20 meters in the total at any time. The adjustment of the instrument is tested daily, and corrected if it exceeds a specified amount.

The **allowable errors** in closing a circuit in precise leveling work of various Surveys are as follows: U. S. Coast and Geodetic Survey, $4^{mm}\sqrt{\textbf{kilometers}}$; U. S. Lake Survey, $10^{mm}\sqrt{\textbf{kilometers}}$; Mississippi River Survey, $5^{mm}\sqrt{\textbf{kilometers}}$; U. S. Geological Survey, **0.017 ft.**$\sqrt{\textbf{miles}}$. The results actually reached fall well within these extreme limits. A high grade of leveling, nearly equal to that of precise leveling, has been done many times with an ordinary wye or dumpy level of good construction, but usually at a greater cost than would have been the case if a precise level were used.

TOPOGRAPHIC SURVEYING

26. Barometric Leveling

The Barometer may be used as a means of measuring differences in elevation, since one inch in the height of the mercury column is equivalent to about 900 ft. in altitude. The atmospheric pressure varies also with changes of temperature and humidity, so that it is necessary in measuring differences in altitudes with the barometer to determine the amounts of these variations and to make proper allowance for them. The ordinary cistern mercurial barometer and the aneroid are used in surveying. The latter on account of its compactness and sensitiveness is more generally employed, but it is liable to derangements if subjected to great ranges of pressure or if roughly handled; it is also subject to errors due to temperature changes.

Barometric Leveling is useful in making a reconnoissance or in determining the contours for a map of very small scale. It is approximate at best, but with a mercurial barometer results as close as 5 ft. may be obtained by careful handling of the instrument, or with an aneroid in good adjustment results correct to 5 or 10 ft. may be obtained but not without repeating the observations and taking great care in the use of the aneroid. The error in height determined by a barometer is approximately a constant, so that the percentage error is much smaller for large differences in elevation than for small differences. The barometer does not give actual heights, but the difference in its readings will be a function of the difference in elevation of the two points provided the atmospheric conditions have not changed so as to affect the readings.

To Read a Mercurial Barometer the screw at the bottom of the barometer is turned until the ivory point is just in contact with the mercury. The vernier is then raised or lowered until its lower edge is just at the height of the mercury column. More than one reading should be taken, and the ivory point should be set in contact with the mercury each time. The temperature of the air and of the mercury are both read when the mercury height is recorded. In carrying the mercurial barometer from place to place the bottom screw should be turned up until the mercury just fills the tube, then the barometer should be inverted and carried in its case upside down.

On the Aneroid Barometer are two scales, the inner one corresponding to inches of mercury and the outer one to feet of altitude, the zero of the altitude scale being in most instruments at 31 in. on the mercury scale. The outer scale should not be movable with reference to the inner scale, for the number of feet of altitude corresponding to one inch of mercury is different in different parts of the scale. Aneroids marked "compensated" are supposed to be adjusted so that changes in temperature of the instrument will not affect the readings. The instrument should be handled carefully in order to avoid disturbing its delicate mechanism. When it is to be read, tap the case lightly to be sure the instrument has adjusted itself to the changed pressure. It should stand a few minutes before it is read so as to allow it to come to the true reading; if should not be heated by the sun's rays or the body; and it may be held in either a vertical or horizontal position when being read, but as the readings in these two positions are different it should be held in the same position at all stations. As accurate results may be obtained from small as from large aneroids.

The Best Field Method requires the use of two barometers, one to remain at some fixed station whose elevation is known, and a continuous record of this instrument will give the atmospheric changes. It is assumed, since the other aneroid will be in use in the same general locality, that the atmospheric changes will be the same at both instruments. It is well to use a mercurial barometer at the fixed station. The second instrument (an aneroid) is read at the start at the fixed station. The difference between the readings of the two barometers at this station is an index correction to be applied to all readings of the moving barometer. The aneroid is then carried to the next station whose elevation is required, and read, and so on to as many points as are desired, making the time of travel between stations as short as possible. At each point the pressure, time and air temperature are read and recorded. Upon the return trip with the aneroid it will be well, as a check, to take readings again at the stations as they are passed, and upon arriving at the fixed station the aneroid is read again. At intervals during the day, every half hour, or oftener if the atmospheric conditions are rapidly changing, the barometer at the fixed station is read and the time, air temperature, and mercury temperature (if a mercurial) are recorded. The interpolated readings of the fixed barometer are entered in the notes of the moving barometer and the index correction applied, thereby eliminating all changes in reading except those due to changes in altitude. When only one barometer is used a reading is taken at the first station when starting on the trip and again at the end of the trip. The difference between these two readings represents the total change due to weather conditions, and interpolated readings for the times when the barometer was read at the other stations must be made for the first station, as illustrated by the example below.

Calculating the Altitude. Differences in elevation are calculated from the differences in pressure either by formula or by table, or it may be found with an aneroid by reading directly the altitude scale which is based on one of the formulas. **Laplace's formula** is one of the most accurate; it is

$$\mathbf{D = 60\,158.6\,(\log h - \log H)\left\{1 + (t_a' + t_a - 64°)/900\right\}},$$

where D = difference in elevation in feet; h = height of mercury at lower station in inches; H = height of mercury at upper station in inches; t_a' and t_a are the observed air temperatures in Fahrenheit degrees. The correction due to air temperature is often a large amount. In case a mercurial barometer is used H is the height of mercury at the upper station reduced to the temperature of the mercury at the lower station by

$$\mathbf{H = h'\left\{1 + 0.00008967\,(t_m - t_m')\right\}},$$

For Determining Difference in Elevation by Barometer

where t_m = the temperature of mercury at lower station and t_m' = the temperature of mercury at upper station. The following table condensed from Guyot is based on this formula.

Example using one aneroid barometer: find difference in elevation between Overlook and Bald Mt.

Station	Time	Barometer, inches	Air temperature
Overlook	9.25 a.m.	29.42	47° F.
Bald Mt.	10.30 a.m.	27.15	30°
Overlook	10.57 a.m.	29.36	43°

Here 10.30 − 9.25 = 1.05 = 65 min., time going up, and 10.57 − 9.25 = 1.32 = 92 min., total time. Also 29.42 − 29.36 = 0.06 in., diff. in barometer height at Overlook, whence 29.42 − (0.06 × 65/92) = 29.38, probable reading at Overlook at 10.30 a.m.

From Barometric table, 29.38 = 28 157
27.15 = 26 095

2 062

Temp. Corr. $= 2\,062\left[\left\{1/2\,(47+43)+30\right\}-64\right]/900$ = + 25

Difference in elevation = 2 087 feet.

The various **barometers** constructed on what is known as the "Paulin System" are capable of giving precise results. These instruments have the following characteristics: They have no inertia due to friction; they are free from lag, and come promptly to the correct reading; they can be locked so that ordinary shocks have no effect and the instrument can be safely transported. They are fully compensated for temperature.

Barometers of this type are made for leveling work, for altimeters of airplanes, and for general use. The ranges vary from 3300 ft. for leveling instruments to 20 000 ft. for altimeters for airplanes.

The principle involved in their construction is as follows: The force exerted by the vacuum chamber is opposed by that of a heavy spiral spring. When a reading is to be taken the spring is compressed until the vacuum box is forced back to its normal position. The force required to do this is read on the scale, either as inches of mercury or as feet of altitude. The vacuum box is always in the same condition when a reading is being taken, instead of being deformed and strained as with the ordinary aneroid. The device for determining when this balance is attained is extremely sensitive and the instrument can be made to read elevations directly to about 2 ft., and by estimation, somewhat closer than this. When the barometer remains in a fixed position this device shows at once the slightest change in atmospheric pressure. On altimeters it shows at once any variation in the altitude of the plane from the altitude to which it was set.

This instrument cannot of course overcome variations in pressure due to atmospheric changes, any more than any other barometer can. It is necessary, therefore, to use two barometers if the work extends over a period and changes are taking place. It is also necessary to make allowance for air temperature, as usual.

27. Trigonometric Leveling

Finding the Difference in Elevation of two points by means of the horizontal distance between them and the vertical angle is called **trigonometric leveling.** It is used chiefly in determining the elevation of triangulation stations and in obtaining the elevation of a plane-table station from any visible triangulation point of known elevation. In triangulation work the vertical angles are usually measured at the same time the horizontal angles are measured, so as to obtain the elevations of triangulation points as well as their horizontal positions. The vertical angle is measured to some definite point on the signal whose height above the center mark of the station was determined when the signal was erected, and the height of the instrument above its station should be measured and recorded. In the most exact work the angles are measured with a special vertical circle instrument. In less precise work an ordinary theodolite whose vertical arc reads by verniers to 30″ or to 20″ may be used, but with such instruments only single readings can be made. The best results with such an instrument are obtained by taking the average of several independent readings half of which are taken with the telescope direct and the other half with the telescope inverted. In every case the index correction, or reading of the vertical arc when the telescope is level, must be recorded.

Simultaneous Observations. The chief difficulty in obtaining accurate results by trigonometric leveling is due to the uncertainty of the angle of refraction, that is, the angular deviation of the line of sight on account of the refraction of the air. This varies with the locality, the temperature and the atmospheric pressure, so that the only way its effect can be practically eliminated is by taking simultaneous observations between two stations, in which case

$$\mathbf{h_1 - h_2 = K \tan \tfrac{1}{2} (\alpha_2 - \alpha_1) \left\{ 1 + \frac{h_1 + h_2}{2\,R} + \frac{K^2}{12\,R^2} \right\}}$$

where $h_1 - h_2$ = difference in elevation of stations in feet; K = arc of the earth subtended between plumb lines through the two station points, approximately equal to the distance between the two stations in feet; α_1 and α_2 are the simultaneously observed vertical angles; R = radius of earth at latitude of the stations; for most work it is close enough to use log R (in feet) = 7.32068.

Observation at One Station. If the observation is made at only one station the **refraction coefficient** must be known and applied to the vertical angle. The refraction coefficient is $m = r/c$, whence $r = mc$, where r = the angle of refraction and c = the angle at the center of the earth between the two stations. For a single observation

$$\mathbf{h_2 - h_1 = K \tan \left[\alpha_1 + (1/2 - m) \frac{K}{R \sin 1''} \right] \left[1 + \frac{h_1 + h_2}{2\,R} + \frac{K^2}{12\,R} \right]}$$

In this formula the letters have the same significance as in the formula for simultaneous observations above. In solving for $h_2 - h_1$, approximate values are first obtained by omitting the last factor; the approximate values are then substituted in the last factor and corrected values are computed.

From a large number of observations the U. S. Coast Survey has determined values of m as follows:

For lines crossing the sea	0.078
Between primary points (high elevation)	0.071
For interior of the country, about	0.065

Clarke, in his "Geodesy," gives:

For rays crossing the sea	0.0809
For rays not crossing the sea	0.0750

A Rough Determination of the difference in height may be found by multiplying the horizontal distance by the tangent of the vertical angle and applying a single correction for curvature and refraction by the formula $\mathbf{h} = \mathbf{K^2/1.7426}$, where K is the distance in miles between the stations and h is the correction in feet. If K is expressed in units of 1000 ft., then $h = 0.02 \times K^2$ (nearly). This correction is applied so as to increase the difference in elevation if the vertical angle is plus, and it should decrease the difference in elevation if the vertical angle is minus. This method is used for the stadia and plane table except that for ordinary sights or for rough work the curvature and refraction correction is omitted.

28. Contours

A Contour Line is the intersection of a level surface with the surface of the ground. For example, a shore line of a pond is a contour line, and if the pond level were raised a foot its new shore line would be the contour line of 1 ft. greater elevation. Contours are used to represent the shape of the ground, and give a means of reading elevations directly from the map. It is customary to locate them a whole number of feet above the datum, such as the 50-ft. contour, and at regular intervals, at, say, every 2 ft. or every 5 ft., the number of the contour is its elevation above the datum. Since the contours are taken equidistant vertically their horizontal distance apart gives a measure of the steepness of slopes.

Characteristics of Contours are: (1) All points on any one contour have the same elevation. (2) Every contour closes on itself, either within or beyond the limits of the map. (3) A contour which closes within the limits of the map encloses either a summit or a depression. In depressions there will usually be found a pond or a lake; but where there is no water the contours are usually marked in some way to indicate a depression. (4) One contour can never cross another except where there is an overhanging cliff, in which case there must be two intersections. (5) On a uniform slope contours are spaced equally. (6) On a plane surface they are straight and parallel. (7) In crossing a valley the contours run up the valley on one side and, turning at the stream, run back on the other side. Since the contours are always at right angles to the lines of steepest slope they are at right angles to the thread of the stream at the point of crossing. (8) Contours cross the ridge lines (divides) at right angles.

Contours and Profiles. If a line is drawn across a contour map, the profile of the surface along that line may be constructed, since the points where the contours are cut by the line are points of known elevation and the horizontal distances between these points can be scaled or projected from the map. The profile shown in Fig. 26 is constructed by first drawing, as a basis for the profile, equidistant lines, corresponding to the contour interval, and parallel to XY. From the points where XY cuts the contours, lines are projected to the corresponding line on the profile. Conversely, if the profiles of a sufficient number of lines on the map are given it is possible to plot these lines on the map, mark the elevations, and then to sketch the contours.

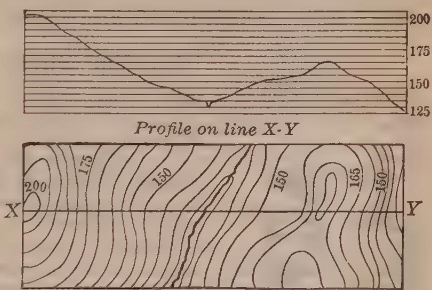

Fig. 26

Locating Contours. Since the topography of much of the country is due to stream erosion the position and fall of streams gives much information regarding the location of contours. These, together with a few ridge elevations, give information from which contours may be readily sketched. It should be borne in mind in sketching contours that they cross the stream at right angles and curve around from the hill on either side so as to represent the valley; they are usually farther apart at the top and bottom of a natural eroded slope (where no wave action is present) than in the middle; a stream is usually steeper near its source than in its lower portion.

Where the contour interval is small and much detail is desired the ground may be cross-sectioned (Art. 24) and from the elevation determined the contours may be sketched. Or the contours may be actually traced out and located by stadia. In this case the rodman moves up or down the slope until a level rod-reading shows that the foot of his rod is on a contour. The position of the rod is then located by distance and azimuth.

The hand level is used to a considerable extent on railroad preliminary surveys to locate contours, and is satisfactory for such work because the contours are located only a short distance from the transit line so that the inaccuracies of hand-level work cannot become very great. In using a hand level for locating contours, first measure the distance from the ground to the levelman's eye, which may be, say, 5.2 ft. Then from a reading of the rod held on a point of known elevation the elevation of the eye of the levelman is determined. The leveler then directs the rodman uphill or downhill until the rod-reading is such as will correspond to the foot of the rod being on a contour. When this point is found it is located by tape or by pacing. Then, if the contours are being located on a sidehill, the levelman moves uphill past the located point on which the rodman stands until the levelman reads the contour interval plus 5.2 on the rod. When this point is reached the levelman is standing on a contour which is then located. The levelman stands on this point and the rodman travels uphill until the levelman reads 5.2 minus the contour interval on the rod, when the rod is resting on the next higher contour. In going downhill the rodman holds his rod on a contour and the levelman will back down the hill until he reads 5.2 minus the contour interval on the rod, at which point the levelman will be standing on the contour next below the rodman; then the rodman passes the levelman and backs down the hill until the rod-reading is 5.2 plus the interval, which determines the next lower contour. Sometimes profiles are run and the elevations plotted on the plan give a basis for sketching the contours. Profiles of valleys and ridges as a rule give the best data.

29. The Stadia

The Stadia Method is one in which distances are measured by observing through the telescope of a transit the space, on a graduated rod, included between two horizontal hairs called **stadia hairs**. If the rod is held at different distances from the instrument different intervals on the rod are included between the stadia hairs, the spaces on the rod being proportional to the distances from the instrument to the rod, so that the intercepted space is a measure of the distance to the rod. This method furnishes a rapid means of measuring distances in filling in details of topographic and hydrographic surveys. It is used either with a transit or a plane table which is provided with the two additional horizontal cross-hairs. It has the great advantage that the intervening country does not have to be traveled, provides a means of measuring inaccessible distances such as across water surfaces, the errors of measurements are compensating rather than cumulative, and it affords an accuracy sufficient for many kinds of work, being applicable even to surveying for area of such lands as wood lots or farms, for an accuracy of one part in 500 may be attained with the stadia. The **rod** used may be of any desired pattern of self-reading rod, the Philadelphia rod being a good type for short distances. It is well to use a rod with the graduations represented by some

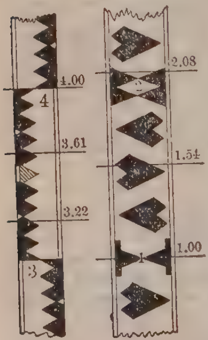

Fig. 27

diagram which can be seen distinctly a long distance away, 1000 to 2000 ft. Portions of two of these rods are shown in Fig. 27, with the reading of the three cross-hairs marked in the figure.

The Fundamental Principle of the stadia is the simple geometric proposition that in two similar triangles homologous sides are proportional. The vertex of these triangles is not the center of the transit but is at a point in front of the objective a distance equal to F, the focal length of the objective, so that the distance from the center of the instrument to the rod $= \frac{\mathbf{F}}{\mathbf{i}}(\mathbf{s}) + (\mathbf{F} + \mathbf{c})$, where i is the distance between the upper and lower stadia hairs; s is the intercepted space on the rod; and c is the distance from the center of the instrument to the objective. Evidently $(F + c)$ is practically a constant for any given instrument; for transits it varies from 0.75 to about 1.35, depending upon the style of instrument. For all ordinary purposes it may be taken as 1 ft. for transits and 2 ft. for plane-table alidades. The other function $(F/i)\,s$ is a variable, but as it is almost always customary to have the stadia hairs spaced so that $F/i = 100$ this reduces the equation to Distance $= 100\,s + 1$. Every hundredth of a foot on the rod is then a measure of one foot of distance.

Inclined Sights. Since it is the horizontal distance which is required it is necessary to reduce all inclined readings to the horizontal, and when the difference in elevation between the instrument station and the rod station is desired the vertical distance also must be computed from the inclined sight. In practice it is customary to hold the rod plumb rather than perpendicular to the line of sight, so that it is evident that if the line of sight is inclined it will subtend an interval on the rod which is too great depending upon the angle of inclination, α, and the distance the rod is from the instrument. By trigonometric proof, with one slight assumption, it may be shown that the

$$\textbf{Vertical Distance} = (\mathbf{F/i})\,\mathbf{s} \cdot \mathbf{1/2 \sin 2\alpha} + (\mathbf{F} + \mathbf{c}) \sin \alpha$$
$$\textbf{Horizontal Distance} = (\mathbf{F/i})\,\mathbf{s} \cdot \mathbf{\cos^2 \alpha} + (\mathbf{F} + \mathbf{c}) \cos \alpha$$

For the ordinary conditions (when $F/i = 100$ and $F + c = 1$) and making the approximations that $\sin\alpha = 1/2 \sin 2\alpha$ and $\cos\alpha = \cos^2\alpha$ in the last terms of the above formulas, which are nearly correct for small angles,

$$\textbf{Vertical Distance} = (100 \times \text{rod interval} + 1)\ 1/2 \sin 2\alpha$$
$$\textbf{Horizontal Distance} = (100 \times \text{rod interval} + 1) \cos^2 \alpha$$

These are in the form used for ordinary transit work. The reduction of the field-notes can be best accomplished, however, by the use of tables, diagrams or stadia slide rules, all of which are based upon these formulas.

The rod intervals are usually read to the nearest hundredth of a foot, giving the distance to the nearest foot only, so that in most topographic work, where the distances are not required to within a foot, the constant $(F + c)$ may be neglected, and in such work there will be no need of applying the horizontal correction for vertical angles under 3 degrees.

30. Stadia Fieldwork

Points are Located by (1) the azimuth, (2) the distance, and (3) the angle of elevation or depression. If elevations are not required the vertical angle is read only to the nearest 10 minutes, for that is close enough for determining the horizontal distance, but if elevations are required the vertical angle should be read to the nearest minute and sometimes to the half-minute and the index correction also read for each vertical angle. The distance and azimuth angle are read with whatever refinement is necessary for the work in hand;

as a rule the distances are recorded to the nearest foot and the azimuth to the nearest minute, although for single "shots" which are to be plotted by use of the ordinary protractor the azimuth to the nearest 5 minutes is close enough. Traverse lines which control the survey are measured by tape or by stadia as the accuracy of the survey may demand. For large-scale maps it may be necessary to tape the distances of the control, but for small-scale maps the stadia method is sufficiently accurate. In the latter case the distances should be read both on the foresight and backsight.

Azimuths. In starting the survey, if the true azimuth of any line is known all of the azimuths of the survey may refer to that meridian, but if no meridian has been established, as is frequently the case, the azimuths may be referred to the magnetic meridian. Azimuth angles are read from the south right-handed for 360°. The horizontal circle is set on 0°, the telescope turned so that it points toward magnetic S and the lower clamp tightened. Then if the upper clamp is loosened and the telescope sighted toward the next station the horizontal arc, if read right-handed, will give the azimuth of the first line referred to the magnetic meridian. The azimuth of any other line may be obtained by simply resetting the upper clamp as each sight is taken. When it is necessary to move to the next instrument station the telescope is oriented, by the method explained in Art. 15, so that it will read 0° when pointing to the south. The bearings of the traverse lines will give a rough check on the azimuths of those lines.

Distances are read by setting one of the stadia hairs on a whole footmark, by means of the vertical arc clamp and tangent screw, and counting the feet, tenths and hundredths of a foot between the stadia hairs. Great care should be taken not to mistake the middle horizontal cross-hair for a stadia hair. This can be avoided by always making a mental estimate of the distance. Occasionally a half-interval may be read when something obstructs the view of the whole interval.

The Vertical Angles are taken by sighting the middle cross-hair on a point on the rod whose distance above the foot of the rod is equal to the distance from the horizontal axis of the telescope to the station beneath the transit. The distance is known as the **height of instrument** (H.I.); it is not the same as the H.I. in ordinary leveling, which is the distance of the telescope above the datum. When the middle hair is sighted at the H.I. point on the rod the line of sight is parallel to a line drawn from the station under the transit to the foot of the rod, and the vertical angle read is the inclination of this line, so that the difference in elevation of the two stations can be directly computed.

It is sometimes impossible to set on the H.I. point on the rod owing to obstacles in the line of sight. In such a case the angle is taken when sighting at some convenient footmark on the rod, and this reading of the middle hair on the rod is recorded in the notes with the vertical angle. The H.I. point is sometimes marked by a red cloth band; its position being changed at each new set-up of the instrument.

The Order of Fieldwork is as follows: First read the distance and record it, then set the middle hair on the H.I. point of the rod and the vertical hair on the rod. Signal the rodman to go to the next point, and while he is moving to the next point read the horizontal circle, the vertical arc and its index correction if necessary. Unless elevations are required, the H.I. is not used, and the vertical arc will not be read except for angles of 3° or more.

Stadia Notes require a large amount of sketching and description of details in order to convey sufficient information to enable a draftsman who may not be familiar with the locality to plot the notes. Where the notes are merely for flat topography, with no elevations, the difficulties are not great. The side shots are numbered, and these numbers should be put on the sketch in such a manner as not to be mistaken for any measured distance which may also be recorded on the sketch. Where the survey is for a contour map the accuracy of the map depends in a large measure upon the completeness of the descriptions given in the notes regarding the slope of the ground between located points. The elevation of points on ridges, valleys, knolls, and depressions will be determined in the field, but without a full description of the slopes of the surface the correct interpretation is often next to impossible. One method is to describe the shape of the ground in the notes; another method is to sketch contours in the notebook, showing approximately the form of the surface.

31. Stadia Computations

Reduction of Stadia Field Notes is usually done by means of tables, diagrams or stadia slide rule rather than by direct use of the formulas. The **stadia slide rule** is the most convenient when the reductions are required in the field as in plane-table surveys. The difference in elevation can be most rapidly obtained by means of a diagram or stadia slide rule, while the horizontal distances can be rapidly computed by use of a table of **horizontal corrections** which gives the distances to be subtracted from the inclined readings to obtain the horizontal distance, to which must be added the instrument constant $(F + c)$. The stadia reduction tables presented here give, for vertical angles up to 20°, the difference in elevation for an inclined distance of 100 ft. If the inclined reading is 612, the instrument constant 1 ft., and the vertical angle 4° 42′, the difference in elevation = 6.13 × 8.17 = 50.1 ft. Since the rod intervals are read as a rule to only three significant figures this multiplication can be accomplished with sufficient accuracy by means of the ordinary 10-inch slide rule. The 50.1 ft. is recorded in the notes and this difference in elevation is applied to the elevation of the station over which the transit is set to give the elevation of the point desired. It will be seen from an inspection of the tables that a half-minute greater vertical angle would have increased the difference in elevation by a little less than 0.1 ft., which shows the importance of reading the vertical angle carefully and of applying its index correction.

Even without this table vertical heights may be computed if a table of horizontal corrections is available. A condensed table of horizontal corrections can be made which can be pasted on a leaf in the back of the notebook. After the horizontal distance has been found by the use of this table the vertical height can be computed by multiplying the horizontal distance by the tangent of the vertical angle, which can be conveniently accomplished by use of the tangent scale on an ordinary slide rule.

Where the vertical angle is not taken to the H.I. mark on the rod this must be taken into account in the working up of the column of differences in elevation as follows. Suppose at a point the distance read was 135, vertical angle −8° 50′ on 2.5, H.I. 4.5; then −(1.36 × 15.17) + 2 = −18.6 ft. Here the 2 ft. is + because the vertical angle was taken to a point 2 ft. lower than the H.I. point. Had the vertical angle been a + angle the 2 ft. would still have been applied so as to increase the difference in elevation.

Beaman's Stadia Arc. Another method of simplifying the calculations of elevations in the field consists in using only those vertical angles for which the differences in elevation are simple multiples of the rod interval. This principle is used in the attachment devised by Beaman for the vertical arc of the transit or plane table. On this attachment are marked the numbers giving multiples of the rod interval, the zero graduation being marked 50 instead of 0 so as to make it easier to determine which are plus and which minus angles. In using a transit with this attachment the observer reads the distance, turns the tangent screw of the telescope until the index line is opposite some

line on the attached arc, and then notes the rod reading of the middle cross-hair. The difference in elevation between the telescope and the reading on the rod is (50 minus the reading of the arc) times the rod interval. From this result must be subtracted the rod reading to give the difference in elevation between the telescope and the foot of the rod. Evidently no stadia tables or slide rule are needed when this attachment is used.

32. The Plane Table and Its Use

The Plane Table is an instrument by means of which points are located in the field by graphical methods directly on the map, which is fastened to a table top supported on a tripod. The accuracy of the map is usually limited by the accuracy of plotting rather than by the field measurements, for it is used mostly for small-scale maps. In the field the map must be protected from becoming distorted by moisture, so as to preserve the accuracy of the plot. The plane table is the only surveying instrument admitting of a rapid solution of the Three-point Problem in the field; this makes it practicable to locate stations independently of each other, so that errors cannot accumulate as they do in traversing. The most important advantage of the plane-table method over other topographic methods, however, is that all of the sketching is done in the field, where the topographer can see the form of the ground that he is mapping. He can sketch details at once in their proper position, without burdening his memory and without making elaborate notes. For this reason the details may be accurately sketched from a much small number of located points than would be required, for instance, by the transit and stadia method.

The plane-table method has the disadvantage of requiring more time for the field-work than other methods, and it is also more dependent upon favorable weather than a method where the map is not exposed. But taking into account both the field and office work the plane table will prove to be much more economical than the transit and stadia for work in open country, and at the same time the results obtained will be sufficiently accurate for most topographic work.

The Plane Table itself consists of a board, usually about 24 by 30 in., mounted on a tripod with a device for leveling and clamping the board, the Johnson ball-and-socket leveling device and clamp being the most commonly employed. The **alidade** consists of a telescope mounted on a horizontal axis resting in wye supports, which are connected to a metal column at the base of which is attached a flat piece of metal about 18 in. long having both edges straight and parallel to the telescope. On this base are two spirit-levels for leveling the table. The telescope has a vertical motion only and a vertical arc. The entire instrument is moved about in azimuth on the board and sighted as desired.

Locating Points by Intersection. In order to begin a survey with a plane table it will in general be necessary to have on the map two plotted points corresponding to two points on the ground the distance between which is known and at least one of which can be occupied with the table. The simplest method of locating points by means of the plane table without measuring any distance is as follows: The base-line ab is plotted on the plane-table sheet, representing, to some scale, the measured base AB. The table is set so that a on the map is vertically above A on the ground and the table is leveled; then one edge of the alidade is placed along the base-line ab drawn on the map, the table is then turned in azimuth until the telescope sights the signal B, and the horizontal motion clamped. The line ab is now parallel to AB and the table is said to be oriented. The alidade is then placed so that the straight-edge passes through a, the telescope is sighted to some signal C, and an indefinite line drawn toward C. The point c on the map (representing the signal C)

is somewhere on this line. If the table is now moved to B (b being set vertically over B) and the process of orienting the table and sighting toward C is repeated, the point c is located on an indefinite line through b; hence it lies at the intersection of these two lines ac and bc. The triangle abc is similar to the triangle ABC, and each line on the map is parallel to the corresponding line on the ground. In a similar manner any number of points may be located.

Locating Points by Direction and Distance. The simplest way of locating points by the plane table is by obtaining the direction with the alidade and measuring the distance by stadia. This is the method most commonly used for filling in the details of a plane-table survey after the table has been oriented.

Locating Points by Resection. It sometimes happens that it is desired to locate a plane-table station from a base only one end of which can be occupied with the table. In such a case we may proceed as follows: Let A and B represent the points on the ground at the ends of the base-line; C is the signal which is to be located, and ab represents the base-line plotted on the plane-table sheet. Set up at A, the end of the base which is accessible, and orient the table by sighting B with the alidade along ab. Then, centering the alidade on a, draw an indefinite line toward C. This line should be drawn the full length of the alidade. The table is then taken to C and oriented by means of the indefinite line just drawn. Since the position of c on the indefinite line is not known it is necessary to estimate its position on the map and to use this point in placing the table over the point C. If the alidade is now centered on b and sighted toward B, a resection line may be drawn, and this line will cut the first indefinite line, thus locating the point c desired. Thus, without going to station B, the same line has been drawn on the map that would have been obtained by an intersection from B. It is evident that this resection method may be advantageous even if B could be occupied, for the point C has been located without taking the time required to go to station B. The position of c found by this method should be checked if possible by resection lines from other points whose positions are known to be correct.

The Three-point Problem. One of the great advantages of the plane table is that it may be set up at any place where three triangulation points (plotted on the sheet) can be seen and the position of this plane-table station located on the sheet simply by observations from this point. The position of the plane table is found by means of the so-called Three-point Problem, which, in this case, is an application of the principle of resection. The two graphical solutions of this problem chiefly used in plane-table surveying are known as (1) **Lehmann's** method, or the **Triangle-of-error** method; and (2) **Bessel's** method, or the **Inscribed Quadrilateral.** The former is a trial method, but it is the more rapid of the two for ordinary work and is used in practice far more than the latter method. Bessel's method gives a direct solution and consequently requires less experience than the former. It has the disadvantage, however, that in certain positions of the signals a part of the required geometric construction falls outside the limits of the plane-table sheet, in which case the solution is not practicable.

Lehmann's Method. If three signals A, B, and C, have their plotted positions at a, b, and c, and if the table be set up at D and oriented correctly, the resection lines drawn from a, b, and c will all pass through d, the plotted position of D. Since there is no means of accurately orienting the table, the position of d being unknown at the start, the table must be oriented approximately by estimation. If the plane table is not oriented exactly the three resection lines will not ordinarily pass through a common point but will form a triangle known as the triangle of error (Fig. 28). From this triangle of error the true position of d may be estimated, and by a second trial a new triangle of error may be obtained which is smaller than the former. By successive trials this triangle may be made so small that it is almost a point. In practice very few trials are necessary, the triangle often being reduced to a point in the second trial, so that the method is in reality a rapid one.

If the table is on the circumference of the circle through the three signals its position is indeterminate. When point D is inside the triangle ABC it is in a favorable position for an accurate location. If the table is outside this triangle there are certain positions of the signals which are not favorable, especially when the angles subtended by the sides of the triangle formed by the signals are small and the middle signal is farthest from D, but if the middle signal is near D the location of d is strong.

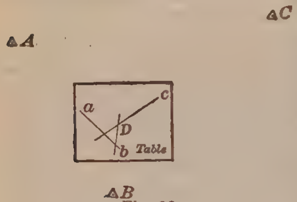

Fig. 28

If D lies inside the triangle ABC then d will lie inside the triangle of error and vice versa. If a circle is passed through a, b and the intersection of the resection lines from a and b it will pass through the true position of d; similarly a circle through b, c and resection lines from b and c may be sketched and in this manner a close estimate of the position of d made for the second trial. The distance of d from any resection line is proportional to the distance of the table from the signal from which that line was drawn.

33. Hydrographic Surveying

Hydrographic Surveying is the term applied to the processes used in surveying any body of water. The determination of the topography of the bottom of a lake, harbor, or other body of water is one of the common problems. In connection with such surveys the character of the material composing the bottom is often desired. The fieldwork is usually done by first establishing certain points on shore, by triangulation or traverse, to which the hydrographic survey may be referred, and then measuring (usually from a boat) the depth of the water at various points and determining the position of these points. Besides the ordinary transit and tape outfit, a sounding-pole or lead-line and a boat with the necessary equipment will be required. A tide gage should be set up in tidal waters and in lakes where the water level changes rapidly. The sounding-poles are made similar to self-reading rods graduated to tenths of a foot. A shoe is sometimes attached to the bottom, provided with a cup-shaped cavity which, if smeared with tallow or soap, enables samples of material to be collected. The lead-line consists of a long chain or a hemp or cotton line at the end of which is attached a lead weight. A brass sash-chain gives very satisfactory results, with cloth tags of various colors for foot-marks. Where there is not much current a 6- to 10-lb. weight will suffice for depths up to 40 ft.

Methods of Locating Soundings. There are six general methods of locating soundings: (1) The boat is rowed on a range at a uniform rate of speed and the soundings are located by time intervals. (2) The boat is rowed on a range line and the positions of the soundings are " cut in " by a transit angle taken on shore or by an angle taken with a sextant from the boat. (3) The boat may or may not be rowed on any definite range, and its position is located by angles taken simultaneously by two transits on shore or by angles taken simultaneously to shore points from the boat by means of two sextants. (4) The positions of the soundings are located by the stadia method. (5) The positions of the soundings are defined by the intersection of fixed ranges. (6) A wire or line is stretched across a stream from shore to shore and soundings are taken at different points along this wire and located by measured distances from one end of it.

Locating a Sounding by a Range and an Angle. In still water where there is no difficulty in keeping the boat in any desired position soundings may be conveniently located by keeping the boat on a range line of known position marked by two objects on shore, such as range poles, and then " cutting in " the position of the leadsman by means of a transit angle taken from shore at the instant the sounding is made. The ranges may be fan-shaped if the pivot-point of the system of ranges is some steeple or other object located far enough back from the shoré so that the lines will not diverge too rapidly. The recorder writes in his notebook the depths as they are called off by the leadsman and also the times when the soundings are made. He also notifies the leadsman by calling out " Sound " about 5 seconds before each sounding is desired. The leadsman takes the soundings as quickly as possible, usually within two or three seconds of the desired time. In the hydrographic work of the Corps of Engineers, U. S. A., where nearly all of the soundings are located by two angles taken with transits on shore, soundings are usually taken at 15, 20, or 30-second intervals, and a location made each minute by the instrument men at the instant the signal is given by the signalman in the boat. The chief of party usually acts as signalman and directs the work in the boat, and sees that the boat is kept on the ranges (if any are used) and that the boat is so propelled as properly to cover the area to be sounded. The signal is given by holding up a flag for about 10 seconds and dropping it suddenly the instant the sounding is taken, at which moment the transitmen on shore take angles to the leadsman or to his hand if visible. In the work of the U. S. Engineers, white, red, and sometimes black flags are used for signaling. Both the recorder's and the instrument men's notes should show the colors of the signal as well as the time for each located sounding, thus giving two means of identifying the angles and the corresponding soundings. This double check is of particular value where the lines of soundings are long. In tidal waters the time record is required also as a means of reducing the soundings to **Mean Low Water** or to whatever other datum is used. The tide gage readings and times are recorded throughout the day.

Where the soundings are taken with a view to obtaining every slight change in the slope of the bottom, instead of taking the soundings at a given interval of time, it is desirable to take them as frequently as the leadsman can conveniently handle the pole. In this method the boat is usually rowed on a range and the instrument men on shore " cut in " only those soundings that are designated by the signalman in the boat. The time in this case is recorded to the nearest second. As a rule every sixth or eighth sounding is located.

In plotting notes like these where the soundings are quite close together the points which were " cut in " are located on the plan and the intermediate readings are interpolated between them; the soundings are assumed to be equally spaced between the located ones.

Locating a Sounding by Two Angles from a Boat. A common method of locating soundings when ranges are not used is by taking two angles simultaneously from the boat to three signals, or any previously determined points, A, B, and C, on shore. This is an application of the Three-point Problem that is frequently used in plane-table work. It is essential that the signals or points should be fixed stations; such points as buoys or floats will not give satisfactory locations.

In measuring angles from a boat it is necessary to employ some instrument which does not require a steady support like the transit. For this reason the angles are usually taken with two sextants. These two angles are sufficient to locate the position of the soundings, except in the one case where the boat happens to be on the circumference of the circle passing through the three signals between which the angles are measured.

This method is less frequently employed than the " range and angle " method or the " two angles from shore " method, because it often happens that the two angles taken with the sextant do not give good intersections; this is especially true when the soundings extend far from shore. Furthermore, if the signal happens to be high above the shore, and consequently not at the level of the boat, the angle measured will be enough different from the horizontal angle to introduce serious error into some parts of the work.

The Sextant is an instrument adapted to measuring angles in any plane. Owing to the fact that it can be used by an observer who is on a moving object, such as a boat, it is especially valuable for hydrographic work. It is employed not only for taking angles from a boat in locating soundings but is also in common use for making astronomical observations which are necessary in determining the latitude, longitude, and time at sea. The **frame** *ABI* (Fig. 29) is usually of brass, on the under side of which is attached the wooden handle *D*. The index arm *IE* is pivoted at *I*, the center of the arc *AB*, and

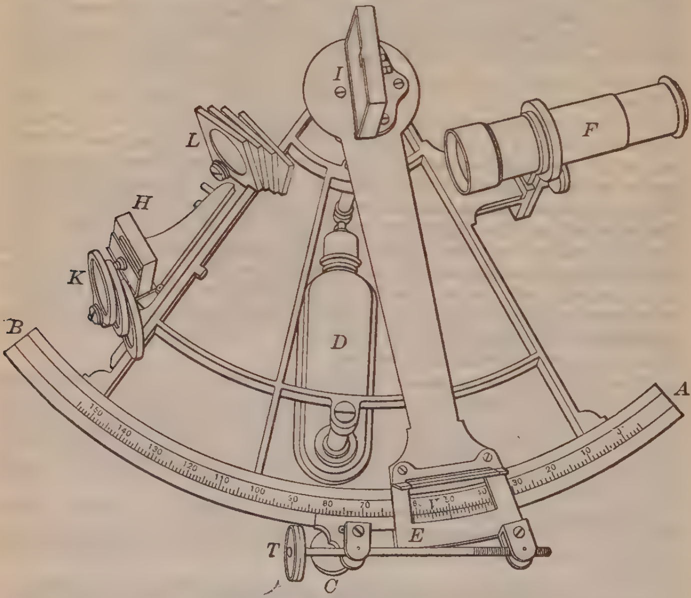

Fig. 29. The Sextant

this arm can be swung around *I* as a center so that the vernier *V* can pass from *A* to *B* on the arc (or limb) and can be set at any position on the arc by means of the clamp *C* and tangent screw *T*. At *I* is a plane glass mirror called the index glass; it is attached rigidly to the index arm and perpendicular to the plane of the sextant, its reflecting surface being over the pivot about which the index arm revolves. Rigidly attached and perpendicular to the frame of the sextant is the plane horizon glass *H*, the upper half of which is transparent and the lower half is a mirror; this glass is set so that its plane is parallel to the index glass when the vernier is set at 0°. The telescope is at *F*. *K* and *L* are colored glasses which are hinged so that they can be swung around the pivot into the path of the rays of light to protect the eye of the observer in making observations on the sun.

It should be borne in mind that the angle measured with the sextant is not the horizontal angle, but is the angle lying in a plane defined by the two objects and the eye of the observer; the objects sighted should therefore be near the shore level unless the sextant is far from shore.

The vertex of the angle is not a fixed point; it moves farther away from the instrument as the angles grow smaller for the lines defining the angle pass from the two objects through the center of the mirrors *I* and of the glass *H*.

The limb *AB* is graduated into spaces which are really half-degrees, but on account of the construction of the instrument each of these is marked as a whole degree, so that the scale has an extent of 120 degrees. The graduations are so subdivided that the angles can be read in most instruments to 10 seconds; in some of the smaller instruments the vernier reads only to half-minutes. In the ordinary sextant the arm is from 5 to 8 in. in length. A pocket sextant having an arm about 2 in. long is very convenient for reconnaissance surveys and for filling in the details of more accurate surveys.

To Measure an Angle with the sextant, hold the instrument by its handle in the right hand and turn it so that the plane of the sextant coincides with the plane through the two objects to be observed, with the telescope on the upper side of the sextant if the angle is horizontal, or on the left-hand side in the case of a vertical angle. Without changing the plane of the sextant twist it in the hand so as to turn the telescope toward the left-hand object and observe it through the upper (transparent) portion of the horizon glass. Then, holding the instrument as steady as possible, turn the index arm with the left hand until the other object appears in the silvered portion of the horizon glass opposite the first point. Bring the second point exactly opposite the first one by means of the clamp and tangent screw of the index arm. The coincidence of the images should be tested by twisting the instrument a little so as to make the reflected image move back and forth across the direct image. Read the vernier and apply the index correction. The telescope is not used for rapid work such as locating soundings; the sight is simply made through the ring in which the telescope fits.

34. Photographic Surveying

A rapid method of locating topographic details for construction of small-scale maps (say 2 or 3 miles to 1 in.) is afforded by photographic surveying. Best results are obtained where the country has characteristic shapes, and is not too thickly wooded to afford good positions for taking the views. To locate a point, it is photographed from two stations the positions of which are known. It is necessary to know the direction in which the camera was pointed when each photograph was taken, and the focal length f of the lens.

The **Instrument** used for this work sometimes consists of a transit, so constructed that standards and telescope can be removed and a camera mounted in their place, so that azimuth angles can be measured, or laid off, by the horizontal circle. The instrument is leveled and the horizontal angles between certain well-defined points are measured while the telescope is on the transit; when the camera is substituted, the same angles are laid off on the circle and the exposures are made. Such instruments cost about $500.

Notches on the four sides of the camera opening yield corresponding points on the edges of every picture; lines are then drawn across photograph connecting these four points. The vertical line is known as the **principal** and the other as the **horizontal** line; their intersection is called the **principal point.**

If the photograph is held at distance f in front of the eye, and normal to the line of sight, points a, b, and c on the picture will appear to cover corresponding points A, *B*, and *C* in the landscape. The photograph, when held in this position, thus gives a measure of the angles between various points in the view, a fact utilized in plotting.

To Plot Map, first locate positions of camera stations *X* and *Y* (Fig. 30). At each station draw a circle of radius *f*, and a radial line representing direction in which camera was pointed when photograph was taken, as *Xm* and *Yn*. Line *op* represents the trace of the photograph, tangent to arc at *m*, its principal line, and *qr* represents photograph taken at *Y*, its principal line passing through *n*. To plot point *a*, first measure on the photograph *op* the distance from *a* to the principal line, and plot that distance on line *po* as *ma'*. Similarly, the distance *na''* is measured on the other photograph and plotted along trace *rq*. The plotted position of *A* thus lies at the intersection of *Xa'* and *Ya''*, or at *a*. In the same manner are plotted as many points as desired.

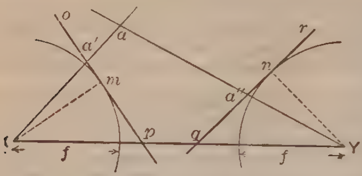

Fig. 30. Plotting Camera Stations

Differences in Elevation are computed as follows: Scale the distance of point *a* above the horizontal line on the photograph. This distance divided by distance from camera station to point *a'* (scaled from map) gives the natural tangent of angle of elevation or depression. The actual horizontal distance *Xa* is then scaled from map, after the point has been plotted, and is multiplied by tangent of vertical angle, to give difference in elevation between camera station and point *a*; or it can be found graphically. Details of the map are now sketched from a study of the photograph, after characteristic points have been plotted.

35. Aerial Surveying

(For further details, see "Higher Surveying," by Breed and Hosmer, 1926 Ed., Chap. 12.)

In photographic surveying from land stations the sensitive plate is always vertical when exposed; photographs of fixed objects are taken from fixed stations, the positions of which have been determined by survey. When photographing from an airplane, only the terrain is fixed; the camera is moving, and the plate or film is held in an approximately horizontal position.

Airplane Mapping is now often used for surveying: electric lines, reservoirs for water power, irrigation and water supply, harbor improvements, city planning, traffic studies, flood control, timber estimates. It is peculiarly adapted to regions difficult to travel. If controlled by triangulation, or by known distances between fixed objects on the ground, airplane mapping is in general accurate within narrow limits; but details may suffer considerably, especially where there are sudden and considerable changes of elevation.

The pictures are taken looking directly downward. To keep the axis of the lens as nearly vertical as possible, the camera is mounted on gimbals; the axis is exactly vertical only when the airplane is horizontal. If the terrain is level, pictures are true perspectives; if hilly, the perspective is true only of points in line with axis if the lens at moment of exposure.

Making Exposures. The airplane flies along nearly straight, parallel courses, so spaced that pictures taken at short intervals completely cover the area to be mapped, and with sufficient overlapping to enable a draftsman to construct a relatively accurate map.

There are 3 steps: (*a*) Piloting the plane in straight courses and at a proper elevation. This requires experience, for if the elevation of the plane varies the area of ground shown on the plate also varies and the scale of photograph is changed—the result is similar in passing over hilly ground; (*b*) taking the photographs, which are timed automatically, according to speed of plane and its elevation; (*c*) making the map.

Since the plane's fuel capacity limits the time it can remain in flight, the distance from the flying field influences the cost of the work. Atmospheric conditions are important; satisfactory pictures can be taken only when the air is free from low clouds, moisture, dust, smoke and haze; generally, about one day in seven is favorable.

Elevation of Airplane is determined by an altimeter. The height that the pilot endeavors to maintain depends upon focal length of camera and scale of map required. Exposures are so timed that pictures overlap about 60% in the direction of flight, and the distance between parallel flights is so chosen that pictures overlap about 50% along their sides. Theoretically, this causes each object to be photographed four times; some of them oftener.

This large amount of overlap is essential to make accurate maps, as the point on the ground corresponding to the projection of the center line of lens must appear on edges of adjacent photographs, so that their relative position will be known. Only the middle portion of each photograph is useful for accurate maps, the edges being subject to errors due to tilting of the camera, and high objects on the ground do not appear in true perspective if near the edges of the pictures. Ample overlap permits elimination of defective exposures, caused by excessive tilting of the camera or cloud shadows; it also affords opportunity to view obscure objects from more than one angle, which is especially valuable when a stereoscope is used in studying details.

A Stereoscope is an instrument in which two views of the same object are seen, one with each eye. Two photographs are placed side by side in the stereoscope, so that the binocular vision is clear. Objects in the picture stand out in sharp relief, and their relative heights and depths are shown. Thus the ground can be examined, relative elevations determined, and contour maps made. An instrument called a **stereograph** is used for tracing contours from the photographs.

Ground Control. Before beginning flying, base lines can be measured on the ground; white rings of cheesecloth, 3 ft. wide by 30 to 50 ft. in diameter, or white crosses, being placed at the ends of the base.

If these lines are laid out on uneven ground, or measured on slopes, and intermediate points are marked upon them, they serve to control details of the pictures near them; any photograph or part of a photograph appearing out of scale can be reproduced in the office to the scale indicated by the base line, provided both ends of that line appear on the photographs. Stations on the larger triangulation system controlling the whole map may also be marked by white circles or crosses, which show up distinctly in the pictures. For maps of large areas, the position of certain well-defined objects, which will appear in the photographs, are determined astronomically.

Choice of Scale of Photographs. A scale of 1 in. = 400 ft. is about as large as can be readily obtained from an airplane; for larger scale, the plane must fly so low as to require excessive speed of the camera.

Maps are readily made to scale of 1 in. = 800 ft., and enlarged by photographic process. The smaller the scale of actual exposures, the fewer the pictures needed. Parts of a map where details are required may be made on a scale of, say, 1 in. = 400 ft., and the outlying portions, 1 in. = 800 ft., the latter to be enlarged to 1 in. = 400 ft. in the office; expense is thus saved.

Office Processes. After developing films and making prints, any prints out of scale are rephotographed to proper scale. The entire set is then assembled upon a large board, on which the triangulation lines are plotted, and the photographs are carefully matched one to another, only the middle portions being retained. The matched plan is then mounted, forming what is known as a mosaic map (see below). For more accurate maps, errors in scale are corrected as stated above; errors of displacement due to objects being near the edge of picture instead of directly under the camera, and errors of distortion due to tilting of the camera, are corrected by geometric processes.

Kinds of Airplane Maps. 1. **Mosaic,** a term applied when pictures are fitted together from the contact prints, with no attempt to bring them to a particular scale (a contact print is made in direct contact with the negative, so that the image is the same size as that on the negative). Mosaics are useful where an exact scale is not needed. In estimating timber in a forestry survey a mosaic gives the required information clearly, as the scale is unimportant. In some traffic studies, the mosaic is also satisfactory. 2. **Photographic map** results from correcting the scale errors of the contact prints as well as possible, by rephotographing the whole strip of connected prints, to bring all to the desired scale. It is often an enlargement of the original. It has been much used for city maps, tax maps, harbor surveys, and locating electric transmission lines. 3. **Line map** is one in which all errors of scale, displacement, and distortion have been corrected so far as possible.

As a matter of convenience, line maps are usually made on tracing cloth, mainly by tracing the photographic details, for reproduction by blueprint or other process. For engineering projects, where contours are important, this is usually the best form of map. Contours placed directly on the photographs are likely to be less satisfactory than if kept separate, as they cover some of the detail in the photographs, and are themselves more difficult to read. A line map showing the main features and the contours, supplemented by numbered and indexed photographs, usually gives completer information than when all is crowded on one map. In some cases, however, photographic maps showing contours are quite effective, and more readily understood by non-technical men than a contour map without photographic detail.

Aerial Cameras: 1. **Eastman,** single-lens, focal-plane shutter type; focal length, 10–20 in. 2. **Air Service,** devised by Major J. W. Bagley. Has 3 and 4 lenses; focal length, 6.5–7.5 in., with between-lens automatic shutter (see instructions, T1 Aircraft camera, Eng. Div., Air Service, Dayton, Ohio). 3. **Fairchild,** single-lens, focal length, 6–28 in. 4. **Brock,** for plates instead of films; the pictures are used in a special stereoscope for correcting errors of tilt and scale.

Cost of Aerial Surveys. So much depends upon extent of the survey, distance from landing field to the site, and frequency of clear days, that the cost varies greatly. Cost of the map itself also depends largely upon the amount of control and of the office work, which is much greater for a line map than for a mosaic.

A mosaic map of an area of 25 sq. miles, in which the middle half of the area is photographed at 1 in. = 400 ft., and the fringes comprising the other half at 1 in. = 800 ft., the landing field being not over 5 miles distant, should cost \$2 000–\$4 000 for one large mosaic, made up of the middle portions of the photographs. Copies cost \$100–\$300 each.

36. Mine Surveying

In Mine Surveys, all accurate measurements are made with the transit and steel tape. Transists used in this work are provided with an auxiliary telescope attached to one side of or above the main telescope, so that it is possible to sight down a vertical shaft. The instrument known as the **eccentric bearing transit** has one telescope which can be used either in its center bearings as in an ordinary transit or in bearings built out over the limb of the instrument so as to take vertical sights.

Transferring a Meridian into the mine is one of the important steps. This is usually done by setting up the transit at the mouth of the shaft and after taking a backsight on a surface station to take a foresight down the shaft, the line of sight being made as much inclined as possible, and the inclined distance measured. The transit is then set up at the bottom of the shaft, a backsight taken on the top station and the traverse carried into the mine. The utmost care must be taken to eliminate all errors of adjustment of the transit, for the accuracy of all the underground survey depends upon this process. Another and probably more accurate method of transferring a meridian into a mine is by means of two heavy plumb-bobs hung from the staging above the shaft. The transit is set up both above and below on this line and thus an azimuth line is established between the surface and the workings. In order to have as long a base as possible the plumbs should be hung near the shaft casing.

Underground Traverses are run through the passages in the mine. It is often necessary to introduce very short lines into the traverse, and since the azimuth is transferred to distant parts of the mine through these short lines great care must be taken to eliminate all instrumental errors by reversing the telescope and using the mean of the two results. The positions of walls and workings are located by measurements from the traverse line. The station points are often placed in the roof; a nail in a wooden plug is a good station mark.

Notes of Mine Surveys are kept as a rule in the form of sketches, especially the details, such as the location and extent of the stopes. The different station points of the survey are numbered consecutively. For convenience, stations on the first level are numbered 101, 102, etc., on the second level, 201, 202, and so on. A column for vertical angles is required, for most of the traverse lines are inclined.

To Plot the Survey the three sets of coordinates must be computed, which give all the data necessary to plot the mine in plan, longitudinal section, and transverse section. The horizontal and vertical distances equal the inclined distance multiplied by the cosine and sine respectively of the vertical angle, and the azimuth or bearings together with the horizontal distances give a means of computing the latitudes and departures of the courses.

Surveying for Patent. By patent proceedings are meant the proceedings necessary to obtain from the government a fee-simple deed of a mining claim. Title to metalliferous land as granted by the United States, conveys the right to all minerals included in the downward prolongation of the portion of vein cut off by the vertical end boundaries of the claim. The federal law allows a claim to cover 1500 ft. located along the direction of a vein and 300 ft. of surface ground on either side of it. These are maximum dimensions and may be reduced by local laws. For further information see the "Manual of Instructions for the Survey of the Mineral Land of the United States," issued by the General Land Office, Washington, D. C.

ASTRONOMICAL OBSERVATIONS

37. Definitions

Practical Astronomy treats of the theory and use of astronomical instruments and the methods of computing the results obtained by observation. In this branch of astronomy only the relative directions of heavenly bodies are considered, not the actual distances, hence it is convenient to regard all such bodies as situated on the surface of a sphere, called the **celestial sphere,** Fig. 31, the radius of which is infinite and the center of which is the center of the earth. The **vertical** at any point on the earth's surface is the direction of the force of gravity at that point. This direction is shown by the plumb-line. The vertical produced upward pierces the celestial sphere in a point called the **zenith.** The point where this line pierces the sphere on the opposite side is the **nadir.** A plane through the center of the earth perpendicular to the vertical cuts the sphere in a great circle called the **horizon.** It is sometimes called the true horizon to distinguish it from the

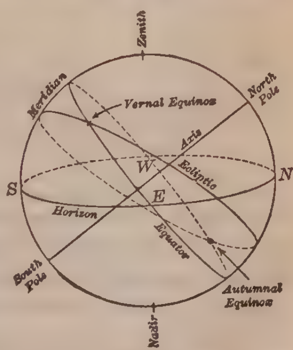

Fig. 31

sea horizon. The latter is a small circle, below the true horizon, the plane of which is parallel to the plane of the true horizon.

The Earth's Rotation upon its axis causes all celestial bodies to appear to revolve in the opposite direction at the same rate. To an observer looking along the axis from north to south all bodies appear to revolve in a right-handed, or clockwise, direction. The **axis** of the celestial sphere is the earth's axis produced. The **poles** are the points where this axis pierces the celestial sphere. The **celestial equator** is a great circle of the celestial sphere midway between the poles; its plane coincides with the plane of the earth's equator. The **meridian** of an observer is that great circle which passes through his zenith and the poles; its plane contains the observer's vertical. The intersection of the plane of the meridian and the plane of the horizon is the **meridian line.** This line cuts the horizon in the north and south points. The **prime vertical** is a great circle through the zenith the plane of which is perpendicular to the meridian. It cuts the horizon in the east and west points.

The **ecliptic** is a great circle of the celestial sphere which the sun appears to describe during the year. It is inclined to the equator at an angle of nearly 23° 27′. The points of intersection of the equator and the ecliptic are the **eqinoxes,** and the points on the equator midway between the equinoxes are the **solstices.**

38. Astronomical Coordinates

Two Spherical Coordinates may be used to designate the position of any point on the sphere. The circles of reference in any system are first, a great circle called the primary, and second, a system of great circles perpendicular to the primary, called secondaries. The following systems are commonly used.

In the Horizon System the circles of reference are the horizon and great circles perpendicular to the horizon, called **vertical circles** (Fig. 32). The

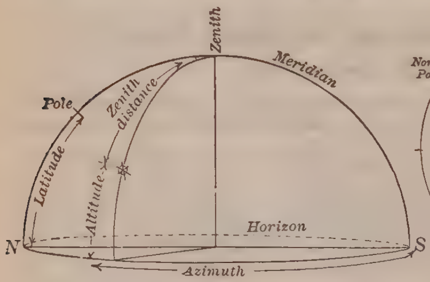

Fig. 32

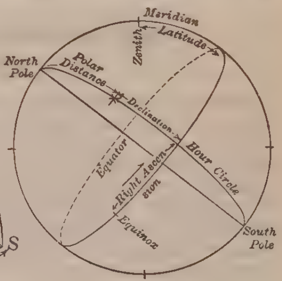

Fig. 33

coordinates are called **altitude** and **azimuth.** The altitude of a point is its angular distance above the horizon measured on a vertical circle through the point. The complement of the altitude is called the **zenith distance.** The azimuth of a body is the arc of the horizon included between the meridian and the vertical circle through the body. It is commonly measured from the south point westward from 0° to 360°; it is sometimes measured from the north point.

In the Equator System (Fig. 33) the circles of reference are the equator and great circles at right angles to the equator, called **hour circles.** The coordinates are called **declination** and **right ascension.** The declination of a point is its angular distance north or south of the equator. Declinations are considered positive when north and negative when south. The complement of the declination is called the **polar distance.** The right ascension of a point is the arc of the equator between the vernal equinox and the hour circle through the point. It is reckoned eastward from the equinox from 0° to 360° or from 0^h to 24^h. The position of a point may also be designated by its **declination** and **hour angle.** The hour angle is the arc of the equator between the meridian and the hour circle through the body. It is reckoned from the meridian westward from 0° to 360° or from 0^h to 24^h. It will be seen that declination and right ascension are independent of the observer's position, whereas the coordinates of the horizon system are dependent upon the observer's position.

Coordinates of the Observer. The observer's position is defined by his latitude and longitude. The **latitude** is the angular distance of the observer's zenith north or south of the equator. The **longitude** is the arc of the equator between the meridian of Greenwich (or other primary meridian) and the meridian of the observer.

The American Ephemeris and Nautical Almanac contains the right ascension and declination of the sun, moon, principal planets and many of the stars, given in most cases for the instant of Greenwich Midnight each day. For any other instant these coordinates must be obtained by interpolation, the variation per hour being given for that purpose. The Almanac also contains other data required in reducing astronomical observations.

Transformation of Coordinates. For a **body on the meridian** let Fig. 34 represent the plane of the meridian, and *EZ* the distance of the zenith north

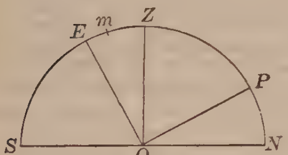

Fig. 34

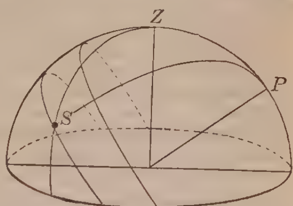

Fig. 35

of the equator, or the latitude. *PN* is the altitude of the pole. The arc *PN* = arc *EZ*. Hence the altitude of the pole equals the latitude of the observer. If *m* is a point on the meridian the relation between the altitude *h*, the declination *D*, and the Latitude *L*, is shown by the equation $90^0 - L = h - D$. If *m* is south of the equator the equation still holds true if *D* is considered to be negative. For a point between the zenith and the pole the relation is expressed by $L = h - p$, where *p* is the polar distance of the point. For a point below the pole the equation becomes $L = h + p$. For a **body off the meridian** Fig. 35 shows the relation between the altitude, declination, azimuth and hour angle of point *S*, and the latitude of *Z*, found by solving the spherical triangle *PZS*. The sides of the triangle are the colatitude *PZ*, the zenith distance *ZS*, and the polar distance *PS*. The angles are *P* the hour angle, *Z* the azimuth, and *S* the parallactic angle. The solution may be effected by means of the ordinary formulas of spherical trigonometry, but it is usually more convenient to apply special formulas derived from the fundamental relations; these will be given in the following paragraphs when required.

39. Measurement of Time

Measurement of Time. Every celestial body passes the meridian twice each day in describing its apparent path around the earth, once on the upper side, that containing the zenith, and once on the lower side. These are called the **upper** and **lower transits** or **culminations.** A **sidereal day** is the interval of time between two successive upper transits of the vernal equinox over the same meridian. A **solar day** is the interval of time between two successive lower transits of the sun's center over the same meridian. The **sidereal time** at any instant is the hour angle of the vernal equinox. The relation between sidereal time S, hour angle t, and right ascension R is given by the equation $\mathbf{S = R + t}$. If the body is on the meridian, $t = 0$, and for this instant $S = R$. The **solar time** at any instant is the hour angle of the sun's center plus 12^h, 0^h occurring at midnight.

Mean and Apparent Time. The apparent angular motion of the sun is not uniform, hence for ordinary purposes it is more convenient to use the time kept by a fictitious sun, or **mean sun,** which moves along the equator uniformly at the average speed of the true sun. Time kept by this mean sun is **mean solar time.** Time kept by the true sun is **apparent solar time.** The difference between the two is the **equation of time,** which is given in the Nautical Almanac for Greenwich Midnight each day.

Example. Given the local apparent time $8^h\ 51^m\ 52^s$ a.m. on Jan. 9, 1928, in longitude $4^h\ 44^m\ 18^s$ west. At Greenwich 0^h the equation of time is $-6^m\ 36^s.77$; the variation per hour is $-1^s.063$. The Greenwich time is $8^h\ 51^m\ 52^s + 4^h\ 44^m\ 18^s = 13^h\ 36^m\ 10^s$. The correction to the equation of time is $-1^s.063 \times 13^h.6 = -14^s.41$, giving $-6^m\ 51^s.18$ for the corrected value. The mean local time is therefore $8^h\ 51^m\ 52^s - (-6^m\ 36^s.77) = 8^h\ 58^m\ 28^s.77$ a.m.

Astronomical and Civil Time. In astronomical reckoning the day began at noon, or when the sun's center was on the meridian. This mode of reckoning was **discontinued in 1925.** The civil day begins at midnight, and, now, for astronomical purposes is numbered continuously from 0^h to 24^h. For ordinary purposes the civil day is divided into two parts of 12^h each. From midnight to noon is called a.m.; from noon to midnight is called p.m. Thus the time of 3 hours after noon may be expressed either 15^h or 3^h p.m.

Longitude and Time. The hour angle of the sun at any meridian is the local solar time p.m. at that meridian. The hour angle of the sun at Greenwich at that instant is the Greenwich time p.m. The difference is the longitude of the place expressed in hours, minutes and seconds. Similarly, for the vernal equinox the result is the sidereal time at the two places and the difference of time is the longitude of the place.

An angle expressed in hours, minutes and seconds of either solar or sidereal time may be expressed in degrees, minutes and seconds by multiplying by 15. Every circle may be divided into 24 hours, or into 360 degrees; hence $15° = 1^h$ for either solar or sidereal time; also $15' = 1^m$ and $15'' = 1^s$. In changing from degrees to hours the following relations are also convenient: $1° = 4^m$, and $1' = 4^s$.

Example. To convert a west longitude of 166° 20′ 05″ into time: $166°\ 20'\ 05'' = 165° + 1° + 15' + 05' + 05'' = 11^h + 04^m + 01^m + 20^s + 0^s.33 = 11^h\ 05^m\ 20^s.33$. To convert $4^h\ 44^m\ 18^s.0$ west longitude into degrees: $4^h\ 44^m\ 18^s.0 = 60° + 11° + 04'\ 30'' = 71°\ 04'\ 30''$.

Solar and Sidereal Intervals of Time. On account of the earth's motion in its orbit the sun appears to move eastward among the stars nearly 1° per day. This causes the sun to reach the meridian later each day as compared with the time of transit of the equinox. For this reason the mean solar day is nearly 4^m longer than the sidereal day. All intervals of mean solar time are correspondingly longer than those of sidereal time. This retardation is just sufficient to bring the sun back to its starting point at the end of a year, so that the number of sidereal days in the year is just one greater than the number of solar days. The year contains 365.2422 solar days and 366.2422 sidereal days. Therefore 1 sidereal day = 0.99726957 solar day and 1 solar day = 1.00273791 sidereal days. Solar time might be converted into sidereal time and vice versa by means of these two equations, but a more convenient way is to calculate the correction to be added in the one case and subtracted in the other. This correction is nearly 10^s per hour. Values of these corrections have been worked out for all hours and minutes from 0^h to 24^h and will be found in the Nautical Almanac.

Example. Convert $9^h\ 26^m\ 32^s.120$ of solar time into sidereal time. From Table III Appendix to Nautical Almanac,

For $9^h\ 26^m$, reduction is	$1^m\ 32^s.979$
For $32^s.120$, reduction is	$.088$
	$1^m\ 33^s.067$
	$9^h\ 26^m\ 32^s.120$
Corresponding sidereal interval	$= 9^h\ 28^m\ 05^s.187$

To convert $9^h\ 28^m\ 05^s.187$ into mean solar time. Table II, Nautical Almanac, gives:

For $9^h\ 28^m$	$1^m\ 33^s.053$
For $05^s.187$	$.014$
	$1^m\ 33^s.067$
	$9^h\ 28^m\ 05^s.187$
Corresponding mean solar interval	$= 9^h\ 26^m\ 32^s.120$

These results may be obtained with sufficient accuracy for many purposes by the following approximate rule. Express the given interval in hours and decimals, multiply by 10 and call the result seconds. Then subtract from this result 1^s for every 6^h in the interval. The result is the desired correction, correct within a few tenths of a second in ordinary cases. In the above example $9^h\ 26^m\ 32^s = 9^h.44$, which gives $94^s.4$. The amount to be subtracted from this is $1^s.6$, leaving $1^m\ 32^s.8$ as the correction to reduce the given interval to sidereal units.

Sidereal and Civil Time at any Instant. The relation between sidereal time S, the right ascension of the mean sun, R_S, and the civil time T is given by the equation $\mathbf{S = R_s + 12^h + T}$. From the Nautical Almanac we may obtain the value of $R_S + 12^h$ at Greenwich midnight. By increasing this by the change for the number of hours in the west longitude it is reduced to the right ascension for local midnight. The above equation may be used more conveniently in the form $\mathbf{S = R_s + 12^h + T + C}$, in which C is the correction to reduce T to a sidereal interval, and R_S is the right ascension for local midnight. If it is desired to find the civil time the equation is Civil Time = $\mathbf{S - (R_s + 12^h) - C'}$, C' being the correction to reduce $S - (R_S + 12^h)$ to a solar interval. It will be noticed that C and C' represent the increase in R_S since midnight.

Example. To find the local sidereal time when the civil time is $9^h\ 22^m\ 18^s.6$ (a.m.), Jan. 7, 1928, in longitude $4^h\ 44^m\ 18^s.0$ west.

$R_S + 12^h$ at Greenwich 0^h =	$7^h\ 01^m\ 17^s.59$
Increase in $4^h\ 44^m\ 18^s$ =	$46\ .70$
R_S at local 0^h =	$7^h\ 02^m\ 04^s.29$
T =	$9\ \ 22\ \ 18^s.60$
C =	$1\ \ 32\ .37$
Sidereal time = S =	$16^h\ 25^m\ 55^s.26$

Whenever the resulting sidereal time exceeds 24^h the actual sidereal time is found by subtracting 24^h. When $R_S + 12^h$ is larger than S, 24^h may be added to S before making the subtraction indicated by the equation for civil time.

Example. To reduce $3^h\ 10^m\ 00^s$ sidereal time, Jan. 7, 1928, to the corresponding civil time in longitude $4^h\ 44^m\ 18^s.0$ west. S must be taken as $27^h\ 10^m\ 00^s$; then $S - (R_S + 12^h) = 27^h\ 10^m\ 00^s - 7^h\ 02^m\ 04^s.29 = 20^h\ 07^m\ 55^s.71$. Subtracting the correction C', we have for the civil time $20^h\ 03^m\ 37^s.82$ (or $8^h\ 03^m\ 37^s.82$ p.m.).

Standard Time. In the United States the territory is divided into time belts, all places in the same belt using the local time at one of the meridians named below. Eastern Time is that of the 75th meridian, Central Time that of the 90th, Mountain Time the 105th and Pacific Time the 120th meridian. By this arrangement the minutes and seconds of time are the same in all parts of the country and also at Greenwich, the clocks in the various belts differing by whole hours. For example, when it is noon at Greenwich it is 7^h a.m. in the Eastern belt, 6^h a.m. in the Central belt, 5^h a.m. in the Mountain belt and 4^h a.m. in the Pacific belt of the United States.

To convert local civil time into Standard Time, take the difference in longitude between the meridian of the place and the Standard Meridian, convert this into hours, minutes and seconds, and add it to the local time if the place is west of the Standard Meridian, subtract if east.

Example 1. Local Civil time = $9^h\ 26^m\ 14^s$ a.m. Longitude 71° 04′ west. Find eastern time. $75°\ 00' - 71°\ 04' = 3°\ 56' = 15^m\ 44^s$. $9^h\ 26^m\ 14^s - 15^m\ 44^s = 9^h\ 10^m\ 30^s$ a.m. eastern time.

Example 2. Central time 8^h p.m. $= 20^h$. Longitude = 91° west. Find the local civil time. $91° - 90° = 1° = 4^m$. Then $20^h - 04^m = 19^h\ 56^m$ ($= 7^h\ 56^m$ p.m.). local civil time.

40. Altitudes

Correcting Measured Altitudes. When the altitude of a heavenly body is measured with a transit or a sextant it is necessary to apply certain corrections to the observed altitude in order to obtain the true altitude. **Refraction** is the bending downward of rays of light from a celestial body upon entering the atmosphere. This causes the object to appear too high above the horizon. To reduce an observed altitude to the true altitude it is necessary to subtract a correction for this refraction, the amount of the correction depending upon the altitude, upon the temperature of the air and upon the barometric pressure. For accurate work the correction must be taken from refraction tables. For rough computations it will be close enough to take the refraction correction in minutes equal to the natural cotangent of the altitude, provided the altitude is not less about about 10°. For low altitudes the refraction correction is uncertain.

Refraction Correction

(In minutes)

True altitude = measured altitude − refraction correction

Altitude	Refraction	Altitude	Refraction	Altitude	Refraction	Altitude	Refraction
5°	9.9	11°	4.9	17°	3.1	35°	1.4
6	8.5	12	4.5	18	3.0	40	1.2
7	7.4	13	4.1	19	2.8	45	1.0
8	6.6	14	3.8	20	2.6	50	0.8
9	5.9	15	3.6	25	2.1	55	0.7
10	5.3	16	3.3	30	1.7	60	0.6

Parallax. An observer on the earth's surface sees an object at a lower altitude than he would if he were at the center of the earth. This is called the error of parallax. The displacement of the object is greatest when it is at the horizon and is zero when the body is in the zenith. The parallax for a body on the horizon is called its horizontal parallax. The correction for any altitude equals the horizontal parallax times the cosine of the altitude. The sun's horizontal parallax is about 9″; that of the moon is nearly a degree.

Dip. If the altitude is measured at sea it must be taken with a sextant and measured from the sea horizon. In this case the observed altitude must be referred to the true horizon by subtracting the angle of dip. The amount of the correction varies with the height of the eye above the surface of the sea. For ordinary observations the dip in minutes may be taken as the square root of the height of the eye in feet above sea level.

Semidiameter. If the object observed is the sun, the moon or a planet, the edge (or limb) of the disk may be observed and the altitude reduced to the center by adding or subtracting the semidiameter. The semidiameter is given in the Nautical Almanac for every day at Greenwich 0^h. For approximate work the sun's semidiameter may be taken as 16′ in March and September, 15′ 45″ in June and 16′ 15″ in December.

41. Constellations Near the Pole

Polaris, the Pole-Star, is a second-magnitude star situated about 1° 05′ from the pole. Its right ascension is about $1^h\ 36^m$; consequently at the instant when the sidereal time is $1^h\ 36^m$ Polaris is vertically above the pole, on the meridian. Directly above Polaris at this time ($1^h\ 36^m$) is the constellation Cassiopeia, shaped like an inverted letter W. Below Polaris is the great dipper, Ursa Major. A line through the two stars in the outer side of the dipper bowl points nearly to Polaris, and these stars are called the "pointers." As this constellation is a conspicuous one the pointers are easily recognized and may be used to identify the pole-star. The positions of these constellations are shown in Fig. 36. When the star is vertically above or below the pole it is said to be **at culmination** (**upper** or **lower**); when the star is at its extreme eastern or western position it is said to be at its greatest **elongation** (**east** or **west**). The figure shows the constellations as they appear when Polaris is at its upper culmination; by looking at it inverted they are seen as they appear at its lower culmination. By looking at the figure from the left and right margins of the page, the positions are seen for the western and eastern elongations of Polaris.

Fig. 36

42. Observations for Latitude

By the Pole-Star. If the altitude of the pole-star (Polaris) is observed when the star is above the pole (upper culmination) and its maximum altitude found by trial, then this will be the meridian altitude. The latitude is then found by the equation $\mathbf{L = h - p}$. The measured value of the altitude h

must be corrected for refraction as well as for any index error of the instrument. The polar distance p is found by looking up the declination of Polaris in the Nautical Almanac and subtracting it from 90°. If the star is at the lower culmination the polar distance must be added.

Example. Observed altitude = 43° 37′ 00″, index error = + 30″, and refraction correction = − 1′ 01″; then true altitude = 43° 36′ 29″. Since declination of star was 88° 44′ 35″, polar distance = 1° 15′ 25″, and hence latitude = 42° 21′ 04″.

By the Sun at Noon. If the maximum altitude of the sun is found at noon this may be taken as the meridian altitude. This altitude is found with the transit by setting the horizontal cross-hair on the lower edge of the sun and following it as long as it continues to rise. When the sun drops below the cross-hair the altitude is read from the vertical arc. This altitude should be corrected for index error, refraction, semidiameter and parallax. The latitude is then found from the equation $\mathbf{L} = 90° - (\mathbf{h} - \mathbf{D})$. This method applies also to a star when crossing the meridian.

Example. In longitude $4^h.74$ west, the observed altitude of the sun's lower limb was 25° 06′.0; index error = + 01′.0; refraction correction = − 02′.0; sun's semidiameter = 16′.3. The corrected altitude = 25° 21′.3. On this day the sun's declination at Greenwich 0^h was − 22° 18′ 21″, the variation for 1 hour being + 19″.75. The change in $16^h.74$ = + 5′ 40′. The corrected declination is therefore −22° 12′ 41″. The formula for the latitude then gives 42° 26′.0 N.

43. Observations for Time

By Transit of Star. If the line of sight of a transit instrument be placed in the plane of the meridian the time can be accurately determined by noting the instant by a watch or a chronometer when some known star passes the vertical cross-hair. The sidereal time at the instant is the same as the star's right ascension. If a sidereal chronometer is used the difference between the chronometer reading and the right ascension is the error of the chronometer on local sidereal time. If a watch is used, then this sidereal time must be converted into solar time of the meridian for which the watch is regulated. This is done by subtracting from the right ascension of the star the right ascension of the mean sun + 12^h corrected to local 0^h. This result reduced to solar interval is the local civil time. This is reduced to standard time by taking the difference between the longitude of the place and that of the standard meridian, converting this into time, and adding it if the place is west of the standard meridian, subtracting if east.

Example. Transit of Star over Meridian. Longitude, $5^h\ 20^m\ 10^s.0$ west. Date, Oct. 5, 1928. Observed transit of β Aquarii = $8^h\ 50^m\ 20^s.0$ p.m. Right ascension of mean sun + 12^h, for Greenwich 0^h, = $0^h\ 53^m\ 40^s.66$. Increase in $5^h\ 20^m\ 10^s.0 = 52^s.60$. Corrected $R_S + 12^h = 0^h\ 54^m\ 33^s.26$.

Right ascension β Aquarii	=	21^h	27^m	$48^s.39$
$R_S + 12^h$ at local 0^h	=	0	54	33 .26
		20^h	33^m	$15^s.13$
Reduction to solar time	=		3	22 .04
		20^h	29^m	$53^s.09$
Reduction to eastern time	=		20	10 .00
Eastern time of transit	=	20^h	50^m	$03^s.09$
Observed time of transit	=	20	50	20 .00
Watch fast	=			$16^s.91$

This method is the one used in the most precise observations for time except that corrections are introduced to allow for the non-adjustment of the instrument, and the observations are recorded with great precision on an automatic register called a chronograph.

By Transit of the Sun. A similar observation may be made on the sun. The watch times of transit of the west and east edges of the sun across the meridian should be noted and the mean taken as the time for the center. This instant is $12^h\ 00^m\ 00^s$ local apparent time. This must be reduced to civil time by applying the equation of time and the result converted into standard time as already explained. The difference between this and the watch reading is the error of the watch on standard time.

Example. Transit of the Sun across the Meridian. Longitude, 71° 04-1/2′. Observed time of west and east edges of sun, $11^h\ 30^m\ 08^s$ and $11^h\ 32^m\ 26^s$.

Local apparent time of transit of center	$= 12^h\ 00^m\ 00^s$
Equation of time	$= \quad -12 \quad 07$
Local civil time	$= 11^h\ 47^m\ 53^s$
Reduction to eastern time	$= \quad -15 \quad 42$
Eastern standard time	$= 11^h\ 32^m\ 11^s$
Mean of observed times	$= 11 \quad 31 \quad 17$
Watch slow	$= 54^s$

Time by Altitude of Sun. The time may be determined by measuring the altitude of the sun's lower edge and noting the watch reading at the same instant. This altitude must be corrected for refraction, parallax, and semidiameter. The hour angle of the sun is then found by solving the *PZS* triangle for the angle at the pole. A convenient formula for this is

$$\sin 1/2\, t = \sqrt{\frac{\cos s \sin (s - h)}{\cos L \sin p}}$$

where t is the hour angle and $s = 1/2\,(L + h + p)$. The latitude L must be known in order to solve the triangle; the polar distance p is found from the Nautical Almanac by subtracting the declination from 90°; h is the corrected altitude. If it is in the forenoon the resulting hour angle (converted into time) must be subtracted from 12^h in order to obtain the apparent time. This apparent time must be corrected for the equation of time and then reduced to standard time as before.

Example. Altitude of Sun's Lower Limb for Time. Latitude, 42° 21′.0 N. Longitude, $4^h\ 44^m\ 18^s.0$ west. Date, Jan. 9, 1928. Mean of watch readings, $8^h\ 45^m\ 01^s$ a.m. Mean of altitudes, 12° 19′.6.

Observed altitude	= 12° 19′.6
Refraction	= −4 .4
	12° 15′.2
Semidiameter	= +16 .3
	12° 31′.5
Parallax	= .1
True altitude	= 12° 31′.6

L =	42° 21′.0	log sec.	= 0.13133
h =	12 31 .6		
p =	112 13 .8	log csc.	= 0.03354
$2s$ =	166° 66′.4		
s =	83 33 .2	log cos	= 9.05032
$s - h$ =	71 01 .6	log sin	= 9.97574
			2)9.19093
		$\log \sin\frac{t}{2}$	= 9.59546
		$\frac{t}{2}$	= 23° 12′.1
		t	= 46° 24′.2
			$= 3^h\ 05^m\ 36^s.8$

Declination at Greenwich 0^h	= −22° 18′ 21″
$19''.8 \times 13^h.7$ =	+4 32
Declination at $8^h\ 45^m$	= −22° 13′ 49″
p =	112° 13 .8

Apparent time	$= 8^h\ 54^m\ 23^s.2$
Equa. of time	$= \quad -6 \quad 51 .3$
Civil time	$= 9^h\ 01^m\ 14^s.5$
	$15 \quad 42 .0$
Eastern time	$= 8^h\ 45^m\ 32^s.5$
Watch time	$= 8 \quad 45 \quad 01 .0$
Watch slow	$= 31^s.5$

Equa. of time at Greenwich 0^h	$= -6^m\ 36^s.77$
$-1^s.06 \times 13^h.7$	$= - \quad 14 .52$
Equa. of time at $8^h\ 45^m$	$= -6^m\ 51^s.29$

By Altitude of a Star. If a star is observed in this manner the calculation is the same except that the resulting hour angle must be added to the star's right ascension to obtain the sidereal time. The sidereal time may then be converted into standard time as already explained. The sun or star should not be near the meridian, or within 10° of the horizon, if an accurate result is sought.

44. Determination of Longitude

If the local time is found at two places and these times are compared, the difference is the difference in longitude expressed in hours. The most precise method of making this comparison is by means of the telegraph, signals being recorded simultaneously on the two chronographs which are used to record the observations for local time at the two places, or, by radio, the 10^h p.m. time signal being received by a special receiving set and recorded on the chronograph. Longitude may also be found by carrying a chronometer or a watch from one place to the other, determining its error on the local time of each place and also the rate at which the timepiece gains or loses, in order to allow for the variation between the two observations. If M = the difference in longitude, e the error of the watch at the first station, e' the error at the second (+ when slow, − when fast), r the gain or loss per day (+ when losing, − when gaining), and d the number of days between the observations, then $M = e + dr - e'$.

Example At a place $4^h\ 44^m\ 18^s$ west of Greenwich a watch was $15^m\ 42^s$ slow on local mean time. At a place farther west the same watch was $14^m\ 10^s$ slow. The watch was gaining $6^s.5$ daily. The second observation was made 26 hours after the first. The difference in longitude is then $15^m\ 42^s - 26/24 \times 6^s.5 - 14^m\ 10^s = 1^m\ 25^s$ and the longitude of the second place is $4^h\ 45^m\ 43^s$.

45. Observations for Azimuth

By a Circumpolar Star at Elongation. The simplest and most accurate method of determining an azimuth or the direction of the true meridian is by observing the direction of a circumpolar star (such as Polaris) when at its greatest eastern or western elongation. An ordinary transit is used and it should be put in good adjustment. About half an hour before the computed time of elongation the transit should be set up over one end of the line whose azimuth is to be found, or at the point through which the meridian is desired. The cross-hairs must be illuminated by means of a flashlight or a lantern, preferably held by an assistant. Set the vertical hair on the star and clamp the plates. It will be observed that the star moves very slowly in azimuth, to the left if approaching western elongation; to the right if eastern elongation. As the star nears its elongation it no longer moves in azimuth but will move vertically, downward if at western elongation, upward if at eastern elongation. This shows that the position of elongation has been reached. Now lower the telescope without disturbing its azimuth and set a point on a stake some 300 ft. north of the transit, in line with the vertical hair. Next quickly reverse the telescope, re-level the plate levels if necessary, point again at the star, and set another point on the stake. If these two points do not agree take a point midway between them. To obtain the meridian lay off from this last point the azimuth of the star at elongation, which may be computed as explained later, or in case of Polaris, may be taken from the table on p. 491. This gives a point exactly north of the transit station.

The azimuth of any line may be found by measuring from this north point to the line in question. Evidently the azimuth might be found by measuring directly from the star to the line in question, since the azimuth of the star is known, provided the vernier was set to read 0° before pointing on the star.

Azimuth of Polaris at Elongation

Latitude	1928	1929	1930	1931	1932	1933	1934	1935

This table was computed using the mean declination of Polaris for the beginning of each year. A more accurate result will be obtained by applying to the tabular values the following corrections, which depend on the difference between the mean and apparent place of the star.

The Azimuth at Elongation may be computed by the equation **sin Z = cos D/cos L,** where D is the declination of the star as found from the Nautical Almanac, L the latitude of the place, and Z the required azimuth. For example, let declination of a star be 88° 55′ 21″ and the latitude of the place be 42° 21′, then azimuth of the star at elongation is 1° 27′ 28″. For an eastern elongation lay off this angle to the left and for a western elongation lay it off to the right in order to determine the true meridian.

Finding the Time of Elongation of Polaris. The circumpolar star generally used for this observation is Polaris (Art. 41). Its azimuths at elongation are given in the table on p. 491 with sufficient precision for the purposes of common surveying, while the tables on pp. 492 and 493 give the time of culmination and the interval by which elongation precedes or follows culmination. These tables are reprinted from "Magnetic Declination in the United States in 1925," issued by the U. S. Coast and Geodetic Survey.

(*c*) To refer to any other than the tabular longitude (90°): Add 0.1^m for each 10° east of the ninetieth meridian or subtract 0.1^m for each 10° west of the ninetieth meridian.

(*d*) To refer to standard time: Add to the quantities in table on p. 492 four minutes for every degree of longitude the place of observation is west of the standard meridian (60°, 75°, 90°, etc.). Subtract when the place is east of the standard meridian.

Example. Illustrating the Use of the Polaris Tables. Find the eastern standard time when the eastern elongation of Polaris occurs in latitude 36° N, longitude 77° W, on Aug. 12, 1928. For Aug. 9, 1926, the table gives for the upper culmination 4^h 26^m 46^s (after midnight). Four days later (Aug. 13) it occurs 15^h 40^m earlier, or at 4^h 11^m 06^s. For the year 1928 we subtract $1.3,^m$ giving 4^h 09^m 48^s. The correction for longitude is $+ 1/10\ (90° - 77°) \times 0.1^m = + 0.13^m = + 8^s$. The correction to obtain eastern standard time is $+8^m$. The standard time of upper culmination on Aug. 13 is therefore $4^h\ 17^m\ 56^s$. Eastern elongation *precedes* culmination by $5^h\ 55^m.9$, giving $22^h\ 22^m\ 02^s$ (or $10^h\ 22^m\ 02^s$ p.m.) for the eastern standard time of eastern elongation on Aug. 12, 1928.

Meridian by Culmination of Polaris. The time of a culmination of Polaris having been found by help of the above table, a rough determination of the meridian may be made by pointing the telescope upon Polaris at that exact instant. Such a determination is liable to be in error 1′ or 2′, since the star moves most rapidly in azimuth when at its culmination. It is always preferable to observe Polaris at elongation as explained above.

By the Altitude of the Sun. If the azimuth of a line *A B* is to be determined, set the transit over *A* and set the vernier to read 0°. Sight the vertical hair on *B* and clamp the lower motion. Loosen the upper clamp, place a dark glass over the eyepiece, and observe the sun as follows: In the forenoon sight first on the right and lower edges of the sun (simultaneously) using the vertical hair and the **middle** horizontal hair, and read the watch, the vertical angle and the horizontal angle; take two more observations in the same way. Then sight on the left and upper edges, taking the same readings as before, and the same number of observations as before. If the transit has a complete vertical circle it is advisable to reverse the telescope between these two half sets of observations. The index error should be determined after the sights on the sun are finished. The error of the watch should have been determined previously by comparing with railroad time or by radio. After completing the pointings on the sun the point *B* should again be sighted and the 0° reading verified. (If the observation is being made in the afternoon sight the left and lower edges and then the right and upper edges.) Before calculating the azimuth the intervals between readings should be examined for errors. The change in azimuth per minute of altitude should be nearly the same as found from the four intervals. The means of the six altitudes, the six horizontal angles, and the six watch readings, correspond to a single observation on the center of the sun in some position. To obtain the true altitude the mean of the vertical circle readings must be corrected for index error and must be diminished by the amount of the refraction. (See table on p. 486.) It should also be increased by the parallax, which is but 9″ times the cosine of the altitude. The latitude of the place must be known. This may be scaled from a reliable map to the nearest minute, or found by observation. (See Art. 42.) The declination of the sun must be taken from the Nautical Almanac. The azimuth of the sun's center (from the north point) is then computed by the formula

$$\cos 1/2\, Z = \sqrt{\frac{\cos s \cos (s - p)}{\cos L \cos h}}$$

in which $s = 1/2\,(L + h + p)$, and L, h, and p stand for the latitude, altitude, and polar distance, respectively. In the forenoon Z will be measured toward the east, in the afternoon toward the west. Avoid taking observations when the sun is near the meridian. Best results are obtained when the sun's bearing is about east or west.

The following form may be found convenient for recording and computing sun observations for azimuth.

		Azimuth of mark =	N 65° 26′.7 E

The azimuth of a star may be found in exactly the same way, except that the star is bisected with both cross-hairs and it is not necessary to note the time. The star observed should not be near the meridian, nor within 10° of the horizon, if an accurate result is desired.

GEODETIC SURVEYING

46. Definitions

Geodetic Surveying may be defined as that branch of surveying in which, on account of the extent of the survey and the required precision of the results, it is necessary to consider the spheroidal form of the earth's surface. The object of an extensive geodetic survey is usually twofold: first, to locate certain points with great accuracy in order to connect different topographic or hydrographic maps and furnish an accurate control of the whole survey; second, to furnish data for perfecting our knowledge of the form and dimensions of the earth.

Triangulation. The most economical way of locating points with the accuracy required for these purposes is to establish a system of triangulation extending over the area. A triangulation system consists of a series of triangles formed by lines connecting observing stations built on prominent mountains or hills, or other points which it is desirable to locate. In this system of triangles the length of one side of some triangle must be known; then if all of the angles in each triangle are measured the lengths of all other lines in the system may be calculated by trigonometry. There are three types of systems which may be recognized: first, a series of approximately equilateral triangles; second, a series of central polygons, for example a row of hexagons each with an interior station; third, a series of quadrilaterals with both diagonals drawn. The first system is the cheapest when it is desired to extend the survey along a narrow belt, as in surveying a river. It has the disadvantage of having but few " checks," that is, few geometric conditions which must be satisfied by the measurements. The second system is adapted to surveying an area of greater width than the first. The third is the most accurate. Traverses of a high order of accuracy are used in flat and wooded country where triangulation would be difficult and expensive.

Triangulation is divided into four grades, according to the accuracy finally reached in the computed lengths of lines. First order triangulation is that in which the average error of closure of a triangle is about 1″ and the discrepancy between measured and computed bases does not exceed 1 in 25 000. In second order triangulation the average closure is 3″ and the check on a base-line 1 in 10 000. Triangulation of the third order is that in which the average closure of a triangle is 5″ and the check on a base is 1 in 5000. Triangulation with ordinary transits or with a plane table is of the fourth order.

Traverses are also divided into four grades, as follows: First order, position check within 1 in 25 000; second order, position check within 1 in 10 000; third order, position check within 1 in 5 000; fourth order, stadia, transit and tape, or wheel.

Subdivision of Fieldwork. The process of carrying out a triangulation scheme may be divided as follows: (*a*) Reconnaissance and Preliminary Work. (*b*) Base-line Measurement. (*c*) The Measurement of the Angles. (*d*) The Astronomical Observations.

47. Reconnaissance

The Reconnaissance includes: (1) Making a rough sketch map of the region and studying the general scheme with regard to the shape of the triangles and the general distribution of stations. Very acute angles should not be chosen if this can be avoided. (2) Testing the lines to see that in each triangle the points are visible, each from the others, and that sights will not be seriously interfered with by excessive atmospheric refraction or by smoke of nearby cities. (3) Making notes in regard to condition of roads, approaches to station, transportation, the lumber available, and any other details that will be useful when the work of measuring the angles is being carried out.

Elevation of Signals. In ascertaining whether one station is visible from another it is always preferable to test the line by sighting directly over it. In some cases this is not practicable and it becomes necessary to obtain the result by calculation. Suppose for example that station A (Fig. 37) has an elevation of 900 ft. and it is desired to sight to station B which is 60 miles distant and

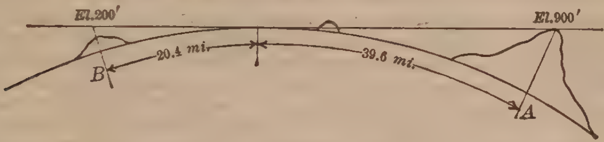

Fig. 37

has an elevation of 200 ft. In this case the sight cannot be taken on account of the curvature of the earth's surface, and it becomes necessary to calculate the height of a tower which when built on B will be visible from A. The distance from a tangent line to the curve may be calculated from the given horizontal distance and the dimensions of the earth. The distance so calculated must be decreased (by about one-seventh part) on account of the refraction of the atmosphere. The combined curvature and refraction is given with sufficient accuracy by the formula $\mathbf{h} = \mathbf{k}^2/\mathbf{1.743}$, where h is the offset from the tangent in feet and k is the horizontal distance in statute miles. In the above example the distance which an observer at A could see over a surface at sea level is given by $\sqrt{\mathbf{h} \times \mathbf{1.743}} = 39.6$ miles. The remaining distance, 20.4 miles, corresponds to $(20.4)^2/1.743 = 238.7$ ft.; that is, the lowest point which an observer at A can see has an elevation of 238.7 ft. above sea level or 38.7 ft. above B. Hence a tower 38.7 ft. high must be erected at B to make the sight possible. In practice it would be necessary to raise the line at least 10 ft. higher in order to avoid the errors due to high refraction of the air near the surface of the ground.

In the above solution it has been assumed that the intervening ground is at sea level, but if there are summits between the two stations it will be necessary to determine how much they rise above the sight line. Suppose that there is a hill 30 miles from A (on line AB) whose elevation is 75 ft. The hill is 9.6 miles from the tangent point and therefore the curvature correction is 53.0 ft. The top of this hill is $75 - 53.0 = 22.0$ ft. above the computed sight line, and the line must be raised 22.0 ft. at this point either by increasing the elevation of both stations by 22.0 ft. or by building the tower at B 44.0 ft. higher.

48. Base-line

Base-Line. To compute the lengths of the triangle sides it is necessary to choose some base-line, usually not the side of a principal triangle, and to measure its length with great accuracy, and then to connect this base-line with a line of the main system by means of a special system of triangles called the **base-net** or **expansion.** The position of the base should be chosen both with regard to its accurate connection with the main system and to convenience in the measurement of the length itself; but the accuracy of the connection should not be sacrificed to convenience in the measurement.

Measurement of the Base-Line may best be made by the invar tape apparatus. This tape is made of an alloy of nickel and steel which has a very low coefficient of expansion (from 1/25 to 1/30 that of steel tapes) and is in consequence much less affected by errors in the determination of the temperature of the tape during the measurements. Invar is softer than steel and is easily bent, but if it is wound on a reel of not less than 16 in. in diameter there is practically no error caused by bending the tape. The tape used in this work is usually 50 meters in length, and is suspended at the ends and at the middle point on stakes or tripods. A definite tension is given by means of a spring balance mounted on a special tension apparatus. The temperature of the tape is determined by means of thermometers clamped on to the tape. The points of support are carefully lined in and brought to a uniform grade. The rate of grade of each tape-length is determined by direct leveling or else by measuring the vertical angles. The positions of the end points of the tape on the intermediate stakes are marked by means of lines scratched on copper or zinc strips tacked to the tops of the stakes. The ends of the base-line are marked by means of bronze markers set in heavy stones or concrete blocks sunk into the ground. The transfer of the end marks to the tape, or vice versa, is made by means of a transit or by a special form of plumb bob.

In making the measurement the tape is hung on the first set of supports and carefully lined in; the tension is then applied and the zero mark is set over the end bolt and the position of the 50-meter end of the tape is marked on the metal strip. The temperature is noted at the same time. The tape is then carried forward to the second set of supports, the zero end being set on the mark previouly made, and the operation is repeated. This process is continued until the final mark is reached. The base is measured at least twice to verify the work and to give a value of the probable error of the measurements. The error of the base-line should not be greater than 1/500 000th part of its length for the main scheme of triangulation.

Corrections. In order to reduce the field measurements to the true length of base it is necessary to apply the following corrections: (1) Grade; (2) alignment; (3) variation of tension from normal; (4) sag (if number of supports is changed); (5) temperature; (6) error in absolute length of tape at standard temperature and tension; (7) reduction to sea level.

Correction for Grade may be made by the formula

$$\mathbf{C_g = -1/2\, L\, (a^2 + 1/4\, a^4)}, \quad \text{where } a = h/L,$$

in which L = the length of the tape or any section of it and h = the fall in the distance L. The second term $1/4\, a^4$ is negligible for ordinary grades, say less than 5%. The correction for errors of alignment may be made by means of the same formula.

The Temperature Correction is made by adding to the length of the tape the correction $\mathbf{C_t = L \times k \times (t_1{}^\circ - t_0{}^\circ)}$, where k is the coefficient of expansion for the tape used, $t_0{}^\circ$ standard temperature for which the length of the tape has been determined, $t_1{}^\circ$ the actual observed temperature, and L = length of tape.

Absolute Length. The error in the length will be determined by the United States Bureau of Standards for a fee depending upon the nature of the test. It is advisable to have the comparison made under exactly the same conditions, as regards the manner of support, tension, etc., in order to eliminate all uncertainty in computed corrections for sag, tension, etc.

Reduction to Sea Level. In order that the whole triangulation system shall be referred to the spheroid selected to represent the figure of the earth it is necessary to reduce the length of the base-line to what it would be if originally measured at sea level. If the elevation h of the base above sea level be determined by leveling, then the reduction is approximately equal to $-\mathbf{Bh/R}$, where B is the length of base and R the earth's radius at the point in question; h and R must be in the same units. (Average value of log R (in meters) = 6.80470; (in feet) = 7.32068.)

Marking the Stations. The position of the triangulation station should be marked by a bronze marker set in a drill-hole, or in concrete, or else by a stone monument set in the ground. In addition to the center mark several witness marks should be set near by, and their azimuths and distances from the center accurately determined so that the center mark could be replaced in case it is disturbed. When a stone monument is used as a mark the precaution is sometimes taken to set another ma.k several feet below the surface to be used in case the surface marks are destroyed.

49. Angle Measurements

Signals. Before the angular measurements are begun signals of some sort are placed over the selected stations to be used for sighting when the angles are measured. In some cases these consist of a mast made of 4 by 4-in. lumber supported by a tripod and marked by black and white stripes, sometimes also by flags (Fig. 38). The foot of the mast is set about 7 or 8 ft. above the ground so that the instrument may be set beneath the signal when measuring angles. Where it is necessary to build a high signal on account of woods this may be done by raising a tall mast made of two or three poles spliced together and bracing it by wire guys. Such signals are suitable for short lines, say up to 10 or 15 miles. For longer lines heliotropes or electric lights are used. A heliotrope is an apparatus for reflecting sunlight to a distant station, and consists of a movable mirror and a device for pointing it with sufficient accuracy so that the light will reach the station. In cases where it is necessary for the triangulation instrument to be raised in order to see over intervening obstacles, towers are built over the station, consisting of an inner tripod for the instrument and an outer structure for the observer, the two being disconnected so that the observer will not disturb the instrument when moving about on the tower. The latest form of tower is built of steel; these steel towers may be taken down and used over and over.

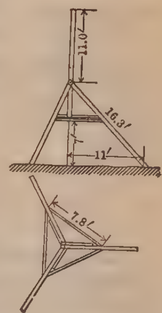

Fig. 38

Measuring the Angles. Instruments designed for triangulation differ from the ordinary transit chiefly in their size, in the fineness of the graduation and in the power of the telescope. Circles of very large diameter were formerly used for triangulation, but the present practice is to use circles 8 to 12 in. in diameter. The instrument is usually designed with three leveling screws, and rests either on a pier or on a tripod, according to its size. There are two types of instrument used in this work, the **repeating** instrument and the **direction** instrument, the latter being used for the most refined geodetic work.

The Repeating Instrument. The repeating instrument is constructed like the ordinary transit except that it has three leveling screws. The telescope is of high magnifying power and the cross-hairs are usually of the X pattern instead of vertical and horizontal. The verniers read either to 10″ or to 5″. In measuring angles in first-order triangulation the instrument is mounted on a tower or a heavy wooden support, and is protected from sun and wind by a tent or a temporary building. For work of a less precise character the instrument may be used on its tripod and sheltered by an umbrella. A common method of observation is to measure the angle six times by repetition, the left-hand signal being sighted first and then the right-hand signal, each time, the telescope being in the direct position; when six repetitions have been made, invert the telescope and measure the angle again six times, beginning with the right-hand object. (The U. S. C. & G. S. practice is to measure from the right-hand object right-handed around to the left-hand object.) It is not necessary to reset the vernier on zero for the second half of the set of angles, but it may be left at the reading it had at the end of the first six repetitions, then at the end of the second half of the set it should read approximately zero again. Both verniers should be read at the beginning and at the end of each half-set. The twelve repetitions made in this manner constitute a "set." For the main triangulation 5 or 6 sets should be measured; for second order work, 2 to 4 sets; for third order, one or more sets according to the size of the instrument. In order to eliminate errors of graduation the first set may be taken starting with vernier A at 0°, the second set starting at 360° mn and so on, m being the number of sets proposed to be taken and n the number of verniers on the instrument.

Record for a Repeating Instrument

Sta. Blue Hill. Date, May 21, 1929. Observer, A. L. Instr. No. 1960.

Station	Time	Tel.	Rep.	Ver. A.	B.	Mean	Angle	Final Angle
Prospect to Shaw	$4^h\ 00^m$ p.m.	D	0	0° 00′ 00″	00″	00″		
			1	123 28 10	20	15		
			6	380 49 40	40	40	123° 28′ 16″.7	
								123° 28′ 15″.8
		R	0	20 49 40	40	40		
			6	0 00 10	10	10	123 28 15 .0	

The Direction Instrument. In the direction instrument the horizontal circle and the upper portion of the instrument can be moved independently. The method of repetition is not used, but the directions of signals are read in order of azimuth around the circle, the angles being derived from the differences in these directions. The degrees and 5-minute spaces are read directly from the circle by means of one of the microscopes. For obtaining the minutes and seconds several micrometers (sometimes three but often two) are used. The angular space between the zero point of any micrometer and the last preceding graduation of the circle passed over by that micrometer is measured by means of the micrometer screw. The precision is increased by reading all the microscopes and taking the mean. To read a direction the circle is clamped in any desired position, the telescope is turned so that the cross-hairs (usually two vertical hairs) point at the signal; the degrees and 5-minute spaces are then read on the first microscope and the minutes, seconds and fractions of seconds are read on all of the microscopes. The mean of all the micrometer readings added to the reading of the index is the direction of the signal referred to the zero graduation of the circle.

Use of Direction Instrument. At each pointing the first microscope is read for the degrees and 5-minute spaces and all the micrometers are read for the seconds and fractions. After the directions of all signals have been read the telescope is reversed in its bearing and the series is repeated in the reverse order. This completes one "position." Sixteen of these positions are taken on first order work; on second order triangulation 4 to 8 position are used. In order to distribute the readings over all parts of the 360° the circle is shifted each time by an amount depending upon the number of positions to be used. Lists of initial settings are given in the following tables.

50. Computations

Reducing the Notes. The reduction of the notes and the calculation of results include the following steps: (1) Station adjustment. (2) Correction of angles for spherical excess. (3) Distribution of error of closure of triangle. (4) Computation of lengths of sides of triangles. (5) Reduction to center when angles are measured at eccentric station, and a repetition of steps 2, 3 and 4. (6) Computation of the geodetic positions of the stations. (7) Figure adjustment. (8) Final recomputation of 4 and 6.

The Station Adjustment is made by applying the Method of Least Squares. The following illustrates the method when the angles are measured by a repeating instrument. Let four lines OA, OB, OC, OD, radiate from the station O, thus giving 12 angles that can be measured. Of these only three are independent, and when the probable values of these are known, those of the others are found at once. First, for each of the measured angles an observation equation is written; second, from these are derived three normal equations; third, the solution of the normal equations gives the most probable values of the three independent angles; fourth, the most probable values of all other angles are then found by simple addition or subtraction.

Example. Let the measured angles and their weights be as follows, the weights being numbers proportional to the numbers of repetitions:

$$
\begin{aligned}
AOB &= 55^\circ\ 57'\ 58''.68 \text{ with weight } 3\\
BOC &= 48\ \ 49\ \ 13\ .64 \text{ with weight } 19\\
AOC &= 104\ \ 47\ \ 12\ .66 \text{ with weight } 17\\
COD &= 54\ \ 38\ \ 15\ .53 \text{ with weight } 13\\
BOD &= 103\ \ 27\ \ 28\ .99 \text{ with weight } 6
\end{aligned}
$$

Let O_1, O_2, O_3 designate the observed values of AOB, BOC, COD, and let z_1, z_2, z_3 be corrections to be applied to O_1, O_2, O_3, in order to give the most probable values of those angles. Then result the five simpler observation equations:

$$z_1 = 0 \quad \text{with weight } 3 \qquad z_3 = 0 \quad \text{with weight } 13$$
$$z_2 = 0 \quad \text{with weight } 19 \qquad z_2 + z_3 = -0''.18 \text{ with weight } 6$$
$$z_1 + z_2 = +0''.34 \text{ with weight } 17$$

Next multiply each observation equation by the coefficient of z_1 in that equation and also by its weight, and add the results, thus finding the normal equation for z_1; similarly form normal equations for z_2 and z_3. The three normal equations are

$$\begin{aligned} 20\,z_1 + 17\,z_2 \qquad\qquad &= +5''.78 \\ 17\,z_1 + 42\,z_2 + 6\,z_3 &= +4\ .70 \\ 6\,z_2 + 19\,z_3 &= -1\ .08 \end{aligned}$$

and the solution of these gives $z_1 = +0''.28$, $z_2 = +0'.01$, $z_3 = -0''.06$ as the most probable corrections. The following are hence the adjusted values of the five observed angles:

$$\begin{aligned} O_1 + z_1 &= 55° \ 57' \ 58''.96 \\ O_2 + z_2 &= 48 \ \ 49 \ \ 13\ .65 \\ O_1 + O_2 + z_1 + z_2 &= 104 \ \ 47 \ \ 12\ .61 \\ O_3 + z_3 &= 54 \ \ 38 \ \ 15\ .47 \\ O_2 + O_3 + z_2 + z_3 &= 103 \ \ 27 \ \ 29\ .12 \end{aligned}$$

which satisfy all the geometric requirements and from which the other 7 angles are readily found.

Spherical Excess. The spherical excess is the amount by which the sum of the three angles of a spherical triangle exceeds 180°. The amount of this correction depends upon the area of the triangle and upon the latitudes of the points. It is nearly equal to one second for each 75 square miles of area. It may be computed from the formula $\mathbf{e''} = \mathbf{bc \sin A/2\, R^2 \sin 1''}$, in which b and c are the sides and A the included angle of the triangle, and R the radius of the earth at the point; the mean value of log R (in meters) = 6.80470. For a more precise value use $\mathbf{e''} = \mathbf{bc \sin A/2\, RN \sin 1''}$, in which R is the radius of curvature of the meridian and N the normal for the given latitude. One third of the spherical excess of the triangle is to be subtracted from each angle, which reduces it to the corresponding plane angle.

Error of Closure. The sum of the three plane angles will not be 180°, however, unless the measurements were perfectly made. A test of the accuracy of the work is found in the error of the sum of these angles. In the triangulation of the U. S. Coast Survey the average error of closure for first order triangles is about 1″; for second order, 3″; and for third order, 5″. After the spherical excess has been calculated the remaining error is due to

Computation of Triangle Sides

O to P					15 067.13	4.178 0306

Note:—In this triangle the spherical excess = 0″.9.

errors of measurement and is distributed equally among the three angles of the triangle.

Computation of Triangles. After the triangle has been adjusted for error of closure the two unknown sides of the triangle are computed from the formula **a/b = sin A/sin B.** The plane angles are used for this calculation because for any triangle which occurs in practice it is sufficiently exact to calculate it as a plane triangle and it is simpler than to compute the spherical triangle.

Reduction to Center. If owing to obstructions it is impossible to place the instrument over the center mark when observing the angles, it may be placed at some other point, called the **eccentric station,** and the angle observed with the same accuracy as for an angle at the center. These angles may then be reduced to the values they would have at the center mark provided the distance and direction to the center from the instrument are accurately determined. This reduction is made by computing the direction of each line reckoned from the center mark as the zero degree point, and then calculating the difference in direction of each distant signal as seen from the instrument and from the center mark. This is done by solving the triangle (Fig. 39) formed by joining the instrument, the center mark, and any distant signal, the result being approximately $s'' = d \sin \alpha / D \sin 1''$, where s'' is the correction in seconds, d is the eccentric distance (measured with a tape), α is the "direction" of the distant station, D is the approximate calculated distance to the distant station. The "direction" α may have any value from 0° to 360°; careful attention should be given to the algebraic signs of $\sin \alpha$. After the corrections (s'') have been calculated they are added algebraically to the corresponding directions previously found. The differences of the corrected directions then give the true angles at the center.

51. Dimensions of the Earth

Elements of the Spheroid deduced by Clarke in 1866, and used since 1880 in geodetic work in the United States, are:

Semi-major axis = 6 378 278 meters = 20 926 062 feet
Semi-minor axis = 6 356 654 meters = 20 855 121 feet
Meridian quadrant = 10 001 997 meters = 32 814 885 feet
Eccentricity = 0.082 271 Ellipticity = 1/294.98

The radius of a sphere which is equal in volume to this spheroid is 6 371 062 meters or 20 902 416 ft. or 3959 statute miles. The radius 3957 statute miles corresponds to a sphere whose quadrant equals the elliptical quadrant.

Hayford's discussion of 1909 gives 6 356 909 meters for the semi-minor axis and 1/297.0 for the ellipticity of the spheroid which best fits the North American continent.

Lengths of One Degree, in Meters, for the Clarke Spheroid

RAILROAD LOCATION

52. Reconnaissance Survey

Three Types of Survey are employed in laying out a new railroad: first, the **reconnaissance,** or an examination of the country through which the railroad is to run for the purpose of choosing the general route (or routes) which it seems worth while to investigate further; second, a topographic or **preliminary survey** of a belt of country chosen by the reconnaissance; and third, the laying out or **location** of the proposed railroad within the belt of the preliminary. If the reconnaissance is carelessly made the subsequent work will not rectify this defect. It is in the reconnaissance that most of the bad errors in railroad location have occurred. Although financial considerations frequently determine that a road must pass through certain towns between its termini, the location of the road depends largely upon the topography, and the choice of route upon the locating engineer.

For a Reconnaissance the first step is to obtain the best available maps of the country in question. The U. S. Geological Survey maps are particularly valuable for such purposes, as their contour lines show elevations. On such maps routes may be sketched and a very good idea of the maximum grades of the road obtained. Routes which are obviously unsatisfactory are eliminated from further consideration and only those which look favorable need be thoroughly examined by traveling over them. The map will save much time and expense and minimize the amount of actual field examination. Unfortunately large portions of the country have never been surveyed and it is not uncommon for the engineer to find himself without any map of the country he is to examine.

The engineer will travel over the most favorable routes on foot, horseback, or by vehicle. Distances are obtained by pacing or by odometer. Elevations are obtained by the use of the aneroid barometer and a hand level, and such data incorporated into a rough map of the proposed road. The engineer must choose not only a route which can be built at a reasonable cost but one that can be maintained and operated economically. He must therefore take into consideration the grades, curvature, length of line. earthwork and character of the soil, bridging, tunneling and general drainage. To give proper weight to these matters he must be familiar with the economic principles of location, the relative economic value of additional length of line, of grade and curvature. The traffic to be accommodated by the proposed road may be heavy in one direction and light in the other, in which case a grade of 1% may not be as serious in one direction as a grade of 0.5% will be in the opposite direction. A large traffic also justifies an expensive line in order to save operating expense.

A ridge location is advantageous because of the small amount of drainage and bridging to be provided. But it more often happens that the termini and the intermediate towns to be tapped are located on rivers, so that a valley location is required. Valley locations are very common; they frequently allow low grades but often require many structures to bridge the lateral streams and are more subject to washouts. Where it is necessary to cross from one bank of a river to another especial care in the selection of the bridge site must be exercised. In valley locations the grade is practically determined by the rate of fall of the river, but in mountainous countries the rivers may be so steep as to be prohibitive for a railroad grade, in which case the road is purposely lengthened by passing up some lateral valley so as to keep the ruling grade down to the desired amount. In routes which cross the drainage of a country it is of the utmost importance to discover the lowest pass and to use this point as one of the governing points on the location. In very mountainous country it may be feasible in getting over the pass to introduce a short stretch of must steeper grade than the working maximum grade and to operate this grade by the use of one or more helper engines.

In early railroading in this country crossings of highways at grade were not avoided, but now practically every state requires that new railroads shall be constructed with no highway grade crossings, a requirement which introduces another important consideration into the choice of location.

In making the reconnaissance the engineer should not only choose routes from the standpoint of cost of construction, maintenance and operation, but he should also gather data of the industries and natural resources of the country through which the road is to pass.

53. Preliminary Survey

The Preliminary Survey is a transit and tape traverse run as near as practicable to the probable location of the railroad from one governing point to another. A governing point may be a town, a river crossing, a pass or other fixed point on the route. Between these points every effort will be made to maintain the lowest practicable and economical rate of grade. The ruling grade of each engine division should be adjusted with reference to those of adjoining divisions and to conditions of local traffic, so as to avoid breaking and making up of trains. All surveys should be made with regard to future permanent construction and every effort used to reduce the amount of temporary construction to the lowest limits. The preliminary should be run with considerable accuracy, for the location survey is to be checked against the preliminary. The distances are usually measured to tenths of a foot, and the deflection angles to the nearest minute.

The Purpose of the Preliminary is to serve as a basis of a topographic survey of a belt of country, varying in width from 300 ft. to 1000 ft. depending upon the character of the country, a belt in which the located railroad will probably lie. The organization of the preliminary survey party is usually as follows: chief of party, transitman, two chainmen, two flagmen, levelman and rodman, topographer and assistants, and axmen. A stake is driven at every 100-ft. station and marked with the station number. Each transit point is carefully marked by a nail in the head of the stake, but intermediate points are set to the nearest tenth only and are marked merely by stakes. A preliminary party in fairly open country will make 5 to 8 miles a day. The level party follows immediately behind the transit party, taking readings for a profile of the preliminary line.

Topographic Details are sketched to scale on cross-section paper, using the elevations obtained by the level party as a basis. As a rule a 5-ft. contour interval is used and the contours are located by means of the hand level and metallic tape, as described in Art. 28. The stadia is employed in some cases to obtain topographic details, and a small plane table is well adapted for this work in open country. The plot of the preliminary map and topographic details together with the profile of the preliminary line should be kept up-to-date so as to give the locating engineer information as regards grade and curvature to aid him in judging whether to push ahead with his line or to "back up" and run the line over somewhat different ground. A common scale for preliminary maps is 200 or 400 ft. to an inch.

The preliminary survey practically fixes the general alignment and grades, and where more than one preliminary has been run the best one can be chosen from a study of the plans and profiles and from other data accumulated when the preliminary is made. The kinds of materials in the excavations, the bridge and tunnel sites, and an estimate of the cost are data which the preliminary should include. The map and profile of the best preliminary line form a basis for the location.

54. Location Survey

The Located Railroad is composed of straight track, called **tangents,** and circular cuves. On most roads a spiral is introduced between the tangents and curves in the trackwork, but this refinement need not enter into the location line. First a trial location line is plotted on the preliminary map and its profile constructed from the data given by the contours on the preliminary. This trial line will pass through the governing points, such as bridge sites or passes, and will be laid out so as to make the total quantity of excavations and embankment a minimum, due regard being given to the grades and the amount of curvature in the alignment. On all curves the rate of grade should be flattened about 0.04% per degree of curve to neutralize the additional train resistance; this is called **curve compensation.** The drainage of the road is of utmost importance; it is good practice to lay out the line across flat country a little higher than the surrounding land. The line through cuts which are more than 500 ft. long should be on a grade for proper drainage, which requires about 0.2 ft. per 100 ft. It should be borne in mind that on account of the necessity for side ditches the cuts are wider than the fills and that this should be taken into account when judging from the profile of the relative amounts of cut and fill.

Several shifts of the location line will probably be made and profiles constructed for each position until the best line is determined. This final line will probably cross and recross the preliminary traverse line many times if the preliminary has been skilfully run. Ties from the location line to the preliminary line are then scaled from the map and are used in the field in laying out the located line as determined by the office study. This method is called **paper location.** Sometimes, in a canyon for example, where there is no choice of location, the preliminary survey is omitted and the located line is run out in the field. This is called **field location.**

After the location line has been actually run it may be found advisable in some instances not to follow exactly the line laid out on the plan. Minor changes and modifications may be made, for example, in fixing with care the location of stations, water tanks, or coaling plants and in adjusting the grades near such points so as to reduce the cost and disadvantage of train stops to the minimum. When train stops at or near the foot of a grade cannot be avoided the rate of grade should be flattened to facilitate the starting of trains. It is not infrequently found that stream diversions, even when of considerable magnitude, prove cheaper than bridging, both in first cost and in maintenance, particularly when the excavated material can be used in embankments. The locating engineer will give special attention to the determination of the necessary length of bridges and size of culverts, character and area of waterway. A cross-section of streams showing along the center line of the railroad, the river bottom, flood height and surface indications of rock should be plotted for each crossing. Thorough drainage is a maxim to be impressed on the mind, and the engineer must not be misled in so-called "rainless districts." In ravines carrying mountain torrents the openings must be left much larger than the appearance of the banks would seem to make necessary.

In Staking Out the center line of location the direction of the tangents is first defined and run to an intersection with adjacent tangents which locate the vertices of the curves. The curves are then staked out as explained in Art. 57. For location work a one-minute transit and 100-ft. steel tape are usually employed, the measurements being made to tenths of a foot. A stake is driven at every full station point and a "hub" with a nail is set at all transit stations together with a proper witness stake. The stakes at the beginning and end of each curve should be marked "P.C." and "P.T." respectively and should be carefully referenced by stakes set far enough on each side of the location to lie outside of the construction or filling. The true bearings of tangents should be accurately determined occasionally by solar or stellar observation so as to check the fieldwork and for the purpose of describing the loca-

tion line. Connections should be made in the location survey to all property lines crossed and to all government land lines and corners.

Immediately behind the transit party comes the level party, which runs a profile of the center line, reading the surface elevations to 0.1 ft. and T.P.'s and B.M.'s to 0.01 ft. A substantial B.M. should be established every 2000 ft. and plainly marked. When the final alignment has been staked out the level party, using the grade line on the location profile as a basis, take the cross-sections (see Art. 64) at each full station or oftener to determine the amount of earthwork and at the same time to give stakes properly marked as guides to the contractor in excavating and filling. These grades refer to the sub-grade, on top of which are to be placed the ballast and track.

55. Simple Circular Curves

A Simple Curve is a circular curve connecting two tangents. The points where the curve is tangent to the tangents are called the **point of curvature P.C.** and the **point of tangency P.T.**, these points being at the beginning and at the end respectively of the curve. The tangents meet at the **vertex V.** The deflection angle at *V* between the two tangents is the **intersection angle I,** which is equal to the **central angle** between radii drawn to the P.C. and P.T. In railroad practice the **length of curve** is the distance from P.C. to P.T. measured by 100-ft. chords (a sub-chord may occur at one or both ends of the measurement). The **degree of curve D** is the angle at the center of the curve subtended by a chord of 100 ft. A chord of less than 100 ft. is called a **sub-chord** and its central angle is a **sub-angle.** The relation between *D* and R is expressed by the formula **$\sin 1/2\ D = 50/R$.**

In the Metric System the degree of curve is usually defined as the angle at the center subtended by a chord of 20 meters. The first and second columns of the following table give degree of curve and radius according to this definition, while the third column gives the equivalent degree of curve corresponding to the definition stated on the preceding page.

Degree of Curve and Radius for Metric System

Degree of curve is angle at center subtended by a chord of 20 meters.

Degree	Radius, meters	Equivalent U. S. degree	Degree	Radius, meters	Equivalent U. S. degree	Degree	Radius, meters	Equivalent U. S. degree

56. Elements of a Simple Curve

In Fig. 40 let I be the central angle between radii drawn to the P.C. and P.T. of the simple curve; this is equal to the intersection angle between the tangents. Also let

Oc = Radius = R,
ac = Chord = C,
Vc = Tangent distance = T,
bd = Middle ordinate = M,
Vb = External distance = E,
ka = Offset from tangent = t.

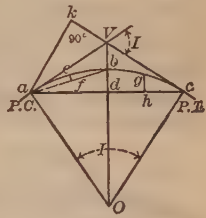

Fig. 40

The following relations between these elements are true when I is less than 180°. The trigonometric function exsec 1/2 I, used in the formulas, is called the external secant, and vers 1/2 I is called the versed sine (see Sect. 2, Art. 4).

Central Angle I $= D \times L/100$ (railroad practice only)
$= \text{arc } abc/R$ (in circular measure) $= (\text{arc } abc/2\pi R) \times 360°$

$\sin 1/2\, I = 1/2\, C/R = (E + M)/T \qquad \tan 1/2\, I = T/R$
$\tan 1/4\, I = M/ 1/2\, C = E/T \qquad \text{vers } 1/2\, I = M/R$
$\cos 1/2\, I = 1/2\, C/T = M/E \qquad \text{exsec } 1/2\, I = E/R$

Radius R $= 50/\sin 1/2\, D = 5730/D$ (approx.) $= 1/2\, C/\sin 1/2\, I = T \cot 1/2\, I$ $= E/\text{exsec } 1/2\, I = M/\text{vers } 1/2\, I = (\text{arc } abc/I)\ (180°/\pi)$.

Degree of Curve D = twice the angle whose sine is $50/R$.

$$D_x° = \frac{5730}{R_x°}\text{(approx.)} = \frac{T_1°}{T_x°}\text{ (approx.)} = \frac{E_1°}{E_x°}\text{ (approx.)}.$$

Chord $C = 2\,R \sin 1/2\, I = 2\,T \cos 1/2\, I = 2\,M \cot 1/4\, I$
$= 2\sqrt{M\,(2\,R - M)} = 2\,E \sin 1/2\, I/\text{exsec } 1/2\, I$
$= \text{arc } abc - (\text{arc } \overline{abc}^3/ 24\,R^2)$ (approx.).

Arc abc $= \pi RI/180° = C + (C^3/24\,R^2)$ approximately
$= R \times$ (Length of arc for radius 1). See Tables 5 and 21, Sect. 1.

Length of Curve L $= 100\, I/D$ (railroad practice only).

Tangent Distance T $= R \tan 1/2\, I = 1/2\, C/\cos 1/2\, I = E \cot 1/4\, I$
$= \sqrt{E\,(2\,R + E)} \doteq T_1°/D$ approximately.

External Distance E $= R \text{ exsec } 1/2\, I = T \tan 1/4\, I = \sqrt{T^2 + R^2} - R$
$= 1/2\, C \text{ exsec } 1/2\, I/\sin 1/2\, I = M/\cos 1/2\, I$
$= RM/(R - M) = E_1°/D$ (approx.).

Middle Ordinate M $= R \text{ vers } 1/2\, I = R - \sqrt{(R + 1/2\, C)\,(R - 1/2\, C)}$
$= E \cos 1/2\, I = 1/2\, C \tan 1/4\, I = T \cot 1/2\, I \times \text{vers } 1/2\, I$
$= C^2/8\,R$ (approx.) $= 4\, ef$ (approx.) $= 1/4\, t$ (approx.).

The chord for M must be the same as the chord for t (see Fig. 40).

Middle Ordinate ef $= 1/4\, M$ (approx.).

Ordinate gh $= \sqrt{(R^2 - \overline{dh}^2)} - \sqrt{R^2 - 1/4\, C^2}$
$= \sqrt{(R - dh)\,(R - dh)} - \sqrt{(R + 1/2\, C)\,(R - 1/2\, C)}$
$= M - (dh^2/2\,R)$ (approx.) $= (ah \times hc)/2\,R$ (approx.).

Offset from Tangent t $= C^2/2\,R = C \sin 1/2\, I = 4\,M$ (approx.). The chord for t must be the same as the chord for M (see Fig. 40).

57. Laying Out Curves

Four Methods of laying out circular curves are: (1) by deflection angles, (2) by offsets from the tangent, (3) by chord deflections, (4) by middle ordinates. It is assumed that the two tangents which are to be connected by a curve have been run out to an intersection and the vertex V set and I measured. The degree of curve being known, T is computed and the P.C. and P.T. stakes are set. The station of P.C. is thus established and the station of P.T. = Sta. P.C. + L. Approximately $L = 100\ I/D$.

The Deflection Angle Method is by far the most common and for nearly all railroad work it is sufficiently exact. To lay out a curve by this method set up the transit at the P.C., vernier reading 0°, and sight on V (Fig. 41). Lay off deflection angle $V\ Aa$ and measure chord Aa, thus locating point a. Angle $VAa = 1/2\ \alpha_a$, and $\alpha_a = D \times Aa/100$. Leaving the lower motion of transit clamped loosen the upper clamp and lay off $VAb = 1/2\alpha_b$ and measure chord ab, and so on, setting each stake and checking at the end of the curve on the P.T. stake.

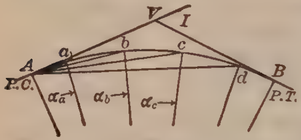

Fig. 41

The total deflection angle to any point on the curve is evidently half the central angle from the P.C. to that point; and where the stations are 100 ft. apart the deflections increase by 1/2 D for each successive station.

$$\text{Deflection angle for any sub-chord} = cD/200 \text{ (in degrees)}$$
$$= c \times 0.3 \times D \text{ (result in minutes when } D \text{ is in degrees)}$$

Example. Find deflection angles of a 6° curve connecting P.C. 8 + 41.7 and P.T. 12 + 73.4, the curve being to the right.

$$\begin{aligned}
58.3 \times 0.3 \times 6 = 105' &= 1^\circ\ 45' \text{ to Sta. 9} \\
1^\circ\ 45' + 3^\circ &= 4^\circ\ 45' \text{ to Sta. 10} \\
4^\circ\ 45' + 3^\circ &= 7^\circ\ 45' \text{ to Sta. 11} \\
7^\circ\ 45' + 3^\circ &= 10^\circ\ 45' \text{ to Sta. 12} \\
73.4 \times 0.3 \times 6 = 132' &= \underline{2^\circ\ 12'} \text{ to Sta. } 12 + 73.4 \\
& \ 12^\circ\ 57'
\end{aligned}$$

$$\text{P.T. } 12 + 73.4 - \text{P.C. } 8 + 41.7 = 431.7 = L$$
$$4.317 \times 6^\circ = 25^\circ.902 = 25^\circ\ 54' = I \text{ and } 12^\circ\ 57' = 1/2\ I.$$

This checks the deflection angle from P.C. to P.T. As a rule the deflection angles should be computed to the nearest half-minute.

It is better practice to lay the curves out backward, starting the chord measurements from the P.C., for example, while the instrument is at the P.T. In this case the circle is set at 0°, a sight taken on the P.C., and the same deflections used for each station as would be used in laying out the curve if the instrument were at the P.C. If the instrument were set up at the P.C. the circle should be set at 1/2 I, a sight taken on P.T., and chords measured beginning with the P.T., using the same deflection angles as before.

Intermediate Set-ups on Curve are necessary when the curve cannot be laid out for its entire length from either the P.C. or P.T. Set the transit up on the intermediate point, then apply one of these two methods: 1. Set the circle at 0°, reverse the telescope and sight P.C., using lower clamp. Turn telescope direct and lay off the same deflection angle to the next station on the curve that was computed for it when transit was at P.C. 2. Set the circle beyond 0° so as to read the same angle that was used in setting the intermediate station, reverse telescope, sight P.C., and clamp lower clamp. Loosen upper clamp and turn circle to read roughly 0° and see if it appears to be sighting along a tangent to the curve through the intermediate point. (If the deflection angle has been laid off on the correct side of the circle the telescope will be sighting along this auxiliary tangent when the circle reads 0°.) Turn telescope direct and lay off the proper deflection angle for the next point ahead on the curve, which will be 1/2 D if the next station is a full station from the intermediate set-up. The curve beyond the intermediate set-up point is therefore laid out like a new curve, starting at the intermediate point. This second method is the one to be used in laying out compound and reversed curves with the instrument set up at the P.C.C. or P.R.C. (Arts. 59 and 60.)

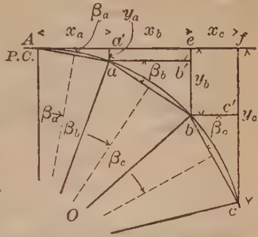

Fig. 42

Offsets-from-Tangent Method. Here no angles are used, every point on the curve being set by measured distances. The first step is to compute the rectangular coordinates of each point, the origin of coordinates being the P.C. and the axes being the tangent and the radius through the P.C. (Fig. 42). In the triangle $Aa'a$, $ab'b$, $bc'c$, etc., the acute angles are equal to the central angle from the P.C. to the middle of the chord forming the hypotenuse of the respective triangles.

$$x_a = Aa \cos \beta_a \qquad y_a = Aa \sin \beta_a$$
$$x_b = x_a + ab \cos \beta_b \qquad y_b = y_a + ab \sin \beta_b$$
$$x_c = x_b + bc \cos \beta_c \qquad y_c = y_b + bc \sin \beta_c$$

As a check, $x_c = R \sin AOc \qquad y_c = R \operatorname{vers} AOc$

In the fieldwork the transit is set up at P.C., sighted along the tangent, and points a', e, f, etc., set and marked by stake and nail. Point a is located by measuring with one tape y_a and with another tape Aa; the intersection of these two measurements locates a Point b is set by intersecting the measurement y_b with ab, etc. This method allows greater precision than the deflection angle method. It is not often used except in setting points where there are obstacles on the curve which prevent sighting across it as is required in the deflection angle method. An isolated point, such as c, can be set by laying off 90° with transit at f and measuring fc.

Deflection Distance Method. (Fig. 43.) This method is employed to lay out a curve by the use only of tapes, plumb-lines, and lining-poles. From the chord or sub-chord Aa, the distances ea and Ae are first computed by

$$\mathbf{ea} = \overline{\mathbf{Aa}}^2/2\,\mathbf{R} \quad \text{and} \quad \mathbf{Ae} = \mathbf{Aa} - (\overline{\mathbf{ae}}^2/2\,\mathbf{Aa}).$$

Sight from A to V and set point e. Set a by measuring ea and Aa. If Aa is a sub-chord, set point d by making $Ad = ea$ and $ad = Ae$. Then daf is a tangent to the curve through a. Compute $bf = \overline{ab}^2/2\,R$, and $af = ab - (\overline{bf}^2/2\,ab)$. Then sight along da and set the point f. Set point b by the ties fb and ab. If $ab = bc$, produce ab to g, making $bg = bc$. Set point c by the ties bc and gc. The chord deflection $gc = 2 \times fb$. The chord deflections can be used, then, whenever the chords on both sides of the last station are equal. When they are not equal an auxiliary tangent must be erected as at a. If chord Aa is very short, point b should also be set by a tangent offset from the main tangent so that the curve will not be produced from too short a base. The chords ab, bc, etc., are often taken less than 100 ft. This method is particularly useful in resetting a stake which has been knocked out of place.

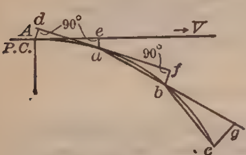

Fig. 43

Middle Ordinate Method. This is employed only for short sharp curves which are to be laid out without the use of a transit. In Fig. 44, the

P.C. and P.T. stakes being in place, chord AB is measured and stake e set by lining it in by eye in the middle of AB. Middle ordinate eb is computed ($M = C^2/8\,R$ approximate) and laid off perpendicular to AB by eye. Similarly points a and c are located, af and $cg = bc/4$.

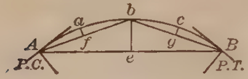

Fig. 44

Fig. 45

58. Curve Problems

Parallel Tangent Problems. In Fig. 45, both curves are of same degree.

$$AA' = VV' = BB' = d/\sin I$$

Fig. 46. Both curves have the same P.C.

$$R - R' = d/\text{vers } I$$

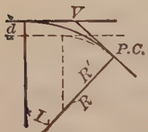

Fig. 46

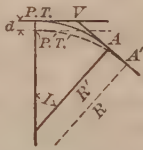

Fig. 47

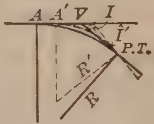

Fig. 48

Fig. 47. Both curves have P.T.'s on same radial line.

$$R - R' = d/\text{exsec } I \text{ and } AA' = (R - R')\tan I$$

Miscellaneous Problems. Fig. 48. The direction of the forward tangent to be changed at the P.T.

$$R' = R \text{ vers } I/\text{vers } I' \text{ and } AA' = R \sin I - R' \sin I'$$

Fig. 49. To find the station of B on a simple curve from which a tangent will pass through C; the radius is known. Measure B and AC. In triangle ACO, compute OC and AOC. In right triangle OBC, compute BOC. Then $AOB = AOC - BOC$, and Sta. B = Sta. $A + 100\ AOB/D$.

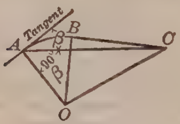

Fig. 49

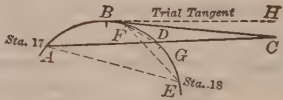

Fig. 50

Fig. 50. To find by approximate field-method the station of B from which a tangent line will pass through C. First find by approximate method the station of D, where line AC cuts the curve. Station A is the nearer full station to B. (If E were nearer than A then CE should be produced until it cuts the curve near A.) To find where CA cuts the curve, set point F in the middle of arc ABE by method of ordinates (Art. 57). If the arc FE is practically a straight line find the intersection of CA and FE. If the arc and chord do not practically coincide then set point G in the middle of arc FE by the method

of ordinates, and then find the intersection of AC and FG. The station D being known, assume point B so as to make AB slightly larger than BD and locate B carefully for a transit point. Set up the transit at B and lay off a tangent to the curve at that point. If this tangent does not pass through C, measure the angle between the tangent and the line BC, angle HBC in this case. Then move point B, forward or backward on the curve as the case requires, a distance $= 100 \times HBC$/degree of curve. A tangent from this new point B should pass almost exactly through C.

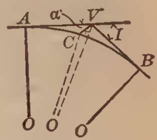

Fig. 51

Fig. 51. To find R of curve which shall join tangents AV and BV and pass through a given point C. Measure angle α and VC. Then $\sin VCO = \cos(1/2\,I + \alpha)/\cos 1/2\,I$. In triangle VOC, $CVO = 90° - 1/2\,I - \alpha$, VCO and VC are known; solve for radius OC. If angle VOC is very small find radius by $VC \sin \alpha/\text{vers}\,AOC$.

Fig. 51. To find distance VC, given R, I and α. Solve triangle VOC for VC; $OC = R$, $OV = R/\cos 1/2\,I$, $OVC = 90° - 1/2\,I - \alpha$.

Obstacles on Curves. When obstacles occur, as frequently happens, so that the entire curve cannot be laid out by deflection angles from one position of the instrument, the difficulty can often be overcome by running out the curve as far as possible and then setting up the transit at the last located point on the curve and running the curve ahead from this intermediate set-up (Art. 57). This method is applicable when the obstacle is not large or when it does not lie directly on the curve. If a large obstacle lies on the curve proper, the curve may be run out until it meets the obstacle, both from the P.C. and P.T., or such obstacles may be passed by use of the Offset-from-Tangent Method, the offset being measured from the main tangent or from an auxiliary tangent thrown off from some intermediate point on the curve. Sometimes an obstacle on a curve can be passed by laying off the deflection angle for a point beyond the obstacle, computing and measuring the long chord to that point, thus locating a station without making a new set-up of the transit, and regular chord measurements may start again from this station.

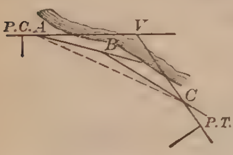

Fig. 52

If the P.C. is inaccessible lay off the curve from the P.T. as far as possible toward the P.C. and check the last point by the Method of Offset from Tangent. In applying this latter method, compute the distance along the tangent from the P.C. and subtract this distance from T, which gives the distance from V to the point on the tangent from which the tangent offset is laid off perpendicular to the tangent.

The vertex V is frequently inaccessible. The central angle I, however, can be found by connecting the tangents through the P.C. and P.T. by a traverse (ABC, Fig. 52). Compute AC, then in triangle AVC compute AV and VC; also determine the value of I. Then the P.C. and P.T. stakes are set by measuring $(T - AV)$ and $(T - VC)$ respectively from points A and C.

59. Compound Curves

Compound Curves are formed by two simple circular curves which run in the same general direction and lie upon the same side of their common tangent at their point of junction. The point where these curves join is called the **Point of Compound Curvature** (P.C.C.). Where more than two curves are in succession the curve is called a **multiple compound curve.** In laying out compound curves in the field, each simple curve portion is laid out separately. From the P.C. the simple curve will be laid out to the P.C.C., and the common tangent is used as a basis for laying out the simple curve to the next

P.C.C. and so on, the methods being the same as those employed in laying out simple curves (Art. 57).

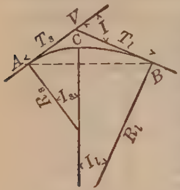

Fig. 53

Elements of Compound Curve. The following apply only to compound curves composed of two simple curves. Where there are more than two simple curves the formulas become quite long. In Fig. 53 it will be observed that all the elements marked with the subscript s refer to the curve of shorter radius, and those marked l refer to the curve of longer radius. Any compound curve composed of two simple curves may be defined by any four of the seven elements marked on Fig. 53. These four elements having been chosen the remainder may be computed by using the following formulas:

Given R_s, R_l, I_s, I_l; required I, T_s, T_l. Here $I = I_l + I_s$ and

$$T_s = R_s \tan 1/2\, I_s + \frac{(R_s \tan 1/2\, I_s + R_l \tan 1/2\, I_l) \sin I_l}{\sin I}$$

$$T_l = R_l \tan 1/2\, I_l + \frac{(R_s \tan 1/2\, I_s + R_l \tan 1/2\, I_l) \sin I_s}{\sin I}$$

Given T_s, R_s, R_l, I; required T_l, I_l, I_s.

$$\text{vers } I_l = \frac{T_s \sin I - R_s \text{ vers } I}{R_l - R_s} \qquad I_s = I - I_l$$

$$T_l = (R_l - R_s) \sin I_l + R_s \sin I - T_s \cos I.$$

Given T_l, R_s, R_l, I; required T_s, I_l, I_s.

$$\text{vers } I_s = \frac{R_l \text{ vers } I - T_l \sin I}{R_l - R_s} \qquad I_l = I - I_s$$

$$T_s = R_l \sin I - (R_l - R_s) \sin I_s - T_l \cos I.$$

Given T_s, R_s, I_s, I; required T_l, R_l, I_l. Here $I_l = I - I_s$ and

$$R_l = R_s + \frac{T_s \sin I - R_s \text{ vers } I}{\text{vers } I_l}$$

$$T_l = (R_l - R_s) \sin I_l + R_s \sin I - T_l \cos I$$

Given T_l, R_l, I_l, I; required T_s, R_s, I_s. Here $I_s = I - I_l$ and

$$R_s = R_l - \frac{R_l \text{ vers } I - T_l \sin I}{\text{vers } I_s}$$

$$T_s = R_l \sin I - (R_l - R_s) \sin I_s - T_l \cos I$$

Given T_l, T_s, R_s, I; required R_l, I_l, I_s.

$$\tan 1/2\, I_l = \frac{T_s \sin I - R_s \text{ vers } I}{T_l + T_s \cos I - R_s \sin I} \qquad I_s = I - I_l$$

$$R_l = R_s + \frac{T_l + T_s \cos I - R_s \sin I}{\sin I_l}$$

Given T_l, T_s, R_l, I; required R_s, I_l, I_s.

$$\tan 1/2\, I_s = \frac{R_l \text{ vers } I - T_l \sin I}{R_l \sin I - T_l \cos I - T_s} \qquad I_l = I - I_s$$

$$R_s = R_l - \frac{R_l \sin I - T_l \cos I - T_s}{\sin I_s}$$

Given AB, VAB, VBA, either R_s or R_l; required either R_l, or R_s, I_l, I_s, I. Solve the triangle AVB for AV and VB, which gives T_l and $T_s \cdot I = VAB + VBA$. Then the four elements T_l, T_s, I and either R_s or R_l are given. The remaining elements may be computed by formulas given above.

Compound Curve Problems. Given a simple curve between two tangents. Curve is to be compounded so as to end in a parallel tangent (Fig. 54). In case the new tangent is inside the old tangent, as in Fig. 54, the radius of the original simple curve becomes R_l, and vers $I_s = d/(R_l - R_s)$. If the new tangent falls outside the old tangent, then the original simple curve becomes R_s, and vers $I_l = d/(R_l - R_s)$.

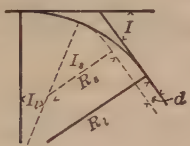

Fig. 54

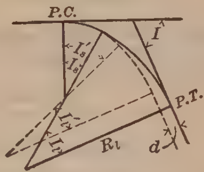

Fig. 55

Given a compound curve between two tangents. Required to retain the same radii but to change the P.C.C. so as to end in a parallel tangent.

(*a*) When the new tangent lies inside the old tangent and the curve of larger radius is at the P.T. end (Fig. 55).

$$\text{vers } I_l' = \text{vers } I_l - \frac{d}{R_l - R_s}$$

(*b*) When the new tangent lies outside the old tangent and the curve of larger radius is at the P.T. end.

$$\text{vers } I_l' = \text{vers } I_l + \frac{d}{R_l - R_s}$$

(*c*) When the new tangent lies inside the old tangent and the curve of shorter radius is at the P.T. end.

$$\text{vers } I_s' = \text{vers } I_s + \frac{d}{R_l - R_s}$$

(*d*) When the new tangent lies outside the old tangent and the curve of shorter radius is at the P.T. end.

$$\text{vers } I_s' = \text{vers } I_s - \frac{d}{R_l - R_s}$$

In the above formulas the angles with the prime mark are the new angles.

60. Reversed Curves

Reversed Curves are formed by two simple circular curves which run in the same general direction but lie on opposite sides of a common tangent at their point of junction. Where these curves meet is called the **Point of Reversed Curvature (P.R.C.)**.

Connecting Parallel Tangents (Fig. 56). In this case the central angles are equal, the P.R.C. lies on the straight line AB, and $BAE = 1/2\ I$.

$$\text{vers } I = \frac{d}{R_1 + R_2} \text{ and } AB = \sqrt{2\,d\,(R_1 + R_2)}$$

If both curves have the same radius, then

$$\text{vers } I = \frac{d}{2R} \text{ and } AB = 2\sqrt{dR}$$

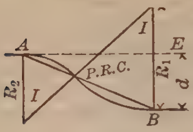

Fig. 56

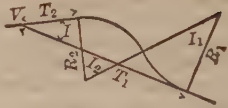

Fig. 57

Connecting Nonparallel Tangents (Fig. 57). As in the compound curve, the choice of four of its elements defines the reversed curve. Given T_1, I, R_1, R_2; required I_1, I_2, T_2.

$$\text{vers } I_2 = \frac{R_1 \text{ vers } I + T_1 \sin I}{R_1 + R_2} \qquad I_1 = I_2 - I$$

$$T_2 = T_1 \cos I + R_1 \sin I - (R_1 + R_2) \sin I_2$$

Given T_2, I, R_1, R_2; required I_1, I_2, T_1.

$$\text{vers } I_1 = \frac{R_2 \text{ vers } I + T_2 \sin I}{R_1 + R_2} \qquad I_2 = I_1 + I$$

$$T_1 = T_2 \cos I + R_2 \sin I + (R_1 + R_2) \sin I_1$$

The two tangents through the P.C. and P.T. are frequently so nearly parallel that the intersection V cannot be readily found, in which case a line V_1V_2 (Fig. 58) may be chosen as the common tangent and angles I_1 and I_2 measured, and the line V_1V_2. To connect these tangents by curves having equal radii:

$$R = \frac{V_1V_2}{\tan 1/2\, I_1 + \tan 1/2\, I_2}$$

Another way to define a reversed curve is, having chosen the P.C. and P.T. (Fig. 59), to measure the distance AB between them and also angles α and β. To connect these tangents by curves having equal radii:

$$\sin C = 1/2\,(\cos\alpha + \cos\beta) \qquad R = \frac{AB}{\sin\alpha + \sin\beta + 2\cos C}$$

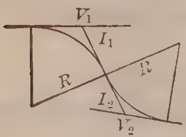

Fig. 58

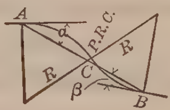

Fig. 59

In reversed curves with nonparallel tangents at the P.C. and P.T. the line AB (Fig. 59) does not pass through the P.R.C.

61. Easement Curves

The Outer Rail on a curve should be elevated to overcome the effect of centrifugal force, but on straight track the rails should be level across. Hence at the P.C. and P.T. conflicting conditions are present; the outer rail cannot be elevated and at the same time have the rails level across. The old practice was to begin to elevate the outer rail for a hundred feet or more along the tangent from the P.C. and P.T. and to reach its proper elevation either at the P.C. or a short distance beyond on the curve. This method was a make-shift, and considerable shock was given to the rolling stock at each end of the curve. To obviate this difficulty an **Easement Curve** is introduced between the tangent and the circular curve. This is a curve of varying radius which leaves the tangent as a very flat curve and grows sharper and sharper until it has the same radius as the circular curve. While the easement curve is developing from a very flat curve to one as sharp as the circular curve the outer rail is gradually elevated so that at any point from the beginning to the end of the easement curve the outer rail is elevated to the proper height.

Cubic Spiral Easement Curve (Fig. 60). AV is a tangent, ABC a **Spiral** connecting the tangent and the circular curve CF, CE is the circular curve produced backward to E, where it is parallel to tangent AV. Let D_c = degree of curcular curve, and R_c = its radius; l_c = total length of spiral AC; l = length of spiral from **P.S.** to any point on spiral; s_c = spiral angle, angle between radius at P.S., and at P.C.C. = angle EOC; s = angle between radius at P.S. and radius at any point on spiral; $q = AD$; $p = DE$; i = deflection angle (instrument at P.S.) to any point on spiral; i_c = deflection angle to P.C.C.; x = offset from tangent to any point on the spiral; x_c = offset GC; y = distance from P.C. to any point on the spiral measured along the tangent; $y_c = AG$. Point B is on the easement curve opposite D.

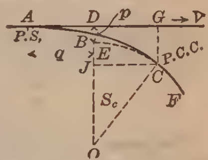

Fig. 60

The equation of the **Cubic Parabola** is $\mathbf{x = y^3/6\ R_c l_c}$.

The equation of the **Cubic Spiral** is $\mathbf{x = l^3/6\ R_c l_c}$. Since y practically equals l for the flat spirals used in railroad practice there is only slight difference between these two curves. The properties of the cubic spiral are:

(1) Degree of curve varies directly with its length from P.S.
(2) Deflection angle varies as square of length from P.S.
(3) Offset from tangent varies as cube of length from P.S.
(4) $x_c = l_c^3/6\ R_c l_c$ (the equation of cubic spiral).
$y_c = l_c - l_c^3/40\ R_c^2$ (this latter term is in most cases negligible).
$x_c = GC = 4/3\ EJ = 4/3\,R_c \text{ vers } s_c = 4\,p$. $EJ = 3\ DE = 6\ DB = 3\ p$.
$q = y_c - R_c \sin s_c$ and $p = x_c - R_c \text{ vers } s_c$.
(5) $s_c = l_c D_c/200$.
(6) Deflection angle to any point $= i = s/3$, $\therefore\ i_c = s_c/3$.
(7) The back deflection is equal to twice the forward deflection.

Example. Given $D = 4°$ and $l_c = 300$ ft. (*a*) Find data to lay out spiral by offsets from tangent, every 50-ft. point to be set. (*b*) Find data to lay out spiral by deflection angles, every 50-ft. point to be set.

(*a*) From (5), $s_c = 300 \times 4/200 = 6°$. From (4), $x_c = 4/3\ R_c \text{ vers } 6° = 10.47$ and $y_c = 300 - 300^3/40\ R_c^2 = 300 - 0.3 = 299.7$ From (3), offset to 50-ft. point $= 50^3/300^3 \times 10.47 = 0.05$, offset to 100-ft. point $= 10.47/27 = 0.39$, to 150-ft. point $= 10.47/8 = 1.31$, to 200-ft. point $= 8 \times 10.47/27 = 3.11$, to 250-ft. point $125 \times 10.4/216 = 6.06$. The y distances to measure along the tangent may be computed by the formula $y = l - l^3/40\ R^2$, in which R for any point is found from (1). But this computation is seldom necessary; it is sufficiently accurate to compute y from (4), or $q = 299.7 - R_c \sin s_c = 149.9$, and to call the y for the 50-ft. point = 50.0. Also for the 100-ft. point $y = 100.0$, for the 150-ft. point $y = q = 149.9$, for the 200-ft. point $y = 199.9$, for the 250-ft. point $y = 249.8$.

(*b*) From (5), $s_c = 300 \times 4/200 = 6°$. From (6), $i_c = 6°/3 = 2°$. From (2), deflection to 50-ft. point = $1/36 \times 2° = 0°\ 03'\ 20''$, to 100-ft. point = $1/9 \times 2° = 0°\ 13'\ 20''$, to 150-ft. point = $1/4 \times 2° = 0°\ 30'$, to 200-ft. point = $4/9 \times 2° = 0°\ 53'\ 20''$, to 250-ft. point = $25/36 \times 2° = 1°\ 23'\ 20''$. Evidently the amount of computation necessary for the deflection angle method is very small.

On many railroads it is the practice to use an easement on all curves sharper than 1° 30′, and the sharper the curve and greater the speed of trains the longer the spiral should be. See Report of Committee on Track of Am. Ry. Eng. & M. W. Assoc., Vol. 10, Part 1, 1909.

Example. Given $D_c = 4°$ and $p = 4$ ft. (*a*) Find data to lay out spiral by offsets, setting every quarter point on spiral. (*b*) Find data to lay out spiral by deflection angles, setting every quarter point on spiral.

(*a*) From (4), $x_c = 16.00$; for $1/4\ l_c$, $x = 1/64 \times 16 = 0.25$; for $1/2\ l_c$, $x = 1/8 \times 16 = 2.00$; for $3/4\ l_c$, $x = 27/64 \times 16 = 6.75$. Then vers $s_c = 3\ p/R_c = 12/R_c$, and $s_c = 7°\ 25'.3$.

From (5), $l_c = (s/D) \times 200 = 371.1$,

From (4), $y_c = 371.1 - (371.1^3/40\ R_c^2) = 370.5$,

$q = 370.5 - R_c \sin 7°\ 25'.3 = 185.6$.

The other values of y are interpolated between these values of y_c and q.

(*b*) Find s as in above $= 7°\ 25'.3$. Then $i_c = 7°\ 25'.3/3 = 2°\ 28'.4$, and

for 1/4 point, $i = 1/16 \times 2°\ 28'.4 = 0°\ 09'.3$,
for 1/2 point, $i = 1/4 \times 2°\ 28'.4 = 0°\ 37'.1$,
for 3/4 point, $i = 9/16 \times 2°\ 28'.4 = 1°\ 23'$.

Fieldwork. In new locations the tangent is usually run as far as point D (Fig. 61), then an offset $p = DC$ is measured, point C set and the circular curve run out from C to E. $DV = (R + p) \tan 1/2\ I$. Later on, when the track is to be laid the P.S. is located by measuring the distance q back from D. Then with the transit at P.S. the spiral is laid out by deflection angles to the P.C.C., where a new set-up of the transit is made. The back deflection (twice the forward deflection) is laid off to establish the auxiliary tangent at P.C.C. from which the circular curve is run to the second P.C.C. The central angle of the circular curve between the P.C.C.'s = I − sum of spiral angles on both ends. If both spirals have the same length, which is the usual case, than $I_c = I - 2\ s = I - l_c D_c/100$. Then the transit is taken to the second P.S. and the spiral at that end is run back and checked on the second P.C.C.

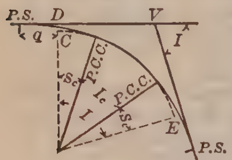

Fig. 61

Compound Curves. Easement curves are required between the two circular curves forming a compound curve for the same reason that calls for their use between a tangent and a simple curve. In case of a compound curve the sharper curve D_s must be at an offset p inside the flatter curve D_l at the point where these two curves are parallel. First determine points A and B (Fig. 62) where the curves will be parallel. $AB = p$, which defines l_c and q. Locate the ends of the spirals C and F by measuring $AC = q$, and $BF = l_c - q$. Set up the transit at C, lay off an angle (clockwise) which equals the deflection angle $XCA = 1/2\ D_l \times q$, and sight on A. If the lower motion is left clamped and the circle turned to 0° the telescope will be sighting along the auxiliary tangent CX. Then lay out the spiral by deflection angles as usual.

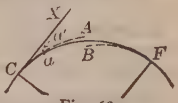

Fig. 62

The deflection angle $XCa = a'Ca + XCa'$. The angle $a'Ca$ is the same as the deflection angle to the first point on a spiral that connects a tangent and a circular curve of degrees $D_s - D_l = D_x$. Find the deflection angles for a spiral of the given length which will join a tangent and a D_x curve.

Then the deflection angle for any point on the spiral to use in laying out the spiral between the compound curves = the deflecting angle found for that point for the spiral to connect D_x + the deflection from the auxiliary tangent to a point on the circular curve CA opposite the required spiral point.

In Revising Old Simple Curve Alignment to introduce spirals, the many existing conditions will as a rule limit the choice of spiral and introduce special problems, one of the most common of which is the following: In Fig. 63, half of a circular curve AB is shown. One of the methods of introducing a spiral into this alignment is to move this simple curve 2 to 4 ft. toward its center and then introduce a spiral on each end. But this requires more track shifting than is allowable under many conditions and another expedient is resorted to as shown in Fig 63: the circular curve is thrown slightly outward in its middle portion and sharpened so that it will fall inside the tangent, making $ED = p$. Calling the distance $BC = k$, R_1 the original curve and R_2 the new curve, then

$$R_1 - R_2 + k = (k + p)/\text{vers } 1/2\ I \text{ and}$$

$$AF = q - (R_1 - R_2 + k) \sin 1/2\ I$$

If the requirement is that the track shall not be thrown at any point more than 1 ft., then since the greatest shift comes along the circular curve between the P.C.C.'s assume $k = 1$; and then assume p about $2\ k$. From the first equation above R_2 may be found, and then AF, which defines the P.S., while D_2 and p determine l_c.

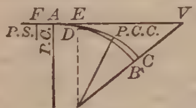

Fig. 63

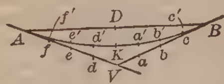

Fig. 64

A Vertical Parabolic Curve is used at the vertex of a grade to avoid the sudden change of direction in passing from one grade to another. If the change of grade is very slight a vertical curve may not be needed, but it is customary to introduce one wherever the change in rate of grade amounts to about 0.2%. In Fig. 64, AV and BV represent the straight grade lines, AKB is the parabolic curve, and Elev. D = 1/2 (Elev. A + Elev. B). In a parabola, point K is always midway between D and V, so that Elev. K = 1/2 [1/2 (Elev. A + Elev. B) + Elev. V]. Since the offsets from the tangent vary as the squares of the distances out along the tangent, $cc' = ff' = 1/16\ KV$, also $bb' = ee' = 1/4\ KV$ and $aa' = dd' = 9/16\ KV$. To find the elevations of points f', e', d', a', b' and c', compute on the straight grade lines the elevation of f, e, d, a, b and c, and then apply the distances ff', ee', and dd'.

EARTHWORK COMPUTATIONS

62. Classification of Grading

Grading usually includes all excavations and embankments, ditching, diversion of roads and streams, foundation pits.

Grading usually has three classifications: Solid rock, loose rock, common excavation; the latter is often called "earth excavation." Additional special classifications are sometimes introduced into the contract.

Solid rock usually comprises rock in solid beds or layers in its original position which may be best removed by blasting; and boulders or detached rocks having a volume of 1 cu. ft. or over (in some specifications 1/2 cu. ft. is this limit).

Loose rock comprises all detached masses of rock or stone greater than 1 cu. ft. and less than 1 cu. yd. (or 1/2 cu. yd.) and all rock which can be properly removed by pick and bar and without blasting, although steam shovel or blasting may be resorted to on favorable occasions in order to facilitate the work

Common excavation comprises all material that does not come under the above two classifications.

Where material is a mixture of loose rock and common excavation it is customary for the engineer to determine frequently (day by day) the percentage of each as the grading progresses and receive approval of his determination by the contractor, if possible.

Where the quantity of excavation is not sufficient to form embankments this deficiency is made up from material within the limits of the job by widening the excavations (as in a railroad), sometimes called **roadway excavation.** Such widening is included under the grading classification for excavation. An illustration of side excavation is the construction of an embankment for railroad or highway across the prairie, the embankment being made by excavating ample ditches at the side.

Borrow is a special classification usually applied to material taken from some pit near an embankment when there is insufficient excavation nearby on the job to form the embankment. Borrow pit excavation is therefore a special classification, usually bid upon as a special item in contracts. It frequently involves the cost of land, or a royalty (2 to 10 cents per cu. yd.) for material taken from the land, where the borrow pit is located; it also often requires the construction of a suitable road to the pit. This type of excavation therefore usually runs higher in cost than ordinary excavation.

Where the quantity of excavation exceeds the quantity required for embankment the surplus is often used to raise the height of an embankment or is deposited in a waste bank.

As a rule the grading is bid upon in the form of price per cubic yard for materials in excavation, no payment being made for embankment quantities.

Prices submitted are: (1) solid rock; (2) loose rock; (3) common excavation; (4) borrow; and the contractor is paid on this basis. He is required to haul the excavated material to any place designated by the engineer and if this haul is beyond the limit of free haul he is paid for the haul (see Art. 67).

Cross-sections in excavations are therefore taken to determine pay quantities. Cross-sections in embankment are taken to determine whether or not excavated material will make the embankment.

In some special cases both excavations and embankment are paid for as separate items; this is termed **two-way payment.**

Excavations in excess of authorized dimensions are usually not paid for unless the causes are beyond the control of the contractor; this applies to slipping of slopes and of trench sides. In trench excavation it is well to specify definitely the limits to which the measurement of pay quantity will be made, so as to avoid dispute by the contractor. This also tends to make the contractor careful, with the result that there is less "over-break," the latter term referring to the amount that the excavation passes outside of the dimensions required.

Another special classification not uncommon is **dry excavation** and **wet excavation,** the dry being defined as excavation above a certain elevation and wet as referring to that below a certain elevation. It is important to state this fixed elevation in the contract so that there may be no dispute as to what is meant by wet and by dry material.

Clearing and grubbing is sometimes included in the item of grading. It involves removing all trees, stumps, brush, rubbish, etc., over the area where construction is to be accomplished. Such work is often paid for at a price per acre. It does not involve any excavation of earth or rock materials.

The removal of the over-burden, that is, the removal of sod or loam, is excavation that is sometimes required to be done separately from the rest of the work. This is the case where loam is to be used for other purposes or where the excavated material would not be suitable if loam were mixed with it. The over-burden is usually a thin layer and where it is required to be removed separately the price for it is sometimes bid upon as a special item because its quantity is small and methods used for removal are different from those used for the rest of the grading.

63. Profiles and Sections

A Profile on which the grade line has been drawn will show the excavated portions above and the embankment portions below the grade line. In a cut, on account of the necessity of providing for drainage, the base of the roadbed is made wider than in fill, so that the area of cut as shown on profile represents more earthwork than an area of the same shape and size in the fill portion of the profile. Although it is true that the depth of the cut or fill and the shape of the ground on either side of the center line have much to do with the amount of earthwork, still it is found satisfactory, before the cross-sections have been taken, to make rough comparisons between the relative amounts of cut and fill by comparing the area of the cut and of the fill as represented on the profile; these may be determined by use of the planimeter.

Cross-sections for the exact computation of earthwork for pay quantities are determined at each full station, and oftener where the shape of the ground demands it. The usual form of these cross-sections (Fig. 65) is level across the base *ab*, with a straight slope extending from the ends of the base until it intersects the surface of the ground *e* and *f*, while its fourth side is formed by the ground surface *ef*. In determining cross-sections, enough dimensions must be taken to define the shape of the surface *ef*. Every slight elevation or hollow in the ground surface is not required; dimensions are taken so as to represent the quantity in the section and its general shape rather than its exact shape, so that there is an opportunity for the exercise of good judgment.

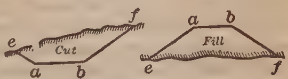

Fig. 65

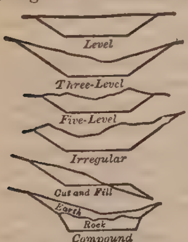

Fig. 66

Ordinary Cross-sections shown in Fig. 66, are: (1) **Level section** in which the ground service is parallel to the base. (2) **Three-level section** in which the ground service is estimated to be straight from the center stake to where each side slope intersects the surface. (3) **Five-level section** in which the surface is estimated to be straight from the center stake to points over the ends of the base, and from these two points to run straight to where the side slopes intersect the surface. (4) **Irregular section,** where the surface is very broken, requiring it to be divided into several straight slopes, the levels being taken where these slopes intersect and also where the two side slopes meet the surface. (5) **Cut-and-fill section** where part of the section is in cut and part in fill. These will be either in the shape of triangles or of shapes similar to a portion of one of the above-named sections. (6) **Compound sections** are formed when materials of different classification occur in the same section, such as rock covered by earth. The ordinary classifications are earth, loose rock and solid rock.

64. Fieldwork

Cross-sections are taken not only at every full station but wherever there is a distinct change in slope along the center line and also where the surface on either side of the center line demands an intermediate section in order to represent properly the volume included between the cross-sections. Cross-sections are taken perpendicular to the center line of the road, and radially on curves. Before this work is begun the following data should be at hand: (1) The center line, marked with alignment stakes at every full station and properly numbered. (2) Notes of alignment and profile. (3) Record of B.M.'s established by the preliminary or location survey party. (4) Width of base for cut and for fill and side slopes to use for each class of material. A slope of 1-1/2 to 1 means 1-1/2 ft. horizontal to 1 vertical.

To find the Cut or Fill at the Center set up the level and find the H.I. to the nearest hundredth of a foot. From the profile obtain the grade elevation at the given station. The H.I. minus the grade elevation gives the **rod-reading for grade,** which is computed to the nearest tenth of a foot. This grade is usually the subgrade on top of which the ballast is to be placed. Take a rod-reading on the ground at the center stake; the difference between the rod-reading for grade and the surface rod-reading gives the cut or fill at that point. It is customary to record cuts as + and fills −. The center cut or fill could be found by determining the elevation of the ground and subtracting it from the H.I., but by using the rod-reading for grade these computations can be readily made mentally. The surface elevation is obtained by adding the cut to the grade elevation, or by subtracting in the case of fill. A grade stake is driven on the center line and marked with the cut or fill as follows, "C 3.2" or "F 6.7."

Slope Stakes are set at the points where the side slopes meet the ground. These stakes are also marked, giving the amount the ground is above or below the base of the section; it is called the cut or fill at the side slope, but strictly speaking there is no cut or fill at the slope stakes. The position of a slope stake is found by trial as follows. In the case of a cut, estimate from the center cut and slope of the surface what the probable side cut will be. The distance from the center stake to a point on the side slope having this cut equals (1/2 base + cut × slope). Make this computation roughly and measure out this distance from the center stake and take a rod-reading at that point. The rod-reading for grade (distance from H.I. to base of section) minus this surface rod-reading gives the cut at the trial point. Compute the distance out from the center stake to a point on the side slope having this cut. If this computed distance equals the measured distance from the center to the rod the trial point was the correct point; if not, then a second trial must be made by holding the rod on another point and repeating the operation. The difference between the measured and calculated distances is an aid in judging where the rod should be held for the second trial. After a little practice it will be possible in most cases to set the slope stake at the second trial. When the correct point is found the stake is marked "C," followed by the feet and tenths of height of this surface point above the base.

The cut and the distance from the center to the slope stakes are entered in the notes. The same process is then repeated for the slope stake on the other side at the center. Rod-readings are taken at intermediate points if they are needed to define the shape of the surface; their positions are located by measuring the distances from the center stake, and the cut at these points is the difference between the rod-reading for grade and the surface rod-reading.

A slope-board is sometimes used in setting slope stakes and in obtaining intermediate elevations. It consists of a long straight wooden board with a spirit-level mounted in its upper edge. After the center cut has been obtained by means of the level instrument, the leveling for the side stakes is done by means of the level-board and a rod. It is particularly useful where there is considerable difference in elevation between the center and side stakes because it obviates the necessity of making a new set-up of the level to obtain the side heights.

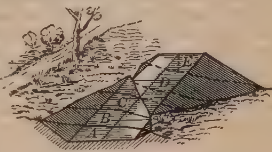

Fig. 67

In Passing from Cut to Fill it is customary to take three intermediate sections: (1) at the point where the cut runs out (is zero) on the down-hill side line, (2) where the cut is zero on the center line, and (3) where the fill begins on the up-hill side line, as shown by sections *B*, *C* and *D* in Fig. 67.

65. Methods of Computation

To Compute the Volume of earthwork between two parallel cross-sections, let A_1 and A_2 be the end areas, A_m the area of a section midway between the ends, c_1 and c_2 the center heights at the end sections, D_1 and D_2 the sums of the side distances d_r and d_l (Fig. 68), l the length of the solid and V its volume.

By Average End Areas, $V = 1/2\ l\ (A_1 + A_2)$,

By Prismoidal Formula, $V = 1/6\ l\ (A_1 + 4\ A_m + A_2)$,

By Average End Areas with prismoidal correction,

$$V = 1/2\ l\ (A_1 + A_2) - 1/12\ l\ (c_1 - c_2)\ (D_1 - D_2).$$

When the given quantities are in feet V is in cubic feet and must be divided by 27 to obtain cubic yards.

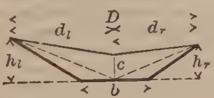

Fig. 68

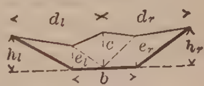

Fig. 69

The Areas of Sections must be found in order to use the above formula. Let b = width of base, c = center height, s = slope. Let h_r and h_l be side heights, d_r and d_l be side distances, and $D = d_r + d_l$. Then

For a Level Section, Fig. 66, $A = c\ (b + sc)$.

For a Three-Level Section, Fig. 68, $A = 1/2 \left\{ 1/2\ b\ (h_r + h_l) + cD \right\}$

For a Five-Level Section, Fig. 69, $A = 1/2\ (cb + e_r d_r + e_l d_l)$

Irregular Sections may be divided into geometrical figures as in Fig. 71, or into triangles by drawing diagonals from where the verticals meet the base (or base produced) to the surface end of the next vertical out, beginning at the center vertical, as shown in Fig. 70. If the latter rule is followed it will be found that the dimensions of the pairs of triangles chosen will be readily taken from the cross-section notes.

Fig. 70

It is the practice of some engineers to plot irregular sections on cross-section paper and to obtain their areas by use of the planimeter. This is not so rapid nor so accurate a method as to compute the area as shown. Where the cross-sections are plotted, however, it gives an excellent opportunity to record on the cross-sections by different colored ink lines the progress of the work from month to month; this is particularly useful where the cutting is deep or for cross-sections of dams or canals. The dimensions of the middle-section area, used in the three-term prismoidal formula, are found by proportion from the dimensions of the two bases.

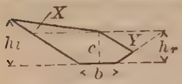

Fig. 71

The prismoidal formula gives an exact volume for a prismoid, which may be defined as "a solid having for its two ends any dissimilar parallel figures of the same number of sides, and all the sides of the solids plane figures." It applies to prisms, wedges and pyramids bounded by planes and to similar solids bounded by warped surfaces. Any solid met with in earthwork computation may be divided into these solids, therefore the formula applies to all ordinary cases of earthwork. It consumes considerable time to compute earthwork by the prismoidal formula method, which is for many cases more exact than is required, consequently the method of **average end areas** has become the most common. The end area method, however, gives results almost always too large. To obtain an exact result by the most rapid means, compute by the average end area method and then apply the prismoidal correction, which gives the same value as the prismoidal formula.

A general method of computing areas applicable to those that are quite irregular was used considerably on I.C.C. valuation work. It is an application of the principle of Art. 16. The cross-section notes should show a distance and a cut (or fill) for every angle point in the section. Write the cuts above grade as + and those below as −. Write the distances to right of center as + and those to left as −. Start at any cut and proceed clockwise around the figure multiplying every cut by (the distance for point next in advance minus distance for point next back) always using algebraic signs. The algebraic values of these quotients divided by 2 is the area.

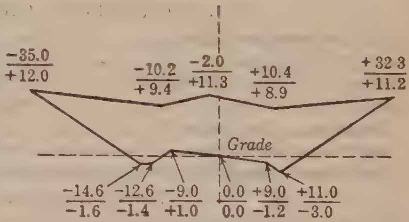

Fig. 72

Example:

	+	−
$+12.0[-10.2-(-14.6)] =$	52.8	
$+9.4[-2.0-(-35.0)] =$	310.2	
$+11.3[+10.4-(-10.2)] =$	232.8	
$+8.9[+32.3-(-2.0)] =$	305.3	
$+11.2[+11.0-(+10.4)] =$	6.7	
$-3.0[+9.0-(+32.3)] =$	69.9	
$-1.2[0.0-(+11.0)] =$	13.2	
$+1.0[-12.6-(0.0)] =$		12.6
$-1.4[-14.6-(-9.0)] =$	7.8	
$-1.6[-35.0-(-12.6)] =$	35.8	
	1034.5	12.6
	− 12.6	
	2)1021.9	
	510.9 sq. ft.	

Correction for Curvature. In making the field measurements the cross-sections on curves are taken along radial lines AB, CD and EF (Fig. 73). But when the earthwork is computed each solid is assumed to have a length equal to the chord (GH or HJ) and to have end sections whose planes are perpendicular to the chord. For example, solids $KGL - MHN$ and $OHP - QJR$ are computed. It will be seen that the solid PMH has been included twice and that WOH has been omitted. If the cross-section taken at H is symmetrical about the center line, then these discrepancies balance, but if at H there is an unsymmetrical cross-section, then a correction must be applied. In Fig. 74 DF has been drawn so as to form a symmetrical figure with DE. For the cross-section $EDFBA$ there is no correction, but for the portion FDC a correction must be applied. This correction may be found by an application of Pappus' Theorem, " If a plane area lying wholly on the same side of a straight line in its own plane revolves about that line and thereby generates a solid of revolution, the volume of that solid thus generated is equal to the product of the revolving area and the path described by the center of gravity of the plane area during the revolution." For the case of Fig. 74 there applies Correction $= (1/2\, b + sc)\,(h_r - h_l)\,(d_r + d_l) \times 0.00291\,\beta$

Fig. 73

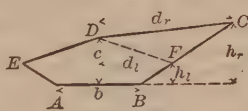

Fig. 74

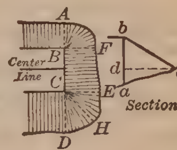

Fig. 75

in which β = sum of half the central angle under the chords GH and HJ, so that, if GH and HJ are each 100 ft., then β = Degree of curve. In above formula β should be taken in degrees. If the greater area is on the outside of the curve the correction should be added, and subtracted when the greater area is on the inside of the curve.

When Openings are Left in Embankments for bridge sites the mass $ABCDEF$ (Fig. 75) must be computed separately from the rest of the earthwork. It is composed of the wedge $BCEF$ and of the quarter cones ABF and DCE, while abc represents a section of the toe slope along the lines BA, BF, CE or CD. The volume by end-area method of the wedge $BCEF = 1/2$ (Area CE+Area BF) $\times$ BC. The volumes of the cones are found by the Pappus Theorem, or Volume of cone ABF = area $abc \times 1/3\, dc \times 1/2\, \pi$.

The prismoidal correction should be added to the volume obtained by the average-end-area method. If the prismoidal correction comes out minus, the numerical value is to be subtracted. This formula for prismoidal correction applies to complete sections of earthwork whose bases are of equal width and bounded at their ends by 3 level sections, triangles or lines. The prismoidal correction for a pyramid or cone is one-third the volume by end-area method and is always subtracted. In applying the prismoidal correction to a solid bounded by irregular sections, however, it is customary to find the dimensions of level sections having the same areas respectively as the two irregular sections and determine the prismoidal correction by using the dimensions of these two level sections. This is an approximation which is consistent with the accuracy of the original measurements taken in the field to define the irregular sections.

66. Earthwork Tables

Level-Section Tables are given below for bases from 12 to 42 ft., and for slopes of 1 to 1 and 1-1/2 to 1. They are especially useful in making preliminary estimates, but may also be used for other sections by finding the heights of level sections which give equivalent areas.

The Prismoidal Correction Tables presented here give quantities to be subtracted from volumes obtained by the method of average end areas. Here

$c_1 - c_2$ and $D_1 - D_2$ must be in feet, and then the quantity found will be in cubic yards. See pp. 532 and 533.

Triangular Prism Tables for prisms with triangular bases and 100 ft. in length are given on pp. 534–537. To use this table each end section is divided into triangles, and the base a and altitude b of each triangle determined in feet. Then $1/2\ ab$ is the area of the triangle and $100/54\ ab$ is the volume in cubic yards of the triangular prism 100 ft. long. The tables here given have been compiled from the triangular prism tables computed by C. Frank Allen. His tables, however, were computed for prisms 50 ft. in length, and for some methods of earthwork computation they are more serviceable than tables for triangular prisms 100 ft. long.

67. Haul; and Mass Diagram

Haul. It is the practice with many engineers to pay the contractor for hauling earthwork as well as for excavation. This item of haul is usually computed as so many cubic yards hauled 100 ft. It is obviously impracticable to trace each cubic yard of excavation to its place of deposit in embankment, so the average haul is computed. The **average length of haul** is the distance between the center of gravity of a mass of earth in cut and the center of gravity of the same mass after it has been deposited in fill. This distance (in feet) times the quantity hauled gives the haul in units of cubic yards hauled one foot. The best way to treat this computation is to consider it in two parts: (1) compute the haul of the cut portion to a vertical plane where the cut ends and the fill begins, (2) compute the haul of the fill portion beginning at the same plane. The practice is growing to allow no payment for any haul found necessary and thus avoid this troublesome item. If, therefore, there will be considerable haul the prices bid for excavation will run relatively high.

To Find the Center of Gravity of a large mass of earthwork composed of several individual volumes of different shape and size it is necessary either to find the position of the center of gravity of each solid and treat the computation of haul as separate loads comprising the volumes contained in a length of 100 ft. (or shorter), or else to assemble these 100-ft. solids in some manner so as to obtain the position of the center of gravity of a series of solids. The latter method may be applied when the individual solids are of equal lengths. Where the lengths are not alike, such as for example where sections have been taken at plus stations, the haul of the material in these volumes of odd length must be computed as a separate item as follows:

If the solid had end sections of equal area its center of gravity would be midway between the ends, but where the end sections are unequal the center of gravity of the solid will lie nearer the larger than the smaller end. An expression for the distance from the mid-section of a volume of earthwork to its center of gravity is

$$x_l = l^2\,(A_1 - A_2)/12\,V_f \text{ for solid of length } l$$

$$\text{or}\quad x_{100} = 100\,(S_1 - S_2)/6\,V_y \text{ for solid 100 ft. long,}$$

where x and x_{100} = distance in feet from mid-section to the center of gravity of solids of length l and 100 ft. respectively; A_1 and A_2 = area of end sections in square feet; l = length of solid in feet; S_1 and S_2 = volume in cubic yards of prisms each 50 ft. long whose end sections are A_1 and A_2 respectively; V_f = volume in cubic feet in a solid of length l and with A_1 and A_2 for end sections; and V_y = same volume in cubic yards of a 100-ft. solid with A_1 and A_2 for end sections. If the solid is less than 100 ft. in length then $x_l = x_{100} \times l/100$. The distance of the center of gravity from the end of the volume being known, its distance from any station is easily found, and the haul to that station will equal this distance times the cubic yards in the solid.

The Mass Diagram gives the best means of measuring haul and of making studies of the comparative economy of different schemes of haul and of excavation and filling. Fig. 76 represents a portion of a railroad profile and its mass diagram which is plotted as follows: At Sta. 0 the ordinate is zero, at Sta. 1 the ordinate represents the quantity of earth between Sta. 0 and Sta. 1, at Sta. 2 it represents the quantity from Sta. 0 to Sta. 2. So that at any station the ordinate represents, the algebraic sum of all the quantities from Sta. 0 up to that station, excavation being considered positive and embankment negative. This diagram (Fig. 76) shows that from Sta. 0 to 28 the cut and fill balance and that from Sta. 0 to 40 there is a little excess of cut.

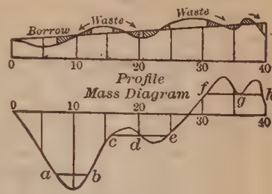

Fig. 76

The Properties of a Mass Diagram are: (1) High and low points in the mass diagram curve occur at points of no cut and fill on the profile. (2) In the mass diagram descending lines denote embankment and ascending lines excavation. (3) The difference in length (algebraically) between any two ordinates is a measure of the total quantity of material between the stations at which the ordinates are drawn. (4) Excavation equals embankment between any two points where a horizontal line intersects the mass diagram. (5) The area between a horizontal line and the curve of mass diagram is a measure of the haul between the two stations where the horizontal line cuts the diagram.

Referring to Fig. 76, the horizontal lines *ab*, *ce*, and *fh* are drawn in a manner explained below. Vertical lines projected from *a*, *b*, *c*, *d*, etc., to the profile will show between which stations the material must be hauled, borrowed or wasted. From Sta. 7 to Sta. 12, for example, the material is to be hauled. The earth in excavation just beyond Sta. 10 is thrown over into fill, each load being carried a short distance at first, the distance the material is hauled increasing until material at Sta. 12 is hauled to Sta. 7, which is called the limit of economical haul. If the cost of earthwork in cut and in fill and the cost of haul are known the length of haul beyond which it is more economical to waste excavated material and to borrow embankment may be readily calculated. This assumes, of course, that the material in cut can be wasted and that filling may be taken from a nearby borrow-pit, both without any appreciable haul or cost for material. Assuming that the economical limit of haul is 1000 ft., then the line *ab* should be drawn 1000 ft. long. Line *fgh* is drawn tangent to the curve at *g*, for had it been drawn lower than *g*, *fg* would be greater than 1000 ft., and had it been drawn a little higher than its present position then point *f* would fall further to the right and point *h* further to the left, with the result that more material would be wasted between Sta. 24 and 31 and more borrowed beyond Sta. 39 than is here shown, and this extra material would be wasted and borrowed while it was more economical to haul it. The line *fgh* as drawn, then, represents the best economy. Similarly the line *cde* is in the most economical position. It is drawn so as to make the sum of the areas above *cd* and below *de* a minimum, and these are a minimum when $cd = de$. This is the most economical condition as regards the cost of earthwork because, had *cd* been drawn any lower, it would have decreased the waste at Sta. 16 and increased the waste at Sta. 25 by exactly the same amount, but it would have made the sum of the two areas cut off by the horizontal line larger than at present, and this would have meant an increase in the amount of haul which is measured by these areas. Evidently the amount borrowed from Sta. 0 to 7 is the ordinate at *a*, the waste from 12 to 16 is the difference between the ordinates at *b* and *c*, and the waste from Sta. 25 to 31 is the sum (algebraic difference) of the ordinates at *e* and *f*. The beginning of a borrow is shown at Sta. 40.

Free Haul. It is sometimes provided that no payment shall be made for earth hauled less than a specified distance. The haul of any material carried

For explanation see p. 526.

beyond this free-haul limit is called **overhaul.** The limits of free haul and the method of computing overhaul have been defined by the Amer. Ry. Engrs. and M. of W. Assoc. in its 1921 Manual.

"The limits of free haul shall be determined by fixing on the profile two points, one on each side of the neutral grade point, one in excavation and the other in embankment, such that the distance between them equals the specified free-haul limit and the included quantities of excavation and embankment balance. All haul on material beyond this free-haul limit will be estimated and paid for on the basis of the following method of computation:

"All material within this limit of free haul will be eliminated from further consideration.

"The distance between the center of gravity of the remaining mass of excavation and center of gravity of the resulting embankment, less the limit of free haul as above described, shall be the overhaul distance.

"Overhaul shall be computed in units of one cubic yard moved 100 ft. and compensation to be rendered therefor shall be computed on such units.

"In case material is obtained from borrow-pits along the embankment and runways constructed, the haul shall be determined by the distance the team necessarily travels. The overhaul shall be determined by multiplying the number of cubic yards so hauled by one-half the round distance made by the team, less than freehaul distance. The runways shall be established by the Engineer."

68. Borrow-pits

In railroad construction it is often more economical when the length of haul becomes great to borrow material from near-by borrow-pits to form embankments. To calculate the amount of earth taken from a borrow-pit it is customary to divide the surface of the ground where the pit is to be excavated into squares and to take levels at each corner of these squares, and at intermediate points when the slope of the surface is not straight from corner to corner. Then when the excavation is completed the same system of square cross-section is again staked out and elevations are taken at the corners and at the necessary intermediate points. Care should be taken when the first system is staked out that it extends far enough to include the entire area which may possibly be covered by the borrow-pit. The field-work of laying out these cross-sections is done as explained in Art. 24. The difference between the original and the final elevations at the corners gives the lengths of the vertical edges of a series of vertical truncated rectangular prisms. Toward the edges of the borrow-pits, where the slopes occur, there probably will be several triangular and trapezoidal truncated prisms. Let A = area of right section of truncated prism, h_1, h_2, h_3, etc. = the lengths of the vertical edges of the prism, and V = volume of prism; then

For Truncated Triangular Prism, $\mathbf{V = A \times (h_1 + h_2 + h_3)/3.}$

For Truncated Rectangular Prism, $\mathbf{V = A \times (h_1 + h_2 + h_3 + h_4)/4.}$

When Additional Heights have been taken at intermediate points the computation is made as follows: (1) When an intermediate level is taken in the center of the square or rectangle, the volume of the rectangular prism is computed by the formula given above, and to it is added algebraically the volume of a pyramid having the rectangle for its base and the center height minus the average of the four corner heights for its altitude. The volume of this entire solid would then be expressed

$$\mathbf{V = A\,(h_1 + h_2 + h_3 + h_4)/4 + A\left\{h_c - (h_1 + h_2 + h_3 + h_4)/4\right\}/3}$$

in which h_c = altitude of prism along its center vertical line.

(2) When an intermediate level is taken at the middle of one side of a rectangle, the volume of the rectangular prism is computed as usual, and to it is added the volume of a pyramid having the rectangle for its base and the difference between the additional height and the average of the heights at the two corners which lie at the extremity of the side on which the additional height has been taken. If the additional height is h_5 and it is taken on the side where the end heights are h_3 and h_4 respectively, then an expression for the entire volume would be

$$V = A\,(h_1 + h_2 + h_3 + h_4)/4 + A\left\{h_5 - 1/2\,(h_3 + h_4)\right\}/3$$

(3) When intermediate heights are taken at any other point in the rectangle except in the center of the rectangle or in the middle of one of its sides, then the rectangular prism should be divided into four triangular prisms; the additional height forms the vertical edge at one of the corners of each of these four triangular prisms.

In arranging the data for computation it is customary to lay out the borrow-pit in plan on cross-section paper and to mark at each corner the depth of excavation, and to sketch any lines representing the proper subdivision of the rectangles or trapezoids as given in the field notes. A plan of a portion of a borrow-pit is shown in Fig. 77, and by the above method the volume of excavation will be found to be 1057 cu. yd. Where there are several rectangular prisms having the same area of cross-section A the computation of the quantity of earthwork may be simplified as follows: Volume of Assembly of Truncated Rectangular Prisms $= A\ (p_1 + 2\ p_2 + 3\ p_3 + 4\ p_4)/4$ in which p_1 = sum of heights common to one prism; p_2 = sum of heights common to two prisms; p_3 = those common to three; p_4 = those common to four prisms.

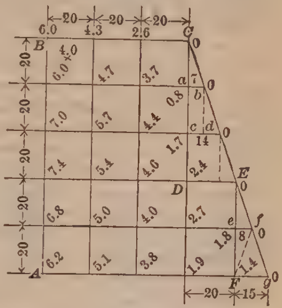

Fig. 77

Measurements of Dredged Material are taken in two ways, (1) measurement in place, and (2) scow measurement. For the **measurement-in-place** method soundings are taken before and again after the dredging work is done, and the volume of the material which has been removed is computed either by the Average End Area Method or by the Borrow-Pit Method. If the dredging covers a large area, contours may be drawn showing the shape of the bottom before and after the dredging has been done, and these may be used as bases of vertical solids. Where a channel has been dredged, sometimes it is more convenient to compute the volume as a series of horizontal solids with vertical end sections similar to a railroad excavation. In channel dredging the contractor is usually required to form the bottom at a given grade and the side slopes at a given slope, in which case it is not necessary to take cross-sections after the work is done, but soundings are taken as the dredging progresses to insure that the excavation is of proper depth.

When Scow Measurements are used to determine the quantity dredged each pocket of the scow is carefully measured and its capacity computed. When the scows have been loaded with the dredged material the surveyor or inspector makes a note of the number of full pockets; if they are not full he measures the distance down from the top of the coaming of the scow to where he estimates that the material in a pocket would come if it were leveled off. The volume of this small rectangular prism is calculated and deducted from the capacity of the corresponding pocket. For each scow in use tables giving the quantity in each pocket at various distances below the top of coaming are usually prepared for convenience. These scow measurements should be taken just before the tow starts for the dumping ground. When scows remain moored for a day or so before being towed to the dumping ground some of the material in the pockets leak out through the bottom doors if they are not tightly closed, and much material may find its way back again into the dredged portion of the channel. In the case of a deck scow where the material is piled on the deck any practical and convenient method may be used to determine the volume, the measurements depending upon the shape of the pile. For **rock** the amount taken out can be calculated by obtaining its weight, and this is ascertained by determining the displacement of the scow before and after loading.

Earthwork Computation from Contours is used in many landscape problems for determining an approximate value of the quantity of earth to be moved in a proposed grading project or in connection with a grading problem to form the shape of the final surface of a certain locality after a definite quantity of material has been removed from it. The use of contours in earthwork computations has been confined almost exclusively to preliminary estimates, but the principles involved in such computations are sufficiently sound so that as accurate determinations may be made in this way as by any of the other more common forms of earthwork computation, provided the contours are determined in the field with sufficient accuracy. It is frequently necessary to use a map, however, in which the contours have been determined by means of the stadia method or by some method of sketching their positions, using as a basis several characteristic points which have been located by the transit and the elevation of which has been determined by leveling. It is not customary or economical to define the contours accurately enough to admit of computing earthwork for payment of contracts because the borrow-pit method (Art. 68) is more readily adapted to this problem. For preliminary studies of all grading problems, however, a contour map is invaluable; its use can be extended to determining approximate quantities of earthwork without the necessity of any additional fieldwork, so that it is adapted to preliminary estimates.

There are three general methods of computing earthwork from data given on a contour map: (1) by computing directly the amount of cut or fill between successive contours; (2) by assuming a horizontal plane below the lowest part of any of the earthwork and first computing the volume of earth between that plane and the original surface, and afterward computing the volume between the same plane and the proposed surface; the difference between these two volumes will be the amount of excess cut or fill; (3) by drawing on the plan first a line of no cut or fill, a second line representing, say, 2-ft. cut or fill, a third line of 4-ft. cut or fill, and so on, and finally computing the volume between these successive 2-ft. layers. In all three cases the most practical way of determining the areas of the end sections is by means of a planimeter. The volumes are preferably computed by the end-area method.

Some surveyors use the prismoidal formula in problems of this nature by either interpolating by the eye the **middle area** or by treating every other area at a contour plane as a "middle area." The error in sketching the contours, in scaling the map, in the shrinkage of the paper on which the map is drawn, and the uncertainty in the amount of shrinkage in the earthwork are large enough to offset any advantage which the prismoidal formula may have over the end-area method in point of accuracy. The end-area method therefore is in practically all instances not only as exact as is the map upon which the computations are based, but is also sufficiently exact for preliminary estimates.

Method (1). The simplest application of this problem is illustrated by Fig. 78, in which the full lines are contours representing the shape of the existing surface, while the dash-line contours represent the proposed shape of the ground; the dotted lines are construction lines marking the limits of the solids to be computed. Such solids as *ANB-FQE*, *EQF-JTI*, *ITJUK-MVL* represent excavation. and solids like *BOC-GRF* and *FRG-J* are embankment. The solid *ANB-FQE* is substantially an inclined prismoid having two parallel horizontal bases whose areas are *ANB* and *FQE*, the perpendicular distance between these being the contour interval, in this case 2 ft. To compute the volume of solid *ANB-FQE*, first determine the area of the parallel bases *A BN* and *EFQ* by planimeter. The perpendicular distance between these bases is the contour interval, 2 ft. The volume is therefore computed by averaging the end areas and multiplying by the contour interval. All the other six excavation solids here shown should be computed in a similar manner; solid *CD-HSG* is a wedge. The solid *FRG-J* is a pyramid whose base is *FRG* and whose altitude is 2 ft.

Method (2). Where the problem is so complicated that the quantities of earthwork cannot be readily separated into prisms, wedges, and pyramids, as was done in Fig. 78, it can be solved by computing the quantity of earth by method (2). Such a treatment is particularly applicable to the problem of

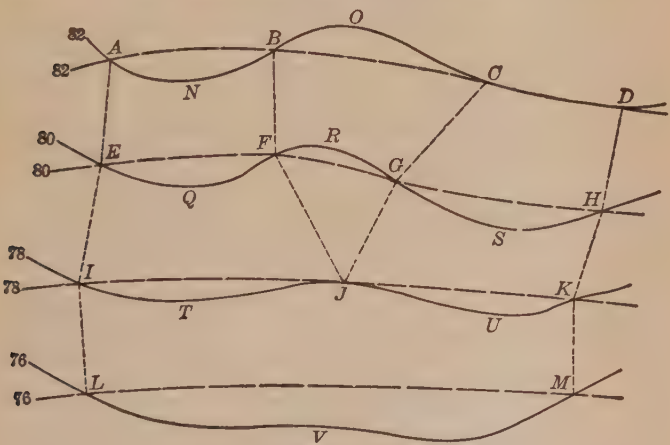

Fig. 78

determining the excess of cut or fill in a given grading project as represented by a set of proposed contours. It can be applied to determining the actual amount of cut and of fill, but for this purpose it is not so convenient of application as method (1).

Method (3). This method is particularly applicable when the original ground is very irregular and the proposed surface is to have an entirely different shape, so that the proposed contours do not cut many of the original contours of the same elevation. The first step in this process is to mark at every intersection of a new with an old contour the cut (or fill) and then to connect by means of a smooth curve the successive points of equal cut. These new curves will enclose areas which are the horizontal projections of irregular surfaces which are parallel to the final surface of the land and which are (if the contour interval is 2 ft.) at the line of no cut or fill, at 2 ft., 4 ft., etc., above the final surface. The solids included between these 2-ft. irregular surfaces are layers of earth each 2 ft. thick, and their volumes are computed by determining the areas of their horizontal projections and applying the usual end area method for volumes. To find the volume of the solid included between the curves of 2-ft. cut and the curves of 4-ft cut, for example, take for the upper surface the area within the dotted 2-ft. line as a plane surface; for the lower surface, the area within the dotted 4-ft. line; then multiply the mean of these two areas by 2 ft. in this case (the difference between the 2-ft. and 4-ft. lines). The solids at the top or bottom of these layers may be treated as wedges or pyramids.

MECHANICS OF SIMPLE STRESSES

1. Tension, Compression, Shear

Stress is the internal force which, when a body is subjected to external forces, tends to hold the molecules in their original relation and to preserve the integrity of the body. Stresses are measured by the same units as forces, namely, in pounds, tons, kilograms.

Unit Stress is the measure of intensity of a stress. It is the quotient obtained by dividing a total uniform stress by the number of units of area over which the stress is distributed. Unit stresses are expressed in pounds per square inch, tons per square foot, kilograms per square centimeter, and the like.

Physicists usually use the term **stress** in place of unit stress, and measure stress in pounds per square inch or kilograms per square centimeter. Confusion between the two uses of the term will be avoided if the units used are always stated.

Ultimate Stress. If the external forces acting on a body are increased to such an extent that the internal force or stress is no longer able to preserve the integrity of the body, rupture occurs. Ultimate stress is the greatest stress which can be produced in a body before rupture occurs. Ultimate unit stress is the ultimate stress on one unit of area. It is customary to compute it on the basis of load and the original size of cross-section. Ultimate stress and ultimate strength are interchangeable terms. The ultimate stress in tension is called the **tensile strength** of a material.

Tension is the name for the stress which tends to keep two adjoining planes of a body from being pulled apart under the influence of two forces acting away from each other. If a bar of uniform cross-section is hung vertically from a rigid support, and a load of 2000 lb. suspended at the lower end, a tensile stress is developed in every section of the bar. In order that equilibrium may obtain, the internal stress or tension in the bar due to the load must equal the external force or load, or 2000 lb.

Compression is the name for the stress which tends to keep two adjoining planes of a body from being pushed together under the influence of two forces acting toward each other. A brick pier of uniform cross-section supporting a column carrying a load of 40 short tons will be subjected to a compressive stress due to the load. When equilibrium obtains this stress must equal 40 short tons. If the area of the pier is four square feet, the unit stress in the pier due to the load will be 10 short tons per square foot.

Shear is the name for the stress which tends to keep two adjoining planes of a body from sliding one on the other under the influence of two equal and parallel forces acting in opposite directions. The forces which induce shearing stresses in a body are termed **Shearing Forces**, and usually are but slightly separated, so that their action is similar to that of a pair of shears, whence the name Shear. When two flat plates, secured together by means of rivets, are subjected to forces which tend to pull the plates apart by sliding one on the other, as in the case of the plates of a boiler under internal steam pressure, shearing stresses are induced in the rivets which hold the plates together. Unless otherwise noted, shearing stress is assumed to be distributed uniformly over the section upon which its acts, although this is rarely, if ever, exactly true.

Axial Forces and Axial Stresses. When forces producing tension or compression act on a body of symmetrical form in such a way that their resultant coincides with the axis of the body, they are termed **Axial Forces**, and the stresses induced thereby, **Axial Stresses.** In simple axial tension or compression alone, the stress is usually assumed to be distributed uniformly over every section of the body normal to the direction of the force, although this is rarely exactly true.

Axial tension and compression are the two commonest forms in which stress is met with in engineering structures. An example of simple axial tension is to be found in a vertical eyebar in a bridge truss, where the only force acting on the bar is along its axis. A horizontal eyebar or one inclined to the vertical, while acted upon by axial forces transmitted through the end pins, is also subjected to a force acting normal to or at an angle with the axis, due to the weight of the bar, which produces stresses not axial, so that the resultant stress in the bar is not uniformly distributed over each section, and the case is not one of simple axial tension.

A short vertical prism, whose length does not exceed about six times the least side or diameter, is subjected to simple axial compression under a load the resultant of which passes through the centers of gravity of the end sections. If the length of the prism is more than eight or ten times its least side or diameter it becomes a **Column,** and although the resultant force is still axial as regards the end sections, some bending is assumed to have taken place in the shaft of the column, resulting in an unequal distribution of stress over a given section, and the case is not considered one of simple axial compression.

Formulas for Simple Stresses. Let P be any force producing tension, compression or shear, A the area over which the induced stress is uniformly distributed, and S the unit stress; then

$$P = SA \qquad S = \frac{P}{A} \qquad A = \frac{P}{S} \tag{1}$$

which are expressions usually assumed to apply to all cases of simple axial tension, compression, or shear. Two quantities being given the other one can be found.

Factor of Safety, Working Stress. In order that the safety of a structure shall be assured, there must be no danger of rupture in any of its members. To secure this assurance of safety the stress induced in any member by any load which the member will be called upon to carry must never approach the ultimate strength of the material. The **Working Stress** for any material is the unit stress which, by experiment, has been found safe to allow in that material and still give a proper degree of security against structural failure, and is the unit stress to be used in determining the sizes of structural members of that material. The **Factor of Safety** is the number by which the ultimate stress must be divided to give the working stress. If in formula (1) S is taken as the ultimate stress, n a factor of safety, and S_w the safe allowable stress or working stress, then $S_w = S/n$.

The purpose of the factor of safety and the working stress is twofold: first, to guard against undiscoverable defects in the structural material employed, which defects reduce the ultimate strength of the material; and second, to provide against the possibility of an increase in the load to be carried due to unforeseen circumstances. The selection of the working stress and the factor of safety therefore depends, first, upon the degree of definiteness with which the ultimate stress for the particular material is known. Thus, the factor of safety for steel or iron is smaller than for timber, since the ultimate strength of each of the various grades of steel or iron is very nearly a constant quantity, while there is a wide variation in the values for the ultimate strength of timber obtained from different specimens of the same variety. Second, upon the definiteness with which the loads to be carried can be computed. Thus, when "dead" load capable of exact calculation forms a large proportion of the total load to be carried, as in the truss members of long and heavy bridges, the factor of safety is smaller than when live or moving loads form a large proportion of the total load, as in the case of girders supporting traveling cranes or heavy moving machinery.

Riveted Joints, such as the longitudinal joints in boilers, are examples of simple stress and are usually designed or investigated by formula (1).

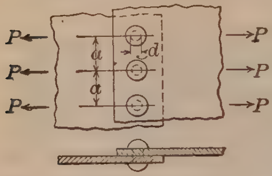

Fig. 1. Single Lap Joint

Case I. Lap joint with single riveting. (Fig. 1.) Here the shear in each rivet comes in one cross-section only and is termed "single shear." Let a = the pitch or rivet spacing, d = the diameter of the rivets, t = the thickness of the plates, P = the load to be transmitted from one plate to the other in the distance a, S_t = the unit tensile stress produced in the plates by the load P, S_c = the unit compressive stress produced in the plates where the rivets bear against them (commonly called "bearing"), S_s = the unit shear produced in the rivets; then

$$S_t = \frac{P}{t(a-d)} \qquad S_c = \frac{P}{td} \qquad S_s = \frac{P}{1/4\,\pi d^2}$$

Case II. Lap joint with double riveting. (Fig. 2.) As in Case I, the rivets are in single shear. Using the same symbols as before,

$$S_t = \frac{P}{t(a-d)} \qquad S_c = \frac{P}{2\,td} \qquad S_s = \frac{P}{2 \cdot 1/4\,\pi d^2}$$

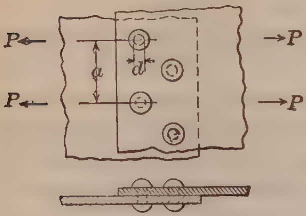

Fig. 2. Double Lap Joint

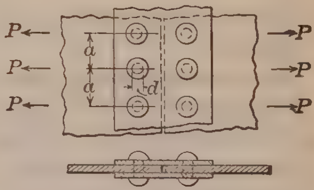

Fig. 3. Butt Joint

Case III. Butt joint with single riveting. (Fig. 3.) In this case the shear in the rivets comes in two cross-sections and is termed "double shear." Using the same symbols as before,

$$S_t = \frac{P}{t(a-d)} \qquad S_c = \frac{P}{td} \qquad S_s = \frac{P}{2 \cdot 1/4\,\pi d^2}$$

2. Deformation under Stress

Deformation is the amount of the change in the shape of a body caused by the action of an external force. Deformations are measured by the same unit as the linear dimensions of a body, namely, inches and millimeters. If a weight is suspended at the end of a steel bar, the effect of the weight is to increase slightly the length of the bar. This increase is the deformation.

Hooke's Law. Whenever a body is subjected to an external force a stress and an accompanying deformation result. From experiment it has been found that when the unit stress does not exceed a certain limit, which limit varies with each particular material, the stress bears a constant ratio to the accompanying deformation. Thus, if a weight W, suspended from a steel bar produces an elongation of 1/100 in., a weight of twice W will produce an elongation of 2/100 in., and a weight of three times W will produce an elongation of 3/100 in.

Stress and Strain. The word **strain** has been frequently used for the internal force in a body, or stress. It is present practice, however, to use the word strain as a synonym for deformation only. Thus the expression " stress and strain " is equivalent to the expression " stress and deformation." Owing to the conflicting meanings of the word Strain it has been suggested that it be avoided, the word **Deformation** being used in its place. Physicists usually define strain as the deformation per unit length.

Kinds of Deformation. Deformation may be of three kinds: elongation, or increase in length, due to tension; shortening, or decrease in length, due to compression; detrusion, or the slipping of one plane on another, due to shear.

Elasticity and Set. It has been found by experiment that up to a certain limit, a body deformed under stress will return to its original shape when the stress is removed. This ability to return to its original form after deformation is termed **Elasticity.** If the unit stress is increased, however, beyond such limit, it is found that the material undergoes a **Set**, or certain amount of permanent change, and is no longer capable of returning to its original shape when the stress is removed.

Elastic Limit. The elastic limit of a material is the highest unit stress to which that material may be subjected and still return to its original shape when the stress is removed.

Proportional Limit. The proportional limit of a material is the highest unit stress for which the deformation is proportional to the stress, or, in other words, the highest unit stress for which Hooke's law holds.

With actual materials it is probable that some very slight inelastic action occurs under any stress whatever, and that Hooke's law is a very close approximation rather than a rigid statement of fact. For the common structural steels and the usual degree of precision in laboratory tests the elastic limit and the proportional limit are nearly coincident, and the terms are, for practical purposes, interchangeable.

Various methods of determining the proportional limit or other practical " limits " closely related to it are in use. Some of these are discussed on p. 608.

Modulus of Elasticity. The modulus of elasticity of a material is the constant which, within the proportional limit, expresses the ratio between unit stress and unit deformation. Thus, let E = the modulus of elasticity, P = an axial force, A = the cross-sectional area of a bar, S = the unit stress produced by the force P, or P/A, d = the deformation produced by the force P in a bar of length l, and $d/l = e$; then

$$\mathbf{E} = \frac{\frac{\mathbf{P}}{\mathbf{A}}}{\frac{\mathbf{d}}{l}} \quad \text{or} \quad \mathbf{E} = \frac{\mathbf{S}}{\mathbf{e}}$$

Since l and d are linear dimensions, e is an abstract number, and E is expressed in the same units as S, such as pounds per square inch, tons per square foot, or kilograms per square centimeter.

Coefficient of Elasticity, and **Young's Modulus** are expressions sometimes used for the Modulus of Elasticity. They are not know in general use in the United States, Modulus of Elasticity being the generally accepted expression for the quantity E.

Deformation within Elastic Limit. The moduli of elasticity of materials measure their relative ability to resist deformation under unit stresses within their proportional limits. The above formula may be written in the form

$d = Sl/E$. For the same unit stress S, d decreases when E increases. It will thus be seen from a comparison of the various moduli of elasticity (Art. 3) that for the same unit stress timber in tension will be deformed ten times as much as cast iron, and cast iron about twice as much as steel. This formula may be employed to determine the total deformation of a bar of a length l when S and E are known.

From the values of the proportional limit and the moduli of elasticity in tension (Art. 3) the unit elongation at the proportional limit may be computed for each of the common structural materials, as follows:

For timber $\frac{1}{500} = 0.0020$ For wrought iron $\frac{1}{900} = 0.0011$

For medium steel $\frac{1}{857} = 0.0012$

The ultimate elongation, or the elongation at rupture, cannot be so readily computed, since beyond the proportional limit the ratio of the unit stress to the unit deformation is a constantly varying quantity.

3. Phenomena of Stress

Stress-deformation Diagrams. The action of a bar under stress may be represented by a curve the ordinates of which represent unit stresses and the abscissas the corresponding unit deformations. For all unit stresses below the

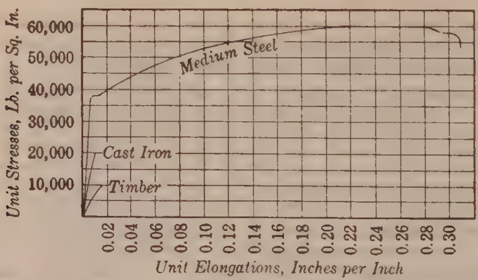

Fig. 4. Stress-elongation Diagram

proportional limit the stress-deformation curve will have the form of a straight line, since the formula $S = Ee$ is an equation which represents a straight line through the origin of coordinates, the slope of which is represented by E. Beyond the proportional limit the curve will take various forms and radii of curvature, depending upon the material. The end of the curve will represent the point of rupture, and the greatest ordinate will represent the ultimate strength of the material. The stress-deformation curve constructed from information derived from actual experiment, a sufficient number of points of the curve being plotted to determine accurately its curvature, affords in most cases the most satisfactory method available for determining the proportional limit of the material, the proportional limit being represented by the ordinate of the point of tangency between the straight line and the rest of the curve. Fig. 4 is a typical stress-deformation diagram, being that for medium steel in tension. The curves for cast iron and timber are shown for comparison.

The stress-deformation curve has various forms depending upon the material in question and whether the stress is tension or compression. In some cases the curve is of such form as to make it difficult to locate the proportional limit with accuracy. In the case of medium steel in tension (Fig. 4) the point of tangency between the straight line and the rest of the curve is fairly well defined, but in the corresponding curve for medium steel in compression the transition from the straight line to the curve is more gradual, and the point of tangency is more difficult to locate. Thus again, timber and cast iron have curves entirely different from medium steel or wrought iron, in that they are curved throughout their length and, for cast iron especially, the proportional limit cannot be at all definitely fixed.

Yield Point. In tests for the determination of the elastic properties and ultimate strength in tension of such metals as structural steel and wrought iron it is noted that after the elastic and proportional limits have been exceeded a point is reached where the unit elongations increase rapidly without any increase in the unit stresses. The unit stress at this point is termed the yield point.

The yield point is often confused with the elastic limit and the former is given for the latter in many reports of tests, owing to the facility with which the yield point may be determined with some testing machines. It is that point where the scale beam of the testing machine drops and remains down until the operating screws have stretched the metal a certain amount. After an interval the bar again rises and the stress in the specimen increases. The yield point is beyond the elastic limit—for structural steel from 3000 to 6000 lb. per sq. in. beyond it. Yield points are observed only in ductile metals, such as wrought iron and steel.

Elasticity and Set. The portion of the stress-deformation curve between the origin of coordinates and the elastic limit represents the range of unit stress and unit deformation within which the material will return to its original shape upon the removal of the stress. Beyond the elastic limit a body under stress only partly recovers its original shape upon the removal of the stress, the body being more or less permanently deformed. The amount of this permanent deformation is termed the **Permanent Set.** Thus a bar of wrought iron subjected to a tensile stress of 30 000 lb. per sq. in. shows a unit elongation of 0.003 in. per in. Upon the removal of the stress the bar will show a recovery of, say, 0.001 in. per in., having a permanent set of 0.002 in. per in.

Ultimate Strength and Stress at Rupture. The ultimate strength of a material is represented by the greatest ordinate in the stress-deformation diagram and is the greatest nominal unit stress to which the material may be subjected before rupture. The ultimate strength of a material as indicated by the stress-deformation diagram is not necessarily at the point of rupture. The stress-deformation curve for such materials as steel and wrought iron shows a decided drop after the ultimate strength has been reached, and the end of the curve corresponds to a nominal unit stress in some cases considerably below the ultimate strength.

To determine the unit stress in direct tension or compression divide the applied load by the area of cross-section of the original bar before the loads were applied. This is not strictly correct, since when the bar is approaching rupture the area of cross-section is considerably reduced. If after the ultimate strength has been reached the actual load, as indicated by the scale beam of the testing machine, could be divided by the actual area at the moment that particular load is acting, it would probably be found that the curve, if properly constructed, would curve upward beyond the point of ultimate strength.

Ultimate Deformation. Since there can be no general expression for the relation between stress and deformation beyond the elastic limit, it is not possible to determine the ultimate deformation, or deformation at the point of rupture, save by actual experiment. Ultimate deformations are rarely determined save in the case of tension tests, where the ultimate deformation becomes the ultimate elongation. It is usually expressed in per cent, and is

Average Properties of Structural Materials

Material	Weight per cubic foot, pounds	Modulus of elasticity: Tension compression	Modulus of elasticity: Shear	Elastic limit and proportional limit: Tension compression	Elastic limit and proportional limit: Shear	Ultimate strength: Tension	Ultimate strength: Compression	Ultimate strength: Shear

* No well-defined elastic limit or proportional limit.

† Strength in shear greater than strength in tension; in shear tests a tension failure on an oblique plane takes place.

‡ No well-defined ultimate in compression. The yield point, which is slightly higher than the proportional limit, is the practical ultimate.

found by determining the amount that a measured length of bar has elongated after rupture and dividing the amount of this elongation by the original measured length. Thus, if a measured length of 8 in. of a bar before testing increases to 10-1/2 in. at rupture, there would be 31.2 per cent ultimate elongation. The elongation after fracture is considered to be an index of the ductility of the material.

4. Methods of Fracture

Brittleness. A material which can be only slightly deformed without rupture is termed brittle. Brittleness is relative, no material being perfectly brittle, that is, capable of no deformation before rupture. Many materials are brittle to a greater or less degree, glass being one of the most brittle of materials. Brittle materials have relatively short stress-deformation curves, the deformations of which they are capable before rupture being relatively very small. Of the common structural materials cast iron, brick, and stone are to be considered brittle in comparison with steel. Brittle materials rupture without appreciable reduction of area, and show a clean, sharp fracture, no flow of material taking place before rupture occurs.

Plasticity is the ability of a solid to change shape without fracture. A perfectly plastic material is one in which an applied load however small produces a permanent deformation.

Brittleness and plasticity are opposite terms. Materials which have a high degree of plasticity have no brittleness, and rupture with considerable reduction of area. The reduction of area at rupture may be considered the measure of the plasticity or brittleness of a material, a large reduction of area indicating a high degree of plasticity and little or no reduction of a area indicating a high degree of brittleness.

Ductility is the ability tó undergo great stretch without fracture.

Toughness is the ability to withstand high stress together with great deformation. Toughness is an index of the ability of a material to withstand impact without complete fracture. Toughness is measured by the area under the stress-deformation diagram for a material, or, less exactly, by the product of ultimate strength and elongation after fracture.

Fracture under Tension. Figs. 5, 6, 7 represent typical fractures under tension. Fig. 5 shows the fracture of a brittle material like hard steel, with a very small reduction of area. Figs. 6 and 7 show the fracture of more plastic materials, such as wrought iron and steel, with a typical cup fracture as for structural steel (Fig. 6), and a fibrous fracture as for wrought iron (Fig. 7), the reduction of area in both cases being marked.

Fig. 5

Fig. 6

Fig. 7

Fig. 8

Fig. 9

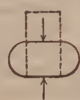

Fig. 10

Fracture under Compression. Figs. 8, 9, 10 represent the rupture of materials under compression. For very brittle materials, such as brick (Fig. 8) fracture frequently occurs along planes nearly parallel to the direction of the applied load with little or no increase in area. This is probably due to lateral deformation. For more plastic materials, such as timber (Fig. 9), fracture occurs along planes inclined to the direction of the load. A perfectly plastic material (Fig. 10) under its ultimate stress has a large increase in area without any shearing planes of fracture.

Relation of Shear to Tension and Compression. A body subjected to a force producing direct tension or compression has induced in it shearing stresses along certain planes of that body. Thus if an axial force P be applied to a bar (Fig. 11) along any plane $a-a$ inclined to the direction of the force, P may be resolved into two components, P_1 and P_2, acting respectively normal and parallel to the plane $a-a$. The component P_2 parallel to $a-a$ produces a shearing stress over the plane $a-a$. For all planes making angles 0° or 90° with the direction of the force P the shearing unit stress will be zero. It will be of maximum intensity along planes inclined 45° to the direction of P, and its value will be one-half of the direct tensile or compressive unit stress. Thus, if S be the tensile or compressive unit stress, the maximum shearing unit stress S_s along planes inclined 45° to the direction of P will be $S_s = 1/2\, S$.

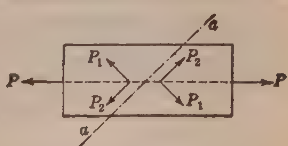

Fig. 11

In a body subjected to shearing stress, such as a shaft in torsion, there are set up tensile or compressive stresses on oblique planes. If in the body shown in Fig. 12 there is set up shearing stress along the plane *mn* there is set up shearing stress of equal intensity along planes at right angles to *mn* and tensile or compressive stress, along an inclined plane *pp*. If *pp* makes an angle of 45° with *mn* the shearing unit stress on *pp* becomes zero and the tensile or compressive unit stress is a maximum and its intensity is equal to that of the shearing unit stress along *mn*. The strength of a body is sometimes determined by stresses along oblique planes. Many brittle materials have great strength in compression, less strength in shear, and still less strength in tension. Under torsion such materials fail by tension along inclined planes; under compression they fail by shearing along inclined planes.

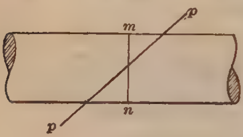

Fig. 12

5. Work and Resilience

External Work. When a load P is applied to a bar and a deformation d results, a force has acted over a certain path in producing this deformation and therefore a certain amount of work has been expended. When the force P is applied in small increments or is increased in amount gradually from zero up to P, the elastic limit of the material not being exceeded, the mean force which has acted to produce the deformation is $1/2\,P$, and the path over which the force has acted is the deformation d. If K is the amount of work expended, $\mathbf{K = 1/2\,Pd}$. Or, if A is the cross-section of the bar, l its length, S the unit stress produced, and e the unit elongation under the unit stress S, then this formula becomes $\mathbf{K = 1/2\,SeA}l$, which is an expression for the external work required to produce deformation within the elastic limit. The factor $1/2\,Se$ is the external work per unit of volume, the volume of the bar being Al.

Resilience is the amount of work which may be stored up in a body in the form of stress energy, and which may be recovered when the force producing the stress is removed. When the force is within the elastic limit, and it has been applied gradually so that no energy has been converted into heat, from the law of the conservation of energy the resilience must equal the external work. The resilience of a bar may be expressed, therefore, by the last formula, which, after making the necessary substitutions, may be written $\mathbf{K = 1/2\,(S^2/E)A}l$. When S is the elastic limit of the material, the factor $1/2\,S^2/E$ is termed the **Modulus of Resilience.**

The above formulas apply to a bar under tension, compression, or uniform shear. In the case of tension and compression the deformation or path of the force is normal to the planes of the body over which the stress is distributed, and parallel to the length, l; while in the case of shear the deformation is parallel to the planes over which the stress is distributed and normal to the length l. It should be further noted that the formulas apply only to elastic resilience, that is, to the resilience within the elastic limit of the material.

Work Required for Rupture. Since beyond the elastic limit the deformations are not proportional to the stresses, $1/2\,P$ does not express the mean value of the force acting. The formula $K = 1/2\,(S^2/E)Al$ therefore does not express the work required for deformations after the elastic limit of the material has been passed, and cannot express the work required for rupture. The work per unit volume required to produce deformations beyond the elastic limit or for rupture may, however, be determined from the stress-deformation diagram, as it is measured by the area included between the axis of abscissas, and the stress-deformation curve up to the deformation in question.

6. Cylinders and Rollers

Thin Cylinders. Under the internal pressure of water or steam, a pipe or a cylindrical boiler tends to rupture longitudinally along an element. The internal force or pressure acts normally to the inner surface and with equal intensity at all points. The tendency to rupture is resisted by the tensile strength of the material. When the thickness of the material is very small compared with the diameter, the stress may be considered uniformly distributed over the thickness without appreciable error and the case is considered one of a thin cylinder. Ordinary pipes and boilers are considered thin cylinders.

Let R be the unit pressure (Fig. 13), d the diameter of the pipe or boiler, l its length, t the thickness of the shell, and S the unit stress in the material. From a principle of hydrostatics the force which tends to produce rupture is ldR. The total resisting stress is $2\,ltS$. In order that equilibrium may obtain, the resisting stress must equal the pressure; hence

$$2\,tS = dR \qquad \text{or} \qquad \frac{S}{R} = \frac{d}{2\,t} \tag{1}$$

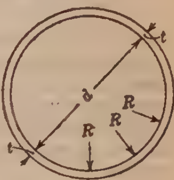

Fig. 13

This is the formula commonly used in investigating pipes, or the cylindrical shells of boilers, under internal pressure.

The Head of a Cylindrical Boiler under pressure tends to tear away from the cylindrical shell by transverse rupture under a force of $1/4\,\pi d^2 R$. This tendency is resisted by the tensile stress in the material distributed over an area equal to πdt. The stress S being considered uniformly distributed over the thickness t,

$$\pi dtS = 1/4\,\pi d^2 R \qquad \text{or} \qquad \frac{S}{R} = \frac{d}{4\,t} \tag{2}$$

A comparison of formulas (1) and (2) shows that in a thin cylinder the resistance to transverse rupture is twice the resistance to longitudinal rupture.

Cylinders under External Pressure, such as fire tubes in a boiler, fail by collapsing, the pressure tending to distort the cross-section of the cylinder from a true circle to an ellipse. While the formula $2\,tS = Rd$ applies to cylinders under external pressure as long as the cross-section remains a true circle, actual experience shows that irregularities of manufacture result in distortion, which the continued pressure tends to increase. No rational method being available for the investigation of cylinders under external pressure, recourse has been made to empirical methods. For tubes having a ratio of length to diameter greater than 6 and a ratio of thickness to diameter greater than 0.03, Carman and Carr found that the collapsing pressures are given by the following empirical formula for lap-welded steel pipe:

$$R = \frac{83\,290\,t}{d} - 1025 \tag{3}$$

in which R is the external pressure in pounds per square inch, d is the external diameter in inches, and t is the thickness of the tube in inches. (Univ. of Ill. Eng. Expt. Sta. Bulletins 5 and 99.)

Thick Cylinders. When the thickness of metal in a pipe or cylinder is such that the difference between the internal and the external radius is large compared with the mean radius, the stresses due to the internal pressure cannot be considered as uniformly distributed over the sectional area of the annulus, and formula (1) therefore does not apply. The most widely used formula for the design and investigation of thick cylinders is Lamé's formula as modified by Clavarino. Let r_1 and r_2 (Fig. 14) be respectively the internal and external radii, R_1 the pressure per square inch on the inside of the cylinder, R_2 the pressure per square inch on the outside of the cylinder, S the equivalent tangential unit stress (E times unit deformation) at a distance x from the axis of the cylinder. Then assuming the factor of the lateral contraction, or Poisson's ratio, to be 1/4,

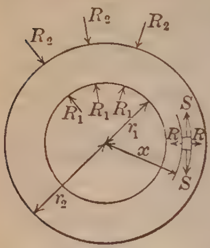

Fig. 14

$$S = \frac{\left[2\,r_1^2\,R_1 - 2\,r_2^2\,R_2 + \dfrac{5\,r_1^2\,r_2^2}{x^2}(R_1 - R_2)\right]}{4\,(r_2^2 - r_1^2)} \tag{4}$$

It will be noted that S decreases as x increases, wherefore S will be a maximum when $x = r_1$, or at the inner surface, and will be a minimum when $x = r_2$, or at the outer surface. When S is positive the stress is tension; when negative, compression. Under ordinary conditions R_2 may be neglected in comparison with R_1, being usually only the atmospheric pressure of 15 lb. per sq. in. Usually only the maximum pressure, or that on the inside of the cylinder, is required. Therefore, making $R_2 = 0$ and $x = r_1$, formula (4) becomes

$$S = \frac{R_1(2\,r_1^2 + 5\,r_2^2)}{4\,(r_2^2 - r_1^2)} \tag{5}$$

which is generally employed for common cases of investigation or design.

In a thick cylinder, in addition to the tangential stress S, which may be either tension or compression depending on the relative values of r_1, r_2, R_1 and R_2, there is a radial compressive stress R which will have its maximum value at the inner surface, where it will equal R_1, and its minimum value at the outer surface, where it will equal R_2.

Cylindrical Rollers are commonly used in providing expansion bearings at the ends of long girders and trusses, to provide for the difference in length due to temperature changes. These rollers are designed to travel between steel plates and to transmit the load from the upper to the lower plate, each roller taking its proper proportion of the total load (Fig. 15).

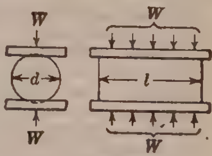

Fig. 15

Let W be the load carried by one roller of a length l and a diameter d, and let S be the maximum compressive stress in the roller and E the modulus of elasticity for the material; then

$$S = \left(\frac{9\,W^2E}{8\,d^2l^2}\right)^{1/3}$$

or

$$dl = \left(\frac{3\,W}{2\,S}\right)\left(\frac{E}{2\,S}\right)^{1/2}$$

The first formula is generally used for the investigation of cylindrical rollers, the load W, the length l, and the diameter d being given; while the second is the proper formula for the design of rollers with a given load, working stress and modulus of elasticity. If w is the load per unit of length of roller, or

$w = W/l$, then this formula becomes $w = 2/3\, dS(2\, S/E)^{1/2}$. Substituting $S = 25\,000$ and $E = 30\,000\,000$ there results $w = 680\, d$ for steel. The rule for bridge rollers given in recent specifications is $w = 600\, d$.

From tests by McDaniel at the University of Illinois the safe load in pounds per inch of length for hardwood rollers rolling on hardwood planks would seem to be about 25 times the diameter in inches.

These formulas are deduced under the assumption that the plates are not deformed. Experiments seem to indicate, however, that the plates are deformed as well as the rollers. The formulas err on the side of safety.

Ball Bearings. The permissible load on a hardened steel ball as determined by Stribeck from experimental data is given by the equation

$W = 565\, d^2$ for balls bearing against flat, hardened steel surfaces, and

$W = 1400\, d^2$ for balls supported in a hardened steel race in the shape of a groove with a radius $= 2/3\, d$

In the above W is the load in pounds, and d the diameter in inches.

7. Repetitive and Impact Stresses

Fatigue of Metals. It is a well-known fact based on experiment and general experience that stresses which can be applied to a body a few times without causing apparent structural damage may, if applied a great many times, cause failure. If a polished surface on a heavily stressed part of a body is examined under a microscope as stress is repeatedly applied, minute flaws will be seen to develop and spread, finally developing cracks. The phenomenon of failure under repeated stress is known as Fatigue of Metals. Progressive Fracture would be a better term.

A view formerly common was that under repeated stress metal "crystallized." This view became common because it seemed to explain the fact that under repeated stress even ductile materials fail by snapping sharply off, and the fracture has a crystalline appearance. The gradual spread of minute cracks would cause the same result, the effect of the crack being to reduce the available area resisting stress and to set up localized stresses of high intensity at the ends of these cracks. The crystallization theory of failure under repeated stress has given way to the progressive fracture theory.

The Endurance (or Fatigue) Limit. Tests on specimens of various metals subjected to repeated stress in specially designed testing machines show that

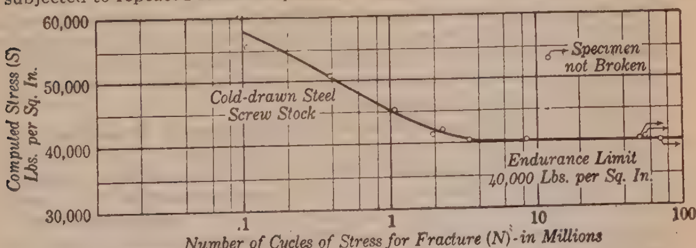

Fig. 16.

for nearly every metal tested there is a fairly well-defined limiting unit stress below which the metal can withstand hundreds of millions of repetitions of stress without fracture. This limit can best be determined for any metal by a series of tests of specimens using various unit stresses. The results of this series is plotted in a **stress-cycle**, or $S-N$ diagram. Fig. 16 shows a typical

$S-N$ diagram. Values of unit stress are plotted as ordinates and number of cycles of stress for fracture are plotted as abscissas (in Fig. 16 the abscissas are plotted to logarithmic coordinates). The unit stress for which the $S-N$ diagram becomes horizontal locates the **Endurance Limit** (or **Fatigue Limit**) for the metal tested. In Fig. 16 the endurance limit is 40 000 lb. per sq. in.

The endurance limit most commonly determined is that under cycles of completely reversed flexure. The table on p. 558 gives values of endurance limit under reversed flexure for a number of structural metals.

Endurance Limit for Various Ranges of Stress. For cycles of stress involving a complete reversal of axial stress (tension followed by compression) the endurance limit is found to be nearly the same as for tests under reversed flexure. In this connection it should be noted that it is exceedingly difficult in machine or structural parts to obtain pure axial stress free from flexure, and also that small localized flexural stresses which have no practical effect on static strength of ductile metals may have a marked effect on the strength under repeated stress.

For cycles of flexural or axial stress involving partial but not complete reversal the following formula has been found to give safe values for rolled or forged steel and iron:

$$(\mathbf{FL})' = \frac{3\,(\mathbf{FL})_{-1}}{(2 - \mathbf{r})} \tag{1}$$

in which $(FL)_{-1}$ is the endurance limit under cycles of completely reversed stress, r is the ratio of the (numerical) minimum stress during a cycle to the maximum stress (r is $-$ for partially or completely reversed stress; for completely reversed stress $r = -1.0$), and $(FL)'$ is the endurance limit under cycles of stress with the range r. If $r = 0$ (stress varying from 0 to a maximum), $(FL)' = 3/2\,(FL)_{-1}$. If during a cycle the stress varies from a given value in tension to 1/4 that value in compression, $r = -1/4$, and $(FL)' = 4/3\,(FL)_{-1}$.

Formula (1) may be used safely for cycles of non-reversed stress (r, positive) but **if it gives values above the elastic limit of the metal,** the danger of failure by inelastic distortion is greater than the danger of failure by progressive fracture, and the elastic limit is the criterion of strength rather than the endurance limit.

Endurance Limit under Repeated Shearing Stress. Test data for tests under cycles of shearing stress (such as would be set up in a shaft under torsion) are rather meager, but available data indicate that the endurance limit under cycles of shearing stress may safely be taken as 50% of the endurance limit under cycles of flexural stress.

Correlation of Endurance Limit with Other Strength Properties. The endurance limit of a metal seems to be more closely correlated with the tensile strength than with the elastic limit. This is not surprising in view of the fact that fatigue failure consists of a gradually spreading **fracture** of the metal. For rolled or forged steel or iron the endurance limit is usually about 50% of the tensile strength, or 250 times the Brinell Hardness Number. For sound steel castings the ratio of endurance limit to tensile strength is about 0.40, for cast iron about 0.33, and for non-ferrous metals the ratio varies from 0.25 to 0.50.

Localized Stress and Fatigue Failure. In designing parts to be subjected to non-repeated loading many localized stresses are commonly neglected (for example, the localized stress at the edge of a rivet hole, which may be two or three times the value computed by the formulas on p. 546). This practice is justified for static loading of ductile metals because the localized overstress does not cause appreciable distortion of the part as a whole. However, under repeated stress a minute area of overstressed metal may serve as a starting point for a spreading crack which ultimately causes failure of the piece, and such failure, if it occurs, comes suddenly without warning, just as if the piece were gradually sawed through with a hacksaw.

Designers should pay especial attention to avoiding notches, sharp shoulders, small holes, and other sources of localized stress in parts subjected to repeated loading. If such localized stress cannot be avoided (for example, in the case of a screw thread) allowance should be made for the localized stress.

The Stress-concentration Factor for localized stress is the ratio of the stress actually existing at the point of localized stress to the value of the stress as computed by the ordinary formulas of mechanics of materials, which take no account of such localized stress. The accompanying table gives safe values for typical stress-concentration factors.

Stress-concentration Factors for Typical Localized Stresses

r = radius at bottom of groove or at shoulder.
d = diameter or thickness of piece.

Location	Stress-concentration factor
Hole in plate, width not greater than one-sixth width of plate	3.0
Bottom of U. S. Standard Screw Thread	4.0
Shoulder on piece: $r/d = 0.5$	1.6
$r/d = 0.3$	1.9
$r/d = 0.2$	2.2
$r/d = 0.1$	2.8
$r/d = 0.05$	3.2
Groove in piece: $r/d = 2.0$	2.6
$r/d = 1.0$	3.0
$r/d = 0.5$	3.7
$r/d = 0.2$	5.4
$r/d = 0.1$	8.0

Corrosion-fatigue. Tests by McAdam and others show that under the **simultaneous** action of a corroding agent and repeated stress the endurance limit of a metal may be greatly reduced. Under the corroding action of a stream of fresh water at ordinary room temperature the endurance limit of heat-treated alloy steel may be reduced as much as 50%. Structural steel as rolled is less affected, and the various "stainless" steels and irons are even less affected than structural steel.

Detection of Fatigue Cracks before Final Failure. Whenever it is feasible to make a periodic examination of a structural member subjected to repeated loading there is a fair chance of detecting a fatigue crack before disastrous failure occurs. Such cracks have been detected in practice for boiler plates, car axles, and bridge members. A careful visual examination will sometimes disclose the crack. Examination with a magnifying glass is still better. A method in successful use consists in rubbing the suspected part with oil, wiping the oil off the surface, coating the surface with a wash of whiting, and when the whiting is dry striking the piece so as to set up slight bending stresses. Some of the oil which has seeped into any fatigue cracks is forced out, discoloring the white coating and locating the fatigue cracks.

Endurance Limits of Common Structural Metals under Cycles of Reversed Flexural Stress

From test results obtained with rotating-beam fatigue testing machines

The values given in this table were obtained from tests of small specimens, not over 1/2 in. in diameter. For large pieces made of materials of the same chemical composition and with the same nominal heat treatment the stresses developed at the endurance limit of the piece would be lower than those shown here. The use of a factor of safety (more accurately a factor of uncertainty) is necessary with these values for determining working stress in machine parts subjected to repeated stress.

Metal	Approximate chemical composition, per cent	Heat treatment	Tensile strength, lb. per sq. in.	Endurance limit, lb. per sq. in.	Endurance ratio *	Brinell hardness number
Armco	0.02 carbon	Annealed	42 400	26 000	0.61	69

* Ratio of endurance limit to tensile strength.

Static and Dynamic Loads. A load at rest, producing no change in the unit stress S, or a load which is increased gradually by increments from 0 up to P, is termed a **Static Load**, and unless otherwise noted is the load usually understood in the discussion of structural members. Many structural members, however, are subject to load applied so rapidly that the momentum of deformation causes strains and stresses beyond the "static" values. Such loads are termed **Dynamic Loads.** It is obvious that the effect of a dynamic load may be much greater than the effect of the same load applied in small increments.

Impact is a word used to denote the effect of a moving load. The blow of a hammer is a good example of impact, the velocity with which the weight of the hammer or the load is moving when it strikes being an important factor in the effect produced. If P is a load in motion with a velocity V at the moment of striking a horizontal bar, the energy due to the velocity, or the kinetic energy, could be expressed by $PV^2/2g$, in which g is the acceleration due to gravity. If h is the height through which a load must fall in order to acquire the velocity V, then $V^2/2g = h$, and the kinetic energy of the moving load may be expressed by Ph. The load P striking the bar produces a stress which increases from 0 up to Q, with a corresponding deformation increasing from 0 up to d_1. The energy stored in the bar is evidently expressed by $1/2\,Qd_1$, which must be equal to the external work provided no energy has been expended as heat or in giving velocity to the bar, or $1/2\,Qd_1 = Ph$. If d is the deformation produced by a static load P, then $d_1/d = Q/P$, whence by combining and solving for Q and d_1 there results

$$Q = P\left(\frac{2h}{d}\right)^{1/2} \qquad d_1 = d\left(\frac{2h}{d}\right)^{1/2}$$

from which it appears that Q and d_1 increase with h or, in other words, with the velocity with which the load is moving when impact occurs. If the bar is vertical instead of horizontal the external work expended is expressed by $P\,(h + d_1)$. Substituting this value for the external work above,

$$Q = P + P\left(\frac{1 + 2h}{d}\right)^{1/2} \qquad d_1 = d + d\left(\frac{1 + 2h}{d}\right)^{1/2}$$

It is obvious that these formulas are valid only when the stresses do not exceed the elastic limit of the material.

Compared with actual experiments the above formulas give values somewhat too large. This is due to the fact that some of the external work is not effective in producing stress, it being expended in giving motion to the bar and in producing heat, the heat being caused by the friction between the displaced molecules. For light bars, however, the values given by the formulas give results approximately correct.

Rupture from Impact. Since the stresses caused by moving loads increase with the velocity of the load, it is obvious that rupture may be caused by impact provided the load has the requisite velocity. The above formulas, however, do not apply, since they are valid only for stresses within the elastic limit. There being no rational formulas for rupture due to impact, the only information available has been obtained through experiment. The relation between the work required for rupture from impact and the work required under static loads has been determined by Hatt. From nearly 200 experiments he determined that the work required for rupture from impact was about 30% greater than that required by static loads. From available test data it does not seem that the ultimate elongation under impact (dynamic) loads is widely different from that under static loads.

Live Load Stresses, Coefficient of Impact. In computing stresses in structural members two classes of loads are usually considered; the dead load, or the weight of the various parts of the structure, and the live loads or the superimposed loads which the structure has been designed to carry. The effects of these two loads are usually computed separately. The stresses due to the dead loads are computed from static loads in the ordinary manner, the actual stresses increasing gradually as the structure is built. Stresses due to the live loads, however, may often be considerably greater than those due to corresponding static loads, since under some circumstances the loads are dynamic loads, as when a heavy, rapidly moving train runs onto the floor system of a bridge. It is evident, therefore, that in computing stresses due to various live loads proper allowance should be made for the dynamic effect. The **Coefficient of Impact** is the factor by which the corresponding static stress must be multiplied in order to give the amount that the live-load stress exceeds the corresponding static stress. Thus let S be the corresponding static unit stress due to a live load W, and i the coefficient of impact. Then the amount that the live-load stress exceeds the corresponding static stress would be iS and the total stress $S + iS$. Values of the coefficient of impact i have been determined by empirical methods, the values varying with existing conditions. The coefficient of impact varies widely for different parts of a structure. For example, the coefficient of impact for the floor-beams of a railroad bridge would be much higher than the coefficient of impact for the chord members of the trusses. At present no general rule can be given for determining values of this coefficient for structural parts. See Sect. 8, Art. 10.

It should be noted that the meaning of the word impact as here used differs somewhat from its strict theoretical meaning. The use of the terms "impact" and "coefficient of impact" in connection with live-load stresses is, however, very general.

8. Combined Stresses

Combinations of Axial Forces. Assume a bar of a cross-section A acted upon at the same time by a number of axial forces some of which produce tension and some compression. Assuming those producing tension to be positive and those producing compression negative, five forces may be represented by P_1, P_2, P_3 and $-P_1$, $-P_2$. Let the unit stress in the bar be S. It is obvious that the unit stress in the bar is equivalent to the stress produced by a load represented by the algebraic sum of the several loads acting, or $S = (P_1 + P_2 + P_3 - P_1 - P_2)/A$. If the forces represented by P_1 and $-P_1$ and P_2 and $-P_2$ have the same numerical values, then $S = P_3/A$. P_3 represents the algebraic sum of the forces acting, and being positive indicates tension.

Change in Cross-section. A body subjected to a simple axial load suffers lateral deformation. If the load is tensile the cross-section is diminished; if compressive, the cross-section is increased. When the elastic limit of the material is not exceeded, experiments show that the lateral unit deformation, or change in diameter or other lateral dimensions, bears a constant ratio to the linear unit deformation. Let this ratio be expressed by p. Let a bar of a diameter d and a length l under a unit stress S within the elastic limit have a linear unit deformation e then the total linear deformation under the unit stress S will be represented by el, and the total lateral deformation, or change in diameter, will be expressed by ped. If d' is the diameter and l' the length of the bar while under the stress S, then

$$\text{For tension,} \quad l' = (1 + e)l \quad \text{and} \quad d' = (1 - pe)d$$
$$\text{For compression,} \quad l' = (1 - e)l \qquad d' = (1 + pe)d$$

The quantity p is sometimes called the "factor of lateral contraction" but more commonly **Poisson's Ratio.** Recent tests by Jasper indicate that for rolled metals Poisson's ratio varies from 0.19 to 0.27; 0.25 seems to be a fairly representative value. For concrete Poisson's ratio is about 0.15.

Shear under Tension or Compression. A body under tensile or compressive forces is subjected to tensile or compressive stresses in planes normal to the direction of the forces, and to shearing stresses between planes inclined to the directions of the forces, the intensity of the shear varying with the inclination of the planes. Assume two forces P_1 and P_2 acting on a bar at right angles to each other, producing apparent normal unit stresses of S_1 and S_2. Let S' represent the maximum shearing stress. Then from the relation existing between the maximum shear and tension or compression, if S_1 and S_2 have the same sign,

$$S' = 1/2\ S_1 \text{ or } 1/2\ S_2, \text{ whichever is greater.}$$

If S_1 and S_2 have opposite signs,

$$S' = 1/2\ (S_1 - S_2)$$

The planes in which the maximum shearing stress occur are found to be those which make angles of 45° with the directions of the two forces.

A bar of cast iron 1 sq. in. in cross-section under a compressive load of 2400 lb. is subjected to unit stresses $S_1 = 2400$ and $S_2 = 0$. The maximum shearing stress is $S' = 2400/2 = 1200$.

Effect of Lateral Deformation. Under the action of two (or three) stresses at right angles, or under the combined action of axial stress and shearing stress, the lateral deformations set up have no effect on the stresses developed, but they do affect the deformations at any point. For example, a boiler shell is subjected to circumferential tensile stress due to the bursting action of the steam pressure, and also to axial stress due to the pull of the boiler heads. The lateral contraction due to the axial pull does not affect the **circumferential stress,** but does affect the **circumferential stretch** due to the bursting pressure, and the resulting **circumferential unit deformation** is less than the circumferential unit deformation due to bursting pressure alone. If the shell were subjected to axial compression the unit circumferential unit deformation would be greater than that due to bursting pressure alone.

Four Theories of Failure of Materials. When structural damage is done to the material in a member is it caused by stress or by deformation? Or is it caused by shearing stress on some oblique plane? Or is it caused by the energy stored up in the stressed material?

The Maximum Strain Theory (**St. Venant's**) holds that **deformation** is the vital factor in causing failure of material. Using this theory as a basis for calculation it is necessary to take account of the lateral deformation accompanying axial stress; Poisson's ratio must be considered.

The Maximum Stress Theory (**Rankine's**) holds that **stress** is the vital factor in causing failure. This is the theory on which the common formulas for strength are based. Using this theory no account is taken of lateral deformation accompanying axial stress; Poisson's ratio is not considered. The weight of experimental evidence seems to show that the maximum stress theory is not strictly true, yet in most cases it is sufficiently accurate for everyday use. Its use is most doubtful for members subjected to tension in one direction and compression at right angles to the tension.

The Maximum Shear Theory (**Guest's**) holds that **shearing stress** is the vital factor in causing failure. If this theory is used a bar under a simple axial load is in danger of failure from the shearing stresses on a plane making an angle of 45° with the axis of the bar. The value of the shearing unit stress on this 45° plane is one-half that of the axial unit stress.

The Maximum Energy Theory (**Haigh's**) holds that the **energy** per unit volume stored up in the stressed part is the vital factor in causing failure. This theory necessitates the consideration of axial stresses, lateral deformations, and shearing stresses.

Experimental Evidence for the Various Theories. Recent experimental studies of these theories have been made by Becker (Univ. of Ill. Eng. Expt. Sta. Bull. 85), by Matsumura and Hamabe (Memoirs of the Coll. of Eng., Kyoto Imperial University, Feb., 1915), and by Haigh (Proc. British Assn., 1919 and 1921 Report of Comm. on Complex Stress). A combination of the maximum strain theory with a consideration of shearing stress seems to fit the test results fairly well. The maximum energy theory seems to fit test data except for the case of axial stresses of the same sign and of nearly equal magnitude acting at right angles to each other. The maximum shear theory seems to give results on the safe side for nearly all cases. For nearly all cases of structural design the common Rankine formulas seem safe.

The different theories give the same results for simple axial stress and for simple shearing stress. For the combinations of axial stress and shearing stress usually found in practice the different theories do not yield widely differing values. For combinations of tension in one direction with compression at right angles to it there is some question as to the safety of the Rankine formulas.

9. Miscellaneous Cases

Eccentric Loads in a Rectangular Bar. An eccentric load is one whose line of action does not coincide with the axis of the bar upon which it acts. In concentric or axial loading the load, or if there are several loads all acting at the same time, their resultant, coincides with the axis of the bar. The result of an eccentric load is an uneven distribution of stress over the area of cross-section, the unit stress in one portion of the cross-section being considerably greater than in another portion, the actual variation depending upon the position of the resultant load with reference to the axis.

Let P be a load acting on a rectangular bar (whose area is A) at a distance e from the axis of the bar, e being measured in the direction of the width d (Fig. 17). Were the load P axial the unit stress S would be the same all over the area of cross-section and would be $S = P/A$. The load P being eccentric, P/A expresses only the average unit stress, the maximum unit stress and the minimum unit stress varying from the average an amount dependent upon the position of the load. Let mn be any section and S_1 be unit stress along edge nearer to P and S_2 unit stress along opposite edge. It has been found that the intermediate stresses between S_1 and S_2 will vary uniformly or as a straight line, so that the plane figure (Fig. 17), of which S_1 and S_2 are two parallel sides, is a trapezoid. In order that equilibrium may obtain, the resultant stress must equal P, and its line of action must be in the same line as P. From these two conditions of equilibrium it results that

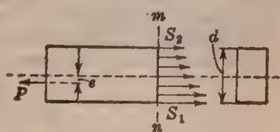

Fig. 17

$$S_1 = \frac{P}{A}\left(1 + \frac{6e}{d}\right) \qquad S_2 = \frac{P}{A}\left(1 - \frac{6e}{d}\right)$$

and these formulas are applicable alike to cases of tension or compression. The same result might have been obtained by considering the bar subject to an axial load P and bending moment Pe.

Making $e = o$ in the formulas, $S_1 = P/A$, and $S_2 = P/A$, which is a case of axial loading. When $e = d/6$, $S_1 = 2\ P/A$ and $S_2 = 0$, which indicates that when the resultant force is at the edge of the middle-third the maximum stress is twice the average stress and the minimum stress is zero. Making e greater than $d/6$, the sign of the stress S_2 changes, indicating a change from tension to compression or vice versa. A brick pier 5 ft. × 4 ft. in cross-section, loaded at a point 1 ft. from the center of the top in the direction of the width, with a load of 16 000 lb., would have a maximum unit compression of $S_1 = (16\,000/20)(1 + 6 \times 1/4) = 2000$ and a stress on the opposite edge of the pier of $S_2 = (16\,000/20)(1 - 6 \times 1/4) = -400$. The minus sign indicates a change in stress, or tension.

Centrifugal Stress in a Revolving Bar. If a weight is secured to an axis of revolution by means of a cord or a bar, and is made to revolve about that axis at a certain radius, a tensile stress is generated in the cord or bar. Let P be a weight revolving about an axis B (Fig. 18) at a radius r from the axis to the center of gravity of P and with a velocity V. Let Q be the centrifugal tension generated. Then from mechanics $Q = PV^2/gr$, in which g is the acceleration due to gravity, the mean value of which is usually taken as 32.16 ft. per second per second. Let n be the number of revolutions per second; then $V = 2\ \pi nr$ and $Q = (4\ P\pi^2n^2r)/g$, which gives the centrifugal stress in the member securing the weight to the axis when that member has no appreciable weight, as would be the case were it a cord. If the connecting member is a bar of a length l and weight W, then

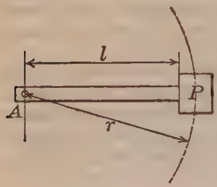

Fig. 18

$$Q = \frac{(4\ P\pi^2n^2r)}{g} + \frac{(2\ W\pi^2n^2l)}{g} \qquad \text{or} \qquad Q = \frac{4\ (Pr + 1/2\ Wl)\ \pi^2n^2}{g}$$

In this formula a portion of the stress Q is due to the weight P revolving with its center of gravity at a distance r from the axis, and a portion is due to the weight of the bar revolving with its center of gravity at a distance $1/2\ l$ from the axis. Q in this case is the stress in the bar at the axis. The stress in a simple bar revolving about an axis at one end varies from Q at the axis to 0 at the outer end. If w be the weight of the bar per unit of volume and A its cross-sectional area, the stress Q' at any point distant x from the axis is

$$Q' = \frac{2\ wA\ (l^2 - x^2)\ \pi^2n^2}{g}$$

Giving Q' its proper value and making $x = 0$, the number of revolutions required to rupture a bar of any given size, length, and material may be found. Thus the number of revolutions required to rupture a steel bar one square inch in cross-section and 4 ft. long will be found by substituting in the formula $x = 0$, $l = 4$ ft., $A = 1$, $w = 3.4$ lb., $Q' = 60\,000$ lb. per sq. in., $g = 32.16$; then n equals about 42 revolutions per second.

Revolving Thin Hoop. A thin circular hoop having a thickness t and a radius r (ft.) revolving about its center generates a tension in the hoop due to the centrifugal force acting radially in a manner similar to the action of an internal pressure on a section of a thin cylinder. If S is the tensile unit stress (lb. per sq.-in.) in the hoop, W = weight of a piece of the material 1 in. square by 12 in. long, and the other symbols as above, then

$$S = \frac{4\pi^2 W n^2 r^2}{g} \quad \text{or} \quad S = \frac{4(\pi n r)^2 W}{g}$$

which applies only when t is very small compared with the radius r.

Revolving Thick Hoop or Solid Wheel. Let a thick hoop have an inside radius of r_1 and an outside radius of r_2. and let R be the radial unit stress and S the tangential unit stress, at a distance x from the axis, due to the angular velocity $2\pi n$. Other symbols remaining as above, then

$$R = \left(\frac{3}{2g}\right)(w\pi^2 n^2)\left(r_1^2 + r_2^2 - \frac{r_1^2 r_2^2}{x^2} - x^2\right)$$

$$S = \left(\frac{3}{2g}\right)(w\pi^2 n^2)\left(r_1^2 + r_2^2 + \frac{r_1^2 r_2^2}{x^2} - x^2\right)$$

For a solid wheel, such as a millstone or a grindstone, $r_1 = 0$ and $r_2 = r$. Whence, when $x=0$, the unit stresses at the center are $R=S=3/2(\pi nr)^2 w/g$. When $x = r$, then $R = 0$, and $S = (\pi nr)^2 w/g$ is the tangential stress at the circumference. The above formulas are deduced by supposing that the revolving body does not change its form, but they give the correct actual stresses at the circumferences. For the center of a solid wheel, the above formula for S does not take account of lateral deformation, but the equivalent simple radial and tangential stresses (the strain equivalents) corresponding to the actual deformation are $3/2\,(1 - p)\,(\pi nr)^2 w/g$. Here p is Poisson's Ratio, or the factor of lateral contraction. For a solid steel wheel, the simple unit stress corresponding to the deformation (the strain equivalent) at the axis is $9/8\,(\pi nr)^2 w/g$, but if there be a very small hole at the axis it is two times as great. All these formulas apply only when the elastic limit of the material is not exceeded.

Temperature Stresses. All structural materials undergo changes in length due to changes in temperature. The **Coefficient of Expansion** for any material is the factor which expresses the change per unit of length for each degree of temperature. A bar or other structural member of a length l under a change in temperature of t degrees will, if free to move, undergo a change in length of tln, n being the coefficient of expansion. If the bar or member is fixed so that the change in length cannot occur it is evident that there is generated in the bar or member a stress equal in amount to that required to produce a deformation of tln or a unit deformation tn. If E is the modulus of elasticity and S the unit stress produced, then

$$\frac{S}{E} = tn \quad \text{or} \quad S = tnE$$

from which it is seen that S is independent of the length of the member.

Average values for the coefficient of expansion based on one degree (Fahrenheit) are as follows: n = 0.000 006 2 for cast iron, 0.000 006 5 for steel, 0.000 006 7 for wrought iron, 0.000 005 0 for brick and stone, and 0.000 005 5 for concrete.

Shrinkage of Hoops. A hoop surrounding a cylinder such as a reinforcing band on a gun or a tire on a wagon wheel or locomotive driver, is usually held in place by turning the hoop to an inside diameter slightly smaller than that of the cylinder it is intended to surround, and then expanding it by heat until large enough to fit, the shrinkage in cooling holding it securely in place. In such a hoop a tangential stress is produced in the hoop and a radial pressure in the cylinder which it encloses. When the thickness of the hoop is small compared with its diameter, all the deformation produced may be considered as confined to the hoop. The tension in the hoop will be proportional to its change in diameter. Let d = the diameter of the cylinder to be enclosed, which is assumed to be the same after the hoop is in place. d_1 = the diameter to which the hoop has been turned. S = the tangential unit stress. E = the modulus of elasticity. R = the radial unit stress acting on the inside of the hoop, and t = the thickness of the hoop. Then

$$S = \frac{E(d - d_1)}{d_1} \quad \text{and} \quad R = \frac{2tS}{d_1}$$

The values found for S from this formula are somewhat too large since some change is made in the diameter d due to the radial pressure. For thick hoops such as the bands on heavy guns more exact formulas are usually employed.

Internal Friction. In 1893 the discovery was made by Hartmann that lines of stress became visible on polished metal specimens, these lines remaining after the removal of the load if the elastic limit had been exceeded. On a cylindrical specimen these lines are two sets of helices; on a flat specimen they are two sets of straight lines. In tension they make angles with the axis greater than 45°, in compression the angles are less than 45°. These lines indicate the direction of planes along which sliding or shearing is occurring. Internal friction occurs along these planes from the theory of which Merriman deduced the ratio between the shearing and compressive strength of brittle materials (Mechanics of Materials, 1910, p. 380) finding 0.13 for anthracite coal, 0.18 for sandstone, 0.23 for hard brick, 0.29 for concrete, and 0.35 for cast iron.

BEAMS, COLUMNS, SHAFTS

10. Moments and Shears

Flexure or Bending is the phenomenon which occurs when a straight bar is subjected to a force or a combination of forces so applied that the axis of the bar is caused to assume the form of a curve. The phenomenon of flexure is a combination of the three simple stresses of tension, compression, and shear. Thus a horizontal bar simply supported at the ends under the influence of its own weight assumes the form of a curve, concave upward, and is undergoing flexure. The fibers on the convex side of the bar are elongated and therefore are in tension, while the fibers on the concave side are shortened and are therefore in compression. Shear is taking place between each vertical plane of the bar and the one adjoining, between the middle of the bar and each support. The structural members which are ordinarily subject to flexure are called **beams** and are usually horizontal members, carrying loads acting vertically. Flexure, however, is not confined entirely to beams, since it may occur in any member of a structure under the influence of loads other than axial loads. Even in the case of a strut or column which is under compression, flexure may occur when the acting forces are eccentric with respect to the axis.

A Simple Beam is a horizontal member simply supported at the ends so that all parts have free movement in a vertical plane under the influence of vertical loads. Simple beams are the commonest structural members. Under ordinary loading the upper fibers are in compression and the lower fibers in tension. A **Cantilever Beam** is a member with one end projecting beyond the point of support, free to move in a vertical plane under the influence of vertical loads placed between the free end and the support. The fibers in the upper side of such a beam are in tension and those in the lower side in compression. A beam with one end rigidly fixed in a brick wall and the other end free is an example of a cantilever beam. Constrained beams are those rigidly fixed at one or both points of support. A beam with one or both ends rigidly built into brickwork is an example. A **Continuous Beam** is one having more than two points of support. More than two points of support cause a distribution of stress similar to that in a constrained beam.

Neutral Surface and Neutral Axis. Any beam under flexure takes the form of a curve. The fibers of the beam on the concave surface are subjected to compression, while those on the convex surface are subjected to tension. It is obvious that these stresses must decrease toward the middle of the depth of the beam; therefore at some point in the depth of the beam there is a surface where the fibers are neither in tension nor in compression and where no deformation is taking place. This surface is termed the **Neutral Surface.** The trace of this surface or plane on any cross-section of the beam is termed the **Neutral Axis** of that section.

From experiment it has been shown that where the elastic limit of the material has not been exceeded the deformation in any fiber and in consequence the stress in that fiber is proportional to its distance from the neutral surface. It may also be demonstrated analytically that the neutral surface passes through the center of gravity of the cross-section, and that for beams of **symmetrical cross-section** loaded in a plane of symmetry or at right angles thereto the neutral axis is perpendicular to the plane of the load.

End Reactions. In order that equilibrium may obtain in any vertical system of forces acting in one plane, as in the case of the loads and reactions of beams, it is known from analytical mechanics that, first, the algebraic sum of all vertical forces must equal zero, and second, the algebraic sum of all moments must equal zero. From the first of these laws it is apparent that the sum of the reactions must equal the sum of the loads. In a simple beam when the loads are systematically placed with reference to the supports, as in the case of loads uniformly distributed, such as the weight of the beam itself, or equal concentrated loads placed at equal distances from the supports or center of beam, each reaction will equal one-half the sum of the loads. When the loads are not systematically placed the reaction at each support may be ascertained from the second of the laws stated above. Thus consider the system of loads, Fig. 19. Taking moments about the left support $R_2 \times 20 - 4000 \times 5 - 5000 \times 8 - 10\,000 \times 10 = 0$, or $R_2 = 8000$ lb. Similarly moments taken at the right support give $R_1 = 11\,000$. It will be noted that the sum of the reactions equals 19 000, the sum of the loads thus fulfilling the first law of equilibrium. When some of the loads are uniformly distributed over a portion of or the whole of the beam the same method may be applied to find the reactions by considering the uniform loads as concentrated at their centers of gravity.

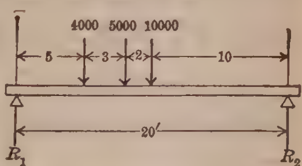

Fig. 19

Vertical Shear. At every section in a beam two equal and opposite forces, the one on the right and the other on the left of the section, tend to shear the beam at that point. This shearing tendency is greatest at the reactions where the shearing forces are each equal in amount to the reaction. The vertical shear at any section is the measure of the shearing tendency at that section and is equal to the algebraic sum of all the forces to the left of that section, upward forces or reactions being taken as positive and the downward forces or loads being taken as negative. The vertical shear may be either negative or positive, depending upon the relative values of the loads and reactions to the left of the section.

Figs. 20*a* and 20*b* illustrate diagrammatically the vertical shear. Fig. 20*a* shows a beam with a uniform load of 100 lb. per ft., the vertical shear at each support being equal to the reaction of 1000 lb. at that support and gradually decreasing to zero at the center. Fig. 20*b* shows diagrammatically the vertical shear under concentrated

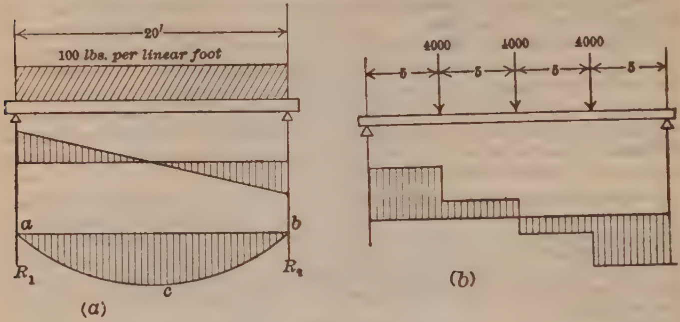

Fig. 20

loads, the vertical shear between the left reaction and first load being 6000 lb., between the first and second loads 2000 lb., at the center zero, between the second and third loads 2000, and between the third load and the right reaction 6000 lb.

The Bending Moment at any section is the algebraic sum of the moments of all forces on the left of that section, moments tending to cause rotation in the same direction as the hands of a clock being taken as positive, and those tending to cause rotation in the opposite direction being taken as negative. The bending moment at any section is the measure of the flexural stress at that section.

In Fig. 21*a* let the beam have a length l and be loaded with a uniform load of w lb. per lin. ft. The left reaction will then be $wl/2$, and if M be the bending moment at the distance x from the left support, then $M = 1/2\ wlx - 1/2\ wx^2$, whence it is seen that

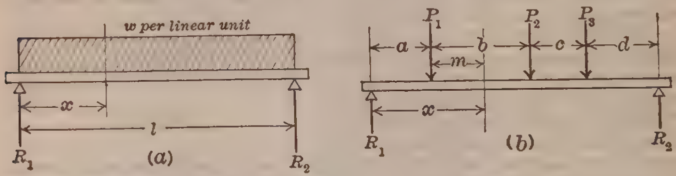

Fig. 21

$M = 0$ when $x = 0$, and $M = 1/8\ wl^2$ when $x = 1/2\ l$. In Fig. 21*b* let the beam be loaded with the loads P_1, P_2, P_3. The reactions R_1 and R_2 may be found by the principle of moments. The bending moment at any point between the first and second loads will be $M = R_1x - P_1m$.

Maximum Bending Moment. In a cantilever beam the maximum bending moment is at the support irrespective of the position of the loads. In a simple beam the point of maximum bending moment, or the dangerous section in a beam, is at the point where the shear passes through zero, that is, where the shear changes from positive to negative, or vice versa. This point may be located in any system of loading by beginning at one reaction and subtracting the loads in order from the reaction until a point is reached where the sum of the loads equals the reaction.

In Fig. 20*a* the bending moment under a uniformly distributed load is illustrated diagrammatically. From the expression for the bending moment at any point, $M = 1/2\ wlx - 1/2\ wx^2$, it will be noted that the bending moment at any section may be represented by the corresponding ordinate of the plane figure (Fig. 20*a*) formed by the straight line *ab* and the parabola *acb*. It will be noted that the maximum ordinate is at the center, coinciding with the axis of the parabola, and that at the supports the ordinates are zero.

11. Formulas for Flexure

Conditions of Equilibrium. The investigation of beams is governed by the following three conditions of equilibrium, which hold for any section:

Sum of all tensile stresses = sum of all compressive stresses.
Resisting shear = vertical shear.
Resisting moment = bending moment.

Resisting Shear. At any section in a beam the internal forces must equal the external forces in order that equilibrium may obtain. At any section, therefore, some internal force must oppose and be equal to the vertical shear at that section. This force is the shearing stress in the material and is called the **Resisting Shear.** Let V be the vertical shear at any section, S_s the maximum unit shearing stress at that section and A the area of the section. The **average** shearing stress at the section is

$$S'_s = \frac{V}{A}$$

The shearing stress is not, however, uniformly distributed over the cross-section and the maximum shearing stress on the section is

$$S_s = \frac{kV}{A} \qquad (1)$$

in which k is a constant depending on the shape of the section. For a rectangle k is 1.50, for a triangle k is 1.33, and for a circle k is 1.33. Values of factors for determining maximum shearing stress in I beams and channel beams are given on pp. 666–677.

In a beam the shearing stress is greatest at some point neat the center of depth and is 0 at the extreme fibers. At any point in a beam the horizontal shearing unit stress is equal to the vertical shearing unit stress at that point. Wooden beams which are weak in shear along the grain are in special danger of failure by horizontal shear.

Resisting Moment. The bending moment at any section tends to cause rotation about that section. The tendency to rotate is resisted by the moment of tensile and compressive stresses in the material at that section, which act as an internal couple. This internal couple is called the resisting moment. Let S be the unit stress at any extreme fiber on the surface of the beam due to the bending moment and c the distance from that fiber to the neutral surface, M the resisting moment or its equal, the bending moment; then

$$M = \frac{SI}{c} \quad \text{or} \quad S = \frac{Mc}{I} \qquad (2)$$

in which I is the moment of inertia of the section about a gravity axis.

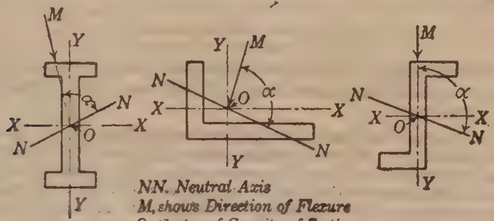
This is the common flexure formula. Strictly speaking it applies only to beams loaded in the plane of a principal axis of the cross-section (e.g., a plane of symmetry). However, in practice most beams are so loaded, and this formula may usually be used.

Properties of Common Sections of Beams

Sections of beams, Fig. 22	Distance from neutral axis to extreme fiber of section	Moment of inertia I	Section modulus I/c	Radius of gyration r $\sqrt{I/A}$
	1/2 h	$1/12\ bh^3$	$1/6\ bh^2$.	$\frac{h}{\sqrt{12}} = 0.289\ h$
	2/3 h	$1/36\ bh^3$	$\text{Min} = \frac{bh^2}{24}$	$\frac{h}{\sqrt{18}} = 0.236\ h$
	1/2 h	$1/12\ (bh^3 - b_1h_1^3)$	$\frac{bh^3 - b_1h_1^3}{6\ h}$	$\sqrt{\frac{bh^3 - b_1h_1^3}{12\ (bh - b_1h_1)}}$
	1/2 d	$\frac{\pi d^4}{64} = .0491\ d^4$	$\frac{\pi d^3}{32} = .0982\ d^3$	$\frac{d}{4}$
	1/2 d	$\frac{\pi(d^4 - d_1^4)}{64} = .0491(d^4 - d_1^4)$	$\frac{\pi(d^4 - d_1^4)}{32\ d} = .0982\frac{(d^4 - d_1^4)}{d}$	$\frac{\sqrt{d^2 + d_1^2}}{4}$
	1/2 h	$\frac{bh^3 - h_1^3(b-t)}{12}$	$\frac{bh^3 - h_1^3(b-t)}{6\ h}$	$\sqrt{\frac{bh^3 - h_1^3(b-t)}{12[bh - h_1(b-t)]}}$
	1/2 b	$\frac{2\ db^3 + h_1t^3}{12}$	$\frac{2\ db^3 + h_1t^3}{6\ b}$	$\sqrt{\frac{2\ db^3 + h_1t^3}{12[bh - h_1(b-t)]}}$
	1/2 h	$\frac{bh^3 - h_1^3(b-t)}{12}$	$\frac{bh^3 - h_1^3(b-t)}{6\ h}$	$\sqrt{\frac{bh^3 - h_1^3(b-t)}{12[bh - h_1(b-t)]}}$
	c	$\frac{h_1t}{12}\left[t^2 + 12\left(b - c - \frac{t}{2}\right)^2\right] + \frac{db}{6}\left[b^2 + 3\ (2\ c - b)^2\right]$	$\frac{I}{c}$	$\sqrt{\frac{I}{A}}$
	c	$\frac{bd}{12}\left[d^2 + 12\left(h - c - \frac{d}{2}\right)^2\right] + \frac{th_1}{12}\left[h_1^2 + 12\left(c - \frac{h_1}{2}\right)^2\right]$	$\frac{I}{c}$	$\sqrt{\frac{I}{A}}$

Oblique Flexure of Beams. If a beam is bent by a lateral force acting obliquely to an axis of symmetry of the cross-section, or if the beam section has no axis of symmetry, in general, the extreme unit stress is different from, and frequently greater than, the value given by formula (2). The neutral axis of a cross-section under oblique loading is not perpendicular to the plane of the load, but makes with it an angle α as illustrated in Fig. 23.

To determine the extreme unit stress set up by oblique flexure it is necessary to know three properties of the cross-section: I_y, the moment of inertia about some gravity axis, I_x, the moment of inertia about a gravity axis perpendicular to the axis for I_y, and J, the **product of inertia** about the axes for I_y and I_x. The product of intertia of an area about two axes at right angles is equal to the sum of the products of each elementary area and the x-coordinate and the y-coordinate of the elementary area, or $\mathbf{J = \Sigma\, xy\, dA}$. J may be either + or −, differing in that respect from the moment of inertia which is always +.



NN, Neutral Axis
M, shows Direction of Flexure
O, Center of Gravity of Section

Fig. 23

If the cross-section of a beam has an axis of symmetry the value of J for this axis and the one at right angles to it is 0. If this is not the case, J may be determined for the common structural shapes by the following graphical method. In Fig. 24 lay off $CA = I_x$ and $AB = I_y$. On CB as a diameter, with center at O, draw a circle, called the **dyadic circle.** In the tables of properties of sections (pp. 673–676 and 679) the minimum radius of gyration of the section $r_{\min}$ is given, then $I_{\min} = r^2_{\min} A$, A being the area of the cross-section. In Fig. 24 lay off $CD = I_{\min}$, and with radius OD draw circle DKF. Then AK perpendicular to CB gives, to scale, the value of J, which is measured in (inches)^4, as are the moments of inertia. Again note that J may be either + or −.

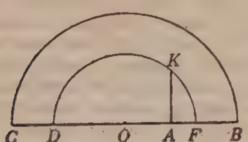


Fig. 24

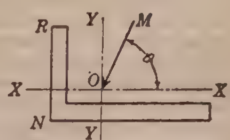

Note that θ is not the same Angle as α in Fig. 23

Fig. 25

Note that θ is not the same angle as α in Fig. 23

If now a beam is subjected to oblique flexure, and the plane of the bending moment makes an angle θ with the X axis, as illustrated in Fig. 25, the extreme unit stress will be at one of the corners of the cross-section. It is usually possible to tell by inspection which corner will develop the maximum unit-stress, but in case of doubt try two or more corners. As an illustration, in Fig. 25 the extreme unit stress will be developed at either R or N, and it is to be noted that for R the x-coordinate is $-$ and the y-coordinate $+$, while for N both coordinates are $-$. The maximum unit stress is

$$S_{max} = \frac{M}{Q}, \text{ and } Q = \frac{I_x I_y - J}{y\,(I_y \sin\theta - J\cos\theta) + x\,(I_x \cos\theta - J\sin\theta)}$$

in which M denotes the bending moment in inch-pounds, and x and y are the coordinates of the critical corner.

For sections for which either the X axis or the Y axis is an axis of symmetry (I beams, H beams, and T beams), and which are obliquely loaded, J becomes zero, and

$$Q = \frac{I_x I_y}{y\,I_y \sin\theta + x\,I_x \cos\theta}$$

The above treatment of oblique flexure is based on the work of Otto Mohr and of Land. For a full discussion see L. J. Johnson, Trans. Am. Soc. C. E., Vol. LVI, p. 169 (1906).

For detail of drawing the dyadic circle is that used by Prof. H. M. Westergaard of the University of Illinois. Strictly speaking, where the term "axis of symmetry" is used the term "principal axis" would be more precise. The principal axes of an area are two axes at right angles for one of which the moment of inertia is a maximum, and for the other a minimum. For a pair of principal axes the product of inertia is zero. An axis of symmetry is always one of the principal axes of an area.

The Moment of Inertia of an area with reference to any axis may be defined as the sum of the products obtained by multiplying each elementary area of cross-section, da, by the square of the distance of that particular elementary area from the axis. The moment of inertia is represented by I, and

$$\mathbf{I = \Sigma z^2 da}$$

in which z is the distance of the elementary area da from the axis. The **Moment of Inertia** is a factor depending on the shape of the cross-section. From the above expression it will be found that the values of I will be greatest for sections having the largest area at the greatest distance from the axis of reference. Unless otherwise noted, the axis of reference is always a gravity axis of the section.

Section Modulus. This is the term $\mathbf{I/c}$ in the common flexure formula for the resisting moment. It is the measure of the resisting moment or the strength of a beam of given cross-section and is largely used as a basis of computation in the design and investigation of beams. In the table Fig. 22 are given the values of the moment of inertia I and of the section modulus I/c for the various sections most commonly used in structural design.

Investigation and Design. Formulas (1) and (2) are the formulas commonly used in the design and investigation of beams. Except in cases of short spans and heavy loads the question of resisting shear is not usually the controlling factor. Having obtained the bending moment from the conditions of loading in any particular case of design, and having assumed a proper working value for S, formula (2) is solved for I/c and the proper beam selected. In the investigation of beams, M is determined from the conditions of loading and from the kind of beam employed. The proper substitutions are then made in formula (2) and the equation solved for S, which may be wither tension or compression. A comparison of the value of S with the allowable working stress for the material will determine the degree of stability. See also the tabulated statement on p. 588 of the various ways in which beams may fail.

Effect of Combined Shearing and Bending Stress. In a beam of I-section or channel section both the shearing stress and the bending stress at the junction of web and flange may be high, and the combination of the two stresses sometimes causes stress on an inclined plane which is greater than the direct stress in the extreme fibers of the flange. This effect of combined stresses is rarely of importance except for deep beams with short spans. If S_t is the maximum stress on an inclined plane at the point under consideration, S' the direct bending stress at the junction of web and flange, and S'_s the shearing stress at the same point, which is slightly less than the shearing stress for the same cross-section at the neutral axis, then

$$S_t = 1/2\, S' + \sqrt{(S'_s)^2 + (1/2\, S')^2}$$

See also paragraph on Flexure and Tension, p. 598.

Elastic Curve. In a horizontal beam under a system of vertical loads the fibers in the upper surface are shortened, while those in the lower surface are elongated. This causes the beam to deflect downward and the neutral surface to assume the form of a curve whose radius of curvature at any section is dependent upon the bending moment at that section and the moment of inertia of the section.

Thus in Fig. 26 let mn represent the elementary section dl of a beam whose length is l and let $b'b$ and $c'c$ represent two sections separated by the distance dl. These sections, before bending, are assumed to be parallel; after bending, the sections produced intersect at some point o, the distance om being the radius of curvature R. Let c'_1c_1 be drawn parallel to $b'b$ through n. The distance c'_1c' represents the deformation of the upper fibers in the length dl, and the distance cc_1 represents the corresponding deformation in the lower fibers. Let $c'c'_1$ be represented by e; then $e = (S/E)dl$, in which S is the unit stress producing the deformation e, and E is the modulus of elasticity. Let c represent the distance from the neutral surface to the extreme fiber; it then follows that $R/dl = c/e$, whence $R = EI/M$, which expresses the value of the radius of curvature R at any section in terms of the modulus of elasticity, the moment of inertia and the bending moment at the section. When $M = 0$, R = infinity, or the curve at that point is a straight line; when M is a maximum, R is a minimum, or the curve is the sharpest. If the curve is referred to a system of coordinate axes in which x represents abscissas or horizontal distances and y ordinates or vertical distances, giving R its value as determined for very flat curves by the differential calculus in terms of x, y and l; then

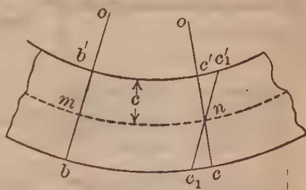

Fig. 26

$$\frac{EI}{R} = EI\frac{d^2y}{dx^2} = M \qquad (3)$$

which is the general differential equation of the elastic curve of any beam under any system of loading expressed in terms of the modulus of elasticity, the moment of inertia and the bending moment.

Slope of Beams. For a beam the integration

$$\int EI\frac{d^2y}{dx^2} = EI\frac{dy}{dx} + C$$

gives an expression involving $\frac{dy}{dx}$, the change of slope, or inclination of the elastic curve for any section of the beam. C is a constant of integration depending upon loading and upon end conditions. A beam so rigidly held that under bending action the slope remains horizontal at a support is said to be fixed at that support, and at the support $\frac{dy}{dx} = 0$.

Deflection. In formula (3), assuming the origin of coordinates at one support, where the deflection of a beam is zero, y becomes the deflection at any point at a distance x from the support or origin of coordinates. Substituting proper values for E, I, and M, integrating twice, and giving proper values to the constants of integration, the value of y, or the deflection, may be determined for any point in the beam.

12. Beams of Uniform Cross-section

Values for shear, V, and for moment, M, at any section; for maximum moment, M_{max}, for slope, dy/dx, and for deflection, y, at any section, and for maximum deflection, y_{max}, are given in the accompanying table for a number of common kinds of beams of uniform cross-section.

It is possible to combine values given in the table for different loadings to give values for loadings not given in the table. For example, by combining the values for a beam loaded with two symmetrical loads with the values for a beam loaded at one point in its span values for a beam with three loads may be obtained.

A beam with ends and loads overhanging the supports may be treated as a combination of a cantilever beam and an end-supported beam.

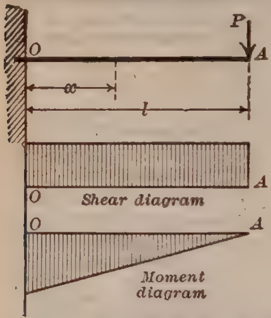

Fig. 27. Cantilever Beam, Concentrated Load at Outer End.

Shear at any section,

$$V = P \text{ (constant)};$$

Moment at any section,

$$M = -P(l - x);$$

$$M_{max} = -Pl \text{ at } O;$$

Equation of slope,

$$dy/dx = (-P/EI)(lx - x^2/2);$$

Equation of elastic curve,

$$y = (-P/EI)\left(\frac{lx^2}{2} - \frac{x^3}{6}\right);$$

Maximum deflection,

$$y_{max} = -Pl^3/3\ EI \text{ at } A.$$

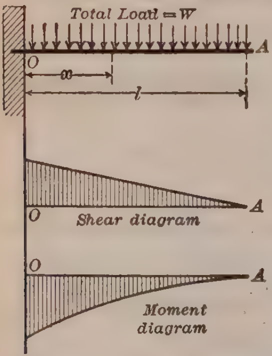

Fig. 28. Cantilever Beam, Uniform Load.

Shear at any section,

$$V = W - \frac{Wx}{l};$$

$$V_{max} = W \text{ at } O;$$

Moment at any section,

$$M = -W\left(l/2 - x + \frac{x^2}{2l}\right);$$

$$M_{max} = -Wl/2 \text{ at } O;$$

Equation of slope,

$$dy/dx = -(W/EI)\left(\frac{lx}{2} - \frac{x^2}{2} + \frac{x^3}{6}\right);$$

Equation of elastic curve,

$$y = -(W/EI)\left(\frac{lx^2}{4} - \frac{x^3}{6} + \frac{x^4}{24\,l}\right);$$

Maximum deflection,

$$y_{max} = -Wl^3/8\ EI \text{ at } A.$$

13. Beams of Uniform Strength

General Principles. The common flexure formula for the investigation and design of beams, $M = SI/c$, indicates that the stress S varies with the bending moment. In beams of uniform strength, S must be constant. Therefore from the flexure formula, since the bending moment varies, the quantity I/c, or section modulus, must be made to vary with the bending moment, in order to provide uniformity of strength for all sections under various conditions of loading. Only beams which are rectangular in cross-section will be considered. From the table in Fig. 22, $\mathbf{I/c = 1/6\ bh^2}$. Substituting in the flexure formula there results

$$\mathbf{M = 1/6\ Sbh^2} \qquad (1)$$

from which beams of uniform strength may be designed, giving proper values to the bending moment M, determined from the conditions of loading.

Deflection of Beams of Uniform Strength. The accompanying table gives values for dimensions, stresses, and deflections for the common kinds of uniform strength beams. (Figs. 46, 46*a*, 46*b*, 46*c*.)

Dimensions Stresses, and Deflections for Uniform Strength Beams with Rectangular Cross-section

At the ends of the beams where shear governs the design, the dimensions of the cross-section must be increased.

I. Cantilever beam, constant depth, load at outer end. Fig. 46.

Depth $= h$; width, $b = b_1 \dfrac{x}{l}$.

Fiber stress due to flexure, $S = \dfrac{6\ Pl}{b_1 h^2}$.

Maximum deflection, $y_{max} = \dfrac{6\ Pl^3}{Eb_1 h^3}$.

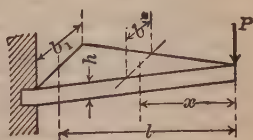

Fig. 46

Note. A flat spring made up of a number of leaves held together by a band acts approximately like a beam of varying width. b = the sum of the widths of the leaves piled together at any section.

II. Cantilever beam, constant width, load at outer end. Fig. 46*a*.

Depth, $h = h_1 \sqrt{\dfrac{x}{l}}$; width $= b$.

Fiber stress due to flexure, $S = \dfrac{6\ Pl}{bh_1^2}$.

Maximum deflection, $y_{max} = \dfrac{8\ Pl^3}{Ebh_1^3}$.

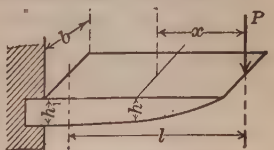

Fig. 46*a*

III. Beam supported at ends, constant depth, load at mid span. Fig. 46*b*.

Depth $= h$; width, $b = \dfrac{2\ b_1 x}{l}$.

Fiber stress due to flexure, $S = \dfrac{3}{2} \dfrac{Pl}{b_1 h^2}$.

Maximum deflection, $y_{max} = \dfrac{3}{8} \dfrac{Pl^3}{Eb_1 h^3}$.

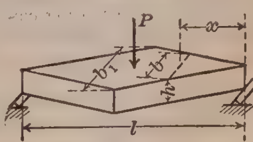

Fig. 46*b*

See note under I, above.

IV. Beam supported at ends, constant width, load at mid span. Fig. 46c.

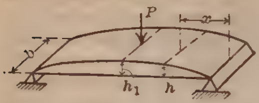

Fig. 46c

Depth, $h = h_1\sqrt{\frac{2x}{l}}$; width $= b$;

Fiber stress due to flexure, $S = \frac{3}{2}\frac{Pl}{bh_1^2}$.

Maximum deflection, $y_{max} = \frac{Pl^3}{2\,Ebh_1^3}$.

In the table of beams of uniform strength, the bending moment has been assumed to be the controlling factor. The shearing strength of the material, however, would modify a number of these forms near the ends, and this fact should be taken into account in actual practice. While the discussion of beams of uniform strength is of considerable interest, theoretically, it is of little practical value, except in the case of plate girders, which are designed in a manner somewhat different from that discussed above, and in the case of flat springs.

14. Continuous Beams

A Continuous Beam is one for which there are more than two supports. In the discussion here given it will be assumed that the supports are all on one level and that the beam is of constant cross-section. The expressions for the resisting shear, for the resisting moment SI/c, and the differential equation for the elastic curve $M = EI\,(d^2y/dx^2)$ apply to continuous beams with the same force as they do to simple, cantilever, or constrained beams. The elements which must be determined in order to apply these expressions are the vertical shears and the bending moments under various conditions of loading. Since the number of reactions will always be greater than two, it is obvious that they cannot be determined by the usual method of moments. It will be noted, moreover, that the several reactions of a continuous beam will depend for their values upon the elastic behavior of the beam under load. Therefore, instead of determining the bending moments from the reactions in the case of continuous beams, the process must be reversed and the bending moments must be determined from the elastic behavior of the beam under load and the reactions and vertical shears determined from the bending moments.

General Formulas. As in the case of simple beams, the vertical shear at any section is the algebraic sum of the reactions and the loads on the left of that section. Let V be the vertical shear at any section distant x to the right of any support. Let V' be the vertical shear at a section to the right of but immediately adjacent to the support. Let ΣP_1 denote the sum of the concentrated loads on the distance x, and let w be the uniform load per linear unit; then

$$\mathbf{V = V' - wx - \Sigma P_1} \qquad (1)$$

Assume any two supports of a continuous beam. The bending moment M at any section distant x from the left support being the algebraic sum of the moments of all forces to the left of that section, rotation in the direction of the hands of a clock being considered positive, and rotation in the opposite direction negative, assuming M' the moment at the left support, then

$$\mathbf{M = M' + V'x - 1/2\,wx^2 - \Sigma\,P_1\,(x - kl)} \qquad (2)$$

in which k is a fraction less than unity and l the distance between supports. If M'' be the moment at the right support, there results the relation

$$\mathbf{V'l = M'' - M' + 1/2\,wl^2 + \Sigma\,P_1\,(1 - kl)} \qquad (3)$$

From formulas (1), (2), and (3) it appears that V and M can always be determined, when M' and M'', or the bending moments at the supports, are known.

Theorem of Three Moments for Uniformly Distributed Load. For the purpose of determining the bending moments at the supports, which from the preceding paragraph it appears are necessary for the determination of the bending moment and the vertical shear at any section, the relation existing between the moment at any support in a continuous beam and the moments at the supports on either side is utilized. This relation between the moments at any three consecutive supports constitutes the theorem of three moments. In Fig. 47 let M', M'', and M''' be the moments at any three consecutive supports in a continuous beam, and let V' and V'' be the vertical shears on the right of the supports where the moments are respectively M' and M''. Let the span between the first and second supports be l' and between the second and third supports l'', and let the uniform load on the first span be w' per linear unit, and the uniform load on the second span w'' per linear unit. From the properties of the elastic curves, and by substituting for V' and V'' their values in terms of M', and M'', and M''' obtained from the use of formula (3), there follows the relation

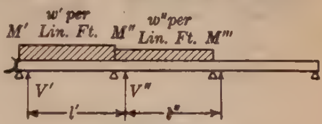

Fig. 47

$$M'l' + 2M''(l' + l'') + M'''l'' = -1/4\, w'l'^3 - 1/4\, w''l''^3 \qquad (4)$$

Formula (4) is the general expression for the theorem of three moments under uniform loads. When $w' = w''$ and when $l' = l''$, or, in other words, when the load is uniform throughout and equal to w per linear unit and the spans equal, formula (4) becomes

$$M' + 4M'' + M''' = -1/2\, wl^2 \qquad (5)$$

Formulas (4) and (5) are used as follows: In any continuous beam of n spans there will be $n + 1$ supports, and assuming the beam not to overhang the end supports, there will be $n - 1$ unknown moments, the moments at the end supports being each zero. An equation in the form of (4) or (5) is written for each of the unknown moments at the supports, and the solution of these equations will give the unknown quantities M', M'', M''', and the like. Substituting M' and M'' in formula (3), the vertical shear V' at a support may be determined, from which the bending moment at any point may be found by means of formula (2) The accompanying Fig. 48 gives reactions, shears, and bending moments for continuous beams with uniform load over from two to five equal spans.

Theorem of Three Moments for Concentrated Loads. If M', M'', and M''' are the moments at three successive supports of a continuous beam shown in Fig. 49, and P' and P'' are concentrated loads in the two spans considered, P' being distant an amount a from the support where the moment is M', and P'' being distant an amount b from the support, where the moment is M''', then the theorem of three moments becomes

$$M'l' + 2M''(l' + l'') + M'''l'' = -\frac{P'a\,(l'^2 - a^2)}{l'} - \frac{P''b\,(l''^2 - b^2)}{l''} \qquad (6)$$

In all cases load per unit length = w

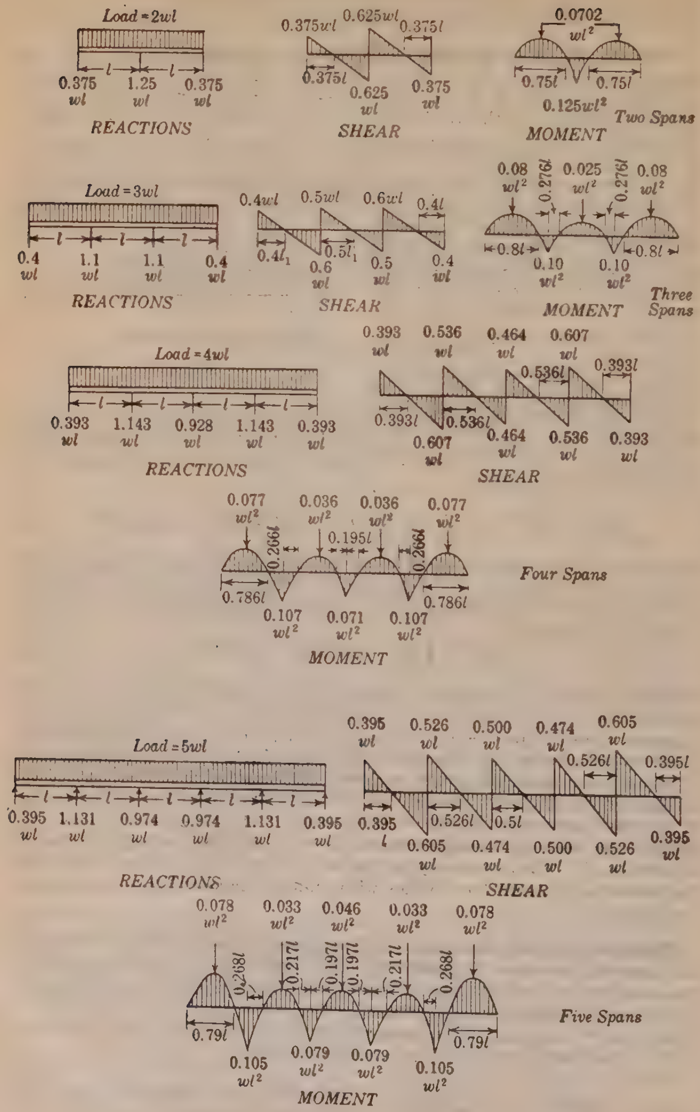

Fig. 48. Continuous Beams with Uniform Load and Equal Spans

If all the spans are the same length l, and all the loads are equal and located at the mid-points of the spans this reduces to

$$M' + 4\,M'' + M''' = -\,3/4\,Pl$$

For a combination of uniformly distributed load and concentrated load or for spans containing more than one concentrated load the moments and shears may be computed separately for uniformly distributed loading and for single concentrated loads in each span, and the resulting moments and shears superposed for the combined loading.

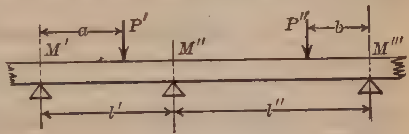

Fig. 49. . Continuous Beam Notation

15. Tests of Beams

Phenomena. In the discussion of beams, the general flexure formula $M = SI/c$ and the formulas for deflection are based upon the assumption that the values of E for stress and deformation below the neutral axis are the same as for stress and deformation above the neutral axis. While in most cases there is a slight difference between the value of E determined from compression tests and its value determined from tension tests, for the materials of which beams are usually constructed (steel, wrought iron, or timber), the difference is so slight that they may be assumed to be the same, as is usually done, without appreciable error. The formulas for the resisting moment and deflection are obviously valid only when the stresses produced are within the elastic limit. Beams under test loads, when the loads are small compared to the ultimate capacity and the deflections slight, exhibit phenomena which tend to confirm the assumption made regarding the distribution of stresses and the deflection. In tests on beams the measured deflections agree closely with the computed deflections and are proportional to the applied loads, as is indicated in the deflection formulas, up to a certain point, beyond which the deflections are found to increase more rapidly than the loads, indicating the elastic limit of the beam.

Modulus of Rupture. Since the expression $M = SI/c$ is no longer valid after the elastic limit of the material has been exceeded, it cannot be applied to determine actual conditions after that point has been reached. For purposes of comparison of brittle materials, however, it has been found convenient to determine the value of S from this formula when M equals the bending moment causing rupture. The value of S thus obtained for any material is termed the **modulus of rupture** and is usually found to lie between the ultimate tensile and the ultimate compressive strength. It is to be noted that the modulus of rupture does not express the actual stress in the extreme fiber of a beam, but is a quantity useful only as a basis of comparison.

Average values for the moduli of rupture of common structural materials are as follows, in pounds per square inch:

Brick	800	Timber	9 000
Stone	2000	Cast iron	40 000

It has been noted from tests that the shape of cross-section and the ratio of diameter to span affect to some extent the value of the modulus of rupture.

The manner of failure of beams under test depends upon the material of which they are constructed and the relative shape. Beams of brittle materials, such as plain concrete, stone or cast iron, fail by the fibers giving way in tension. In other cases where the material is less brittle and more plastic, such as timber, the beam fails by the crushing of the compression fibers. Beams of ductile materials, such as structural steel, bend when the yield point is reached and no value for the modulus of rupture can be obtained. Beams that are very deep in comparison to their length sometimes fail by the material shearing off near the supports. This manner of failure is, however, rare, except in the case of plain concrete or stone beams, where failure sometimes takes place along a diagonal line near a support.

16. Methods of Failure of Beams

The accompanying table gives a number of kinds of typical failures of beams with the general precaution to be observed in order to prevent such failures.

Typical Failures of Beams and General Methods of Prevention

Kind of beam	Danger of failure by	Precaution against failure
All beams.	Rupture or excessive deformation of extreme fibers.	Sufficiently large section modulus, I/c.
Long-span I beams and channel beams; long-span timber beams.	Sidewise buckling of compression fibers.	Additional material on compression side; sidewise bracing, low working stress in flexure formula, $S = Mc/I$.
Short-span beams.	Buckling of web of beam.	Sufficient thickness of web to resist diagonal column action; stiffening angles riveted to web.
Short-span beams with thin webs.	Excessive shearing stress in web.	Sufficient thickness of web.
Wooden beams.	Horizontal shear along neutral axis.	Sufficient breadth of beam to allow low working stress in shear.
Short beams, beams with short end-bearings, beams carrying concentrated loads.	Crushing of web adjacent to load or to end-bearing.	Sufficient thickness of web to carry compression under load or over bearing block; stiffening angles riveted to web and fitted against flange of beam under load or over bearing block.

17. Resilience and Impact on Beams

Resilience of a beam is the measure of its elastic resistance to external work. If in a simple beam a load P is gradually applied at the center until the beam comes to rest with a deflection of f, the load P has acted over the path f with a mean intensity of 1/2 P, so that the external work K producing the deflection f is $K = 1/2\ Pf$. This formula will also express the resilience of the beam provided the load P has been applied so that no energy has been lost in producing heat. For any beam of length l and under any conditions of loading, the work K may be expressed in terms of the volume of the beam by substituting for P its value obtained from the general flexure formula for the particular condition of loading, and substituting for f its value obtained from the proper deflection formula, thus:

$$\mathbf{K} = \frac{\mathbf{a}^2}{\mathbf{b}}\left(\frac{\mathbf{r}}{\mathbf{c}}\right)^2 \frac{1}{2}\frac{\mathbf{S}^2}{\mathbf{E}}\mathbf{A}l$$

in which a is a coefficient depending upon the kind of beam and the manner of loading being 1 for a cantilever loaded at the end, 2 for a cantilever with uniform load, and 4 for a simple beam loaded at the middle; b is a coefficient obtained from the formula for deflection, being 3 for a cantilever loaded at the end and 48 for a simple beam loaded at the middle and r is the radius of gyration of the section with respect to the neutral axis and is equal to $\sqrt{I/A}$, where A is the sectional area. The quantity Al is the volume of the beam.

Stresses Due to Impact. The effect of a weight falling upon a beam is to produce a deflection considerably greater than would be produced by the same weight being applied to the beam gradually or in small increments. Let P be a load which when falling from a height h on a horizontal beam produces a maximum deflection d_1. The work performed in producing this deflection is therefore $P\,(h + d_1)$. Let S_1 be the unit stress in the extreme fiber produced by the load P falling from the height h and S the unit stress produced by a static load P, and let d be the deflection which would be produced by the static load P. The elastic limit not being exceeded, the deflections are proportional to the unit stresses or $d_1/d = S_1/S$, or if Q be the static load which would produce the deflection d_1, then $d_1/d = Q/P$, or $Q/P = S_1/S$. If none of the energy is lost in producing heat or giving movement to the beam, the external work and the internal energy stored in the beam at the moment the deflection reaches d_1 may be expressed by $1/2\,Qd_1$, whence $1/2\,Qd_1 = P\,(h + d_1)$, whence by combination with the above

$$S_1 = S + S\left(1 + \frac{2\,h}{d}\right)^{1/2} \quad \text{and} \quad d_1 = d + d\left(1 + \frac{2\,h}{d}\right)^{1/2}$$

These formulas give the maximum unit fiber stress and the maximum deflection due to the dynamic load P. In place of h in the above discussion its value $V^2/2\,g$ may be substitured, in which V is the velocity at the moment of impact and g the acceleration due to gravity, usually taken at 32.16 feet per second per second. S may be obtained from the general formula for flexure, $M = SI/c$, and d from the proper formula for deflection under a static load.

If a force P moving horizontally with a velocity V strikes a beam the ends of which are secured against horizontal movement, producing a lateral deflection d_1, the work expended in producing this deflection may be expressed by Pd_1, whence

$$S_1 = S\,(2\,h/d)^{1/2} \quad \text{and} \quad d_1 = d\,(2\,h/d)^{1/2}$$

give values for the maximum unit stress in the extreme fiber under impact from a horizontal load moving with a velocity V, in which $h = V^2/2\,g$.

18. Columns

A Column is a structural member in which the length is such compared with its least lateral dimension that failure under compression is most likely to occur by the rupture of the material in the extreme fiber owing to flexural stresses accompanying lateral deflection. Any compression member in which the length exceeds 8 or 10 times its least lateral dimension is usually termed a column, strut, or post.

Columns differ from other compression members in that in a column it is assumed that an unequal distribution of stress is liable to take place, resulting in flexure and lateral deflection. While theoretically an axial load in a perfectly straight symmetrical member can produce only uniformly distributed stresses with consequently no flexure, actual experience teaches that when the length exceeds 8 or 10 times the least lateral dimension appreciable flexure will result owing to the fact that it is practically impossible to construct an absolutely straight and symmetrical member and to load it absolutely axially. It is evident, moreover, that under compression a lateral deflection once present, due to whatever cause, tends to increase with a corresponding increase in the flexural stress.

The Length of a Column is usually taken as the distance between the points at which it is rigidly secured against lateral deflection. A long compression member with a number of points of support dividing it into several sections may consist of several columns as in the case of the columns in a high steel building. In determining the unsupported length of each section, however, only such points of support are to be considered as will prevent deflection of the column in any direction.

Radius of Gyration. Since the strength of a column is so largely dependent upon its ability to resist flexural stress, the moment of inertia of its cross-section is an important factor in the determination of its carrying capacity. In place of the moment of inertia, however, for the purpose of comparison it has been found more convenient to use the **Radius of Gyration**, which is a linear dimension. If I is the moment of inertia of a section with reference to an axis, A the area of the section, and r the radius of gyration with reference to that axis, then the value of the radius of gyration in terms of the area and the moment of inertia may be found from the relation $r^2 = I/A$. Unless otherwise noted the radius of gyration is always taken with respect to the axis through the center of gravity of the cross-section.

The axis of a column is a line drawn through the centers of gravity of the cross-sections. If the column be perfectly symmetrical the moment of inertia and the radius of gyration will be the same for every axis through the center of gravity of every section. In many columns used in structural design the cross-sections are not perfectly symmetrical, and there are therefore several values for the radius of gyration, depending upon the position of the axis through the center of gravity. In the design of columns, therefore, it is necessary to know the value for the least radius of gyration in each particular case.

The radius of gyration for a circle is $d/4$, where d is the diameter. For a rectangle of height d and width b the radius of gyration for an axis parallel to d is $0.289\,b$ and that for an axis parallel to b is $0.289\,d$. For sections of rolled beams and shapes the values of the radius of gyration are given in Arts. 46–48.

The Slenderness Ratio of a column is the number obtained by dividing the length by the radius of gyration. The length and the radius of gyration both being linear dimensions, the slenderness ratio is an abstract number. The radius of gyration and the length must be expressed in the same linear unit, and since it is current practice to give the radius of gyration in inches, it is necessary also to reduce the length of the column to inches before the slenderness ratio can be obtained.

Condition of Ends of Columns. The strength of a column being dependent largely upon its ability to resist lateral deflection, the condition of the ends has a marked effect upon the carrying capacity. The various conditions which may exist at the ends of columns are usually divided into four classes. Columns with **round ends** are such that at the bearing at either end there is perfect freedom of motion, as would be the case were there a ball-and-socket joint at each end. Columns with **hinged ends** are such as have perfect freedom of motion at the ends in one plane, as would be the case of compression members in bridge trusses where the loads are transmitted through end pins. Columns with **flat ends** have the bearing surface normal to the axis of the column and of sufficient area to give at least partial fixity to the ends of the columns against lateral deflection. Columns with **fixed ends** have the ends rigidly secured so that under any load the tangent to the elastic curve at the ends will be parallel to the axis in its original position.

Experiments prove that columns with fixed ends are stronger than columns with either flat, hinged, or round ends, and that columns with round ends are weaker than any of the other types. Columns with hinged ends are equivalent to those with round ends in the plane in which they have free movement, while columns with flat ends have a value intermediate between columns with fixed ends and columns with round ends. It often happens that columns have one end fixed and one end hinged or have various other combinations. Their relative values may be taken as intermediate between those represented by the condition at either end.

Euler's Formula. Let A be the cross-sectional area of a column whose length is l and let P be an axial load under which the column is considered to assume a small lateral deflection f. Were the column absolutely straight and loaded absolutely axially and the material homogeneous it is evident that the load P could produce no lateral deflection. The deflection f, however, is assumed to be present, due to whatever cause, the load P being just sufficient to maintain the deflection f without the column returning to its original position or deflecting further. Assuming the origin of coordinates at one end with abscissas measured in the direction of the length and ordinates representing the deflections, the elastic curve assumed by the column would have the differential equation $EId^2y/dx^2 = -Pf$. From the integration of this equation and the determination of the constants of integration there results

$$\mathbf{P = n^2\pi^2EI}/l^2 \qquad (1)$$

in which E has its usual value and n is a number dependent upon the inclination of the tangent of the elastic curve at the ends. Giving to n proper values, formulas may be written for the several conditions of ends. For round ends n is taken as 1 and formula (1) becomes $P = \pi^2EI/l^2$, or, since $I = Ar^2$, in which r is the radius of gyration,

$$\mathbf{P/A = \pi^2E\,(r}/l)^2 \qquad (2)$$

For a column with fixed ends n is taken as 2, and formula (1) becomes

$$\mathbf{P = 4\,\pi^2\frac{EI}{\mathit{l}^2}} \quad \text{or} \quad \mathbf{\frac{P}{A} = 4\,\pi^2E\left(\frac{r}{\mathit{l}}\right)^2} \qquad (3)$$

Formula (1), of which formulas (2) and (3) are special cases, is the general form of Euler's formula for long columns. It is to be noted that the quantity f, or the deflection, does not appear. The load P in Euler's formula, therefore, is the load which would be required to maintain in the column any deflection which it might happen to have. A decrease in the load P would cause the column to return to its original position, while an increase in the load P would cause the deflection to increase indefinitely. The value of P in formula (1), therefore, may be taken as the ultimate strength of the column. For very long columns, where small loads produce marked lateral deflections, experimental results agree very closely with values computed from Euler's formula. It will be noted that Euler's formula does not involve the crushing strength of the material. For short columns failure occurs by crushing, not by flexure. For columns with values of l/r from 50 to 150 failure occurs by a combination of crushing and flexure. For short columns Euler's formula does not apply at all, the criterion being the ultimate in compression for brittle materials, or the yield point in compression for ductile materials. For columns with a value of l/r less than that about 150 Euler's formula gives results distinctly higher than those observed in tests. Euler's formula is rarely used in practice.

Rankine's Formula is widely used for the design and investigation of columns employed in engineering practice. It is a modification of the formula which for many years was in current use under the name of "Gordon's formula." Rankine's formula is based on the assumption that columns in engineering practice are intermediate between long columns and short prisms failing by a combination of direct compression and flexural stresses accompanying lateral deflection. While under an axial load a perfectly straight column will be stressed uniformly over its entire cross-section, any variation in structure will produce uneven distribution of stresses, resulting in lateral deflection, which must be taken into account in safe design. Thus in a column in which P is the direct load, A the cross-sectional area, and S_1 the compressive stress due to bending, the maximum unit stress in the column will be expressed by $P/A + S_1$. Determining the values of S_1 from the ordinary phenomena of flexure assuming that flexure action in columns is analogous to that in beams and taking into consideration the condition of ends of the column, Rankine's formula may be wirtten

$$\frac{P}{A} = \frac{S}{1 + \phi\,(l/r)^2}$$

in which S is the maximum stress in the column, P the axial load, A the area of cross-section, l the unsupported length of the column, r the radius of gyration of the cross-section, and ϕ a number depending upon the condition of the ends of the column and material of which it is constructed. The values of ϕ for various conditions are determined experimentally. Wide variations in the values are found in columns of different shapes and materials. Rankine's formula in the form above stated is applicable to the investigation of columns in which the factors P, A, l and r are known and ϕ is assumed for the given conditions. The value of S then determined when compared with the ultimate strength and yield point of the material will determine the factor of safety and the degree of stability of the column.

In Rankine's formula the average values for ϕ given in the accompanying table are to be used: see also Sect. 2, Arts. 2, 8 and 28, paragraphs on columns.

Material	Columns both ends fixed	Columns one end fixed, one end round	Columns both ends round
Timber	1/3000	1.95/3000	4/3000
Cast iron	1/5000	1.95/5000	4/5000
Wrought iron	1/36 000	1.95/36 000	4/36 000
Structural steel	1/25 000	1.95/25 000	4/25 000

The value of S to be used in the design of columns should be the allowable compressive unit stress, while for computing in cases of rupture it should be the ultimate compressive unit stress for brittle materials or the yield point in compression for ductile materials. Rankine's formula should be used between the limits of 20 and 150 for l/r.

Straight-line Formula. The plotted results of actual tests on columns show that the relation between ultimate load and l/r is fairly well represented by a straight line, for columns which fail by flexure of the whole column, and not by local collapse. For a value of $l/r = 0$ the average unit stress on the section, P/A, is equal to the ultimate in compression for brittle materials and to the yield point in compression for ductile materials. From the point thus determined the straight line representing the average results of tests is drawn tangent to the curve of Euler's formula for the material. The equation of the straight line is

$$P/A = S - C\,l/r$$

in which S is the unit stress at the ultimate in compression for a brittle material or at the yield point in compression for a ductile material, and C is a constant determined by experiment.

The accompanying table gives average values of S and C for structural steel, cast iron, and wood. The loads given by the straight-line formula using the constants in this table are ultimate loads:

Ultimate Strength Constants for the Straight-line Column Formula

$$P/A = S - Cl/r$$

Material and end condition	S	C	Limit of l/r
Structural steel:			
Round ends	35 000	150	160
Fixed ends	35 000	75	320
One end round, one fixed	35 000	100	240
Cast iron:			
Round ends	34 000*	175	90
Fixed ends	34 000*	88	160
One end round, one fixed	34 000*	116	115
Wood:			
Round ends	5 000*	40	75
Fixed ends	5 000*	20	150
One end round, one fixed	5 000*	30	112

* This is less than the ultimate in compression for small specimens of cast iron or wood, but from tests of full-size columns seems to be the value to be used for full-size castings or timbers which may contain defects.

For purposes of design the straight line formula is usually put in a form which gives working loads directly. Both the constant S and the constant C are divided by a factor of safety. Examples of such straight-line formulas for working loads on columns are given in Sect. 12, Art. 8, for structural steel columns; in the same article for cast-iron columns; and Sect. 9, Art. 3, for wooden columns. In a general way, in the straight-line formula P/A represents the average unit stress on the cross-section of the column at the middle of its length, and C^l/r represents the unit stress at the extreme fiber on the concave side due to flexure. S represents the stress at the extreme fiber on the concave side due to both direct compression and flexure.

Eccentric Loads. In many column designs the loading will not act along the axis of the column but at some distance from the axis; such loads are called eccentric loads, and the distance from the axis is called the eccentricity. It is evident that the greater the eccentricity the greater the flexural stresses, and that the unit compressive stress S on the most compressed side of the column will be greater than for axial loading. Let P be the load at distance z from axis of column; then $Pz = M$, the moment at axis. If the amount of unit stress along the side nearest the load is called S, then Rankine's formula may be written in the following form:

$$S = \frac{P}{A}\left(1 + \phi\left(\frac{l}{r}\right)^2 + \frac{cz}{r^2}\right)$$

where c = distance from axis of column to side of greatest compression. The straight-line formula may be notified for eccentrically loaded columns as follows:

$$(P/A)\ (1 + cz/r^2) = S - C\,l/r$$

Shear in Columns. For columns built up of two or more members held together by lattice bars the shear is of importance because the stress in the lattice bars is due mainly to shear in the column. The distribution of flexural stress in actual structural columns is too irregular to permit a satisfactory analysis for shear. Tests at the University of Illinois and general successful practice in the design of large columns indicate that the total shear on any cross-section of a column may be taken as not greater than 2.5% of the axial load, and that the lattice bars may be designed to take the stress corresponding to this shear.

If P is the axial load on the column, then the shear at any cross-section may be taken as 0.025 P. If there are lattice bars on each side of the column and θ is the angle which the lattice bars make with the axis of the column then the load carried by each bar is 0 025 $P/2 \cos \theta$ for single latticing and 0.025 $P/4 \cos \theta$ for double latticing. The average stress in the lattice bars should be very low as they themselves are often long, slender and eccentrically loaded columns. The average stress for a lattice bar should not be over 5000–6000 lb. per sq. in. Lattice bar design is further discussed in Sect. 12, Art. 29.

19. The Behavior of Columns under Load

Steel Columns may be either one-piece columns, such as H-section columns, or built-up columns, such as latticed channel columns. Fig. 50 shows various forms of cross-section for structural steel columns, and others are shown in Sect. 12, Art. 29. When loaded to failure well-designed steel columns fail by buckling of the whole column, showing points of inflection if the test column is fixed-ended. Columns made up of very thin parts may fail by local " wrinkling " of metal. The Manual of the Am. Ry. Eng. Assn. specifies that

Fig. 50. Sections of Steel Columns

the minimum thickness of web for a built-up steel column shall be 1/30 the width between the lines of rivets connecting it to the flanges, and that the minimum thickness of cover plate shall be 1/40 the distance between nearest rivet lines.

Several series of tests of full-size steel columns have been made, during recent years, at the U. S. Bureau of Standards (see Technologic Papers 101 and 328). Various types of structural steel column were tested and the values of l/r ranged from 15 to 90. The columns were tested " flat-ended." The yield point of the metal seemed to be the outstanding factor governing column strength. The effect of slenderness (l/r) was less than that indicated by the ordinary column formulas, which, in general, seem to give results on the safe side. The strength of structural steel in compression was found in some cases to be distinctly less than the strength in tension. No marked superiority was found for any particular type of column, but columns made up of channels connected by batten plates were found to be weaker than columns in which the flange members were connected by latticing.

Cast-iron Columns. The majority of designers at the present time have turned from the use of cast-iron columns to those of steel, but yet there seems to exist in the mind of some designers an impression that cast iron fulfills the necessary qualification as a material for columns. Tests of full-size cast-iron columns have been made at the Watertown Arsenal and at Phoenixville, Pa., and both series of tests showed that for short columns the strength in compression is much less than the strength of small test specimens of cast iron. This is probably due to the imperfections always present in iron castings. The cross-section of cast-iron columns is usually a hollow circle. For short columns failure of test columns takes place by shearing on an inclined plane; for long columns failure takes place by rupture on the convex side. Failure of cast-iron columns is always a sudden, shattering failure. Where the load is concentric and the stresses can be accurately determined, cast iron is used, by a good many designers, in certain places where steel would be more expensive. It is important that a very careful inspection be made of the cast iron and all pieces with flaws and blowholes be rejected.

Wood Columns are usually square in cross-section. Tests of full-size wood columns show lower strength for short columns than is shown by compression tests of small specimens of wood, the cause being, doubtless, the presence of defects and the non-homogeneity of the material. Wood columns fail less suddenly than cast-iron columns, but more suddenly and completely than steel columns. Wood columns are especially sensitive to effect of length on strength.

Brick and Terra Cotta Columns usually have low values of l/r so that length does not play much part in determining their strength. The care used in laying up the brick or the terra cotta tile, and the strength of the mortar used are important strength factors. If loaded to the danger point brick and terra cotta columns are liable to fail very suddenly and to collapse completely. See p. 645.

Concrete Columns are discussed in Sect. 11.

20. Torsion of Shafts

If a straight bar of material such as a round shaft be thoroughly gripped at one end and a twisting force applied at the other end, a state of stress is set up in the bar called **torsion**. The angle through which a fiber of unit's length is turned is called the **angle of torsion.** The twisting of the bar is produced by two couples, one consisting of the applied force with its lever arm, and one at the grip, with its lever arm. The conditions of equilibrium are that the moments of these couples must be equal.

Resisting Moment is the couple acting at the grip multiplied by its lever arm. If S is the unit shearing stress acting at a distance c from the axis of the bar, then S/c = the unit shearing stress at a unit's distance from axis of bar, and Sz/c would be the unit stress at any distance z from the axis. If this is considered to act over an elementary area da, then the moment of this stress, at distance z from axis, about axis would be $da.Sz^2/c$, and the summation of this between proper limits would be the resisting moment. The summation of da multiplied by z^2 is the sum of the products of each elementary area $\times$ square of its distance from the axis of bar. This expression is called the polar moment of inertia and is represented by the letter J.

The Polar Moment of Inertia of an area is the moment of inertia about an axis which is perpendicular to the plane of the area. It is equal to the sum of the moments of inertia of the area about two axes which are in the plane of the area, which intersect at the point where the axis of the polar moment of inertia pierces that plane, and which are at right angles to each other. For torsion the polar moment of inertia about an axis through the center of gravity of the area is of most importance. The polar moment of inertia of a circle is $\frac{\pi}{32} d^4$, twice its moment of inertia about a diameter.

Torsion Formula for Round Shafts. Considering a force P acting at one end of a shaft at a distance e from the axis, the moment of this force about the axis is equal to Pe. The resisting moment at the gripped end would be SJ/c, and from the conditions of equilibrium $\mathbf{SJ/c = Pe}$, or $\mathbf{S = Pec/J}$, which is the torsion formula for round shafts.

The twist of a circular shaft of length l subjected to a twisting moment Pe is $\theta = \mathbf{Pel/JF}$ in which F is the modulus of elasticity of the material in shear, and θ the angle of twist in radians. Values of F for various materials are approximately:

Steel (all grades)	12 000 000
Wrought iron	10 000 000
Cast iron	6 000 000

Solid and Hollow Shafts. In the design of a solid round shaft $J = \pi d^4/32$ and $c = 1/2\, d$. These values substituted in the preceding formula give $Pe = 1/16\, \pi d^3 S$. If the shaft is to be designed for the transmission of power, $d = 68.5\, (H/nS)1/3$, where H is the horsepower transmitted, n the number of revolutions per minute, S the allowable unit stress in pounds per square inch. On account of the greater strength of hollow round shafts over solid shafts of the same section area the former are often used for large sizes or where light weight is essential. In the design of hollow round shafts the value of J must be expressed in terms of the inner and outer diameters. Letting d_1 be the outer diameter, d_2 the inner diameter, $J = 1/32\, \pi\, (d_1^4 - d_2^4)$, and $c = 1/2\, d_1$, the torsion formula then becomes $S(d_1^4 - d_2^4)/d_1 = 321\,000\, H/n$. In hollow shafts as in hollow beams the material is removed from the axis where it is but little stressed and placed where it can resist the twisting moment more efficiently. It is obvious that the formulas for solid and for hollow shafts become the same when d^3 equals $(d_1^4 - d_2^4)/d_1$. When the section areas are equal then d^2 must equal $(d_1^2 - d_2^2)$. From these two equations the ratio of strength of a hollow shaft to a solid shaft of the same section area is $(2\, d_1^2 - d^2)/dd_1$.

Shafts with Non-circular Cross-section. The distribution of shearing stress in such shafts, while somewhat similar to the round shafts, is more complex. As an example, it has been found from experiments that no shearing stress exists at the corners of a rectangular shaft, while at the middle of the wide side the shearing unit stress is greater than at the middle of the long side. For any section with re-entrant angles, such as an I section, the stress at the apex of the angle is, theoretically, infinite, and practically there is a minute area of very high stress which may not be important under static loading, but forms a nucleus for cracks under repeated loading. The accompanying table gives values for the approximate stress set up under torsion in shafts of various cross-section. The values are those determined by Bach, and later modified by Kommers as the result of experiments on specimens of brittle material.

Shaft Couplings. When two lengths of shafting are to be joined together the connection is made with a coupling. The bolts used in such coupling transmit the torsion from one length of shafting to the other and therefore are subjected to shearing stress. This shearing stress is similar to that in the body of the shaft and is the greatest upon the side of the bolt most remote from the axis of shaft. If J_1 represents the polar moment of inertia of one bolt with respect to the axis of shaft, being equal to the polar moment of inertia of its cross-section about its axis plus the section area of the bolt into the square of the distance between the axis of shaft and axis of bolt, then in order that the strength of bolts and shaft be the same $\mathbf{J/c = J_1 n/c_1}$, c_1 being distance of the most remote fiber of bolt from axis of shaft, and n the number of bolts. Calling D the diameter of shaft, d the diameter of each bolt, and h the distance between axis of bolt and axis of shaft, and substituting the values of J and J_1 in the equation $J/c = J_1 n/c_1$, an expression for finding the proper diameter of the bolts would be formed. As this equation with proper substitutions is an awkward expression for finding the value of the diameter, it is general practice to assume the shearing stress uniformly distributed over the area of the bolts. On this assumption $c_1 = h$, $J_1 = 1/4\,\pi d^2h^2$, and $J/c = 1/16\,\pi D^3$. Equating the equation $J/c = J_1 n/c_1$, with the proper substitutions it reduces

Shearing Stress under Torsion in Shafts of Various Cross-sections.

S, maximum unit shearing stress, in pounds per square inch
Pe, twisting moment in inch pounds

Cross-section Fig. 51a	S	Cross-section Fig. 51b	S
	$\frac{16}{\pi}\frac{Pe}{d^3}$		$\frac{9}{2}\frac{Pe}{b^2h}$
	$\frac{16}{\pi}\frac{Ped}{d^4 - d_0^4}$		$\frac{9}{2}\frac{Pe}{ht^2}$
	$\frac{2}{\pi}\frac{Pe}{ab^2}$ If $2a > 2b$		$\frac{9}{2}\frac{Pe}{ht^2}$
	$\frac{2}{\pi}\frac{Peb}{ab^3 - a_0b_0^3}$		$\frac{9}{2}\frac{Pe}{ht^2}$
	$\frac{1.09\,Pe}{b^3}$		$\frac{9}{2}\frac{Pe}{ht^2}$
	$\frac{20\,Pe}{b^3}$		$\frac{9}{2}\frac{Peb}{b^3h - b_0^3h_0}$

For a shaft of any cross-section not having re-entrant angles St. Venant gives an approximate expression for the angle of twist measured in radians,

$$\theta = \frac{4\,\pi^2 PeJ}{FA^4}$$

in which A is the area of cross-section and the other symbols have the same significance as in the preceding paragraphs.

to $D^3 = 4\,nhd^2$ and $d = 1/2\ (D^3/nh)\ 1/2$, from which if n is known the diameter of bolt necessary can be found. The value found from the approximate formula is about 10% larger than the value found from the accurate formula.

21. Combined Stresses

Flexure and Compression. The ordinary manner of determining the amount of compression existing in a bar under an axial force is to consider the axial compression and the compression produced by flexure. Thus, calling

S the maximum unit stress due to the axial force and the flexure, S_a the axial compressive stress, S_f the unit compressive stress due to flexure, then $S = S_f + S_a$, where $S_f = Mc/I$ and $S_a = P/A$, I being the moment of inertia, c the distance of the extreme fiber, and A the area of cross-section. If the member is slender, a more exact method must be used in finding the total compression. Calling M the bending moment due to the transverse loads, P the axial load, e the deflection, then the total bending moment is $M + Pe$ and $S_f = (M + Pe)c/I$. The value of e may be assumed to equal $\alpha l^2 S_f/\beta Ec$ from the action of beams under transverse loads. Substituting this value of e, the maximum unit stress on the concave side of the column is

$$\mathbf{S} = \frac{\mathbf{P}}{\mathbf{A}} + \frac{\frac{\mathbf{Mc}}{\mathbf{I}}}{1 - \frac{\alpha \mathbf{Pl}^2}{\beta \mathbf{EI}}}$$

in which E is the modulus of elasticity, l the span, and α and β members depending upon the arrangement of ends and the kind of loading of the beam.

	α	β
Cantilever beam loaded at end	1	3
Cantilever beam uniformly loaded	2	8
Simple beam loaded at middle	4	48
Simple beam uniformly loaded	8	384/5
Beam fixed at one end, supported at other, uniform load	8	186
Beam fixed at both ends, loaded at middle	8	192
Beam fixed at both ends, uniformly loaded	12	384

In Flexure and Tension the method of finding the total amount of tension is similar to that for flexure and compression. Calling S the maximum unit stress due to the axial force and flexure, S_a the axial tensile unit stress, S_f the tensile unit stress due to flexure, then $S = S_a + S_f$, where $S_f = Mc/I$ and $S_a = P/A$. For a more exact formula, let M_1 equal the bending moment that produces the stress S, M the bending moment due to flexure, P the axial load or force, e the decreased deflection; then $M_1 = M - Pe$, and using the same reasoning as in the more exact method of flexure and compression, the maximum tensile unit stress is

$$\mathbf{S} = \frac{\mathbf{P}}{\mathbf{A}} + \frac{\frac{\mathbf{Mc}}{\mathbf{I}}}{\left(1 + \frac{\alpha \mathbf{Pl}^2}{\beta \mathbf{EI}}\right)}$$

the value of α and β being the same as given in the previous paragraph.

Flexure and Torsion result when a shaft is supported by hangers and loaded with pulleys for the transmission of the horsepower H. Find the flexural unit stress from $S = 32\ M/\pi d^3$ and the torsional unit stress from $S_s = 321\ 000\ H/nd^3$. Then the maximum tensile and compressive unit stresses S_t and S_c, and the maximum shearing unit stress S_{sh}, are given by

$$\mathbf{S_t} = \mathbf{S_c} = 1/2\ \mathbf{S} + \sqrt{\mathbf{S_s}^2 + (1/2\ \mathbf{S})^2} \qquad \mathbf{S_{sh}} = \sqrt{\mathbf{S_s}^2 + (1/2\ \mathbf{S})^2}$$

The above formulas may be used whether the shaft is solid or hollow by substituting the proper values for d. If shaft is round and hollow $(d_1^4 - d_2^4)/d_1$ should be substituted for d^3, where d_1 equals outer diameter and d_2 equals inner diameter.

Using the maximum strain theory the maximum "strain equivalent" ($E\times$ unit deformation) is

$$\mathbf{T_t} = 1/2\ (1 - \mathbf{p})\ \mathbf{S} + (1 + \mathbf{p})\sqrt{\mathbf{S_s}^2 + (1/2\ \mathbf{S})^2}$$

in which p is Poisson's ratio. For steel p may be taken as 1/4, and the above equation becomes

$$T_t = 3/8\,S + 5/4\,\sqrt{S_s^2 + (1/2\,S)^2}$$

22. Miscellaneous Cases

Eccentric Forces are sometimes applied longitudinally to the ends of a simple beam, instead of along the axis, in order that they may not increase the deflection of the beam. Let P be an eccentric tensile force acting at the distance e above the centers of gravity of the end sections, let f be the deflection and M the bending moment before the application of P. Then $P\,(e+f) = M$, whence the distance e should be $e = \dfrac{M}{P} - f$. When P is a compressive force it is applied below the axis at the distance $e = \dfrac{M}{P} + f$. As an approximation for both cases $e = \dfrac{M}{P}$.

Curved Beams. If the axis of a beam is curved the neutral axis no longer passes through the center of gravity of a cross-section, but is shifted towards the concave side of the beam. The maximum unit stress is increased by the curvature of the beam. The Winkler-Bach analysis for curved beams is the most widely used (see Appendix 1, Bulletin 18, Eng. Exp. Sta., Univ. of Ill.).

Wilson and Quereau, at the University of Illinois, from a study of the Winkler-Bach formula, have developed the following approximate formula, which, with an error not exceeding 15%, fits a large range of beams with cross-sections in the form of rectangles, ellipses, circles, trapezoids, T-sections, I-sections, and channel sections.

$$k = 1.0 + 0.5\,\frac{I}{bc^2}\left(\frac{1}{(R - c)} + \frac{1}{R}\right) \tag{1}$$

in which k = a correction factor by which the stress determined by the ordinary " straight beam " formula (formula (2), p. 569) is to be multiplied to give the extreme unit stress for the concave side of the curved beam.

I = the moment of inertia of cross-section.

c = the distance from the axis through the center of gravity of cross-section to the extreme fiber on the concave side of the curved beam.

b = the maximum breadth of the cross-section.

R = the radius of curvature of the centroidal line of the beam.

Helical Springs. A helical spring is formed by winding a wire closely around a cylinder which is then removed. Let d be the diameter of the wire, D the mean diameter of the helical coil, N the number of coils, P the londigitunal axial compressive load on the spring, and F the modulus of elasticity for shearing. The stress produced in the wire is one of shearing. The unit stress S_s and the shortening e of the spring are approximately

$$S_s = \frac{8\,DP}{\pi d^3} \qquad e = \frac{8\,ND^3P}{d^4F}$$

when P is a tensile load then e is the elongation of the spring. These formulas are valid only when S_s does not exceed the shearing elastic limit of the wire which is from 0.5 to 0.6 of the elastic limit in tension.

Circular Plates. A flat circular plate of radius r and thickness t supports a uniformly distributed load of p per square unit The flexural unit stress S of tension or compression at the middle of the plate is given by

$$S = m\,(r/t)^2 p$$

where m is a constant which varies with the kind of material and method of support.

	Wrought iron and steel and cast iron	Plain concrete
Plate supported around the circumference.	$m = 1.12$	$m = 1.27$
Plate fixed around the circumference.....	$m = 0.75$	$m = 0.85$

For a circular plate which carries at the middle a load of p lb. per sq. in. uniformly distributed over a circle of radius r_0, the value of S is, for a supported plate,

$$S = m\left(1 + 2\,\text{Nap}\log\frac{r}{r_0}\right)(r_0/t)^2 p$$

in which m has the same values as above. Example: when $r_0 = 1/4\,r$, then S is 0.26 $(r/t)^2p$ for cast iron and for steel.

Elliptical Plates. Let $2a$ and $2b$ be the axes, t the thickness and p be the uniform load per square unit. The plate tends to crack along the longer axis, and the greatest unit stress is

$$S = m\,\frac{a^2b^2}{a^2 + b^2}\,\frac{2p}{t^2}$$

in which the above values of m for circular plates may be used.

Rectangular Plates. Let 2 a be the shorter and 2 b the longer side; when the plate is fixed at the corners, then above formula for the elliptical plate may be used with above values of m for a circular supported plate. For a square plate of side 2 a and supported on edges $S = 9/8\,m\,(a/t)^2p$, while for one fixed on all edges $S = 3/4\,m\,(a/t)^2\,p$ in which m has above values for supported and fixed circular plates.

Sqaure Panels. Let an unlimited plate have many supports dividing the plate into many square panels, $2a$ being the side of each panel. The greatest unit stress S in the plate is $S = 8/9\,m\,(a/t)^2p$ in which m has the values given above for circular fixed plates. This applies to the flat stayed plates of steam boilers.

Fig. 52

Hooks. When a hook sustains a load P there exists in the bend of the hook combined tension and flexure. Let e be the distance from the line of action of P to the center of gravity of the cross-section at the bend, c the distance from that center of gravity to the inner edge of the bend, A the area and r the least radius of gyration of the cross-section then

$$S = k\frac{P}{A}\left(1 + \frac{ce}{r^2}\right)$$

gives the tensile unit stress at the inner edge of the bend in which k is the correction factor for curved beams given by formula (1), p. 599.

Circular Ring. When a circular ring of mean radius R is pulled in the direction of a diameter by two tensile forces each equal to P, the maximum bending moment is at the section, where P is applied, where it equals 0.318 PR and the unit stress is

$$S = \frac{0.318\ kPR}{0.098\ d^3}$$

in which k is the correction factor for curved beams given by formula (1), p. 599, and d is the diameter of the cross-section of the ring.

TESTING AND INSPECTION

23. Testing Apparatus

Testing Machines for determining the strength of materials of construction are of various types. A testing machine consists of a mechanism for applying a large force to a test specimen and a mechanism for determining the magnitude of the force applied.

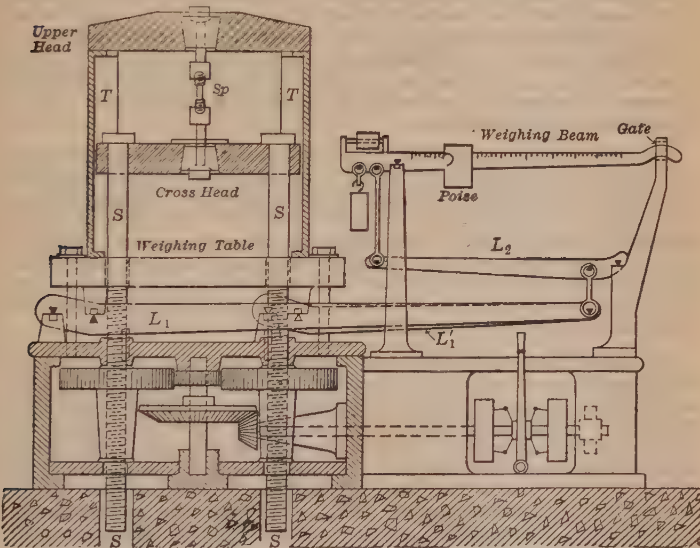

Fig. 53. Screw-power, Compound-lever Testing Machine

The Screw-power Compound-lever Testing Machine (Riehlé or Olsen **Machines**) is the type in most common use in the United States, and it is shown in diagram in Fig. 53. Power is supplied by a belt drive or by a direct-connected motor, and the power is transmitted through a series of gears to vertical screws which operate the crosshead of the machine. The force applied by the belt is multiplied many times by the gearing and the screws. This multiplied force is applied to the test specimen by the crosshead. If the specimen is a tension specimen it is placed between the crosshead and the upper head of the testing machine, if it is a compression specimen or a cross-bending specimen it is placed between the crosshead and the weighing table. In any event as the crosshead moves downward the specimen transmits downward pressure to the weighing table. The weighing table is supported on compound levers, $L_1L'_1$, Fig. 53, which are fitted with knife-edge bearings, and these compound levers transmit the force, reduced, to a simple lever, L_2, Fig. 53, which, in turn, transmits the force, still further reduced, to the weighing beam. As load is applied the beam is kept in balance by moving the poise, the position of which indicates the load on the specimen, when the beam is in balance.

For Flexure Tests, I-beams may be placed upon the weighing table, with suitable bearing blocks on their top flanges to support the beams to be tested, or the machines may be arranged with wings extending from the side and forming a part of the weighing table. The method of applying and registering the load is the same as in the compression test.

Hydraulic Pressure Testing Machines. The hydraulic press is a simple and comparatively inexpensive mechanism for applying the large forces required in testing machines. By using a pressure gage the total force on a ram of known size may be estimated with a fair degree of accuracy if the friction of packing against the ram is determined. The ordinary Bourdon pressure gage should be calibrated frequently, and very frequent adjustments made for zero reading.

The Amsler testing machine is made with rams so carefully ground to fit the cylinder that no packing is necessary, and the error due to friction is no larger than the error due to friction in knife-edge lever weighing devices. The pressure is measured by the load on a small piston which moves a pendulum so that the position of the pendulum bob indicates the force. This is a self-indicating weighing device, which eliminates much of the personal equation of balancing a weighing beam. The Amsler testing machine can be handled by a single observer, even when measurements of deformation are made, and is very rapid in its operation.

The Emery Testing Machine uses hydraulic pressure to apply the load to the specimen and transmits the load from the specimen to a hydraulic pressure cylinder, or pressure box, in which the plunger is replaced by a plate mounted on a thin metal diaphragm. This pressure box is filled with liquid and connected by means of a pipe to a smaller pressure box fitted with a plate and diaphragm, and the load on the smaller pressure box is weighed by means of a compound-lever balance. This hydraulic weighing device is extremely sensitive, and its accuracy is high. A recent model of the Emery machine uses a Bourdon pressure gage in place of the small pressure box and the compound-lever balance. The Bourdon gage is fitted with a special adjustment for zero load.

Calibration of Testing Machines. For small loads, testing machines may be calibrated by means of standard weights applied directly. For loads up to about 30 000 lb. testing machines may be calibrated by means of standard weights applied at the ends of a pair of simple levers of known leverage.

For larger loads the readings of the weighing mechanism of the testing machine may be checked against the elastic deformation of a standardized elastic member (a bar in tension, a block in compression, an elastic ring in flexure). The elastic member must have been previously calibrated by loading with standard weights, or with weights applied through simple levers of known leverage. At the U. S. Bureau of Standards is a dead weight calibrating apparatus with a capacity of 100 000 lb. Elastic calibrating devices up to 1 000 000 are on the market.

A fairly accurate calibration of a testing machine may be carried out by tests of a number of tension test pieces cut from a bar of mild steel. Half of these test pieces are tested to destruction in the machine to be calibrated, and half in a testing machine which has been standardized by one of the methods previously mentioned. The comparison of the average tensile strength of the two sets of specimens gives a measure of the accuracy of the testing machine under calibration.

Detailed specifications for calibrating testing machines are given in the 1927 Standards of the American Society for Testing Materials.

Accuracy and Sensitiveness of Testing Machines are two distinct characteristics. A machine is accurate if the readings of the machine agree closely with the actual loads applied by the machine. A testing machine is sensitive if a small change of load is indicated by a distinct movement of the beam or other weighing mechanism. A testing machine may be very sensitive, and yet very inaccurate.

Machines for Torsion Tests are of two types. In the Thurston type of machine one end of the specimen is held by a chuck in a horizontal spindle in the top of an A-frame. The other end is held in a similar manner in a parallel frame. One spindle is rotated by means of a worm gear and crank. The motion is transmitted through the specimen to the other spindle, to which is attached a weight on the end of a vertical bar. Any motion of this spindle will move the weight out of the vertical, and a torsional stress in the specimen results. The position of the weight will then be a measure of the stress, since its moment will be proportional to its deviation from the vertical.

Another form of machine consists of two parallel heads in which are chucks for holding the specimen, one head being operated by gears and the other attached to a weighing system, consisting of a compound lever. The moment in inch-pounds is read from a scale beam.

Abrasion Machines are used for determining the toughness or resistance of road materials to wear. The Deval machine is widely used. It consists of four cylinders 20 cm. in diameter and 34 cm. in depth, inside, mounted on a shaft at an angle of 30° with the axis of rotation. A charge of 5 kilograms of broken stone is placed in each cylinder, each charge consisting of 50 pieces. The cylinders are rotated 10 000 times at the rate of 30 to 33 per minute. The percentage of loss is computed from the amount of worn-off material that will pass through a 1/16-mesh screen.

For Abrasion Tests of paving brick, the cylinder or rattler adopted by the National Brick Manufacturers' Association is used. This consists of a barrel 20 in. in length, inside, and whose cross-section is a fourteen-sided polygon, inscribed in a circle 28-3/8 in. in diameter, supported on trunnions. The heads are made of cast iron, and the staves are of steel. The space between the staves must not exceed 5/16 in. The charge for bricks of "block-size" is ten bricks and with these bricks are placed in the rattler ten cast-iron spheres 3-3/4 in. in diameter and 300 lb. of cast-iron spheres 1-7/8 in. in diameter. These cast-iron spheres are weighed after every ten tests and when a large sphere is found to weigh less than 7 lb. or a small sphere less than 3/4 lb. new spheres are substituted.

The charge is rotated 1800 times at the rate of 29.5 to 30.5 per minute, and the percentage of loss is calculated in terms of the weight of the dry brick composing the charge. The average of five tests on separate charges of brick is considered an official test. (See p. 617.) For fuller details see 1927 Standards of the American Society for Testing Materials, Part II, p. 126.

Extensometers are used for measuring the small elastic deformations within the elastic limit, and for detecting the stress at which the elastic limit is exceeded. An extensometer consists essentially of two clamps which are fastened to the test specimen, and one or more micrometer devices by means of which a very small change of distance between the clamps can be measured. For all accurate measurement of elastic deformation of tension or compression specimens the extensometer should be attached so as to measure deformation along two or three symmetrically spaced axial lines on the specimen. Types of micrometer devices used in extensometers are: the screw micrometer, in which a very small axial motion of a screw is accompanied by a large circumferential motion of a dial attached to the screw; clockwork dial gages; multiplying levers; microscopes; and the "optical lever" in which a very small angular motion of a mirror changes the direction of a reflected ray of light. Extensometers for general use usually measure deformations to the nearest ten-thousandth of an inch.

The Strain Gage is a special form of extensometer which can be attached to a specimen or moved from one gage line to another between readings. It consists of a pair of trammel points PP', Fig. 54, attached to a frame F. One

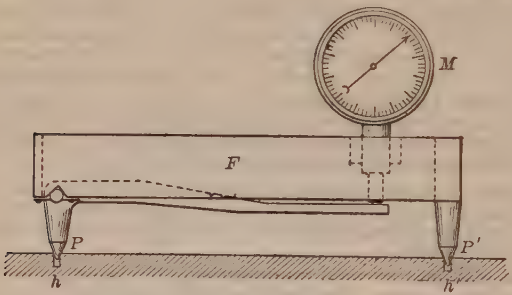

Fig. 54. Strain Gage

of the points, P, is movable and the motion of this point is measured by means of some micrometer device, M, usually a clockwork dial gage. The trammel points are conical in shape, and are made of hardened steel. On the specimen there are laid out gage lines along which deformation is to be measured, and at the ends of each gage line are drilled small holes hh' into which the trammel points fit. The strain gage may be clamped to a specimen, or the reading of the strain gage may be taken under zero load, the instrument removed, and after an increment of load has been applied another reading taken, the difference in the readings being the deformation. Corrections for temperature deformations are made by taking readings on a "standard bar" which is not subjected to stress, but is subjected to the same temperature changes as the specimen or structure under test. In skillful hands deformations can be measured with a strain gage to the nearest ten-thousandth of an inch The strain gage can be used to measure deformations in a structure or machine as well as in a test specimen. One instrument can be used for a large number of gage lines. In a test of stress determination in a reinforced concrete floor slab in the Soo Line Freight Terminal in Chicago measurements of deformation along over 1000 gage lines were made, and five strain gages were used. For detailed discussion of the use of the strain gage see Proceedings of the American Society for Testing Materials, Vol. XIII, p. 1019.

Recording Extensometers. One form of extensometer indicates changes of length by the change of electrical resistance of a pile of carbon disks when slightly compressed. This extensometer can be used as an indicating instrument, or, by the use of a mirror galvanometer recording the throw of its beam of light on a sensitized photographic film, as a recording extensometer.

It is especially useful for measurements in which the observer cannot conveniently be near the place where the deformation occurs.

See Proceedings of the American Society for Testing Materials, Vol. 23, Part II, p. 392 (1923), and Vol. 27, Part II, p. 522 (1927), articles by Peters and Johnston.

Another type of extensometer indicates changes in length by the change of impedance in an alternating-current electric circuit when the air gap between an electric magnet and its armature is slightly changed. This type may be used as a recording extensometer by the use of an oscillograph (a.c. galvanometer with very short period of vibration). It is also useful when it is convenient for the observer to be at a distance from the place where deformation occurs.

This type of instrument has been used by the Westinghouse Elec. & Mfg. Co., and by Prof. Earl Smith of Iowa State College.

A very simple form of recording extensometer is called the stremmatograph. In this form changes of length are recorded directly by the motion of a needle point over a plate of lightly smoked glass. This record is afterward examined under a microscope fitted with a micrometer eyepiece. The stremmatograph has been used successfully by P. H. Dudley and by Talbot to measure strains in railroad rails under moving trains.

See Trans. Am. Soc. C. E., Vol. LXXXII (1918), Progress Report of Committee on Stresses in Track.

For measuring the dimensions of cross-section of a test specimen micrometer calipers are usually used. For measuring the relatively large deformations beyond the yield point, and the elongation of tension test specimens after fracture measurements with dividers and steel scales are sufficiently accurate.

The Speed of Testing has an appreciable effect on the values determined for the mechanical properties of many structural materials. The accompanying table gives the requirements for speed in testing iron and steel as given in in 1928 Tentative Standards of the American Society for Testing Materials.

In testing steel and wrought iron in gage lengths of 2 and 8 in. in accordance with the specifications of the American Society for Testing Materials, the speed of the machine, by which is meant the speed of the crosshead when the machine is running idle, shall conform to the following requirements:

The crosshead speed of the testing machine shall be such that the beam of the machine can be kept balanced, but in no case shall the values given in the following table be exceeded:

Specified minimum tensile strength of material, lb. per sq. in.	Gage length, in.	Maximum crosshead speed for testing machine in determining, in. per minute	
		Yield point	Tensile strength
80 000 or under	2	0.50	2.0
	8	2.00	6.0
Over 80 000	2	0.25	1.0
	8	0.50	2.0

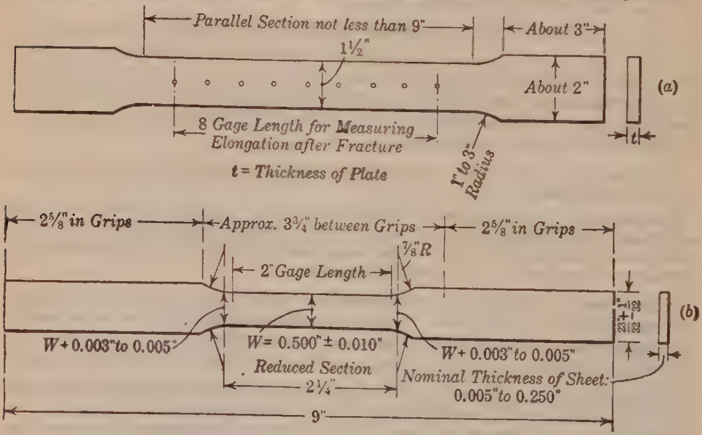
In determining the elastic limit by method I of the American Society for Testing Materials, described on p. 608, the crosshead speed for a specimen with a 2-in. gage length shall not exceed 0.125 in. per min. In determining the limit by method II (see p. 608), the crosshead speed shall not exceed 0.025 in. per in. of gage length per min.

Large Testing Machines in the United States. The U. S. Bureau of Standards has a compression testing machine of 10 000 000 lb. capacity, and another machine of 2 400 000 lb. capacity in compression and 1 200 000 lb. in tension. Several other government laboratories, college laboratories, and commercial laboratories have machines of 1 000 000 lb. capacity or more. The National Tube Co., Pittsburgh, Pa., has a torsion testing machine of 1 500 000 in-lb. capacity.

24. Tests and Test Specimens for Metals

This article is based largely on the Standards and the Tentative Standards of the American Society for Testing Materials.

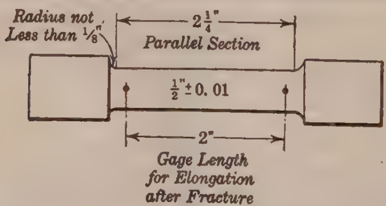
Tension Test Specimens for wire or for round bars usually consist of full-size pieces of the wire or the bar. Specimens of round bars are usually about



Note:- Reduced Section has Gradual Taper from Ends to Middle

Fig. 55

18 in. long, and the elongation after fracture is measured over a gage length of 8 in. Specimens for plate and shape material are usually of the form shown in Fig. 55*a* for material 1/4 in. thick and over. For material under 1/4 in. thick the specimen shown in Fig. 55*b* is recommended.



Note:- The Gage Length, Parallel Section, and Fillets shall be as Shown, but the Ends may be of any Shape to fit the Holders of the Testing Machine

Fig. 56

For thick plate material, forgings, large pieces, and general use in tension tests the specimen shown in Fig. 56 is recommended. Fig. 57 shows two designs of end for the specimen shown in Fig. 56, both of which have given satisfactory service. The gradual transition in cross-section from ends to middle of length is especially important in specimens of brittle metals.

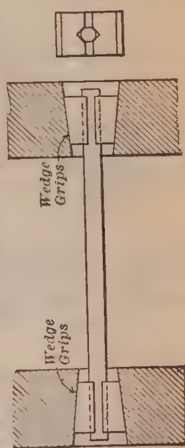
(b) SPECIMEN WITH THREADED ENDS

Fig. 57

Grips for Tension Test Specimens. For long bars of ductile metal and for the flat specimens shown in Fig. 55 wedge grips with file-toothed faces are satisfactory (see Fig. 58). For short specimens and for specimens of brittle metals wedge grips are not satisfactory, usually causing fracture at the edge of a gripping wedge. For such specimens it is necessary to use the machined specimen (Figs. 56 and 57). Fig. 59*a* shows a satisfactory gripping device for machined specimens with screw ends, and Fig. 59*b* shows a device for machined specimens with shouldered ends. Both these devices transmit the applied force to the heads of the testing machine through spherical-seated bearings. For very brittle metals, such as cast iron, even the spherical-seated bearings shown in Fig. 59 are not always effective in avoiding bending stresses in the specimen. The gripping device shown in Fig. 60, known as the Robertson shackle, has proved satisfactory for testing specimens of brittle material, and it is an excellent device for gripping any machined tension test specimen.



Tension Specimen for Rod or Wire

Fig. 58

The gripping device is shown as used with threaded end specimens. A similar device fitted with split sockets would be used with shouldered specimens.

For specimens of thin sheet metal ordinary wedge grips are liable to cut the specimen near the edges of the grips, causing a tearing action rather than an axial pull. The self-aligning wedge grips shown in Fig. 61 (known as Templin grips) have proved satisfactory for tests of thin sheet metals.

Preparation of Tension Test Specimens. All machined surfaces on specimens should have a smooth finish. All shoulders should have generous fillets. If specimens of rolled metal are sheared from plates or shapes, or are roughed out with a cutting torch, at least 1/8 in. of the metal should be removed from the sheared or burnt edges of the specimen. For steel castings test coupons are usually attached to the casting, and the specimens machined from these coupons. The coupons should remain attached to the casting until the annealing or other heat treatment of the casting is completed.

Determination of the Elastic Limit in Tension Tests. The determination of elastic limit as defined on p. 547 logically involves the application and release of a series of increasing loads on the specimen until there is observed a set after the release of a load. This procedure is very slow, and since for many metals experience does not indicate any significant difference between the elastic limit so determined and the proportional limit, the determination of the proportional limit is regarded as a satisfactory determination of the elastic limit. It is obvious that the precise value obtained for elastic limit, or for proportional limit, depends on the delicacy of methods and instruments

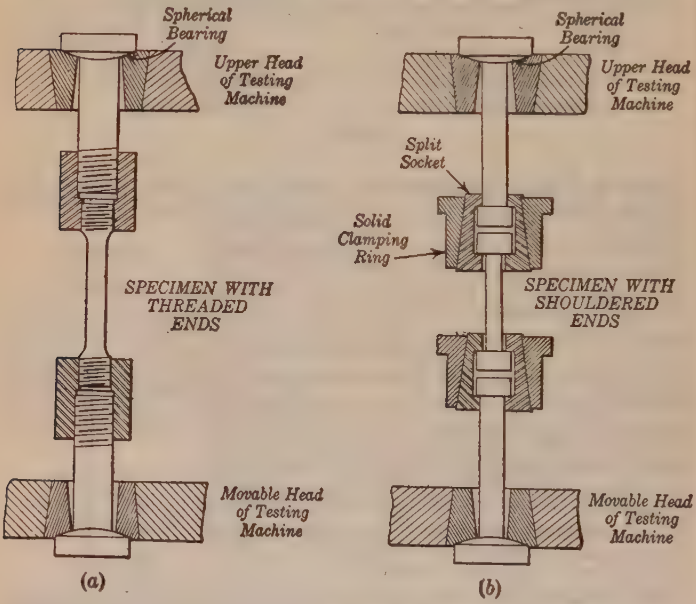


Fig. 59

used. It becomes necessary, therefore, that in any test the method used shall be clearly stated. The following methods are in common use for determining a value designated as the elastic limit:

Method I is suitable for metals of a fair degree of ductility. An extensometer, reading to 0.0002 in. (usually with a 2-in. gage length), shall be attached to the specimen. When the specimen is in the testing machine and the extensometer attached the testing machine shall be operated so as to increase the load on the specimen at a uniform rate. The observer shall watch the elongation of the specimen as shown by the extensometer and shall note the load for which the rate of elongation shows a sudden increase. The unit stress corresponding to this load shall be reported as the elastic limit.

Method II (the J. B. Johnson method) is somewhat more delicate than method I and is suitable for tests of metals of rather low ductility. The elastic limit is taken as that unit stress at which the rate of deformation is

50% greater than the initial rate of deformation. It is necessary to take a series of readings of load and stretch, or to use an autographic or a semi-autographic recording device to obtain a stress-strain diagram. Fig. 62 shows such a diagram. The initial rate of deformation is given by the ratio mn/Om; $nq = 0.5\ mn$, $mq = 1.5\ mn$, and the slope of Oq represents a rate of deformation 50% greater than the initial rate. $O'q'$ is drawn parallel to Oq and tangent to the stress-strain diagram. The point of tangency J locates the elastic limit. In using method II it is recommended that the extensometer

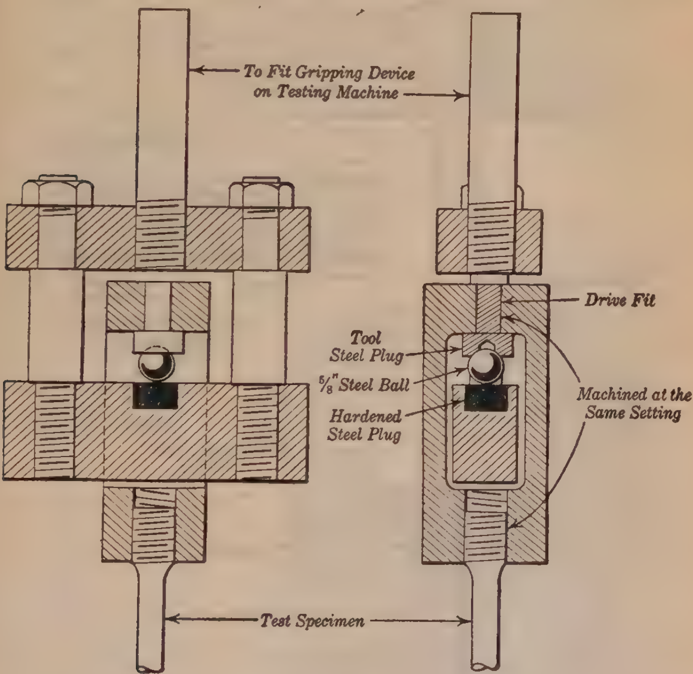

Fig. 60

be of such sensitiveness that it will indicate a change of one ten-thousandth of the gage length.

Determination of the Yield Point in Tension Tests. The yield point is the unit stress at which there occurs a marked increase of deformation without an increase in load. Two methods for determining yield point are in use.

Method I (" Drop of the Beam "). Load is applied to the specimen at a steady rate of increase and the operator keeps the beam in balance by running out the poise. At the yield point the increase of load ceases temporarily, but the operator, running out the poise at a steady rate, runs it a trifle beyond the balance position, and the beam of the machine drops for a brief but appreciable interval of time. In a machine fitted with a self-indicating weighing device there is a sudden halt in the motion of the load-indicating pointer, corresponding to the drop of the beam. The load at the " drop " or the " halt " is noted and the corresponding unit stress reported as the yield point.

Method II. An observer with a pair of dividers watches for visible elongation between two gage marks on the specimen. When visible stretch is

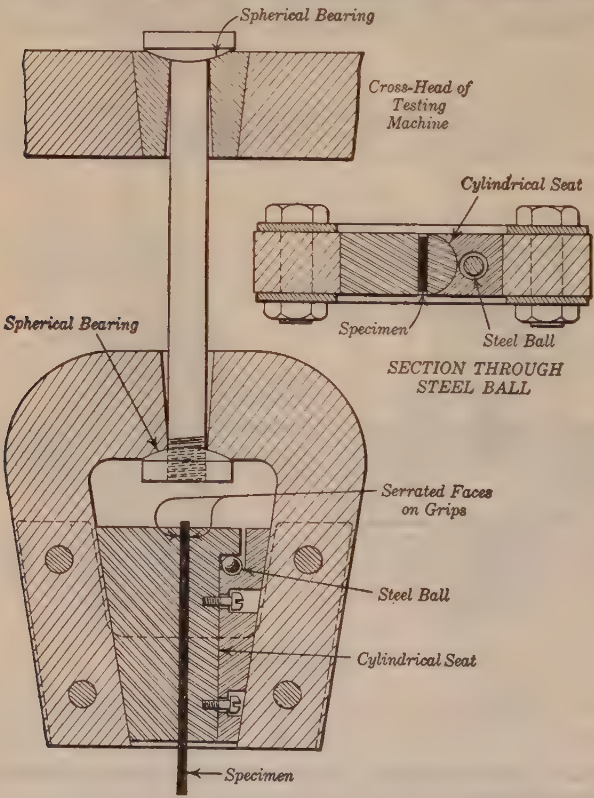

Fig. 61

observed the load is noted and the corresponding unit stress reported as the yield point. The gage length should not be greater than 2 in.

It should be noted that many metals do not have a well-defined yield point.

Significance of Elastic Limit and of Yield Point. Using careful methods of testing and especially avoiding high speeds of pulling, the yield point, if sharply defined, may be regarded as a satisfactory index of the elastic strength of a ductile metal. For metals of a good degree of ductility which do not show a clearly marked yield point method I for elastic limit gives a satisfactory index of elastic strength. For metals of fair ductility **method II gives a** satisfactory index of elastic limit (method II may also be used for metals of high ductility). For metals of low ductility (e.g., cast iron) none of the methods previously mentioned, nor any other as yet proposed, give a satisfactory index of elastic strength. It is doubtful whether any elastic limit should be reported in tests of such metals.

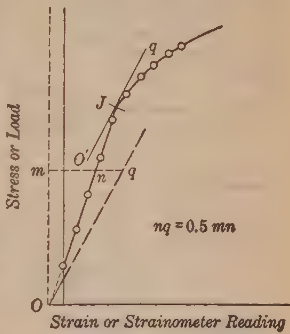

Fig. 62. Illustrating Method II for Determining Elastic Limit

Determination of Tensile Strength (Ultimate). The tensile strength of a material is determined by dividing the maximum load carried in a tension test by the original area of cross-section of the specimen. It is important that the speed of testing should not be so high as to render uncertain the balancing of the beam of the testing machine, or to cause "surging" of the indicating mechanism of a self-indicating load measuring device.

Determination of Elongation and Reduction of Area after Fracture. The measurement of elongation of a tension test specimen after fracture can be made with sufficient accuracy by means of a pair of dividers and a scale. In general, the elongation should not be measured on any specimen which breaks outside the middle third of the gage length. The measurement of reduction of the dimensions of specimen after fracture may be made by the direct measurement with a micrometer of the smallest cross-section of the specimen. For round specimens this measurement can best be made by holding the broken pieces together in a vise or between centers and then measuring the average diameter of the smallest section by means of a micrometer fitted with rather sharp points.

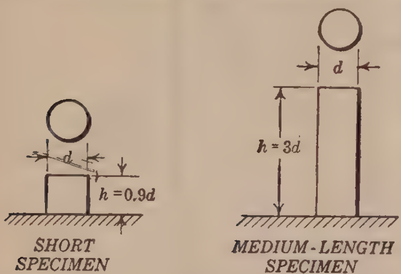

Fig. 63

Compression Test Specimens. Fig. 63 shows specimens for compression tests. The short specimen is used for tests of such metals as bearing metals, which in service are used in the form of a thin plate or shell. The medium-length specimen is useful for general use in compression tests. Compression specimens of metals should have all machined surfaces smooth and all ragged edges smoothed off.

Bearing Blocks for Compression Specimens. Both ends of a compression test specimen should bear on a carefully machined plane surface. The bearing blocks should be made of hardened steel or faced with hardened steel. One end of the specimen should bear on a spherical-seated bearing block. Fig. 64 shows a satisfactory arrangement of specimen and bearing block. The bearing block should be at the upper end of the specimen. It is important that the center of the spherical surface should be in the flat face which bears on the specimen; otherwise lack of parallelism between faces of the specimen sets up bending action in the specimen.

The object of using a spherical-seated bearing block is to give the specimen as even a distribution of initial load as possible. Owing to friction, the spherical-seated bearing cannot be relied on to adjust itself to bending action which may be set up after the test is started.

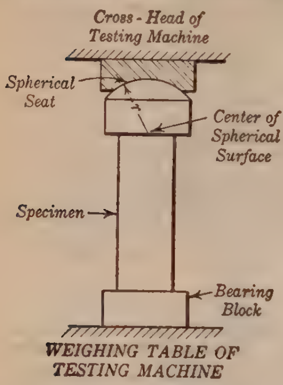

Fig. 64

Determination of Elastic Limit, Yield Point and Compressive Strength. The methods used for determining elastic limit and yield point in compression tests are, in general, the same as those used in tension tests. The compressive strength is determined by dividing the maximum load by the original area of cross-section of the specimen.

In the case of a material which fails in compression with a shattering fracture the compressive strength has a very definite value. In the case of materials which do not fail by a shattering fracture the value obtained for compressive strength is an arbitrary value depending on the degree of distortion which is regarded as indicating complete failure of the material.

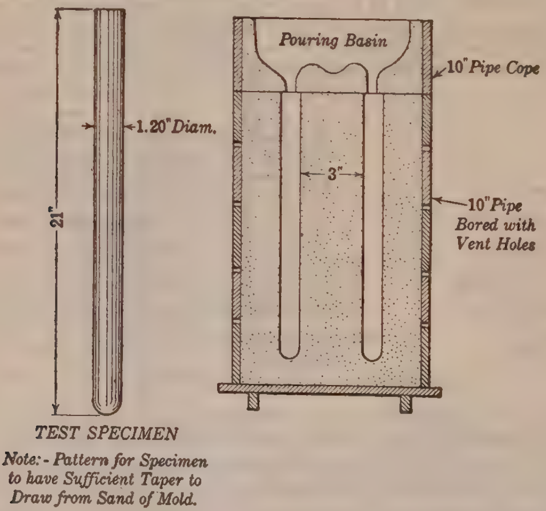

Fig. 65

Flexure Tests are used in determining the strength qualities of cast iron. For gray iron castings the standard test specimen is an "arbitration bar," the specifications for which are given by the 1927 Tentative Standards of the American Society for Testing Materials as follows:

"The mold for the bars is shown in Fig. 65. The bottom of the bar is 0.05 in. smaller in diameter than the top, to allow for draft and the strain of pouring. The pattern should not be rapped before withdrawing. The flask shall be rammed with green sand, a little damper than usual, well mixed and put through a No. 8 sieve, with a mixture of 1 to 12 bituminous facing. The mold shall be rammed evenly and fairly hard, thoroughly dried and not cast until it is cold. The test bar shall not be removed from the mold until cold enough to be handled. It shall not be rumbled or otherwise treated, being simply brushed off before testing."

The arbitration bar is loaded at the center of an 18-in. span, as shown in Fig. 66, and the load is applied at such a rate that 20 to 40 seconds are required to produce a deflection of 0.1 in.

For cast-iron pipes the standard test specimen is 26 in. long, 2 in. wide, and 1 in. thick, and is loaded at the middle of a 24-in. span.

Hardness Tests of Metals in common use are the Brinnell test, the Rockwell test and the Scleroscope test. In the Brinnell test a hardened steel ball of known diameter is pressed against the surface of the metal to be tested, the pressure exerted and the diameter (or depth) of the resulting permanent impression being noted. The smaller the indentation the harder the metal. The hardness is indicated by a "hardness number," which is the quotient obtained by dividing the pressure by the spherical surface of the indentation. The standard steel ball used is 10 mm. in diameter, and the standard pressure is 3000 kg. for the harder metals, and 500 kg. for the softer metals. A modification of the Brinnell test which is used to some extent is the Ludwik cone test, in which a hardened steel conical point is used in place of a steel ball.

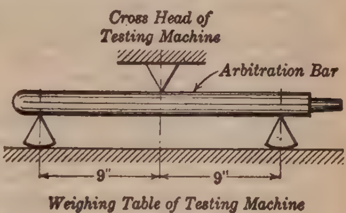

Fig. 66

In the Rockwell test a steel ball 1/16 in. in diameter (the Rockwell "B" test) or a conical diamond point (the Rockwell "C" test) is pressed against the surface of the specimen with a small but definite initial load. Then a load of 100 kg. ("B" test) or 150 kg. ("C" test) is applied by means of a weight acting at the end of a compound lever. This weight is removed leaving the small initial load still on the penetrating point and the depth of impression is measured by means of a micrometer dial gage attached to the indenting point. This gage is graduated to read directly an arbitrary system of hardness numbers corresponding (inversely) to the depth of impression. The Rockwell "B" numbers are different from the Rockwell "C" numbers.

The Scleroscope consists of a diamond-pointed plunger weighing 1 gram which drops vertically down the inside of a graduated glass tube to the surface of the metal to be tested, which is placed at the lower end of the tube. The height of rebound is measured, and is a measure of the hardness of the metal.

Brinnell tests, Rockwell tests, and scleroscope tests possess the great advantage that they may be made without damage to the material which is to be used, instead of being vicarious tests on samples chosen to represent the material. They are especially useful in testing the uniformity of different parts of the same piece, for example, the uniformity of hardness of the different teeth of a gear wheel.

In a general way there seems to be a fairly well defined relation between the Brinnell, Rockwell, and scleroscope hardness, and the tensile strength for the different grades of iron and steel. (See paper by R. R. Abbott, Proc. American Society for Testing Materials, Vol. XV, Part II, p. 42.) The relation between Rockwell number and Brinnell number is rather complicated and varies somewhat for different metals. (See Petrenko in Technologic Paper 334 of the U. S. Bureau of Standards.)

Impact Tests of Metals are sometimes made for the purpose of determining toughness, that is, the ability to resist without actual rupture a combination of high stress and great deformation. Tough metals resist heavy accidental overload without shattering failure. In impact tests the amount of energy required to rupture or permanently deform the test specimen is the quantity measured rather than the stress. In general, the results of an impact test may be predicted by measuring the area under the load-deformation diagram for a static test of the specimen, though there may be some variation introduced by the very rapid application of load in an impact test.

The Master Car Builders' Drop Testing Machine is an impact machine consisting of a framework fitted with a hoist and a weight which can be varied from 1640 lb. to 2000 lb. and which can be dropped from a height varying from 0 to 50 ft. The specimen is supported on an anvil weighing 20 000 lb. and the anvil is supported on heavy springs. With this machine tests are made of rails in flexure, of car couplers in tension, of car axles and locomotive axles in flexure. Impact tests of cast-iron car wheels are made on a machine somewhat similar to this. Drop tests are made by delivering on a test specimen one or more blows from a given height, and observing signs of failure in the test specimen.
