Unit Stresses in Pounds per Square Inch specified for some large cantilever bridges. **Firth of Forth**: maximum compression 17 000; maximum tension 16 350; ultimate tensile strength of steel 67 000 to 74 000 and ultimate compressive strength of 76 000 to 83 000. **Monongahela River** at Pittsburgh: dead load compression 21 000 where $l/r < 40$; dead load tension 22 000; live load stresses one-half these values; ultimate tensilve strength for eyebar steel 63 000 to 73 000 and for plates and angles 60 000 to 70 000; shearing on rivets 10 000 for rivet steel of ultimate tensile strength of 52 000 to 63 000. **Queensboro**: compression for structural steel under ordinary loads $20\,000 - 90\,l/r$, and for congested loads $24\,000 - 100\,l/r$; tension for nickel steel eyebars under ordinary loads 30 000 and under congested loads 39 000; tension for structural steel in main members of trusses, towers and bracing 20 000 for ordinary and 24 000 for congested loads respectively; shear on shop rivets 13 000 and 16 000 for ordinary and congested loads; full sized annealed nickel steel eyebars up to a maximum size of 16 in. × 2.5 in. were required to show a minimum elastic limit of 48 000, a minimum ultimate tensile strength of 85 000 and an elongation of 9% in 18 ft.; open-hearth structural steel eyebars, minimum elastic limit 28 000 and minimum ultimate strength of 56 000 and elongation of 10% in body of bar. **First Quebec**: compression, ordinary, $12\,000\,(1 + \text{min./max.})$, extreme 24 000, both for $l/r < 50$; tension, ordinary $12\,000\,(1 + \text{min./max.})$, extreme 24 000; structural steel with ultimate tensile strength of 62 000 to 70 000.

Compression Members of large cantilever bridges in America are latticed box sections as shown in Figs. 125, 126 and 127. The Forth bridge members are hollow cylinders some of which are 12 ft. in diameter and made of plates, 1-1/4 in. in thickness, riveted together and stiffened by inside stiffening frames. Fig. 125 shows a section of a lower chord member of the ill-fated Quebec bridge, Fig. 126 of the Queensboro, and Fig. 127 of the Monongahela River bridge. These are typical sections for the three bridges respectively. The segments of the Quebec chord were connected by latticing only, and except at splices there were no diaphragms, while the segments of the Queensboro and the Monongahela chords are braced by both latticing and diaphragms. The latticing and diaphragms are not completely shown here. The largest

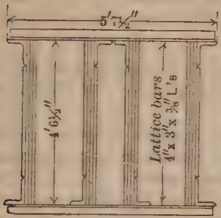

Fig. 125

Fig. 126

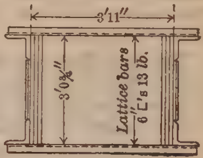

Fig. 127

cross-sectional area of any compression chord in the Queensboro bridge is 1072.1 sq. in.

Typical Compression Chords of Large Cantilever Bridges

Bridge	Area of cross-section	Sectional area of lattice *	Sectional area of lattice rivets †	Length of chord l	Radius of gyration r ‡	l/r
	Sq. In.	Sq. In.	Sq. In.	Ft. In.	In.	
Quebec (first)...	781	10	4.8	57 0-9/32	19.7	35
Memphis (old)..	213	10	4.8	28 2-3/4	14.8	23
Queensboro.....	852	25	4.8	31 6-1/8	22	17

* Total area (measured at right angles to axis of lattice bar) of lattice bars cut by cross-section of chord. † Area of rivets connecting all lattice bars cut by a cross-section chord to outside web, one end only. ‡ Axis normal to latticing; not necessarily the least radius of gyration.

The Lower Chord, L13-L14 of the New Quebec bridge, Fig. 128, adjacent to the main pier, has a cross-sectional area of 1902 sq. in., being about 42 ft. 11 in. long and 10 ft. 3-1/4 in. wide. The depth of the lower chord diminishes in accordance with a regular taper of 1/32 in. in 12 in., from about 7 ft. 2 in. at the main shoe to 4 ft. 1-3/4 in. at the end of the anchor arm. The chord section has four vertical ribs each consisting (L 13–L 14) of 4 web plates with an aggregate thickness of 3-3/4 in.; 4 flange L's, 8 in. × 8 in. × 1 in.; 2 cover plates, 20 in. × 1-1/8 in.; 2 cover plates, 20 in. × 1-3/16 in. Each outer pair of ribs is connected at top and bottom flanges by 8-1/2 in. × 1 in. lattice bars, and at mid-height by a horizontal diaphragm consisting of 1 web plate, 33 in. × 11/16 in., and 4 flange L's, 8 in. × 8 in. × 5/8 in. The areas of these longitudinal diaphragms are included in the cross-section of the member. The webs are also strengthened transversely by cross (vertical) diaphragms about 15 ft. apart, having 10 in. × 16-in. manholes. The 8-1/2 in. × 1-in. lattice bars have 2 rows of 3 rivets each in each end and 4 rivets at the intersection. The inner pairs of ribs are tied together by vertical and mid-horizontal diaphragms and by tie plates in the planes of the flanges. The weight of L 13-L 14 is about 400 short tons. In order to facilitate shipment and erection this member was spliced at the center and each of the two sections divided longitudinally. The **Main Vertical Post** is 310 ft. between centers of end pins. Its unsupported length is 145 ft. It is composed of four separate columns latticed together, its outside dimensions being about 9 ft. by 10 ft. Its cross-sectional area is 1903 sq. in.; its weight 1500 short tons and it was shipped in 26 pieces.

The New Memphis Bridge compression chords also have four webs 42 in. deep reinforced with side plates, and 8 flange L's 8 in. × 8 in. The maximum cross-sectional area is 445 sq. in.

The Length of the Cantilever Arm for a given location may be varied considerably, but the location of the abutments and piers is generally limited by local conditions. In such a bridge as the Monongahela, Fig. 123, the central span between piers is determined by the width of the waterway, and the abutments are frequently located by other similar requirements. If the abutments are fixed, the position of the piers should be such as to make the total cost of the bridge a minimum, which will practically be when the material in the trusses is a minimum. On account of the varying live and dead loads, different shapes of trusses and different unit stresses, the relation between the length of anchor arm and the entire length of bridge between abutments can be expressed only approximately. With the general arrangement shown in Fig. 123, the anchor arm is usually about 0.20 L, the cantilever arm about 0.17 L and the suspended span about 0.26 L, where L is the total length between abutments. These values are average values only, and many cantilever structures have been built in which the ratios of lengths do not agree with the fractions given.

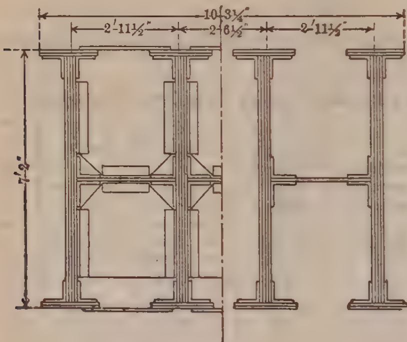

Fig. 128

Anchorages. Most cantilevers with a central suspended span require anchoring at each shore end of the bridge to produce a downward reaction on the anchor-arm truss. These anchorages usually consist of a series of eyebars attached to the end pin of the truss and extending down into the masonry where they are connected to girders. The anchorage for each end of each anchor-arm truss of the first Quebec bridge consisted of sixteen 10 in. by 2-1/16-in. eyebars connected by pins to a series of eight plate girders each 6 ft. deep and 17 ft. 6 in. long. Above these girders was another layer of girders 8 ft. 6 in. deep and 36 ft. long and above this a layer consisting of twelve 15-in. I-beams 22 ft. long. The eyebars and the grillage of beams and girders were embedded in the masonry and grouted. In several of the large cantilevers the anchorages are placed in inspection galleries.

37. Reactions of Cantilevers

Reactions may be determined by ordinary methods when the structure is statically determinate as regards the outer forces, and by deflections when statically indeterminate. A cantilever bridge having the points of application of all reactions known and having all bearing points but one arranged so that they can exert only vertical reactions on the truss is **statically determinate** as regards outer forces when the number of equations given by the manner of construction is equal to $n - 2$ where n is number of supports. Thus the reactions on truss in Fig. 129 may be found by statics because the

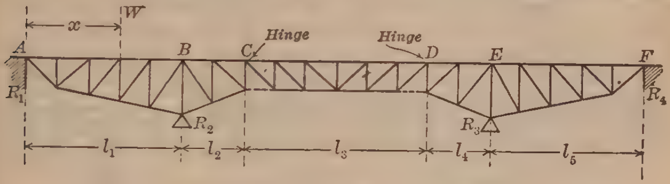

Fig. 129

number of equations given by the method of construction, that is, by the insertion of a hinge at C and D, is equal to $n - 2 = 2$. Similarly the truss in Fig. 130 is statically determinate because the two hinges, P and T, and the omission of diagonals in panel LM and the corresponding panel on right of center give the $n - 2 = 4$ equations required. Each hinge makes the bending moment at the section where it is inserted equal to zero. The dotted members in Fig. 129 and Fig. 130 receive stress only during erection.

Reactions for Fig. 129, having a central suspended span and four supports. For a load on the anchor arm AB, R_1 and R_2 are upward; for a load on the cantilever arm BC, R_1 is downward and R_2 upward; in either case R_3 and R_4 are each zero and R_1 and R_2 are as follows:

$$\mathbf{x} \leq l_1 + l_2 \quad \mathbf{R}_1 = \mathbf{W}(l_1 - \mathbf{x})/l_1 \quad \mathbf{R}_2 = \mathbf{W}\mathbf{x}/l_1$$

The suspended span is a simple truss supported at C and D, and for a load on that span the pressure on cantilever arm BC at $C = W(l_1 + l_3 + l_3 - x)/l_3$ and on cantilever arm DE at $D = W(x - l_1 - l_2)/l_3$; in this case R_1 and R_4 are downward, R_2 and R_3 are upward, and their values are as follows:

for $\mathbf{x} > l_1 + l_2$ for $\mathbf{x} < l_1 + l_2 + l_3$

$$\mathbf{R}_1 = -\frac{\mathbf{W}(l_1 + l_2 + {}_3 - \mathbf{x})l_2}{l_3 l_1} \qquad \mathbf{R}_2 = \frac{\mathbf{W}(l_1 + l_2 + l_3 - \mathbf{x})(l_1 + l_2)}{l_3 l_1}$$

$$\mathbf{R}_3 = \frac{\mathbf{W}(\mathbf{x} - l_1 - l_2)(l_4 + l_5)}{l_3 l_5} \qquad \mathbf{R}_4 = -\frac{\mathbf{W}(\mathbf{x} - l_1 - l_2)l_4}{l_3 l_5}$$

With a load on the portion DF, Fig. 129, there are reactions at R_3 and R_4 only, and if x be taken as the distance from load to F, their values are the same as for R_2 and R_1 respectively when the load is on the portion AC.

With a **uniformly distributed live load** the maximum downward R_1 (Fig. 129) and maximum downward R_4 occur for live load covering the central span B to E; maximum upward R_1 and R_4, load spans l_1 and l_5 respectively; maximum R_2, load spans l_1, l_2 and l_3; maximum R_3, load spans l_3, l_4 and l_5.

Reactions for Fig. 130, having a central suspended span and six supports, only three of which are shown. Hinges at P and T make the bending moments at those points zero; and the omission of diagonals in panel LM makes the shear in that panel zero; when the top and bottom chords in panel LM are horizontal, and therefore $M_2 = M_3$. If one of the chords in panel LM were inclined, the shear in that panel would be equal to vertical component of the inclined chord, and $\mathbf{M}_2/\mathbf{h}_2 = \mathbf{M}_3/\mathbf{h}_3$, where M_2 and M_3, h_2 and h_3 are the bending moments and heights at supports 2 and 3 respectively. For a concentrated load on the anchor arm GL reactions exist at R_1 and R_2 only, and this arm is a simple truss supported at R_1 and R_2. With the load on the cantilever arm MP distant x_1 from M there are reactions at R_1, R_2 and R_3; R_1 being downward, R_2 and R_3 upward, and their values are

$$x_1 \leq l_3 \qquad R_1 = -\frac{Wx_1}{l_1} \qquad R_2 = \frac{Wx_1}{l_1} \qquad R_3 = W$$

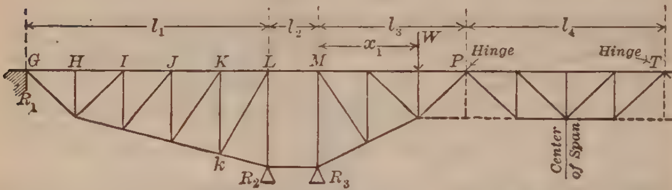

Fig. 130

For a load on the suspended span PT, reactions exist at the six supports, the end ones (at the two abutments) being downward and the four central ones (at the piers) being upward.

38. Stresses in Cantilevers

Stresses in Truss Members may be computed directly or found with aid of influence lines. Let it be required to compute maximum tension, P_{L-M}, in top chord member LM in Fig. 130, for a dead panel load of 10, all on top chord, and a live panel load of 20 thousands of pounds. Let the panel length be 20 ft.; depth of truss at L and M 40 ft., and at H 20 ft. Pass a vertical section through LM, consider forces on right of the section and write moment equation about the origin of moments, namely, R_3. The live load should be placed on all top chord panel points between M and T. The moment equation for dead loads is:

$$10(20 + 40) + 2.5 \times 10 \times 60 - 40P_{L-M} = 0,$$

and P_{L-M} for dead loads is 52.5 tension. Live $P_{L-M} = 2 \times 52.5 = 105.0$ thousands of pounds tension.

Maximum Stresses in Top Chord Member IJ (Fig. 130). Pass vertical section through IJ, consider left side of section and take origin of moments at lower chord joint 25 ft. under I. Effective dead load $R_1 = -10\ (20 + 40)/100 - 2.5\ (10)\ 60/100 + 2\ (10) = -1.0$, the minus sign denoting a downward reaction. Moment equation for dead loads about origin of moments is

$$25\ P_{I-J} - 10 \times 20 - 1 \times 40 = 0$$

from which P_{I-J} for dead loads is 9.6 tension. For live tension, load all panel points between M and T, and for live compression load joints H, I, J, K.

$$\text{Live tension, } P_{I-J} = \frac{[20\ (20 + 40) + 20 \times 2.5 \times 60]40}{100 \times 25} = 67.2$$

$$\text{Live compression, } P_{I-J} = \frac{40 \times 40 - 20 \times 20}{25} = 48.0$$

Combining the above live and dead stresses: maximum tension in $IJ = 76.8$ and maximum compression = 38.4 thousands of pounds.

Maximum Stresses in Vertical Kk (Fig. 130). Origin of moments 60 ft. to left of R_1. Effective dead load R_1 is 1.0 downward, as previously found, hence dead load causes compression in Kk. For live load in any position on the bridge there is compression in Kk. Dividing the moment above the origin by the lever arm of the bar, 140 ft.,

$$\text{Dead compression, } P_{K-k} = \frac{1 \times 60 + 10\,(80 + 100 + 120 + 140)}{140} = 31.86$$

Live compression = 2 × 31.86 = 63.72, and the maximum compression is 95.58. There can be no tension in Kk.

The Maximum Uplift at Abutment G (Fig. 130) occurs when the live load covers the central span from M to T. Under dead loads alone the effective reaction R_1 is 1.0 downward, but the total dead R_1 is really upward and is 5.0 − 1.0 = 4.0 if the dead load on the joint G be 5.0. The maximum live uplift, that is, the maximum downward live R_1, is 20(20 + 40) + 20 × 2.5 × 60/100 = 42.0, hence the true maximum uplift is 42.0 − 4.0 = 38.0.

39. Influence Lines for Cantilevers

Definition of Influence Line. If a load of unity is allowed to pass over a structure, and at each position of the load there is plotted the shear, moment, reaction or stress which exists at some fixed section of the structure, the

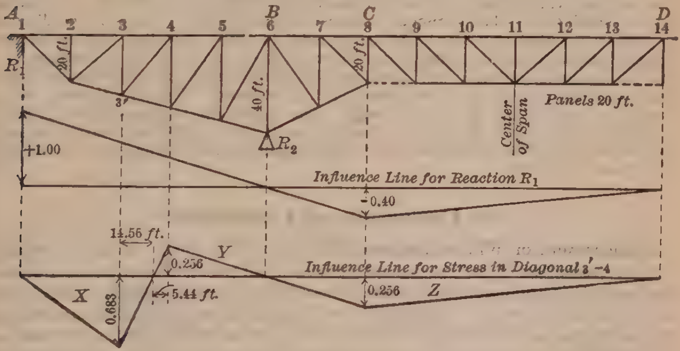

Fig. 131

resulting curve is called an influence line. These lines are useful in determining what portion of a structure should be loaded with a live load to produce the maximum or the minimum effect, and in determining the amount of the effect. For example, Fig. 131 shows the influence line for reaction R_1 and the influence line for stress in diagonal 3′–4.

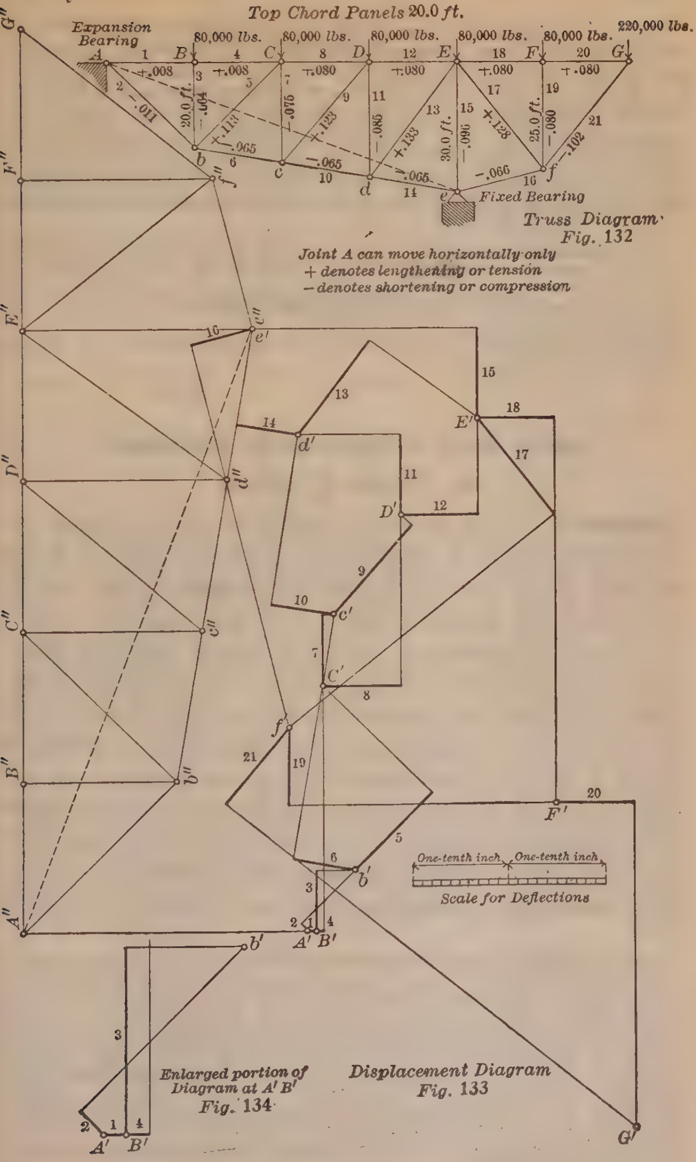
Influence Line for Reaction R_1 (Fig. 131). Let the load of unity approach from the right. There is no reaction at R_1 until the load is to the left of hinge D, and as the load moves from D to C, R_1 gradually increases until the load gets to C, when its value is − 1 × 40/100 = − 0.40. As the load moves from C to A, R_1 gradually changes from a downward force of 0.40 to an upward one of 1.00, passing through zero at B. Upward reactions are called positive and are plotted above the horizontal axis in the diagram. With a uniform dead load the value of R_1 is found from the influence line by multiplying the load per foot by the algebraic sum of the areas of the positive and negative triangles, and with a uniform live load the maximum upward or downward live R_1 is found by multiplying the live load per foot by the area of the positive and negative triangles respectively, the load in the first case being placed only over the positive triangles and in the second case over the negative triangles.

Influence Line for Stress in Diagonal 3′–4 (Fig. 131). As the load of unity approaches from the right the stress in the diagonal is zero until the load passes D, when the stress gradually increases until the load is at C. With load at C the stress is most easily found by considering forces to the left of a vertical section through the diagonal 3′–4 and taking moments about the origin, which is 60 ft. to the left of R_1. This stress is $0.40 \times 60 \times 32.02/120 \times 25 = 0.256$ tension, and is plotted at the load, namely at C. As the load moves from C to joint 4 the stress changes uniformly from tension to compression, and when it is at 4 the compression in the diagonal is 0.256 which is plotted at the load at 4. When the load crosses the panel 4–3 the stress changes from compression to tension and during the remainder of the movement to A there is tension in the bar 3′–4 as shown. Given a dead and a live load of 1000 and 2000 lb. per ft. per truss respectively, let it be required to find the maximum tension, $P_{3'-4}$, in bar 3′–4. The area of triangle X, Fig. 131, is $54.55 \times 0.683/2 = 18.63$, of Y 5.82 and of Z 20.48. The units used are the foot and the pound. For tension in 3–4 the live load must cover the distances represented by the bases of the triangles X and Z, hence live $P_{3'-4} = 2000\ (18.63 + 20.48) = 78\ 220$ lb. tension; dead $P_{3'-4} = 1000\ (18.63 + 20.48 - 5.82) = 33\ 290$ lb. tension; total tension, $P_{3'-4} = 111\ 510$ lb.

Stresses from Concentrated Loadings are most readily found from the influence lines. The latter are nearly always triangular. (Exceptions: the Queensboro Bridge and continuous bridges.) See X, Y, Z, Fig. 131. The position of the loading lying between the joints 14 and 6, producing maximum tension in the diagonal 3′–4, is the same as that which would produce the maximum moment at a point 8 in a simple span of length 6–14. The triangular influence lines enclosing the areas Y and X may be used in a similar way for the groups of loads in these respective portions of the bridge, those in X causing additional tension in 3′–4, and those in Y compression. The L.L. stress is obtained still more quickly when a table of equivalent uniform loads, such as is given for M–60, page 1171, is at hand. Thus, for the part 14–6, $l_1 = 40$, $l_2 = 120$. For M–60, $w = 8617$. The maximum tension $= 20.48 \times 8617 = 176\ 650$. For loads in X, $l_1 = 14.56$, $l_2 = 40$, $w = 12\ 000$, and maximum tension $= 18.63 \times 12\ 000 = 223\ 560$. The total tension in the diagonal 3–4 $= 176\ 650 + 223\ 560 = 400\ 210$.

40. Deflection of Cantilevers

Displacement or Williot Diagram (Figs. 132, 133, 134). This is a graphical determination of the exact displacement of all points of a truss for a given loading. It is applicable to all cases where the changes in lengths of the truss members can be found. There are three steps in the solution as illustrated by the determination of deflections of all joints of truss in Fig. 132, which shows the diagram of truss drawn to scale, the joints lettered, the bars numbered in order in which their deformations are laid off in Fig. 133 and the changes in lengths of the various bars due to the loading shown, these changes due to stress being found by dividing the actual unit stress for each bar by the modulus of elasticity. The second step is to draw the displacement diagram by beginning at any joint and assuming this joint fixed in position and one of the bars at the joint fixed in direction. Usually start with a bar which appears to have a small movement. On lines parallel to the bars in the truss diagram lay off the changes in length for the bars and erect perpendiculars to these deformations. Thus, in Fig. 133, starting with joint A as fixed in position and bar AB fixed in direction lay off to scale and to the right from A' the change $+ .008$ in. for the bar AB, thus locating $A'B'$; then from A' lay off $- .011$ in. for bar Ab, marked 2 in Fig. 133, and erect a perpendicular to this line, and similarly with bar Bb, or number 3, thus locating b', $A'b'$ showing the actual movement to scale of point b with respect to A and the fixed direction AB. Continuing in this way the displacement diagram is finally ended by locating G'. Care must be taken to lay off the deformations in proper directions; thus, bar Ab is in compression and its deformation is laid upward and to the left



Figs. 132, 133, 134. Displacements for a Cantilever from A'. This diagram has been drawn on the assumption that A is fixed, whereas e is really fixed and A can and does move horizontally. The third step then is to rotate the truss about e, the real fixed joint, till all bars in the truss in Fig. 133 are at right angles to the corresponding bars in Fig. 132. This is here done by moving A' horizontally until $A''e'$ is at right angles to Ae, then completing truss $A''G''\epsilon''$. The true displacement of any joint is shown in Fig. 133; for example, joint A has moved to the right a distance $A''A'$; E has moved to the right and downward from E'' to E'. Fig. 134 shows a part of Fig. 133 on an enlarged scale, and is here made necessary on account of the reduction in printing.

The displacement diagram not only shows the final resultant motion of each joint but it also shows the horizontal and vertical motion as well. Thus, while joint A has moved only horizontally to the right a distance equal to $A''A'$, joint B has moved vertically a distance equal to the vertical projection of $B''B'$ and horizontally a distance equal to the horizontal projection of $B''B'$.

Two scales are necessary, one of distances for the truss diagram in Fig. 132 and the other for the deflections in Fig. 133.

ARCH AND SUSPENSION BRIDGES

41. Types of Arches

Classification. An arch is a structure which under any and all loads produces inclined reactions at the supports. Arches are classified as to the number of hinges used in one rib, there being three-hinged, two-hinged, one-hinged and hingeless arches. When **three hinges** are used there is one at each support and one at the crown; when only **two hinges** are used, one is placed at each support; and if an arch has only **one hinge** it is located at the crown. **Hingeless arches** are also called fixed or continuous. Structures with only one hinge are seldom built, but the other types are common. As to the arrangement of the ribs, arches are also classified into two types, namely, those having solid webs extending between and connected to the flanges and those in which the webs are open and consisting of web members connecting the upper and lower chords in the same manner as in ordinary trusses. In ribs having **solid webs** both flanges are usually (though not always) curved, thus making the rib a curved plate girder. Ribs with **open webs** may be either spandrel-braced, in which case the upper chord is horizontal and the lower is curved, or they may have the two chords curved, either parallel or lune-shaped, and be connected by the web members, thus forming what are sometimes called trussed-arch ribs. There are, then, **spandrel-braced, trussed-arch,** and **solid ribs,** and any one of these may be hinged or fixed.

Historical and Descriptive. The **earliest metallic arch** of note in the United States is the cast-iron hingeless arch bridge carrying Chestnut St. over the Schuylkill River in Philadelphia. This bridge was completed in 1866, and has spans of 185 ft., and the ribs, bracing and floor plates are all of cast iron. The Eads bridge in St. Louis having a span of 519 ft. 9-3/8 in. and the Kaiser Wilhelm bridge over the Wupper River in Germany with a span of approximately 558 ft. are the longest hingeless arches in the United States and Europe respectively. **Longest three-hinged arch-bridge** in the United States is the 618-ft. span at the Grand Canyon, Ariz. **Longest arch span** is the two-hinged highway bridge across the Kill van Kull, Staten Island, N. Y., with a span of 1675 ft. **Longest three-hinged arches** for supporting roofs were used in the Manufactures and Liberal Arts Building, Columbian Exposition, Chicago, 1893, the span being 368 ft.

42. Two-hinged Arches

Notation. Δx and Δy, horizontal and vertical movements respectively of origin of coordinates of a curved beam: $\Delta\phi$, angular movement of axis of curved beam at origin of coordinates. M, bending moment of vertical forces at point on arch axis (gravity axis), x and y, coordinates of a point on arch axis. ds, elementary length of arch axis. E, modulus of elasticity of material. I, moment of inertia of cross-section of rib. I_0, moment of inertia of cross-section of rib at crown. c, coefficient of linear expansion, t, change in temperature in degrees Fahrenheit from normal. S, average value of compressive unity stress. L, length. A, area of cross-section of bar. U, stress in bar due to load of unity acting horizontally at one hinge of braced arch. P, stress in bar of braced arch due to vertical loads and vertical reactions.

Arches with Two Hinges have less deflection at the crown due to changes in temperature, and are more rigid than those having three hinges, but the temperature stresses are large and any horizontal movement of one support produces stress throughout the arch. The two hinges are placed at the supports, and the arch may be spandrel-braced or may have two or more ribs with solid or open webs. The two arches over Niagara River are typical structures, the Grand Trunk Railway bridge being a deck spandrel-braced structure with span of 550 ft., carrying two railroad tracks on the upper deck and a highway immediately under this deck. The Niagara and Clifton bridge is near the Grand Trunk bridge and carries a highway on the upper deck, the highway being supported on vertical columns which are carried by the curved trussed ribs.

Deflection of a Curved Beam. If beam *OA* (Fig. 135) is fixed at *A* and is free at *O*, the horizontal, vertical and angular movements of the axis of the beam at the origin of coordinates *O* are

$$\Delta x = \int_0^A \frac{Myd_s}{EI} \qquad \Delta y = \int_0^A \frac{Mxd_s}{EI} \qquad \Delta\phi = \int_0^A \frac{Md_s}{EI}$$

Reactions on Arch with a Solid Web (Fig. 136). An arch with two hinges is statically indeterminate as regards the outer forces, one condition or equa-

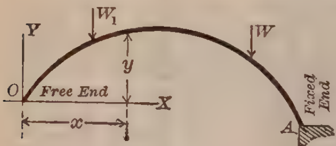

Fig. 135

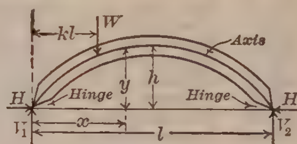

Fig. 136

tion being required in addition to those of statics. This additional equation may be obtained by the principle of least work or by deflections.

$$V_1 = W(1-k) \qquad V_2 = Wk \qquad H = \frac{\int \frac{Myd_s}{EI}}{\int \frac{y^2 d_s}{EI}}$$

This equation for *H* can be integrated only when the equation of arch axis is known, in which case *M*, d_s and *I* must be expressed in terms of the coordinates *x* and *y*. The integration extends over entire length of rib. If the material and the cross-section of rib are uniform for whole length the value of *H* becomes $H = \frac{\int Myd_s}{\int y^2 d_s}$. In case the arch axis is not a regular curve so that the integration cannot be performed, the value of *H* for an arch of uniform material and cross-section may be determined approximately by dividing the axis into a number of equal parts and letting *M* be the bending moment due to vertical loads and reactions and *y* the ordinate at the center of each division, $H = \frac{\Sigma My}{\Sigma y^2}$, where ΣMy denotes the summation of the various products of *M* and *y* for the center of each division and Σy^2 the summation of the squares of the several ordinates to these centers. In all of the above equations for H the effect of shear and axial force is neglected and only the effect of the moment is considered.

Parabolic Arch Rib with Solid Web (Fig. 137). A parabolic arch rib is one which has a parabola for an axis, the vertex being at the crown. The formula for H gives its value for bending only and assumes a rib of uniform material but with a moment of inertia varying from a minimum at the crown to a maximum at the skew-back hinges; the moment of inertia at any section equals that at the crown times the secant of the angle the arch axis makes with the horizontal at that section.

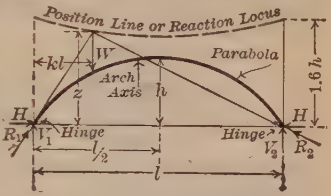

Fig. 137

$$V_1 = W(1 - k) \qquad V_2 = Wk$$

$$H = \frac{5Wl}{8h}(k - 2k^3 + k^4) \qquad z = \frac{1.6\,h}{1 + k - k^2}$$

Effect of Temperature on Arch Ribs with Solid Webs. A rise in the temperature tends to increase the span length and a fall in temperature to decrease it. If the span cannot change, a horizontal reaction is exerted on the arch at each support, and temperature stresses are produced within the rib. For the general case, Fig. 148, the horizontal reaction is

$$H = \frac{EI_0clt}{\int^1 y^2dx}$$

For a **parabolic rib,** (Fig. 137), with solid web this equation for horizontal reaction becomes $H = 15EI_0ct/8h^2$. The temperature range t is frequently taken as $\pm$ 75° Fahr. from the mean temperature of 50° Fahr. For a rise in temperature above normal, t is positive and the reactions H act inwardly and for a fall in temperature below normal, t is negative and the reactions H act outwardly. The bending moment at any section due to temperature is Hy, being positive for a fall and negative for a rise in temperature. I is here assumed to increase from the crown towards the abutments.

Rib Shortening in Arch Ribs with Solid Webs. The compression of the rib due to the thrust acting along the arch axis shortens the arch axis and produces outward horizontal reactions at the supports. The horizontal reaction is

For general case (Fig. 136) $\quad H = -\dfrac{SI_0l}{\int_0^1 y^2dx}$

For the parabolic rib (Fig. 137) $H = -\dfrac{15\,SI_0}{8\,h^2}$

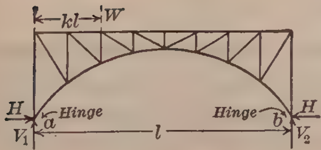

Fig. 138

Rib shortening is similar in effect to a fall in temperature. The moments are all positive. For a rib having a small rise the effect of rib shortening should not be neglected.

Reactions on a Braced Arch due to Vertical Loads. If in Fig. 138 the arch

With the reactions known, a stress polygon showing all stresses in both portions of the rib is

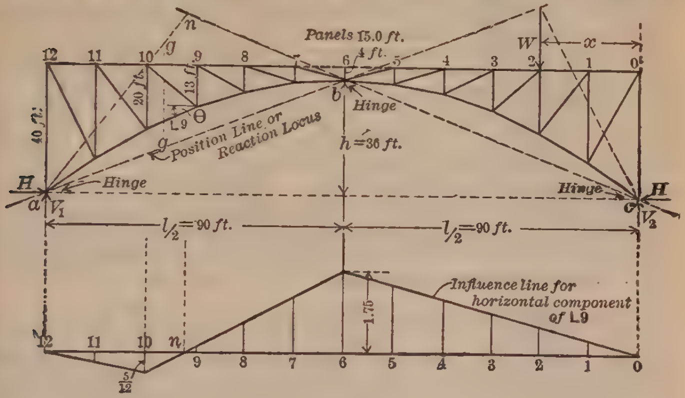

Fig. 139

drawn in the usual way by beginning at joint a. These stresses may be checked algebraically by method of moments, using the true equilibrium polygon; this polygon being started through a, using the first force polygon

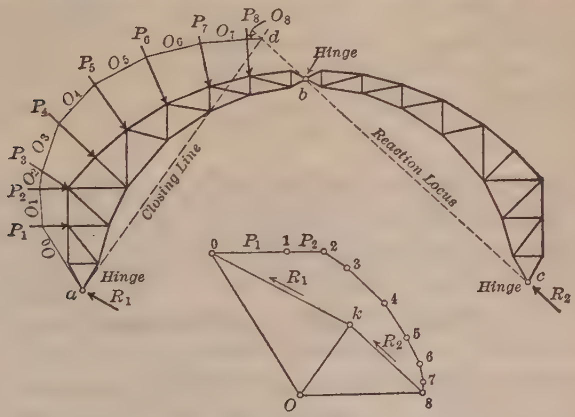

Fig. 140

with k as the pole, the reaction $R_1 = ko$ being drawn through a till it intersects P_1, then the string $k1$ till it meets P_2, and so on. The true polygon finally passes through the three hinges. By method of moments the stress in a bar is equal to moment at the origin of moments divided by the lever arm.

Computation of Reactions and Stresses for Spandrel-braced Arch. With a dead panel load of 20 and a live panel load of 40 thousands of pounds per truss, required the maximum stresses in lower chord L_9 (Fig. 139). Passing a vertical section g–g through L_9, taking origin of moments at 10 and drawing the line an through 10, it is seen that for a load to right of n the bar L_9 is in compression, for a load at n L_9 is zero, and when the load is to left of n L_9 is in tension. For maximum compression, load joints 1 to 9 inclusive, and for maximum tension joints 10 and 11. Loads at 0 and 12 produce stresses in end-posts only. Consider first the dead load. For this loading the thrust at crown hinge is horizontal, and by taking moments about a for left half of rib is found to be $6 \times 20 \times 3 \times 15/36 = 150$. With origin at 10 and considering the part of rib between b and section g–g the dead load stress in $L_9 = \sec \theta\,[150 \times 4 + 20\,(15 + 30 + 45) + 10 \times 60]\,.20 = 165.53$ = compression; where θ is angle L_9 makes with horizontal. For live load tension, loads on joints 10 and 11 cause $V_2 = 40\ (1 + 2)/12 = 10$ and $H = V_2 \times 90/36 = 25$, and considering the part of structure between c and g–g with origin at 10, the moment equation is $20\ L_9/\sec \theta - 10 \times 150 + 25 \times 40 = 0$; $L_9 = 27.59$ = tension. The live load compression in L_9 is most easily found as follows. Since ratio of live to dead panel load is 2, the compression in L_9 for full live load only $= 2 \times 165.53 = 331.06$, and compression for live loads on joints 1 to 9 inclusive is full live load compression plus live load tension due to live loads on 10 and 11, or maximum live compression $L_9 = 331.06 + 27.59 = 358.65$. Results: maximum compression = 524.18 and minimum compression = 137.94.

Influence Line for horizontal component of stress in L_9 is shown in Fig. 139. This influence line consists of three straight lines the ordinates to which represent the horizontal components of stress in L_9 due to a load of unity on the portions 0–6, 6–10, and 10–12, respectively. It is only necessary to compute the ordinate at 6 and 10. With load at 6 the moment at 10, Fig. 151, divided by 20 ft. gives the horizontal component of $L_9 = 1.75$ compression and this is plotted at joint 6, similarly with load of unity at 10 the ordinate at 10 is 5/12 tension. The horizontal component of L_9 may now be found from the diagram either by multiplying the areas of the triangles by the load per foot, which gives exact results, or by multiplying the ordinates to the influence line at the panel points by the panel load giving approximate results that are slightly larger than the exact. For example, using dead and live panel loads of 20 and 40 respectively, the following results verify those obtained in the preceding paragraph, which are computed by the usual approximate methods. Live tension in $L_9 = [40(1 + 1/2)5/12] \sec \theta = 27.59$. Live compression in $L_9 = [40(1/8 + 2/3 + 29/24) + 40(1 + 5/6 + 4/6 + 3/6 + 2/6 + 1/6)1.75] \sec \theta = 358.65$.

The Position of Live Load for Maximum Stress in a given bar must be determined for each case. For example, the point n, Fig. 139, is the neutral point for bar L_9, and if a load is placed on the right of n as at joint 8, the left reaction acts through a and through the intersection of position line bc with the vertical at 8, and since the left reaction is the only force acting on left at section g–g, the moment at origin of moments 10 is negative, hence L_9 must cause a positive moment about 10 and is compression. Similarly for a load to left of n, P_9 is tension. With a system of **concentrated loads** the influence line is useful. Referring to Fig. 139, the part of the influence line from O to n is the same shape as an influence line for bending moments at joint 6 on a simple span of length O–n, hence the position of loads for maximum compression in L_9 is the same as the position of loads that will cause maximum moment at 6 on span O–n, and the maximum tension in L_9 is caused by the same position of loads as will cause maximum moment at 10 on span 12–n.

44. Fixed Arches

Notation. y_1 and y_2 = ordinates of points of application of reactions at left and right ends respectively, ds = elementary length of arch axis, E = modulus of elasticity of material, I = moment of inertia of cross-section of rib, I_0 = moment of inertia of cross-section of rib at crown, M_L = moment at any point on left half of arch axis of all outer loads between that point and the crown, M_R = moment at any point on right half of arch axis of all loads between that point and the crown, m = number of divisions into which each half of arch axis is divided; H_C, V_C, M_C, respectively, are the thrust, shear and moment at crown, z = ordinate of the reaction locus, M_1 = moment at each support, c = coefficient of linear expansion, t = change in temperature in degrees Fahrenheit from normal, S = average compressive unit stress.

A Fixed or Continuous Arch has no hinges, and it is so rigidly held at its ends that the arch axis cannot change its direction at those points. Arches without hinges are more rigid than those having hinges, have greater temperature stresses and are more affected by settlements of the supports.

Reactions for Fixed Arches. With vertical load W as shown in Fig. 141 there are five unknown quantities V_1, V_2, H, y_1, y_2 to be determined to completely find the reactions. The following five equations give relations between these unknowns:

$$V_1 + V_2 - W = 0 \qquad Wkl - V_2 l + H(y_1 + y_2) = 0$$

$$\int_0^1 \frac{Myd_s}{EI} = 0 \qquad \int_0^1 \frac{Mxd_s}{EI} = 0 \qquad \int_0^1 \frac{Md_s}{EI} = 0$$

The first two of the above equations are from statics and the last three from the conditions that the horizontal, vertical and angular movement of the arch axis at the origin of coordinates A is each equal to zero. Moment at A is Hy_1, at B is Hy_2, and at any point D is Hu.

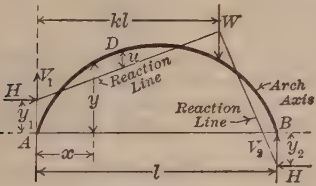

Fig. 141

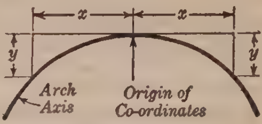

Fig. 142

The Thrust, Shear and Moment at Crown of a fixed arch (Fig. 142) having a shape such that the integration of the preceding paragraph cannot be performed, are given approximately by the following formulas, which assume the arch axis to be divided into short lengths such that the ratio of the length of each division, d_s, to the moment of inertia, I, at center of division is a constant.

$$H_c = \frac{m\Sigma M_R y + m\Sigma M_L y - \Sigma M_R \Sigma y - \Sigma M_L \Sigma y}{2\,[m\Sigma y^2 - (\Sigma y)^2]}$$

$$V_c = \frac{\Sigma M_L x - \Sigma M_R x}{2\,\Sigma x^2} \qquad M_c = \frac{\Sigma M_R + \Sigma M_L - 2\,H_c \Sigma y}{2\,m}$$

In these equations numerical values of M_R, M_L, x, and y are positive; the summations cover one-half the length of the span only; a positive value of M_C denotes a positive moment at the crown and a negative value denotes a negative moment there; for a positive value of V_C the line of pressure at the crown slopes upward towards the left and for a negative value upwards towards the right.

Reactions for a Parabolic Arch Rib having fixed ends and a variable moment of inertia of cross-section (Fig. 143). The modulus of elasticity is assumed constant and the moment of inertia assumed to vary from the crown to the abutments; at any section being equal to the moment of inertia at the crown times the secant of angle of inclination of arch axis at that section,

$$V_1 = W(1 + 2k)(1 - k)^2 \qquad V_2 = W(3k^2 - 2k^3)$$

$$H = \frac{15\,Plk^2}{4\,h}(1 - k)^2 \qquad y_1 = \frac{10\,k - 4}{15\,k}h$$

$$z = \frac{6\,h}{5} \qquad y_2 = \frac{6 - 10\,k}{15(1 - k)}h$$

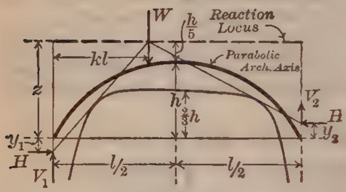

Fig. 143

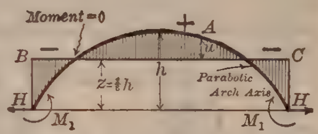

Fig. 144

The lines of reactions are tangent to a curve which consists of parts of two hyperbolas.

Temperature Stresses in a Parabolic Rib (Fig. 144).

$$H = \pm\frac{45\,EI_0ct}{4\,h^2} \qquad z = \frac{2\,h}{3} \qquad M_1 = \pm\frac{2\,Hh}{3}$$

For a fall in temperature the moment at each support is negative and the reaction H acts outward as shown in Fig. 144; moment at any point such as A is Hu, and is negative at all points below line BC and positive at all points above BC. For a rise in temperature the reaction H and the moments are opposite to those in Fig. 144.

Rib Shortening for a Parabolic Rib causes outward horizontal reactions H and bending moments like those for a fall in temperature.

$$H = -\frac{45\,SI_0}{4\,h^2} \qquad z = \frac{2\,h}{3} \qquad M_1 = -\frac{2\,Hh}{3}$$

45. Suspension Systems

Historical and Descriptive. A suspension bridge consists of a floor suspended from cables or chains which are supported by passing over towers and by being anchored to the earth at their ends. In the early suspension bridges chains were used, but they were soon superseded by wire cables. To prevent undue oscillation or deflection the cables are provided with stays or stiffening trusses or else are trussed. When the cables are trussed they are usually made of eyebars, and the system then becomes an inverted arch suspended between the tops of the towers and having the inward pull from the main arch span resisted by an outward pull from the back stays extending from the top of each tower to the anchorage in the earth. The **first suspension bridge** of note in the United States was built in 1801 by James Finley at Greensburg, Pa., and had a span of 70 ft. carried by chains. The Chain Bridge near Newburyport, Mass., was built in 1810 by John Templeman on Finley's design, was strengthened in 1900 and again in 1910. The **first wire suspension bridge** in America was a foot bridge of 408-ft. span built in 1816 over the Schuylkill River; in Europe the first one was built in 1834 at Freiburg. In 1855 John A. Roebling completed the Niagara suspension bridge, which had a span of 821 ft. 4 in. and carried a railroad on the upper and a highway on the lower deck; wooden stiffening trusses 16 ft. deep were

* Rebuilt 1895–98, two new cables being added above the two old ones. † Rebuilt 1854 and 1862. Before the reconstruction in 1862 the bridge had twelve cables arranged in two groups of six each, placed side by side.

used. In 1880 iron trusses replaced the wooden ones in this structure, in 1886 wrought-iron towers replaced the stone towers, and in 1897 the structure was replaced by a two-hinged spandrel-braced arch. The largest suspension bridge in the world is now under construction across the Hudson River at New York. It will have a central span of 3500 ft. The present (1928) longest suspension bridge is the one across the Delaware River at Philadelphia. It has a central span of 1750 ft.

46. Cables

Notation. w_1 = intensity of load at point having coordinates x and y. H = horizontal component of tension in cable. T = tension in cable at any point. w = uniform load per horizontal unit of length. l = horizontal length of span of cable. h = sag or vertical distance from lowest point of cable to its support at top of tower. l_1 = length of cable between towers.

Cables for small bridges are made of wire rope, and for large structures they are made by compacting a number of steel wires into cylindrical form and clamping them in this shape by means of steel clamps placed above the panel points of the stiffening trusses thus serving as saddles for the suspenders. Each of the four main cables of the Manhattan bridge in New York is composed of 9472 parallel wires arranged in 37 strands, each wire being 0.192 in. in diameter before and not over 0.197 in. in diameter after galvanizing. These cables are approximately 20-3/4 in. in diameter, and are wrapped with galvanized-iron wire and painted. The Williamsburgh bridge in New York has four main cables, each 18-3/4 in. in diameter and each composed of 7696 wires arranged in 37 strands clamped together and covered between clamps with cotton duck soaked in oxidized linseed oil and varnish gum composition and with a sheet-iron shell. The Delaware River bridge has two main cables, each 30 in. in diameter composed of 18 666 wires arranged in 61 strands of 306 wires each. Each wire galvanized has a diameter of 0.196 in. Each of the two Bear Mountain bridge cables is made up of 37 strands of 196 wires each, making a total of 7252 wires, and has a finished diameter, after compacting and wrapping, of 18 in. The new Hudson River bridge at New York has four main cables, each 30 in. in diameter, of 26 474 wires arranged in 61 strands of 434 No. 6 galvanized wire, 0.196 in. diameter over galvanizing. Each cable will have a total steel area of 800 sq. in. and will carry a maximum tension of 65 400 000 lb. Cables are cradled when the horizontal distance between the two cables at a pier is greater than that at the center of the span.

Linear Arch. A linear arch for a given set of forces is the true equilibrium polygon for those forces, and hence it may be defined as an arch in which there is only direct tension or compression, and is incapable of carrying bending moment. The general equation of the linear arch is $d^2y/dx^2 = w_1/H$, where the left side of the equation denotes the second differential. A cable of uniform cross-section and material suspended at its ends and subjected only to its own weight assumes the form of a catenary.

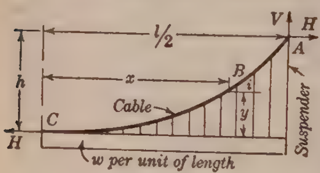

Fig. 145

Cable Carrying a Uniform Load. Fig. 145 shows one-half of such a cable, and for this loading the curve of the cable becomes a parabola with axis vertical and vertex at lowest point of curve, C, and its equation is

$$y = \frac{4\,hx^2}{l^2} \quad \text{or} \quad y = \frac{wx^2}{2\,H}$$

The **tension in the cable** at the lowest point C is the horizontal component H, this component being constant throughout the length of the span, and is $H = wl^2/8\,h$. Tension at any point such as B is given by the following:

$$T_B = \sqrt{H^2 + w^2x^2} = \frac{w}{8\,h}\sqrt{l^4 + 64\,h^2x^2}$$

Maximum tension exists at the tower A and its value is

$$T_A = \frac{w}{8\,h}\sqrt{l^4 + 16\,h^2l^2}$$

Tangent of angle of slope ($\tan i$) at any point B and at the upper A is $8\,hx/l^2$

and $4\,h/l$ respectively. **Length of cable** between supports, that is, twice the length of curve AC, Fig. 145, is

$$l_1 = 2\int_0^{\frac{l}{2}}\left[1+\left(\frac{dy}{dx}\right)^2\right]^{1/2}dx = l\left(1+\frac{8}{3}\frac{h^2}{l^2}-\frac{32}{5}\frac{h^4}{l^4}+\ldots\right)$$

The **Sag Ratio** or **Dip Ratio** is the ratio of the sag of the cable, h in Fig. 145, to the span l, and this ratio varies from about 1/8 to 1/15. The term versine is also used to denote the sag h, but this is not a proper use since the curve is not a circle. The greater the sag the smaller the tension in the cables but the larger the towers. Sag ratio for Williamsburgh bridge is 1/9; for Brooklyn bridge, about 1/12.5; for the Bear Mountain bridge, about 1/8; for the Delaware River bridge, about 1/8.75, and for the Hudson River bridge at New York, about 1/10.75.

Steel Wires for Cables, Suspenders and Hand Ropes of Manhattan bridge were required to be made in an open-hearth furnace lined with silica. Maximum percentages for chemical requirements: C, 0.85%; Mn, 0.55%; Si, 0.20%; P, 0.04%; S, 0.035%; Cu, 0.02%; Strength: 215 000 and 200 000 lb. per sq. in. before and after galvanizing respectively; minimum elongation in 12 in., 2% and 4% before and after galvanizing. For the Williamsburgh bridge the following were the maximum chemical requirements: P, 0.04%; *S*, 0.03%; Mn, 0.05%; Si, 0.1%; Cu, 0.02%. Minimum ultimate strength, 200 000 lb. per sq. in.; elongation of 2-1/2% in 5 ft. and of 5% in 8 in. The wire reached an ultimate strength of 225 000 lb. per sq. in. The minimum ultimate strength for the Bear Mountain and Delaware River bridges was about 215 000 lb. per sq. in.

47. Stiffening Trusses

Notation. w = uniform live load per unit of length. w_1 and w_2 = live loads per unit of length borne by the cable and stiffening truss respectively. h = sag of cable. d = deflection at center of span. A = cross-sectional area of cable. E = modulus of elasticity of material in cable and truss. I = moment of inertia of truss. V = shear in truss. M = bending moment on truss.

Stiffening Trusses are used to distribute a concentrated load or a partial uniform load over the whole or a part of the length of the cable and they are usually steel riveted trusses, although in small bridges are sometimes made of wood. Where riveted trusses are used they are of the Warren type with one, two or three web systems. For highway bridges, where permissible deflections are large and the loads light, the stiffening trusses are light, whereas for railroad bridges, which are subjected to heavy and unequal loads and where the allowable deflection is small, the stiffening system must be heavy. The trusses are usually suspended from the cables by hangers or suspenders, which are wire rope or rods attached to the trusses at their panel points. These trusses may be continuous from anchorage to anchorage, may extend unbroken from tower to tower only or may extend from tower to tower with a hinge at the center and at each tower.

Stiffening Trusses without a Center Hinge. Under a uniformly distributed load covering the entire span there are no moments and shears in the truss. With a uniformly distributed live load extending from the left tower, A (Fig. 146) a distance x, the following approximate functions of this load exist. Upward pull on truss per unit of length is wx/l.

$$R_1 = \frac{1/2\,wx(l-x)}{l}, \qquad R_2 = -\frac{1/2\,wx(l-x)}{l}$$

The shear at any section distant z from A is

$$z < x, \qquad V = \frac{w}{2\,l}(xl - x^2 - 2\,zl + 2\,zx)$$

$$z > x, \qquad V = \frac{w}{2\,l}(-\,xl - x^2 + 2\,zx)$$

When $z = 0$, x, or l, $V = wx(l - x)/2\,l$, being positive at the towers A and B and negative at D. The **greatest shear** possible occurs when the half span is loaded, that is, when $x = l/2$ and maximum $V = 1/8\,wl$. This maximum shear occurs at the towers and at the center of span. The moment at any section distant z from A, (Fig. 146), is

$$z < x, \qquad M = \frac{wz}{2l}(xl - x^2 - zl + xz)$$

this moment being positive with a maximum $wx^2(l - x)/8\,l$ when $z = x/2$;

$$z > x, \qquad M = \frac{wx}{2l}(xl - zl - xz + z^2)$$

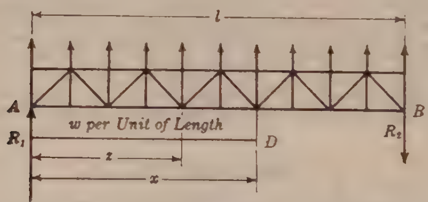

Fig. 146

and these are negative moments with a maximum value of $M = -wx(x - l)^2/8l$ when $z = (l + x)/2$. The **greatest positive moment** occurs at the center of the loaded part when the live load extends 2/3 across the span from A and is $M = wl^2/54$; the **greatest negative moment** has this same value at the center of the unloaded part when the load covers the left third of the span.

More Accurate Methods for Determining Stresses in cables and stiffening trusses make use of deflections; for example, with a stiffening truss without a center hinge the deflections of the cable and of the truss at any vertical section such as the center are equal. The **deflection of the cable** at the center of a span is approximately

$$d = \frac{w_1 l^2(3\,l^2 + 16\,h^2)}{128\,h^2AE}$$

And the deflection of the stiffening truss which is supported at the towers is

$$d = \frac{5}{384}\,\frac{w_2 l^4}{EI}$$

The ratio of the load borne by the cable to that borne by the truss is

$$\frac{w_1}{w_2} = \frac{5\,l^2h^2A}{3\,I(3\,l^2 + 16\,h^2)}$$

The total load $w_1 + w_2$ is here assumed to cover the entire span.

Stiffening Trusses Having a Center Hinge (Fig. 147). Shear but no moment can be transmitted across the hinge. For a uniform live load of w per unit of length maximum positive shear occurs at R_1 when the load extends from R_1 to $X = 1/3\, l$. Then $R_1 = wl/6$ and acts upward. The maximum negative shear has the same value and occurs at the same point when the load extends from $X = 1/3\, l$ to R_2. The maximum shear at the center hinge occurs when the load covers half the span, and is equal to $wl/8$. Maximum positive moment occurs at $x = 0.234\, l$ from R_1 when the load extends from R_1 to $X = 0.395\, l$, and is equal to $0.019\, wl^2$. Maximum negative moment occurs at the same point and has the same value, $0.019\, wl^2$ when the load covers the remaining portion of the span. When the load covers the entire span the cable takes the entire load and the stiffening truss is without stress.

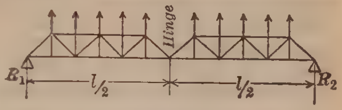

Fig. 147

Trussed or Stiffened Cables are also used to prevent excessive deformation of the cables, the stiffening trusses being omitted. The cables are made

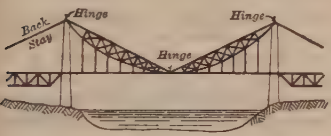

Fig. 148

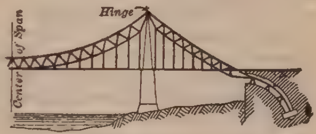

Fig. 149

of eyebars or links, and serve as members of the trusses from which the roadway is suspended as in Figs. 148 and 149. These structures are inverted arches, the first being three-hinged and the second two-hinged.

48. Stays and Anchorages

A Back Stay is that portion of the main cable which extends from the anchorage to the top of the tower. It may be a continuation of the main cable, as is usual, or it may be a separate member, in which case the main cable extends from tower to tower only. That part of the roadway under the back stay is sometimes suspended from the back stay as in the Manhattan and Brooklyn bridges, or it may be carried on separate trusses as in the old (now replaced) Point bridge in Pittsburgh, Pa., or on the stiffening trusses as in the Williamsburgh bridge. When the main cable passes over a movable saddle on the tower the maximum horizontal components of the stresses in the main cable and back stay are equal, and the maximum stresses are equal if the two parts are inclined at equal angles. The friction between the saddle and the tower produces a horizontal force on the tower equal to the vertical weight on the saddle times the coefficient of friction of the roller bearing. It has been found by experience that this friction is often great enough to prevent horizontal motion of the saddle. Stresses and deflections are then set up in the towers for which they were not designed. In several of the most recent bridges the cables are fixed to the top of the steel towers, which deflect horizontally under the unbalanced pull of the cables (from temperature and loading). With the Bear Mountain and Delaware River bridges the base of the tower is fixed and the top deflects elastically. With the Florianopolis bridge the base of the tower is hinged and the tower rocks about this hinge.

Anchorages for the back stays are provided by attaching them to eyebar chains and girders or castings which are set in masonry at each end of the bridge. The chain of eyebars may be inclined in a straight line or in a series of broken lines, and they may be placed in an inspection tunnel as in the Williamsburgh bridge or may be completely embedded in concrete. The eyebars of the anchor chains in the Point bridge in Pittsburgh were embedded in a poor quality of masonry, and when examined after 27 years of service were found to be in good condition except that they were pitted considerably for 5 or 6 ft. near the surface of the ground.

Hangers or Suspenders are vertical wire cables or members built of structural shapes which connect the stiffening trusses to the main cables. When the main cables are made of wire the suspenders are also of wire rope, as in the Manhattan bridge, where the suspenders consist of four wire ropes 1-3/4 in. in diameter at each panel point of each stiffening truss, that is, two loops over the main cable. These ropes rest in two grooves in the cast-steel cable bands which clasp the main cables, and the stiffening trusses are suspended from their lower ends. In the Budapest suspension bridge the cables are made of links of eyebars connected by pins, and the stiffening trusses are suspended from these chain cables by suspenders consisting of two channels. **Stay-cables** are inclined cables extending from the tops of the towers to the stiffening trusses, where they are attached at the suspender connections. They were used in the main and side spans of the Brooklyn bridge and in the main span of Roebling's bridge at Niagara Falls, but in recent suspension bridges they have not been used.

Saddles are castings resting on the top of the towers to support the main cables at these points. They usually consist of a steel casting on each tower, and each cable is laid in a groove in the casting, the groove and cable being covered with a cast or rolled steel cover. In the Manhattan bridge the tower saddles are rigidly connected to the towers, whereas in the Williamsburgh bridge each saddle rests on a nest of forty cylindrical steel rollers each 2-1/4 in. in diameter and 7 ft. 6 in. long. In the latter bridge each saddle is in one piece, weighs about 72 000 lb. and is 7 ft. 8 in. wide and 19 ft. long. The chain cables of the Budapest bridge are connected to the tops of the steel towers by links and pins and the towers are hinged at their bases.

Piers. There are usually two piers in a suspension bridge, one at either shore. They may be either of masonry or of steel. Masonry gives a better appearance, but is more costly and takes up greater space. A steel towers or pier may be a single bent of two supports hinged at the bottom or a framed tower with four or more supports. The forces on the pier depend on the arrangement of the cables. It was proposed by Morison, Trans. Am. Soc. C. E., Dec., 1896, to connect the cable of the main span and the back stay of the end span in two separate sockets at the top of the tower. In this case there would at times be great inequalities in the horizontal components of the stresses in the main cable and the back stay, and provision would have to be made for these differences in the design of the pier. When saddles on rollers are used to support the cables the maximum longitudinal force which can act on the top of a tower may be taken approximately at 1/100 the total load on the rollers. This assumes the rollers to be in good condition and free from excessive rust. The horizontal force in this case acts just before and until the rollers move. The movement equalizes the horizontal components of the stresses on the two sides of the saddle and the pressure is then vertical on the pier, except in so far as wind pressure and cradling of the cables produce horizontal forces.

MISCELLANEOUS STRUCTURES

49. Viaducts

A Viaduct is a bridge consisting of a series of spans supported on towers, the spans being usually plate girders, though sometimes trusses are used. Viaducts are used to carry railroads or highways over valleys or rivers. They are also called trestles. Each tower usually has four legs or columns, although six or two may be used. When two are used they are connected by transverse bracing only, thus forming a **rocker tower**; and when four or more legs are

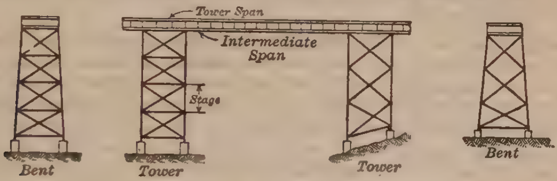

Fig. 150. Viaduct Towers

used in one tower they are connected by transverse and longitudinal bracing. A **stage** or story in a tower is that portion of the tower between the level of one horizontal brace and the level of the one above it. Fig. 150 shows the two usual types of viaduct towers.

Length of Span. For a given viaduct the tower span is usually made constant, 30 ft. for low and 45 ft. for high structures being common. The intermediate spans should increase in length as the heights of the adjacent towers increase, but to simplify construction not more than two or three different lengths should be used in any one structure. The intermediate span should be approximately twice as long as the tower span, 60 ft. for intermediate spans being common practice for ordinary viaducts. The Boone viaduct has alternate spans of 75 and 45 ft. throughout its length except

High Railroad Viaducts

Viaduct	Railroad	Length, Ft.	Maximum height, Ft.	Number of tracks	Weight of metal, Short Tons	Tower spans, Ft.	Ordinary intermediate spans, Ft.

Snake River	Ore. Wash. & Nav.	3920	300	1	8100	60	80

* Burmah. † Chile.

for the 300-ft. truss span near the center. In the Gokteik structure all tower spans are 40 ft., with intermediate truss spans of 120 ft., except those near the ends, which are plate girder spans of 60 ft. The girders may all be of the same depth, even though the spans are of various lengths as in the Boone viaduct or of different depths as in the second Kinzua viaduct built in 1900. The length of the tower span should be sufficient to prevent an upward pull on the anchorages due to traction.

Lateral Stability. A tower consisting of two transverse vertical bents has in each bent two inclined columns which are connected by bracing. The width of the bent at the top varies from 8 to 11 ft. for single-track railroad structures, and the two lines of girders are usually spaced the same distance apart as the columns. The double-track Boone viaduct has four lines of girders spaced with three equal spaces of 6.5 ft., and the outer girders are vertically over the tops of the columns. The batter of columns is frequently made such that the width of the bent at the bottom is sufficient to prevent an upward pull on the foundation when the structure is loaded with the lightest vertical load consistent with the greatest wind pressure. The batter varies from 1.5 to 3 in. per foot.

Bracing. The main girders should be connected together with transverse sway frames and with top and bottom horizontal lateral bracing. The diagonals and horizontal members of the transverse and of the longitudinal bracing of the towers may be made of latticed angles or channels connected to the tower legs with gusset plates which are usually shop-riveted to the columns. Rods and adjustable members should not be used for laterals. The second Kinzua viaduct has ordinary longitudinal bracing, but the transverse bracing in the bents consists of horizontal portal girders at intervals of about 30 ft. without any diagonals.

Connections of Longitudinal Girders to the bents are usually made in single-tract viaducts by resting them directly upon the horizontal caps of the inclined columns, although in some cases, the second Kinzua viaduct for example, the tower and intermediate span girders are riveted to the vertical faces of the columns, except at expansion joints, where one end of the intermediate girder rests in an expansion bearing or pocket which is attached to the vertical side of the column. The expansion joints in this structure are from 199 to 260 ft. apart. The longitudinal girders may be connected to a transverse girder which is riveted between the columns of each bent. Fig. 151

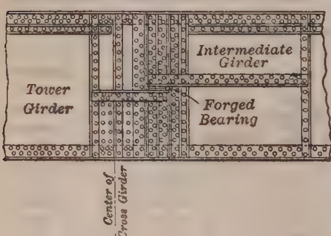

Fig. 151

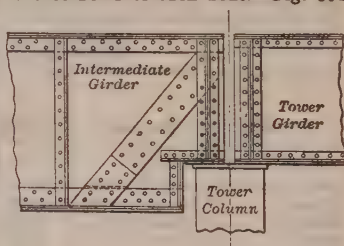

Fig. 152

shows the design used in the Boone viaduct where the tower girders rest upon the upper flanges of transverse girders and are notched to receive the ends of the intermediate girders which have drop ends. The tower and intermediate girders here have a uniform depth of 7 ft. A forged-steel bearing between the lower and upper girders allows for deflection and temperature displacements. In Fig. 152 is shown another form of drop end where the girders have different depths.

Column Bases. In high towers provision should be made for expansion at the bottom of the towers in a direction at right angles to the length of the viaduct. In the Boone viaduct this is accomplished by bolting the base of one column in a bent to the cast pedestal which is anchored to the masonry, while the other column in the same bent has slotted holes for the anchor bolts in its base so that it may move on a phosphor-bronze sliding plate which is inserted between column base and pedestal. The Kinzua viaduct has a nest of rollers under one column in each bent.

Live Loads. **First Kinzua** viaduct was designed and built in 1882 for locomotives weighing 161 340 lb. on a wheel base of 54.25 ft.; maximum wind pressure 30 lb. per sq. ft. **Second Kinzua**: built in 1900; two locomotives each of 274 000 lb. followed by 4000 lb. per linear foot; longitudinal traction of 0.2 of the maximum live load; temperature stresses due to 150° variation; wind pressure for the loaded structure of 30 lb. per square foot of vertical surface of train, floor and girders and 100 lb. per vertical foot of bent, and for the unloaded structure 50 lb. per square foot of vertical surface of floor and girders and 160 lb. per vertical foot of bent. **Boone** viaduct: built 1900–01; 75-ft. spans, 6100 lb. live and 1400 lb. dead per linear foot; 45-ft. spans, 7600 lb. live and 1250 lb. dead per linear foot. **Fort Dodge** viaduct: two locomotives each of 308 000 lb. followed by 4000 lb. per linear foot.

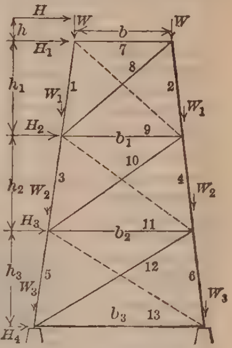

Fig. 153

Stresses in Towers due to vertical loads. The vertical loads consist of the weights of the locomotives and train, and the dead loads. In Fig. 153 let W be the total live and dead load acting at the top of each post and W_1, W_2, and W_3 the dead loads at the joints. Stress in bar 1 is designated by P_1 and so on. θ is angle between any bar and the vertical.

$$P_1 = P_2 = W \sec\theta \qquad P_3 = P_4 = (W + W_1)\sec\theta$$
$$P_5 = P_6 = (W + W_1 + W_2)\sec\theta$$
$$P_7 = W\tan\theta \qquad P_9 = W_1\tan\theta$$
$$P_{11} = W_2\tan\theta \qquad P_{13} = (W + W_1 + W_2)\tan\theta$$

The diagonals have no stress under vertical loading. All of the above stresses are compression except P_{13}.

Stresses in Towers Due to Wind. In Fig. 153 the horizontal forces shown are those due to wind, H being the wind pressure on the train and H_1, H_2, H_3 the pressures on the structure. + denotes tension, − compression. The diagonals are tension members and the dotted bars are not in action for the forces shown. The stresses are

$$P_1 = Hh\sec\theta/b$$
$$P_2 = -[H(h + h_1) + H_1h_1]\sec\theta/b_1$$
$$P_3 = [H(h + h_1) + H_1h_1]\sec\theta/b_1$$
$$P_4 = -[H(h + h_1 + h_2) + H_1(h_1 + h_2) + H_2h_2]\sec\theta/b_2$$
$$P_5 = -P_4$$
$$P_6 = -[H(h + h_1 + h_2 + h_3) + H_1(h_1 + h_2 + h_3) + H_2(h_2 + h_3) + H_3h_3]\sec\theta/b_3$$

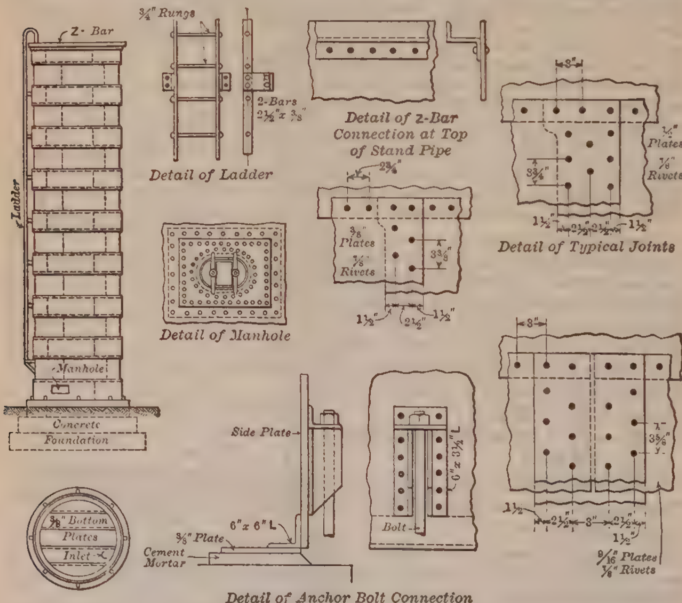
For the horizontal and diagonal members the stresses are most easily found by taking moments about the origin, which is at the intersection of the columns produced. The stresses due to traction and temperature should be found.

50. Standpipes

Notation. H = height in feet from a point to surface of water in stand-pipe. D = internal diameter of stand-pipe in feet. t = thickness of side plate in inches. S =

allowable tensile unit stress in pounds per square inch. e = efficiency of vertical riveted joint. b = circumferential distance in inches between centers of anchor bolts. W = weight of metal in stand-pipe above a given horizontal joint in pounds. p = pitch of rivets in horizontal joint in inches. M = moment in foot-pounds of wind pressure at a horizontal joint. V = allowable stress on a rivet in pounds.

A Standpipe is a metallic tank, usually of cylindrical form, with a flat bottom resting directly upon a masonry or sand foundation and used for the storage of liquids, usually water or oil. For storing water standpipes vary in diameter from 12 to 30 ft. and in height from 35 to 100 ft., although there has



Detail of Anchor Bolt Connection

Fig. 154. Stand-pipe, with Details

been constructed a standpipe with a diameter of 150 ft. and a height of 20 ft. and also one with a diameter of 4 ft. and a height of 210 ft.; the latter being surrounded by a masonry tower. Standpipes for the storage of water should generally have no roofs in cold climates but in warm climates should be covered. One pipe may be used to serve as an inlet as well as an outlet and this may connect with the standpipe in the horizontal base plate or in the side near the base. Failures of standpipes have been caused by defective foundations, by wind or ice pressure, or by hydrostatic pressure. Fig. 154 shows details of stand-pipe construction.

The Thickness of Side Plates must be computed to withstand the tension due to water pressure, proper allowance being made for weakening of plates at the vertical seams or joints. Side plates less than 1/4 in. in thickness should not be used. The maximum thickness required seldom exceeds 1-1/8 in. Tension in side plates at a point H distance down from water surface = 2.6 HD per vertical linear inch, and the thickness of plate required at that depth for the sides of a cylindrical standpipe containing water is $t = 2.6HD/Se$, in which S should be taken at from 10 000 to 12 000 lb. per sq. in. for structural steel. The efficiency e depends on the design of the vertical joints, which should be so made as to develop an efficiency of from 60% to 75%. With a depth of water of 60 ft., an internal diameter of 18 ft., allowable tension of 12 000 lb. per sq. in., and efficiency of 66-2/3%, the thickness of plate required at that depth = 2.6 × 60 × 18/12 000 × .66-2/3 = .35 in., or practically 3/8 in.

Side Plates in cylindrical standpipes are arranged in horizontal rings or courses about 5 ft. deep, with adjacent courses of different diameters so that the courses lap over each other. Plates should be bent by cold-rolling, then punched and finally planed to a bevel along all edges for calking. Rivet holes in plates having thickness of 9/16 or less should be punched 1/16 in. larger than the diameter of the cold rivet; those in 5/8 to 3/4 in. inclusive should be sub-punched 3/16 in. less in diameter than the cold rivet and then reamed to 1/16 in. larger than the rivet; those in plates over 3/4 in. in thickness should be drilled 1/16 in. larger than the rivet. Plates should be open-hearth "structural" steel and rivets of "rivet" steel or wrought iron.

Bottom Plates for flat-bottom standpipes should be not less than 5/16 in. in thickness when laid on concrete foundations; when laid on sand as in the case of oil-tanks of large diameters bottom plates are frequently made 1/4 in. If on a concrete foundation they should be completely riveted and then laid on a 2-in. layer of portland cement mortar before the mortar hardens, or else they should be bedded by pouring cement grout through 1-1/2-in. temporary iron pipes screwed into holes in the plates, the pipes being replaced with screw plugs. Side and bottom plates are connected by one or two ∟'s having beveled edges for calking. When only one ∟ is used its thickness should be approximately equal to that of the lowest side plate.

A Steel Ladder, extending from the top to within 8 or 9 ft. of the ground should be attached to the outside of the standpipe. The rungs may be made 15 in. long, 3/4 in. in diameter, from 12 to 14 in. apart and attached to two vertical bars 2-1/2 in. by 3/8 in. A manhole is necessary near the bottom, the side plates being reinforced around this opening by plates or steel forgings. Openings for supply pipes, whether in the bottom or side, must be similarly reinforced.

Wind Pressure may generally be taken at 30 lb. per sq. ft. on vertical surfaces, except in the most exposed locations, where 40 lb. per sq. ft. should be used. On a cylindrical surface it should be taken as 2/3 that on a plane surface equal to the diameter of cylinder multiplied by its height, and this pressure is assumed to act horizontally in any direction. Unless anchored to the foundation an empty standpipe will overturn when the overturning moment of wind pressure taken about the base, that is, 10 H^2D ft.-lb. for above pressure of 30 lb. per sq. ft., is greater than the moment of the weight of the empty standpipe taken about the outer edge of the base. **Anchor bolts** should always be used and should be computed for a tensile unit stress of not more than 15 000 lb. per sq. in.; minimum diameter 1-1/4 in., and they should be attached to anchor plates embedded in the foundation at sufficient depth to take at least 1-1/2 times the computed tension in the bolts. Maximum tension in the anchor bolts may be found by regarding the standpipe as a cantilever subjected to the overturning moment of the wind and the righting moment of the weight of the empty tank, about the neutral axis. This neutral axis can best be found by trial. On its windward side all of the tension is taken by the bolts; on its leeward side all of the compression is taken by the portion of the base plate immediately under the edge of the tank. It is assumed that the anchor bolt nuts are just brought to a bearing.

In Fig. 155, N–A is the neutral axis taken close to the leeward edge. A_B = area of bolts on the right of N–A; A_T = area of base angle on the left of N–A,

$A = A_B + A_T$, G–G = axis through center of gravity of the two areas A_B and A_T; c_1 and c_2 = distances from G–G to extreme points in tension and compression respectively; g = distance from G–G to the center of the tank; I = moment of inertia of A, the section under stress, about G–G; S_B = maximum unit tension at extreme point on the windward side; S_c = maximum unit compression at extreme point on the leeward side. $\mathbf{S_B = \frac{(M - Wg)c_1}{I} - \frac{W}{A}}$. $\mathbf{S_c = \frac{(M - Wg)c_2}{I} + \frac{W}{A}}$. If all dimensions are taken in feet, S_B and S_c will be pounds per square feet. By proportion, from the extreme fiber stresses S_B and S_c, the correct position of the neutral axis can be found. If it does not agree with the trial one a new position of the line N–A should be taken and the process repeated until the assumed and the computed positions of N–A agree closely. S_B may be found with sufficient accuracy by assuming the gravity axis G–G to coincide with the tangent G'–G' at the inner edge of the rim circle, and I to be the moment of inertia of the bolt areas about G'–G' = sum of the products of the areas of the bolts into the square of their distances to G'–G'. The W/A term, being small, may be neglected. If included, $A = A_B +$ the bearing area of about 1/8 of the rim base angle. Then $\mathbf{S_B = (M - Wr)D/I}$, where $r = D/2$.

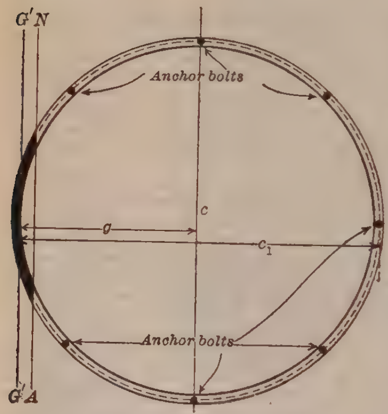


Fig. 155. Section at Base of Tank

For example, let H = 80 ft.; D = 20 ft.; W = 75 000 lb.; wind = 30 lb. per sq. ft. $M = 2/3 \times 20 \times 80 \times 30 \times 40 = 1\,280\,000$ ft-lb. $Wr = 75\,000 \times 10 = 750\,000$. $M - Wr = 530\,000$ ft-lb. Assume eight 1-1/4-in. anchor bolts upset to 1-5/8 in. Area of each bolt = 1.227 sq. in. = .00854 sq. ft. $I = 2 \times 0.00854\,(1/2 \times 2^2 + 1.7^2 + 1^2 + 0.3^2)\,10^2 = 10.2$. Neglecting W/A, $S_B = 530\,000 \times 20/10.2 = 1\,040\,000$ lb. per sq. ft. = 7230 lb. per sq. in. The area of 1/8 of the rim bearing, assuming the effective bearing width of base angle to be 3 in. = 282.6 sq. in. $A = 1.227 \times 7 + 282.6 = 291.2$ sq. in. $W/A = 75\,000/291.2 = 260$ lb. per sq. in. Including W/A $S_B = 7230 - 260 = 6970$ lb. per sq. in. Total stress S in extreme windward bolt = $6970 \times 1.227 = 8550$ lb. The total tension in the bolts from $M - Wr = 2 \times 7230 \times 1.227\,(1/2 \times 20 + 17 + 10 + 3)/20 = 35\,500$ lb. The average compression over 1/8 the area of the rim from $M - Wr = 35\,500/282.6 = 125$ lb. Approximate average compression on the masonry $= 260 + 125 = 385$ lb. per sq. in. The actual maximum on outer edge of angle is slightly greater than this but well within the safe bearing strength of the concrete. Assume it to be 500 lb. By proportion the neutral axis lies $500 \times 20/(6970 + 500) = 1.4$ ft. from the tangent $G'-G'$. The assumed position $N-A$ was 0.8 ft. from $G'-G'$, indicating that a small portion only of the rim circle takes all of the compression and justifying the approximate assumptions made.

The Pitch of Rivets connecting the base angle to the rim of the tank should also be computed. Assuming the maximum compression to be 500 lb. per sq. in., the compression per lineal inch of angle $= 500 \times 3 = 1500$ lb. Safe single shearing strength of a 3/4-in. rivet = 4400. $p = \frac{4400}{1500} = 3$ in.

Anchor bolts must be connected to the sides, not to the bottom plate of the structure. To prevent buckling of the side plates under wind pressure a ⊏ or a heavy ∟ must be riveted around the upper edge. In addition ∟'s are sometimes riveted circumferentially on the outside at different elevations.

The Stress on a Rivet in a horizontal joint in pounds due to the weight of the standpipe above that joint = $0.027\ pW/D$; and due to wind pressure acting on the cylindrical surface above the joint = $0.106\ pM/D^2$. With a pressure of 30 lb. per sq. ft. this stress on a rivet due to wind becomes $1.06\ pH^2/D$. Or the pitch of these rivets in inches required to withstand the combined stresses due to weight and wind = $DV/(.027\ W + 1.06\ H^2)$. The stresses due to ice are indeterminate. All joints must be calked after riveting.

Allowable stresses per square inch on steel field rivets: shearing 9000, bearing 18 000. For 1/4-in. plates 5/8-in. rivets should be used; for 5/16-in. plates, 3/4-in. rivets; for 3/8 to 7/8-in. plates, 7/8-in. rivets; for 15/16 to 1-1/8-in. plates, 1-in. rivets. For horizontal joints use lap-joints, usually single riveted. For vertical joints use double-riveted lap-joints for 1/4, 5/16 and 3/8-in. plates; triple-riveted lap-joints for 7/16 and 1/2-in. plates; double-riveted butt-joints for 9/16 to 3/4-in. plates inclusive; triple-riveted butt-joints for 13/16 to 1-in. plates inclusive.

51. Water Tanks on Towers

Notation. W_1 = weight of water in pounds vertically above and below a horizontal section together with the weight of the conical or hemispherical bottom below the section. W = weight of water in pounds in the tank together with the weight of bottom. θ = angle between element of conical bottom, or between tangent to spherical bottom, and horizontal. D = diameter of cylindrical portion of tank in feet. d = diameter of a horizontal joint in a conical bottom in feet. h = distance in feet from surface of water to any point in a radial joint of a conical bottom. l = unsupported length and r = least radius of gyration of cross-section of column, both in inches. M = moment at a horizontal plane due to wind pressure on structure above that plane. r_1 = radius of circle passing through column centers.

A Water Tank on a Tower consists of a steel tank, usually cylindrical, supported on a steel tower which may have four or more columns connected to the tank at or near the bottom and connected to each other by horizontal and diagonal braces. The bottom of the tank may be flat, conical or hemispherical; the latter is the best and is riveted directly to the lowest cylindrical side plates at intersection of center line of column with side plate. Elevated tanks are more economical and of more pleasing appearance that standpipes. Ice pressure causes fewer failures of elevated tanks than of standpipes, and the tanks are usually covered with conical or curved roofs. Fig. 156 shows typical details of construction of a water tank and tower. The cylindrical part is similar in action to the corresponding portion of a standpipe.

The Riser or Inlet Pipe is the supply pipe, which usually also serves as an outlet; enters the tank at the center of the bottom, at which place the tank must be reinforced. An **expansion joint** is placed in the riser at or near the junction with the tank. Risers should be braced laterally at each panel point of the tower and in cold climates should be covered with a **frost-proof casing** consisting of three thicknesses of planking and two of tarred paper with air spaces between the thicknesses of planking.

A Conical Roof made of 1/8-in. sheet steel is self-supporting for diameters of 20 ft. or less if the roof plates are riveted to the upper edge of the top side plate; for diameters greater than 20 ft. ∟ rafters must be used. Iron ladders extend from a trap-door in the lower part of the roof down the outside and inside of the tank, ending on the balcony on the outside. Another ladder, attached to one of the tower columns, should run from the balcony to within 8 or 9 ft. of the ground. The balcony should be

3 ft. wide and its floor should be a horizontal plate girder placed at intersection of bottom and side plates.

Conical Bottoms. Tension in pounds per linear inch of any horizontal joint or section $= \dfrac{0.0265\ W_1}{d \sin \theta}$; at intersection of bottom and side plates this tension becomes $0.0265\ W/D \sin \theta$. Tension at any point of a radial joint

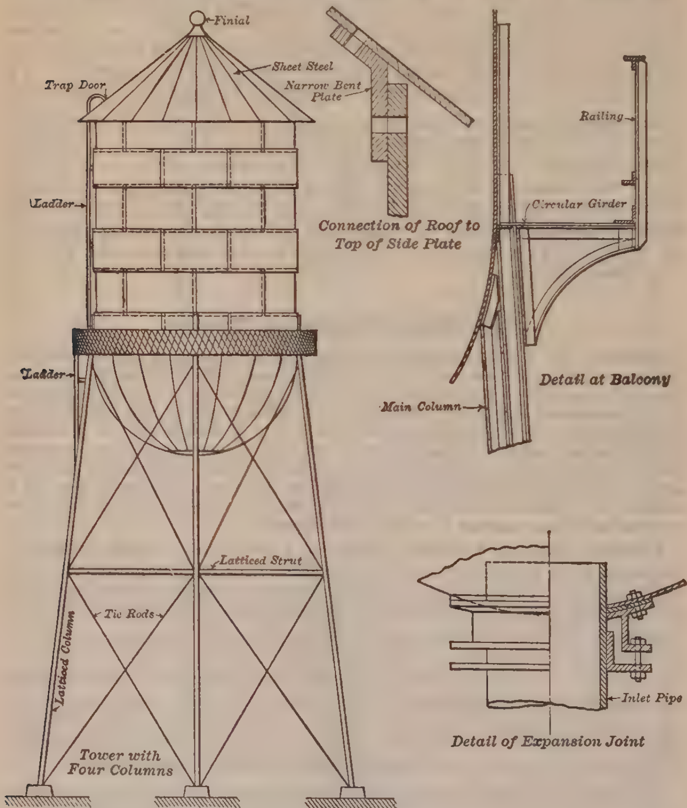

Fig. 156. Water Tank on a Tower

in pounds per linear inch, that is, of a joint coinciding with an element of cone $= \dfrac{2.6\ dh}{\sin \theta}$. A horizontal outside girder must be used at the intersection of side plates with the bottom to resist the annular compression caused by the inward pull from the bottom. Horizontal component of inward pull from bottom $= 0.0265\ W/D \tan \theta$ pounds per circumferential inch; annular compression $= 0.0132\ W/\tan \theta$; and vertical component $= 0.0265\ W/D$ pounds per circumferential inch. This vertical component is resisted by a vertical circular girder.

Spherical Bottoms. Tension in pounds per linear inch of any horizontal joint or section $= \dfrac{0.0265\ W_1}{D \sin^2 \theta}$. The spherical bottom exerts only a vertical pull on the cylindrical side, amounting to 0.0265 W/D pounds per circumferential inch. Best design requires the thickness of spherical bottoms to be equal to that of the lowest side plate in the cylindrical part. The cylindrical side plates must be reinforced at column connections.

Allowable Unit Stresses in pounds per square inch. Tension: in tank plates, 12 000; other parts, 16 000. Compression, 16 000 − 70 l/r; the ratio l/r should in no case exceed 120. Shear: on field rivets in tank, and bolts, 9000; on shop rivets and pins, 12 000. Bearing: field rivets in tank, and bolts, 18 000; shop rivets and pins, 24 000. Bending in pins, 24 000. For combined wind and other loads the above unit stresses may be increased 25%. All steel except rivets to be of "structural" grade; rivets of "rivet" steel.

Stresses in Columns are due to weight of structure, weight of water in tank, and overturning effect of the wind. The vertical component of stress in any column due to the first two forces is equal to the total weight divided by the number of columns.

52. Coal, Ore, and Grain Bins

A Steel Bin consists of a tank supported on columns and is used for handling or storing materials such as coal, ashes, ore, broken stone, sand and grain. Bins for coal, ashes or other similar materials are usually shallow, and admit of a variety of designs, while grain bins are deep and of cylindrical form. There are three types of bins, the hopper bin, the suspension bin or bunker and the cylindrical bin. For handling coal and ore the construction is such that these materials are dumped into the top of the bins from cars, or conveyors above and when needed are taken from the bottom or side by means of gates and chutes.

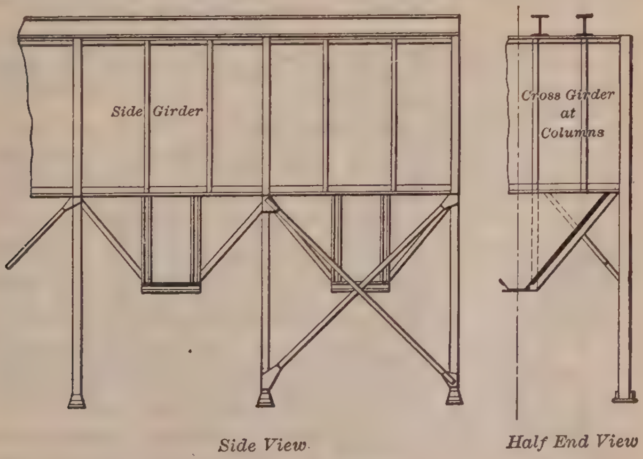

Fig. 157. Hopper Bin

Hopper Bins (Fig. 157) are generally arranged in units, each unit consisting of a square or rectangular box with four vertical sides and having an

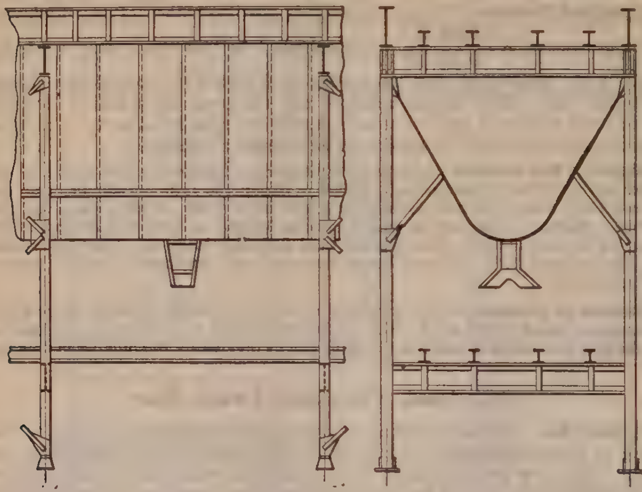

Fig. 158. Suspension Bin.

inverted frustum of a pyramid for a bottom. This bin is mounted on columns, which may be braced longitudinally with diagonal bracing, and transversely with knee-braces or diagonals. The gate through which the bin is emptied is placed at the bottom of each hopper, and the inclination of the sides of the hopper should be such that the bin can be emptied by gravity alone.

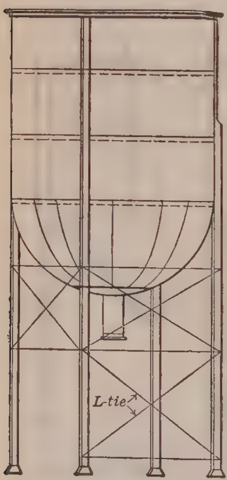

Fig. 159

Suspension Bins (Fig. 158) are steel bunkers supported on steel columns, the bunker being made of plates suspended from two parallel girders which are supported by the columns. The plates are subjected to tension only, and the side girders should be placed with their webs in the plane of this tension, or if placed vertically some provision must be made for resisting the horizontal component of pull from the plates. The ends of the bunker are made of plates stiffened by I beams or ∟'s. To protect the steel against action of materials stored in the bunker, the inside is covered with a layer of concrete reinforced with expanded metal or other similar fabric.

Circular Bins (Fig. 159) are cylindrical, with hemispherical bottoms, and with supporting columns riveted to the cylinder at the junction of the hemisphere. They are used principally for the storage or handling of ore, the outlet gate being placed at the center of the bottom. The construction is similar to that of water tanks on towers, except that the columns are vertical, and no balcony, with its accompanying horizontal circular girder, is necessary.

Steel Grain Bins are usually cylindrical, with either flat or hemispherical bottoms, and for large grain elevators are arranged in groups. The Great Northern elevator at Buffalo, N. Y., has thirty bins 38 ft. in diameter and 85 ft. deep set in three rows of ten bins each, and between these are eighteen smaller ones each 15.5 ft. in diameter arranged in two rows. All of these have hemispherical bottoms tapering into cones and are supported on circular girders resting on columns.

Weight and Angle of Repose of Dry Materials

Material	Weight, lb. per cu. ft.	Angle of repose, degrees	Material	Weight, lb. per cu. ft.	Angle of repose, degrees
Anthracite coal. .	52	27	Wheat.	50	28
Bituminous coal.	47 to 55	35	Barley.	39	27
Ashes.	40	40	Oats.	28	28
Sand.	90 to 115	34	Corn.	44	28

53. Catenary Bridges

A Catenary Bridge, (Fig. 160), is a light truss bridge which crosses the track of an electrified railroad, and the main function of which is to support an overhead wire over the center of each track. It is supported at the sides of the outside tracks, and occasionally at an intermediate point when many tracks have to be crossed, by latticed posts or towers to which it is securely riveted. The end towers extend above the bridge to support cross arms which carry the feed, signal and grounding wires.

The trolley wire is supported by a system of suspension cables, called the **catenary**, which carries the weight of the trolley and maintains the latter in a plane parallel to the tracks. The types of catenaries and their supporting bridges described in this article are those in use on the N. Y., N. H. & H. R. R. The two systems of catenaries are known as the single and the compound. The single consists of a main **messenger cable** which supports, by hangers and clips, the trolley or contact wires. The latter consists of two wires, the top one of copper (to secure proper conductivity), the bottom one of steel for contact purposes, it having been found that copper wire is too rapidly abraded. The copper feeds the steel wire at intervals of ten feet. The entire system is alive and is suspended below the bridges from which it is insulated. The advantages of this system are its lightness, ease of erection and permanency of position on curves. It weighs about 1200 lb. per track for spans of 280 to 300 ft. between bridges. The disadvantage is the non-protection of the track wire, in electrical storms, by an overhead wire. The compound system consists of a main messenger cable, supported by saddles on top of the bridges, Fig. 160, from which, at the quarter points of the cable span, is supported and insulated from it a single catenary system. In this type the main cable is dead. The advantage of this system is the protection afforded by the main cable by being grounded where it passes over each bridge. The disadvantages are its weight, which is about 2400 lb. per track for spans of 300 ft., the additional cost of erection,

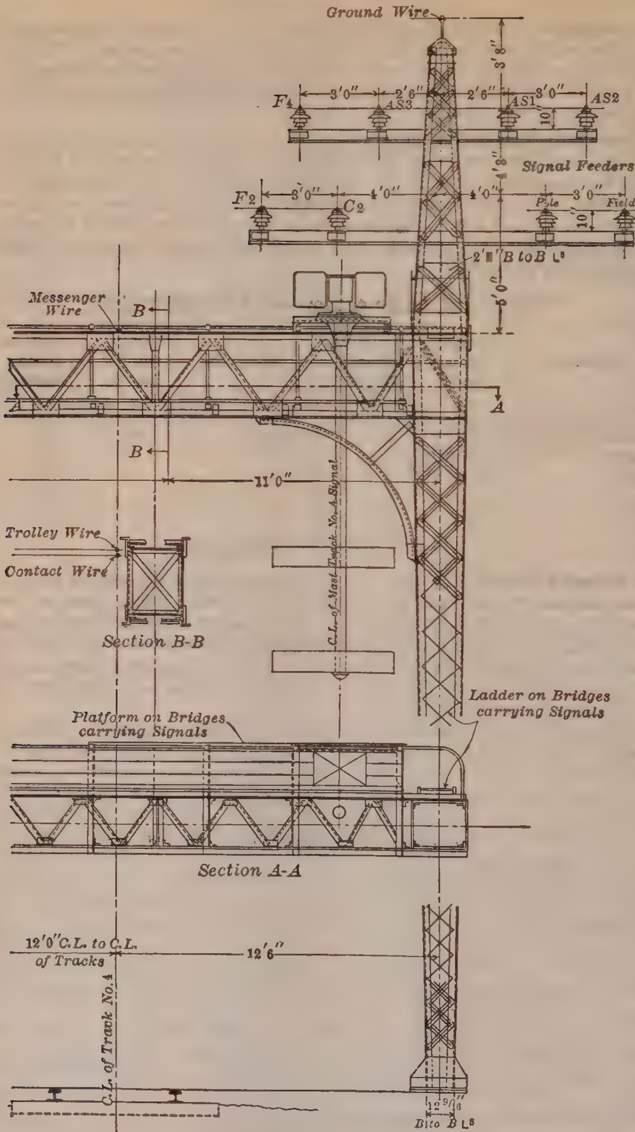

Fig. 160. One End and Tower, Four-track Catenary Bridge

the effect of temperature in changing alignment on curves, and the greater maintenance cost.

The Economical Spacing of the bridges on the New Haven road is from 150 to 315 ft. In addition to carrying the catenary system a secondary function of the catenary bridges is to support signals where they are required by the necessities of the block system sidings, bridges, etc., and the platforms needed for the maintenance of the signals. Visibility requires that the signals should project downward and frequent changes in tracks, location of cross-overs, etc., necessitating the relocation of signals make it advisable to design each bridge with sufficient strength to carry the signal loadings. The approximate weight of one automatic signal and its platform is 2400 lb.

The Loads for which the bridges are designed are (1) a signal over each track, (2) the vertical and horizontal loads from the catenary over each track, (3) the weight of the bridge, (4) the vertical and horizontal loads from the feed, signal and grounding wires on each cross arm, (5) the wind on the bridge surface, acting either along the track or laterally, and (6) the wind acting laterally upon the wires regarded either as bare or covered with ice.

The Catenaries are strung at definite tensions which depend upon the sag and accordingly vary with the temperature (Art. 46). When the catenaries are taken around curves the messenger cable is pulled away from the track in order to maintain the trolley wire over the center line. The catenary then lies in an inclined surface and the hangers resist the tendency of the trolley wire to straighten out. The lateral force required to maintain this condition is the **curve pull** which has to be supported by the catenary bridge as a horizontal load. The curve pull is very approximately equal to the cable tension multiplied by the span length and divided by the radius of the curve. Wind is assumed at 30 lb. per sq. ft. on the full windward and half the leeward surfaces of bridges, and upon two-thirds the projected areas of all bare wires. It is taken at 8 lb. per sq. ft. upon two-thirds the projected areas of wires coated with 1/2 in. of ice all around. A higher wind does not permit the ice to form, or will break it off if already formed. The wind blowing across the tracks on the catenaries and cross-arm wires constitutes a lateral load upon the catenary bridges.

Stresses in trusses and towers of the usual two-post type may be found approximately by the method employed for mill-building bents (Art. 3). The towers may be regarded as hinged or as partially fixed at the base according to the degree of efficiency of the anchorage. Equal horizontal reactions may be assumed at the feet of the towers (or at the points of contraflexure when the feet are regarded as partially fixed).

The Allowable Unit Stresses adapted by the New Haven road are as follows: tension from vertical loads, 20 000 lb. per sq. in.; tension from combined wind and vertical loads, 25 000 lb. per sq. in.; compression from all conditions of loading, $21\,000 - 70\,l/r$. Open-hearth steel with an ultimate strength of 60 000 lb. per sq. in. is used.

54. Transmission Towers

(Much of the following Article has, with the permission of the American Bridge Company, been taken from its Handbook, Transmission Towers.)

Steel towers, bents and poles are used to support high-tension transmission lines. The spacing depends upon the strength of the cables and the topography of the country, and varies from 200 or 300 ft. to several thousand. The average span is 400 or 500 ft., but river crossings may be much longer. The longest span at present is that of the Cushman Project over the Narrows, near Seattle, Wash., which is 6240 ft. The highest towers are those of the Pacific Gas & Electric Co. at the Vaca-Contra-Costa Crossing near San Francisco, with a maximum height of 459 ft. from the ground. When topographical conditions permit, the span and sag are made such that the tension in the cables, under the worst conditions of dead load, minimum temperature, wind and ice coating, will be slightly below the elastic limit of the cables. The choice of cables, and consequent spacing and height of towers, is an economic problem depending for its solution upon many attendant conditions. Properties of solid and stranded cables made of copper, aluminum or aluminum reinforced with steel, and copper-clad steel wire are given in the handbooks of structural and wire companies.

Cables. The greater the ratio of sag to span the greater is the allowable span for a given cable. On the other hand, the greater will be the height of the towers and the absolute length of cable needed. The economic sag ratio is about 3 to 4%. For this small sag ratio the curve of the cable very closely approximates a parabola, and that assumption is generally made.

For supports on the same level, Fig. 161:

$$H = \frac{WL^2}{8S}, \quad S = \frac{WL^2}{8H} = \sqrt{\frac{(L_c - L)\,3L}{8}}, \quad L_c = L + \frac{8S^2}{3L}.$$

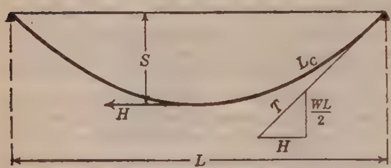

Fig. 161

L = span length in feet; L_c = cable length in feet; S = sag in feet; H = tension in cable at center of span; W = weight of cable in pounds per linear foot. With ice on the cable W = weight of cable plus weight of ice per linear foot. With horizontal wind on bare or ice-covered cable, W = square root of the sum of the squares of the vertical and horizontal loads. The Joint Committee of the National Electric Light Association recommends the following classes of loading on cables:

Class A. A horizontal wind load of 15 lb. per sq. ft. on projected area of bare cable, combined with its dead load.

Class B. A horizontal wind load of 8 lb. per sq. ft. on projected area of cable when covered with a coating of 1/2 in. of ice (total 1 in., plus diameter of wire), combined with the vertical load of cable and ice.

When severe sleet conditions may occur:

Class C. A horizontal wind load of 11 lb. per sq. ft. on projected area of cable when covered with a coating of 3/4 in. of ice (total 1-1/2 in. plus diameter of wire), combined with the vertical load of cable and ice. These wind loads are equivalent to about 60% of the actual normal pressure upon a flat diametral surface.

When the supports are at different levels, (Fig. 162), the actual weight of the cable WLc does not differ appreciably from WL_0, but may differ considerably from WL. To bring the parabolic formulas to the same degree of approximation as those for supports on the same level, the total load is taken as WL_0, making the average load per horizontal foot $= WL_0/L = W/\cos a$. The following formulas are based upon this assumption.

$$S_0 = WLL_0/8\,T = WL^2/8\,T \cos a$$
$$S_1 = WL_1^2/8\,H \qquad L_1/2 = L/2 - hH \cos a/WL$$
$$S_2 = WL_2^2/8\,H \qquad L_2/2 = L/2 + hH \cos a/WL$$
$$Lc = L + 4/3\,(S_1^2/L_1 + S_2^2/L_2).$$

Further, $S_0 = S$. That is, the normal sag of the inclined cable, loaded with $W/\cos a$ per horizontal foot, equals the vertical sag of a cable with the same horizontal span, with supports at the same level, and loaded with W pounds per horizontal foot.

The maximum tension occurs at the lowest temperature at which the maximum loading of ice and wind is possible, and this will vary with the locality. The maximum tension actually occurs, at the supports, but with such small sag ratios the error in using the more convenient center tension is negligible. Given the span, the maximum allowable tension in the cable, and the loading, the sag and length of cable can be found by the above formulas. For any other temperature or condition of loading the corresponding sag and cable length are most readily obtained from charts or it may quickly be computed by the method of successive approximations.

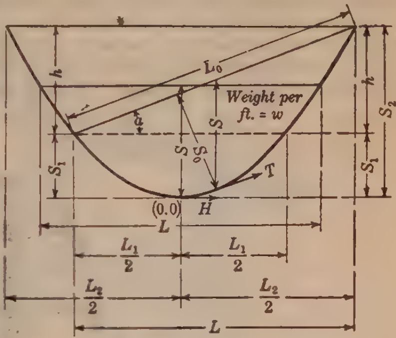

Fig. 162. Supports at Different Elevations.

Example. Span = 1000 ft.; diameter of cable = 0.63 in.; area of cable = 0.236 sq. in.; ultimate strength of cable = 14 154 lb.; maximum allowable tension = 7000 lb.; lowest temperature at which Class B loading may occur = 20° F. Find the sag, length and tension in the bare cable, without wind, at 120° F. Weight of bare cable = .93 lb. per lin. ft. Weight of 1/2 in. of ice = .64 lb. per lin. ft. Total vertical load = 1.57 lb. per lin. ft. Resultant load from dead weight, ice and horizontal wind = $\sqrt{(1.10^2) + (1.57)^2}$ = 1.90 lb. per lin. ft.

Sag at 20° = $1000^2 \times 1.90/8 \times 7000$ = 34 ft.

$Lc = 1000 + 8 \times 34^2/3000 = 1003.09$. Increase in length due to 100 degrees rise of temperature = $1000 \times .0000095 \times 100 = 0.95$ ft. Assume a decrease in tension at 120° of 3580 lb. due to increased sag and no ice or wind. Corresponding decrease in length = stress per square inch $\times$ length/E = $3580 \times 1000/.236 \times 16\,000\,000$ = 0.95 ft., where E = modulus of elasticity of the cable. Total length = 1003.09 + .95 − .95 = 1003.09 ft. Corresponding sag = $\sqrt{3.09 \times 3000/8}$ = 34 ft. Tension = $WL^2/8\,S = 1000^2 \times .93/8 \times 34 = 3420$ lb., which agrees with the assumed tension. It is merely a coincidence that, in this example, the lengths and sags, respectively, at the two temperatures are the same. The length and sag at any stringing temperature can be found in a similar manner.

Towers. Self-supporting towers with three or four legs, capable of resisting an unbalanced pull in the direction of the line from one or more conductors, as well as a transverse wind load from the wires, are generally used, although flexible bents and even steel latticed poles are sometimes employed on secondary lines. In the latter case self-supporting towers should be introduced frequently along the line.

Ordinary towers, (Fig.163), are called **suspension or line towers** when placed on tangents, or when the angle in the line does not exceed 5°, and **angle towers** when the angle is greater than 5°. The latter are designed for the same loads as the former with the addition of the transverse pull due to the angle in the line. **Dead-end** or **Anchor towers,** (Fig. 164), are designed to take the dead-end pulls from all of the cables on one side.

Loads. In addition to the weight of the tower itself, the insulators and the bare or ice-covered cables, the tower must be designed for the lateral pressure of the wind on tower and cables, and for an unbalanced pull in the direction of the line from the cables due to dead-ending, or to the breaking of one or two wires in one of the adjacent spans. The wind on the towers should be taken at 25 lb., or 13 lb. per sq. ft. on 1.5 times the projected area of one face, depending upon whether Class A or Class B loading is used for the cables. When the tower is at an angle in the line the transverse pull from all or part of the conductors must be included. The necessary combinations of possible simultaneous loadings should be considered.

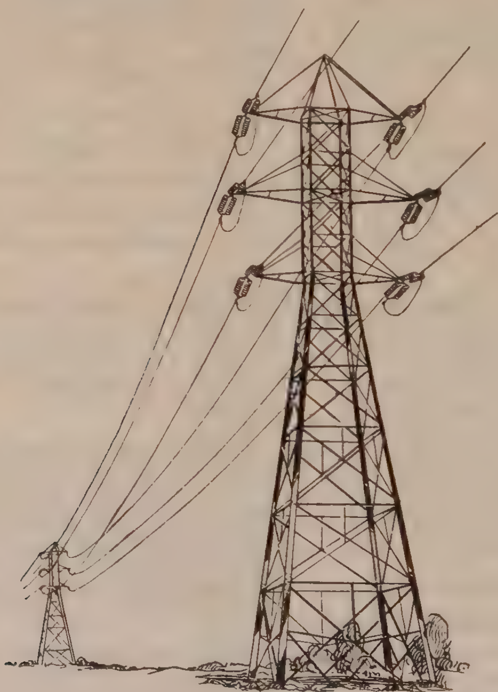

Fig. 163. Line Tower

Stresses. The towers should be made as simple in design as possible. The stresses in line or angle towers due to vertical and transverse loads will occasion no difficulty. The external forces are resolved into components lying in the planes of the faces and the stresses in each plane may be found either by graphical or analytic methods as in planar bents. At every change of slope of the faces the stresses in the preceding zone which act at the top joints of the new faces should likewise, together with the external forces at the same joints, be resolved into components lying in the planes of the new slope. The lower slope is then treated as a planar bent for the forces lying in its plane.

Provision should always be made for a possible unbalanced pull in the direction of the line, due to the dead-ending or breaking of one or more wires on one side of the tower. Such a pull will tend to twist the tower about its vertical axis and will create stresses in all of the faces. Fig. 165 is a standard

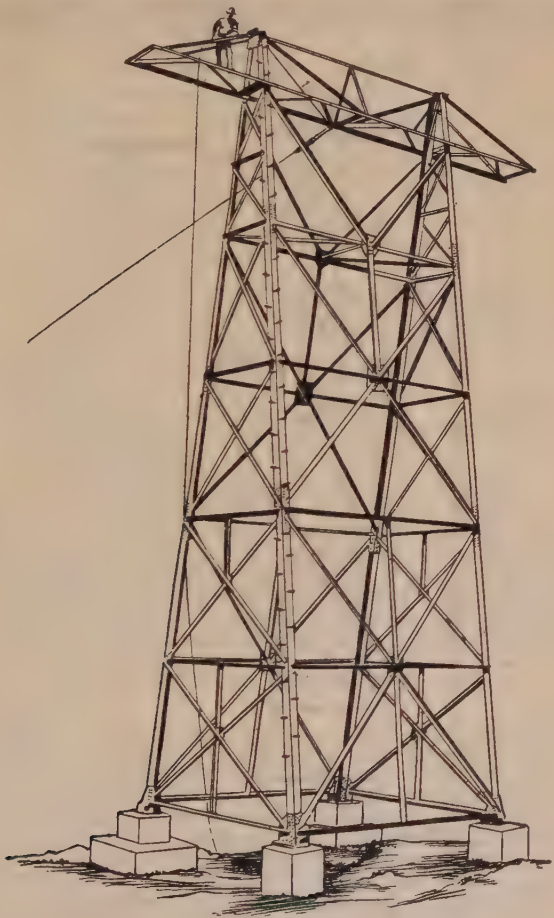

Fig. 164. Anchor Tower, River Crossing

four-legged, square, line or angle tower of the American Bridge Company. Assume an unbalanced horizontal pull P at one end of a cross arm (Fig. 165). There is created a torsion Pc about the vertical axis, and a longitudinal shear P at the center of the tower. The shear tends to overturn the tower longitudinally and may be replaced by two forces, each, $S = P/2$, acting in faces 1 and 3. If two diagonals, X, each capable of taking either compresssion or tension, be placed in the cross frame, $S/2$ will act at each corner of faces 1 and 3.

If the tower is square and all faces alike and equally rigid, the torsion Pc may be replaced by two equal couples, Tb, acting in the faces 1, 3, and 2, 4, respectively, or

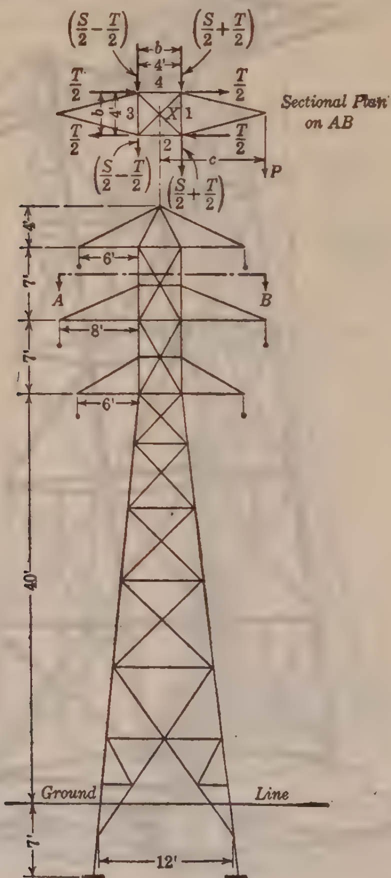

Fig. 165

$Pc = 2\ Tb$, $T = Pc/2\ b$. With two stiff diagonals X, $T/2$ will act at each corner of each face, all tending to rotate the tower about its vertical axis in the same direction as P. The stresses in the transverse faces 2 and 4 are then due to the two equal horizontal forces, $T/2$, applied in the plane of the cross frame at each corner. Similarly, the stresses in the longitudinal faces 1, 3, are due to a pair of horizontal forces, $S/2 + T/2$, and $S/2 - T/2$, respectively, likewise applied at the corners. The stresses in the columns due to these forces will be small, as they tend to neutralize each other in adjacent faces. The diagonal in the cross frame must transmit from face 1 to face 3 the total shear $S-T$. With two stiff diagonals in a square panel the stress in each is $0.7\ (S-T)$. A similar analysis should be made for every cross-frame bearing an unbalanced pull, P. If the tower is rectangular, or the faces are not equally rigid, the torsion is not resisted equally by each pair of faces, and the problem becomes indeterminate. An approximate assumption, however, may be made.

Unit Stresses. It is customary to use higher unit stresses for transmission towers than for bridges or buildings. The specifications of the American Bridge Company recommend:

For ordinary transmission towers:

Axial tension on net section....................20 000
(a) Axial compression on gross section (Max. 15 000)..20 000 − 85 l/r
(b) Axial compression on gross section...............15 500 − 55 l/r

Use (a) when l/r does not exceed 150.
Use (b) when l/r exceeds 150.

Shear on bolts or rivets........................13 500
Bearing on bolts or rivets......................27 000

l/r shall not exceed, for legs, 140; for all other members having calculated stress, 200; for members having nominal stress only, 250.

For river crossing, and other important structures:

(a) Axial compression on gross section (Max. 14 000)..18 000 − 80 l/r
(b) Axial compression on gross section...............13 500 − 50 l/r

Use (a) when l/r does not exceed 150.
Use (b) when l/r exceeds 150.

Shear on bolts or rivets........................12 000
Bearing on bolts or rivets......................24 000

Transmission towers are made relatively light. The bracing generally consists of single angles which are riveted or bolted directly to the tower legs. The latter are also either single angles, or very simple channel or angle sections, arranged so as to avoid latticing or expensive shop work. The same grade of steel and of workmanship should be used as for bridges. Towers are painted or galvanized, but the latter is preferable except for large towers and special structures where galvanizing is impracticable. When bolts are used for connecting galvanized members they should be "hot-dip" galvanized.

Anchors. The design of the foundations under the tower legs is an economic problem of great importance, requiring the best engineering judgment. In addition to the vertical loads, these foundations or anchors under the legs of the towers have to resist vertical uplift, and the horizontal shear from the unbalanced horizontal forces applied at the top of the tower. Anchors may be either of concrete, or of steel, or a combination of both. Concrete anchors may be either of the solid pedestal type, or a concrete slab buried several feet below the surface of the ground and connected therewith by a narrow concrete shaft. In the former case the tower rests on the top of the pedestal and is anchored thereto by long bolts that extend down nearly to the bottom. In the latter case the angle leg of the tower extends into the concrete slab, terminating at the bottom with angle lugs to give a good bond (Fig. 166). The angle leg is cut and spliced a little above the top of the concrete shaft, in order that the stub part may be set in the concrete when the latter is poured. If the projection of the slab beyond the shaft is more than its thickness steel reinforcing bars must be used.

Fig. 167 shows the all-steel anchor of the American Bridge Company. The vertical force and part of the horizontal is carried, by means of a stub angle, to a steel grillage. The bracing of the tower is attached to the stub angle at a point below the surface where sufficient earth resistance is met to take the major part of the horizontal force. If necessary to increase the resistance short channel lugs are bolted to the stub angle legs at this point. All-steel anchors should be galvanized for protection against corrosion. Sometimes, to insure further protection, the grillage and stub angles are embedded in concrete. Resistance of an anchor to uplift may be assumed equivalent to all of the weight contained in the inverted frustum of a pyramid whose base is the grillage and whose sides make an angle of 30° with the vertical. The weight of earth may be assumed at 90 lb. and that of the concrete at 140 lb. per cu. ft.

SECTION 13

HYDRAULICS, PUMPING, WATER POWER

BY

GARDNER S. WILLIAMS

FORMERLY PROFESSOR OF CIVIL, HYDRAULIC, AND SANITARY ENGINEERING IN UNIVERSITY OF MICHIGAN

PRINCIPLES OF HYDROMECHANICS

1. Definitions

Hydromechanics deals with the equilibrium and motion of fluids and of bodies in or surrounding them. **Fluids** are those bodies which offer very small resistance to deformation. **Liquids** are those fluids whose particles tend to cling together. **Gases** are those fluids whose particles tend to separate from each other.

Hydromechanics is divided into **Hydrostatics,** which treats of fluids at rest, and **Hydrodynamics,** which treats of fluids in motion. **Hydraulics** is that part of Hydrodynamics which treats of water in motion.

Pressure is the force with which one body presses or acts upon another. The pressure acting on any surface is understood to be the sum of all the normal pressures and normal components of pressures acting on that surface. **Intensity of pressure** at any point is the pressure exerted upon a unit area at that point.

Pressure Head, at any point in a fluid at rest, is the vertical distance of the point from the free surface of the fluid. $\mathbf{h = p/w}$, where h is the head, p is the pressure in pounds per square foot, and w is the weight per cubic foot of the fluid. A pressure of one pound per square inch is approximately equal to that of a column of water 2.31 ft. in height.

Velocity Head. If, through a small area, the velocity of a fluid is v feet per second, the velocity head is $\mathbf{v^2/2\,g}$, g being the acceleration due to gravity in feet per second per second.

Head of Elevation is the height of a point above any assumed datum. If any point is z ft. above any convenient datum level, the head of elevation at that point above the given datum is said to be z ft.

Friction Head is the head absorbed in a fluid in motion, among its own particles and between itself and its bounding surfaces.

Density is the number of units of mass in unit volume of a substance. **Relative density** is the ratio of a given density to some density taken as a standard. When pure water at its maximum density is taken as a standard, the relative density becomes the specific gravity. Resistance to flow in liquids increases with density.

One Atmosphere gives a pressure equal to 14.7 lb. per sq. in. This is equal to the pressure at the base of a column of water 34.0 ft. high or of a column of mercury 30 in. high.

2. Properties of Water

Compressibility of water is very slight and varies greatly with the temperature and amount of air in solution. M. Grassi obtained the following results with distilled water:

Temperature Fahr.	Maximum pressure, atmospheres	Mean compressibility per atmosphere	Temperature Fahr.	Maximum pressure, atmospheres	Mean compressibility per atmosphere
32°	7.4	0.0000502	56°	8.4	0.0000476
35°	10.0	0.0000515	79°	7.2	0.0000455
51°	5.1	0.0000480	128°	6.3	0.0000444

At a pressure of 65 000 lb. per sq. in., water is said to be compressed over 10%. (Eng. News, Oct. 4, 1900.)

Modulus of Compressibility or of Elasticity in Compression

Lord Kelvin (Enc. Brit., IX Ed., Vol. VII, p. 818) on the authority of Grassi gives the following values:

Temperature		Modulus of compressibility or elasticity		
Cent.	Fahr.	Grams per sq. cm.	Lb. per sq. in.	Lb. per sq. ft.
0°	32°	20 600 000	293 000	42 192 000
1.5°	34.7°	20 200 000	287 000	41 373 000
4.1°	39.4°	20 700 000	294 000	42 397 000
10.8°	51.4°	21 500 000	306 000	44 036 000
13.4°	56.1°	21 600 000	307 000	44 240 000
18°	64.4°	22 400 000	319 000	45 879 000
25°	77.0°	22 600 000	321 000	46 289 000
34°	93.2°	22 800 000	324 000	46 698 000
43°	109.4°	23 300 000	331 000	47 722 000
53°	127.4°	23 500 000	334 000	48 132 000

Impurities in water slightly affect the specific gravity, as shown by the following values from various authorities:

Rivers: Garonne, France	1.000149
Thames, England	1.0003
Mississippi, U. S. (filtered)	1.00025
Springs	1.0003 to 1.006
Pacific Ocean	1.0265
Dead Sea	1.172

Tests at the Cornell Hydraulic Laboratory showed turbid water to be lighter than the water from the same source when clear, probably because of air adhering to the material causing turbidity.

Air ordinarily dissolved in water varies with the temperature. The amounts of oxygen and of air dissolved at different temperatures under a pressure of one atmosphere, as determined at the Lawrence Experimental Station, are as follows:

Oxygen and Air Dissolved in Water under a Pressure of One Atmosphere

In parts per 100 000 by weight

Temperature Fahr.	Oxygen	Air	Temperature Fahr.	Oxygen	Air	Temperature Fahr.	Oxygen	Air
32°	1.470	6.38	51°	1.117	4.84	70°	0.899	3.91
33°	1.445	6.28	52	1.103	4.78	71	0.889	3.87
34	1.422	6.19	53	1.089	4.72	72	0.880	3.83
35	1.400	6.08	54	1.076	4.67	73	0.871	3.79
36	1.379	5.99	55	1.063	4.62	74	0.862	3.75

3. Hydrostatics

Laws of Perfect Liquids. (1) At any point in a liquid at rest the hydrostatic pressure is the same in all directions. (2) At all points in a horizontal plane in a liquid at rest the pressure is the same. (3) The pressure of water at rest, upon the surface of the vessel containing it, is normal to that surface at every point of it. (4) If a body is immersed in a liquid, the pressure upon it will be normal at every point of the surface of the body. (5) Every external pressure upon a liquid in a vessel will be transmitted with equal intensity to all parts of the liquid and of the containing surface.

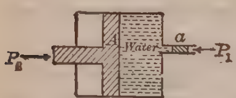

Fig. 1

The Hydrostatic Press, often called the hydraulic press, is used to exert heavy pressures generated in accordance with law (5). Let P_1 be a force applied through the small area a; its intensity per unit of area is P_1/a, and this acts with equal intensity upon all parts of the area A of a large piston in a strong cylinder. Thus the total pressure P_2 on the large piston is $\mathbf{P_2 = P_1 A/a}$. If $A = 1000a$, then $P_2 = 1000\ P_1$. The work of the resisting force P_2 cannot, however, be greater than the work of the applied force P_1.

Head and Pressure. In still water the unit pressure at any point is directly proportional to its distance below the surface. A head of 1 ft. gives a pressure of 0.4335 lb. per sq. in.; 1 lb. per sq. in. pressure is produced by a head of 2.3068 ft. These values are for fresh water at its maximum density (39.3° F.)

The Center of Pressure for any plane surface acted upon by a fluid is the point of action of the resultant pressure acting upon the surface. The resultant presssure $\mathbf{P}$ on any submerged plane area $= \mathbf{Az_gw}$, where A is the area, z_g is the vertical distance from the free surface of the fluid to the center of gravity of the area, and w is the weight of unit volume of the fluid.

To find the location of the center of pressure of a plane area, extend the plane until it cuts the free surface of the liquid and call the trace OY then

$$x_c = \frac{I_y}{Ax_g} = \frac{r^2{}_{gy}}{x_g}$$

where x_c is the perpendicular distance from the center of pressure to OY, I_y is the moment of inertia of the area about OY, A is the area, x_g is the perpendicular distance from the center of gravity of the area to OY, and r_{gy} is the radius of gyration of the surface about the axis Y, and $r^2{}_{gy} = x_g^2 + r_g^2$. Values of x_g and r_g^2 are found from Sect. 4, for common plane areas, x_g being equal to the disrance from the center of gravity to the upper edge plus the distance from that edge to the axis OY, and r_g is radius of gyration corresponding to axis through G. For example, let a triangle of base b and altitude d be immersed vertically in water with its vertex at a distance $2\ d$ below the surface and its base parallel to the surface; then $x_g = 2\ d + 2/3\ d$, and $r_g^2 = 1/18\ d^2$, whence $x_c = 129/48\ d$.

Flotation. When a body floats in a fluid, the surface of the body in contact with the fluid is subject to hydrostatic pressures, the intensity of pressure on any element of the surface depending upon its depth below the surface. The resultant of the vertical components of these hydrostatic pressures is called **buoyancy.**

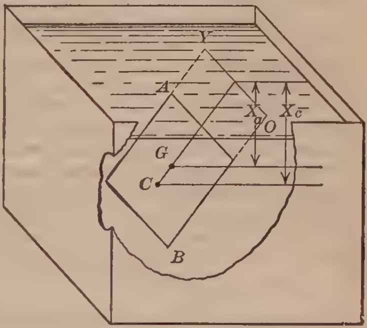

Fig. 2

Archimedes' Principle. The resultant pressure of a fluid on a body immersed in it acts vertically upward through the center of gravity of the displaced fluid and is equal to the weight of the fluid displaced.

Center of Buoyancy is the center of gravity of the displaced fluid and is the point of application of the resultant of all the upward forces acting on the body.

Stability of Floating Bodies. If the weight of the solid is not equal to the weight of the displaced fluid, that is, to the buoyancy effort, or if its center of gravity does not lie in the same vertical line with the center of buoyancy, the two forces form an unbalanced system and motion begins. If, when the forces are equal, the center of gravity of the solid lies in the same vertical line as the center of buoyancy and underneath the latter, the equilibrium is stable, whereas, if above, the equilibrium is unstable, and if the two centers coincide, the equilibrium is indifferent.

The equilibrium may be stable throughout a limited displacement with the center of gravity above the center of buoyancy depending on the shape of the body.

Viscosity is the evidence of cohesion between the particles of a fluid and is that physical property of a fluid which causes it to offer a resistance, analogous to friction, to the relative sliding motion of two adjacent particles. This property, chiefly noticeable when the fluid is in motion, is the cause of all so-called fluid friction.

The viscosity of a liquid is assumed to be derived from Poiseuille's equation:

$$h_f = \frac{32\ \mu L v_m}{gD^2}$$

wherein h_f = loss of head, in feet of water, in length of pipe;
L = length of pipe in feet;
v_m = mean velocity in pipe in feet per second;
D = diameter of pipe in feet;
g = acceleration due to gravity = 32.16 ft. per sec., per second;
μ = absolute viscosity in pounds per second per square foot.
= at 32° Fahr. 0.001203
= at 50° Fahr. 0.000880
= at 68.4° Fahr. 0.000672
= at 100° Fahr. 0.000464
= at 160° Fahr. 0.000269
for water.

Viscosity decreases as temperature increases. To convert **absolute viscosity** in the C. G. S. system to the English system, multiply its value by 0.0672. **Kinematic viscosity** is the quotient obtained by dividing the absolute viscosity by the specific gravity of the liquid.

Surface Tension is caused by the cohesion of the molecules of a fluid and gives it the appearance of having an elastic skin at its surface of separation from a gas or any other fluid.

The Specific Gravity of a solid or liquid is the ratio of its weight to the weight of an equal volume of water. Thus, the specific gravity of a stone which weighs 150 lb. per cu. ft. is 150/62.5 = 2.4. For a body heavier than water the specific gravity is also the ratio of its weight to the loss of weight in water when entirely submerged. Thus, if W is the weight in air, and W' the weight in water, then **specific gravity** = $W/(W - W')$; for example, if a piece of lead weighing 6.45 lb. in air weighs 5.88 lb. when submerged, then the specific gravity of lead is 6.45/0.57 = 11.3. For a body lighter than water, sink it by means of a heavier body and then deduct the weight of the latter. For porous substances and for liquids special methods are used; see Sect. 11, Art. 3, for cement tests.

4. Hydrodynamic Laws

Torricelli's Theorem. The velocity of a jet of liquid discharging under a head H is the same as that acquired by a body falling through the same height.

Bernouilli's Theorem. In steady flow the sum of the velocity head, pressure head, and head of elevation at any point is equal to the sum of the corresponding heads at any other point ± the losses of head due to friction, + if the last point is downstream from the first point, − if upstream. This may be expressed by the following equation, known as Bernouilli's Theorem. Let two points be 1 and 2, 2 being downstream from 1; p_1 and p_2 be the fluid pressures at 1 and 2; v_1 and v_2 be the velocities at 1 and 2; h_{e1} and h_{e2} be the elevations of 1 and 2 above any convenient datum level; w be the weight of a cubic unit of the fluid; g be the acceleration due to gravity; h_f be the loss of head due to friction between 1 and 2. Then

$$\frac{v_1^2}{2g} + \frac{p_1}{w} + h_{e1} = \frac{v_2^2}{2g} + \frac{p_2}{w} + h_{e2} + h_f$$

Conservation of Energy. In steady flow the sum of kinetic and potential energies at any point in a stream is equal to the sum of the kinetic and potential energies at any other point in the stream ± the loss of energy due to friction between the two points, + if the second point is downstream from the first point, − if upstream. If both sides of the equation of Bernouilli are multiplied by the mass passing either of the two points in unit time, the two sides can be reduced to the form of the summation of kinetic and potential energies.

Charles' or Gay-Lussac's Law. The pressure remaining constant, the volume of a given mass of gas varies directly with the absolute temperature. If the pressure is constant, the heaviness (and therefore the specific gravity) varies inversely with the absolute temperature. The volume and heaviness remaining constant, the pressure of a given mass of gas varies directly with the absolute temperature.

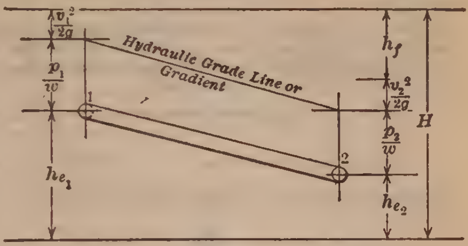

Fig. 3. Bernouilli's Theorem

Boyle's or Mariotte's Law. The temperature remaining constant, the pressure of a given mass of gas varies inversely with the volume and directly with the heaviness.

Dalton's Laws. In a mixture of different gases when there is equilibrium, each gas behaves as a vacuum to all the rest. If one or more liquids are introduced into a space of given volume, the amount of vapor given off by each depends only upon the temperature and pressure and is independent of any other gas or vapor present, and therefore the total pressures of the gases and vapors contained in the space is the sum of the separate pressures which each would exert if it were the only one present. The law does not hold good when the respective liquids and gases act chemically with one another.

Avogadro's Law. In equal volumes of gases having the same temperature and pressure the numbers of molecules are the same.

5. Jets and Vortices

Impact and Reaction. When a stream of a fluid impinges on a solid surface, it presses on the surface with a force equal and opposite to that by which the velocity and direction of motion of the fluid are changed. Generally in problems on the impact of fluids it is necessary to neglect the effect of friction between the fluid and the surface on which it moves and in the jet itself.

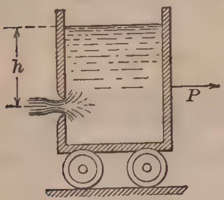

Fig. 4. Reaction of Jet

Reaction of Jet upon a vessel from which it issues. Let A be the area of the orifice, h be the head on the orifice, w be the weight of unit volume of the fluid. Then the reaction of jet is $P = 2\,Ahw$.

If the orifice is in a thin plate with a coefficient of velocity = 0.96 and a coefficient of contraction 0.64, then $P = 0.96 \times 0.64 \times 2\,Ahw$, or $P = 1.23\,Ahw$.

Impulse of a Jet on a Fixed Curved Vane with borders. Let θ be the angle through which the jet is turned, Q the volume of discharge of the jet per unit of time, U the absolute mean velocity of the jet. Taking the X axis as the axis of the jet before deflection and the Y axis at right angles to that in the plane of the jet, then,

$$P_x = \frac{Qw}{g} U (1 - \cos\theta) \qquad P_y = \frac{Qw}{g} U \sin\theta \qquad P = \frac{Qw}{g} U \sqrt{2\,(1 - \cos\theta)}$$

If ψ is the angle the force P makes with the X axis, $\tan\psi = \sin\theta/(1 - \cos\theta)$. For a flat vane perpendicular to axis of jet, $P = P_x = QwU/g$.

Impulse of a Jet on a Fixed Solid of Revolution whose axis coincides with the axis of the jet is the same as in the preceding case except that $Py = 0$. Then $P = P_x = Q_w U/g\ (1 - \cos\theta)$. The direction of the force is along the axis of the jet.

Impulse of a jet upon a curved vane with flanges at the sides to prevent water leaving it except in the direction of the tangent to its tip, and the vane moving with a uniform velocity in the direction of the jet, is found as follows: Let V be the absolute velocity of the vane, A the area of the jet; then

Force with which vane is moved is $P_x = \frac{Aw}{g}(U - V)^2(1 - \cos\theta)$

Work done on the vane, $W = \frac{Aw}{g}(U - V)^2\ V(1 - \cos\theta)$

Maximum efficiency is obtained when $\theta = 180°$ and $V = U/3$, and is 16/27, or 59.3%.

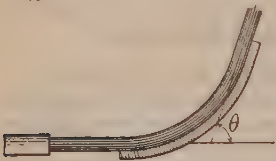

Fig. 5. Impulse upon Curved Vane

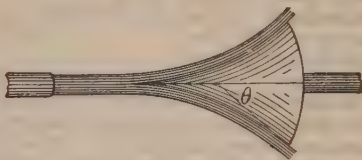

Fig. 6. Solid of Revolution

Impulse of a jet upon a solid of revolution, whose axis coincides with the axis of the jet, moving with a uniform velocity in the direction of the jet, is the same as in the above case of a moving curved vane.

Impulse of a jet upon a series of curved vanes with borders, or upon a series of surfaces of revolution, whose axes coincide with the axis of the jet; moving in the direction of the jet, is found as follows:

The force and work are

$$P = \frac{Aw}{g} U\ (U - V)\ (1 - \cos\theta) \qquad W = \frac{Aw}{g} U\ (U - V)\ V\ (1 - \cos\theta)$$

Maximum efficiency is obtained when $\theta = 180°$ and $V = U/2$, and is unity.

Impulse of a jet upon a flat vane without borders, moving in the direction of the jet is as follows:

Force and work are

$$P = \frac{Aw}{g}\ (U - V)^2 \sin^2\theta \qquad W = \frac{Aw}{g}\ (U - V)^2\ V \sin^2\theta$$

In this case θ is the minimum angle between the vane and the jet, and is 90° when vane is normal to axis of jet. The maximum efficiency is obtained when $\theta = 90°$ and $V = U/3$, and is 29.6%.

Impulse of a jet upon a series of flat vanes without borders, moving in the direction of the jet, is as follows:

Force and work are

$$P = \frac{Aw}{g}\ (U - V) \sin^2\theta \qquad W = \frac{Aw}{g}\ (U - V)\ V \sin^2\theta$$

The maximum efficiency is obtained when $\theta - 90°$ and $V - U/2$, and is 50%.

When the distance between nozzle and vane is less than the diameter of the nozzle, the discharge is reduced and the reaction on the vane is **decreased** whereas the pressure within the nozzle is increased.

Radiating Current. If water flows from a center outward between two parallel plates, and friction be neglected, the pressure head at any point distant R_2 from the center is

$$\frac{P_2}{w} = H - \frac{R_1{}^2 V_1{}^2}{2\ gR_2{}^2} \quad \text{and} \quad R_1V_1 = R_2V_2$$

where V_1 is the velocity at radius R_1 and V_2 that at R_2. If the discharge from between the plates is into air, the pressure at the outlet is atmospheric, and as the pressures decrease toward the center the pressure on the top of the upper plate is greater than that on the bottom of it. This explains the phenomenon of the so-called "ball nozzle."

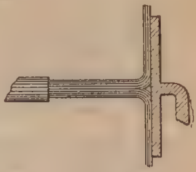

Fig. 7. Flat Plate

Vortices. A Free Circular Vortex is a revolving mass of water in which the stream lines are concentric circles and in which the total head for each stream line is the same, or $R_1V_1 = R_2V_2$ as in a radiating current.

A Free Spiral Vortex is a revolving mass of water having a radiating flow combined with a circular flow, in both of which

$$R_1V_1 = R_2V_2$$

and the same equation holds for the spiral motion in which the direction of the current will make a constant angle with the radius to its axis, or when the path of the current is a logarithmic spiral. The centrifugal pump delivers water into its shell in a free vortex of this kind, the velocity diminishing and the pressure increasing as it flows outward.

A Forced Vortex is a revolving mass of water in which, by the application of some force or forces, the law of velocity variation is caused to be different from the above. The simple case is that in which all the particles have equal angular velocity. Then if ω = angular velocity and $v = R\omega$, the pressure head at any point is

$$\frac{P}{w} = \frac{R^2\omega^2}{2g} + \text{a constant}$$

and the relations at any two points, 1 and 2, in the same horizontal plane are

$$\frac{P_2 - P_1}{w} = \frac{\omega^2}{2g}(R_2^2 - R_1^2) = \frac{V_2^2 - V_1^2}{2g}$$

This is the equation of the surface assumed by the water in a revolving vessel, and indicates that radial planes will cut the surface in parabolas with vertices downward and at the center. The height z_x of the surface at any point x above a tangent to the parabola at its vertex o is

$$z_x = \frac{P_x - P_o}{w} = \frac{\omega^2 R_x^2}{2g} = \frac{V_x^2}{2g}$$

Rectilinear Translation and Acceleration. When a mass of water is contained in a vessel and moves in a straight line with uniform velocity, the pressure upon each surface along horizontal planes will be uniform, but if the motion is uniformly accelerated, then the pressure decreases from the front to the rear of the vessel for positive acceleration and vice versa for negative acceleration or retardation.

If points 1 and 2 are distant x apart horizontally, and j is the acceleration,

$$(P_1 - P_2)/w = z_1 - z_2 = xj/g$$

and the surface has an angle of inclination ϕ whose tangent is j/g.

6. Hydraulic Computations and Tables

Units of Measure used in this Section are the second, the foot, and the pound-weight. For some minor quantities such as pressures and diameters the inch is employed instead of the foot, but the latter is to be used in all standard hydraulic formulas. (Art. 9 employs some metric units.)

column contains values of the velocity-head $n^2/2g$ for various values of n, and the last column but one gives values of the theoretic velocity $\sqrt{2gn}$ for a head n. The value of g used for these columns is 32.162 ft. per sec. per sec.

See Sect. 1, Art. 9. for a more extended table of three-halves powers.

FLOW IN PIPES AND CHANNELS

7. Orifices and Short Pipes

Small Orifice in a Thin Plate. When the efflux takes place through an orifice in a thin plate whose diameter is not greater than 1/8 the head, a contracted vein, or "vena contracta," is formed, the filaments of water not becoming parallel until they reach a plane at right angles to the axis of the jet and about 1/2 its diameter from the orifice; and not until reaching this plane does the internal fluid pressure become the same as the pressure of the surrounding medium. If the vessel were large enough so that the velocity at the surface were zero, the theoretical velocity at the place of greatest contraction would be $\mathbf{v} = \sqrt{2\,gh}$, where h is the head at its center of pressure and g is the acceleration due to gravity. For orifices where the diameter is not greater than **1/8 h,** the center of pressure and center of gravity are assumed to coincide, and, in the case of orifices in a vertical wall, the centers of gravity of the orifice and of the contracted vein are assumed at the same elevation. Practically, however, the velocity $\mathbf{v} = C_v \sqrt{2\,gh}$, where C_v, the coefficient of velocity, is determined experimentally. The discharge then would be $\mathbf{Q} = C_cA\mathbf{v}$, where A is the area of the orifice, C_c the coefficient of contraction, and v the actual velocity at the place of greatest contraction. Then:

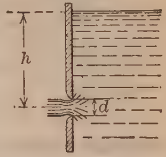

Fig. 8. Small Orifice in Thin Plate

$$Q = C_cC_vA\sqrt{2\,gh} = CA\sqrt{2\,gh}$$

where C is the coefficient of discharge.

For ordinary work very satisfactory results are obtained by using $C_v = 0.97$ and $C_c = 0.62$. C then $= C_cC_v = 0.61$. The values of C generally range from 0.63 to 0.60, the lower values occurring with the higher heads. Square and rectangular orifices have slightly higher discharges than circular ones, the increases being between 1% and 1-1/2%.

Submerged Orifices. The theoretical discharge is $Q = A\sqrt{2\,gh}$, where h is the difference in level of the free surfaces on the two sides of the orifice. Coefficients in this case are, according to Weisbach, 1/75 less than for free discharge into the air.

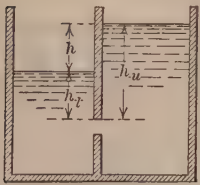

Fig. 9. Submerged Orifice

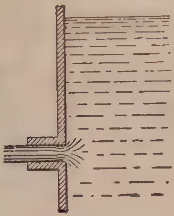

Fig. 10. Short Tube

Short Tube. If an external tube of the same diameter as the orifice and at least 2-1/2 diameters long is attached to it, the effluent stream, after forming a **"vena contracta,"** re-expands and fills the tube, and the discharge is increased. To attain this result, however, the tube must be full of water before the outer end is unstopped, and must not be oily; nor must the head h be greater than about 40 ft. for efflux into the air. The coefficient of velocity is then the coefficient of discharge, since the coefficient of contraction is unity. $C = 0.815$ for tubes from **2-1/2** to **3** diameters long. For other lengths the coefficients for tubes and short pipes are:

Length in diameters....	1	3	5	10	25	50	75	100
Coefficient...........	0.62	0.815	0.79	0.77	0.71	0.64	0.59	0.55

Borda's Tube is a short tube, of the same diameter as the orifice, attached to the orifice on the inside of the wall. If this tube is short enough so that the water is discharged without filling the tube, the theoretical coefficient C is 0.5, which is very nearly that obtained by experiment.

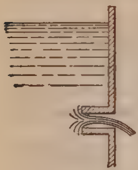

Fig. 11.
Borda's Tube

Converging Mouthpieces. The discharge through an orifice is increased as the filaments of water are made to approach it in a more nearly normal direction. Hence, if walls of an orifice converge downstream, the flow is increased until it reaches a maximum when the angle between two opposite sides is about 13-1/2°, and C then is about 0.94. For other angles the value of C is

For angle........	0°	10°	13.5°	20°	30°	40°	60°
C..............	**0.84**	**0.93**	**0.94**	**0.93**	**0.90**	**0.87**	**0.82**

Rounded Mouthpiece. Rounding the entrance further reduces the contraction and when the curve approximates to the "vena contracta," **C = unity** and $Q = C_v A \sqrt{2gh}$. Experimentally $C = C_v$ varies from 0.96 to 0.99.

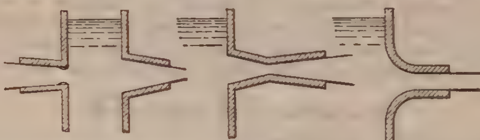

Fig. 12. Divergent, Convergent, Compound and Rounded Mouthpieces

When the upstream edge of an orifice is rounded, the discharge is increased. Schoder and Dawson ("Hydraulics," McGraw-Hill, N. Y.) give the following from the Cornell Hydraulic Laboratory, on discharge of orifices into air.

Values for 6 Ft. Heads

C = circular S = square

Orifice, in. shape	Radius of upstream edge in per cent of diameter	Coefficient of discharge	Per cent increase over sharp edge	Orifice, in. shape	Radius of upstream edge in per cent of diameter	Coefficient of discharge	Per cent increase over sharp edge

Divergent Mouthpieces, if they flow full and are more than 5 diameters in length, will increase the value of C above that for the orifice at the inlet and in some cases to as much as 1.4 times.

Compound Mouthpieces. If a divergent tube, whose angle of divergence between opposite sides is about 10°, is attached to a rounded mouthpiece and caused to flow full, the head at the throat becomess less than the atmospheric pressure and may practically fall as low as − 24 ft. of water. The total head producing flow through the throat then is $\mathbf{h} +$ 24 ft. and $\mathbf{v} = \mathbf{C}\sqrt{2\,\mathbf{g}(\mathbf{h} + 24)}$, where C is for the rounded orifice less a small allowance for friction in the diverging tube. Theoretically it would be possible to have C as high as 8.0 or 9.0 for heads less than 1 ft. but experimentally 2.43 is the highest value obtained.

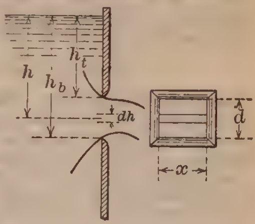

Fig. 13. Large Orifices

Large Orifices. This case differs from the discharge of " small orifices " in that the difference of head between the top and bottom of the orifice is so great that it must be taken into account. Let $\mathbf{h_t}$ be the distance from the free surface of the water to the top of the orifice; $\mathbf{h_b}$ be the distance from the free surface of the water to the bottom of the orifice; $\mathbf{x}$ be the width and $\mathbf{d} = \mathbf{h_b} - \mathbf{h_t}$ the depth of the orifice; $\mathbf{h}$ be the distance from the free surface of the water to any horizontal layer through the orifice of $\mathbf{dh}$ depth and width $\mathbf{x}$. Then the velocity of water through this thin layer is $\sqrt{2\,\mathbf{gh}}$, the small discharge $\mathbf{dQ}$ for this area is $\sqrt{2\,\mathbf{gh}} \cdot \mathbf{xdh}$, and the total theoretical discharge is

$$\mathbf{Q} = \int_{\mathbf{h_b}}^{\mathbf{h_t}} \sqrt{2\,\mathbf{gh}} \cdot \mathbf{xdh}$$

The width x may be either constant or variable, and if the latter, must be expressed in terms of h before integrating.

For a rectangle with $\mathbf{x} =$ **constant,** $\mathbf{Q} = 2/3\,\mathbf{x}\sqrt{2\,\mathbf{g}}(\mathbf{h_b}^{3/2} - \mathbf{h_t}^{3/2})$

For a vertical triangle, base x at the top and horizontal.

$$\mathbf{Q} = \frac{2}{15}\frac{\mathbf{x}\sqrt{2\,\mathbf{g}}}{\mathbf{h_b} - \mathbf{h_t}}[2\,\mathbf{h_b}^{5/2} - 5\,\mathbf{h_b h_t}^{3/2} + 3\,\mathbf{h_t}^{5/2}]$$

These equations are not exact theoretically, because the head is completely changed into velocity head at the " vena contracta " and not at the orifice as was assumed; because the assumption is that the velocity is constant for any area $x \cdot dh$, when it is known that at the edges the velocity is materially decreased; and because it is assumed that the water flows in plain layers at the orifice, which is not the case. A correct result could be more nearly approached were a point taken at the " vena contracta " instead of at the orifice, but accurate measurement is there impossible. However, by the introduction of an experimental coefficient, which is less variable than the C in the preceding articles, these equations answer every purpose when correction for the velocity v_a with which the water approaches the orifice is made by adding to the observed head the **head** to which the **velocity of approach** is due, $= \mathbf{v_t}^2/2\,\mathbf{g} = \mathbf{h_v}$. For heads above 2 ft., the value of C for square orifices varies from 0.60 to 0.62 and for circular orifices from 0.59 to 0.61.

Submerged Rectangular Orifices. Let h_u be the depth of the top of the orifice on the incoming or upper side; h_l be the depth of the top of the orifice on the discharge or lower side; A be the area of the orifice; $h_v = v_a^2/2\,g$ the equivalent head of the velocity of approach. Then (Fig. 9):

$$\mathbf{Q} = \mathbf{CA}\sqrt{2\,\mathbf{g}(\mathbf{h_u} + \mathbf{h_v} - \mathbf{h_l})}$$

The value of C for a submerged orifice may be taken as about 1% less than its value for the same orifice under the same effective head when discharging freely into the air.

Partially Submerged Orifices. Let h_t and h_b be as before, b the width of the orifice, h the difference in elevation of water on the two sides of the orifice. Then values of C are closely the same as for submerged orifices, and

$$Q = C\sqrt{2g}\,b\,[2/3\,(h^{3/2} - h_t^{3/2}) + (h_b - h)h^{1/2}]$$

Incomplete Contraction. The foregoing matter on orifices is based upon the assumption that the contraction is complete. Suppression of contraction is accomplished by adding an internal projection at the edge of the orifice extending over the entire perimeter. If the projection does not extend over the entire perimeter, or if it is a short distance from the orifice, partial contraction results. Suppressing the contraction increases the discharge, but decreases the energy of the jet. If k is the ratio of the periphery of the orifice with a border to the whole periphery, the coefficient of discharge for partial contraction is, according to Bidone,

$$\text{For rectangular orifices, } C_s = C\,(1 + 0.152\,k)$$
$$\text{For circular orifices, } C_s = C\,(1 + 0.128\,k)$$

If the sides of a vessel are less than 2.7 times the corresponding width of the orifice distant from any side of the orifice, their influence is felt in partially reducing the contraction.

The effect of suppression of contraction is less when it is produced by extending the plane of the sides upstream from the aperture than when it is caused by a curved entrance.

Increase of Discharge of Square Orifices by Suppression of Contraction

Suppression	Authority: Lesbros * — Suppression by planes. Free discharge. Orifice 0.656 ft. sq., per cent increase	Authority: Stewart, Wisconsin experiments — Suppression by curved surfaces. Submerged discharge. Orifice 4.0 ft. sq., per cent increase
Bottom	3.4	4.0
Bottom and one side	....	12.0
Two opposite sides	6.1	....
Bottom and two sides	12.7	27.0
Four sides	....	54.0

* See Hamilton Smith: "Hydraulics," and Wisconsin Engineer, Dec. 1907.

The suppression in the Wisconsin Experiments was produced by a quarter of an elliptic cylinder so set that its major semi-axis, which was 3.0 ft., was parallel to the flow and its minor semi-axis, 2 ft. 10-1/2 in., was perpendicular thereto.

Two Orifices Adjacent, separated by a narrow bar, discharge more than the two considered separately, because of mutual velocity influences. When the width of bar is less than the least dimension of the orifices the discharge will nearly equal that through an orifice of area and form like orifices and bar combined less that of an orifice of area and form equal to the bar with contractions suppressed next the orifices.

8. Long Pipes

Resistances. When water flows through a pipe of such length that the particles come in contact with the wall, resistance is produced by what is commonly termed fluid friction. For short pipes this is inconsiderable and is provided for in the coefficients of discharge, but when a pipe is more than 50 diameters in length this element becomes important, and as the length increases it makes up the major part of the loss encountered.

Hydraulic Grade Line. When water flows from rest into a channel of any sort, an amount of head $\mathbf{h_v}$ equal to $\mathbf{v^2/2\,g}$ is absorbed in creating the velocity with which it discharges, and a small amount more is used up in frictional resistances. As the water passes through the channel, an amount of head $\mathbf{h_f}$ is used up in overcoming the resistance to flow. If the pipe expands the velocity is reduced and a part of the h_v is returned and appears as pressure head $\mathbf{h_p}$. If the pipe contracts, some of the h_p is converted into h_v. The pressure head measures the height of a column of water which would exert the same pressure as does the water against the walls of the channel. The **Hydraulic Grade Line, or Hydraulic Gradient,** is the locus of the tops of all such columns of water that can be placed along the channel, and the distance from the grade line to the center of the pipe at any point measures the pressure head at the latter. In an open channel the surface of the stream is the Hydraulic Grade Line.

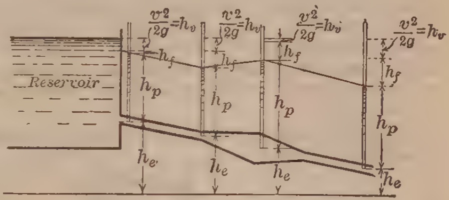

Fig. 14. Hydraulic Grade Line

The total head producing flow is equal to the sum of the velocity head $v^2/2\,g$ at discharge and all losses of head along the line.

Conditions of Flow. Normal flow is a flow such that the components of the velocities in the direction of flow at any section vary in approximate accordance with the ordinates of a cylinder with an ellipsoidal end, such that the maximum ordinate is approximately 1.19 times the mean, the lengths of the cylinder being the component of the velocity in the direction of flow at the surface of contact and the lengths of the ellipsoidal end being the difference between the components of the velocities in the direction of flow at the axis of the pipe and at the surface of contact. This condition of flow is disturbed by contraction, expansion or curvature of the stream, and the water requires a length of about 40 diameters of the pipe to readjust itself after passing a contraction, about 50 to 60 diameters after passing an expansion, and from 100 to 300 diameters after passing a curve. In any region of abnormal flow the pressure indicated by an orifice in the pipe wall will be different for the same mean velocity from that indicated in case of normal flow. In the cases of contractions and expansions, the indication of pressure will usually be greater than that for normal flow, and after a curve, if the pressure be read on the concave side of the stream, the indication will be high, whereas if read on the opposite side it will be low, as also to a less degree if read at right angles to the direction of curvature. It is therefore essential, when making accurate measurements of loss of head, to take observations only at points where the flow is known to be normal. In very rough pipes, on account of the retardation of velocity at the wall, the ratio between the mean and the maximum is reduced and may possibly be as low as 0.60. After a contraction, on the other hand, the ratio may be increased to 0.95, and in the case of a jet from a tapering nozzle to 0.995.

Under normal flow the absorption of head in overcoming the resistances to the motion of the water, called the friction head, h_f, varies as a power of the mean velocity between the 1.7 and the square.

Low Velocity or Viscous Flow. When water flows in capillary tubes or between plates close together, the friction head has been found to vary as the first power of the velocity, and at very low velocities in larger pipes the same law holds. The velocity below which this form of flow occurs is called the **critical velocity.** The critical velocity occupies a considerable range depending upon whether the flow is changing from sub-critical velocity to super-critical velocity flow, or vice versa. In either case the existing condition of flow tends to continue itself, so that for an increasing velocity the critical velocity will be higher than for a decreasing one. Experiments by means of coloring matter in the water have shown that as long as the friction head varies as the first power of the velocity the flow is taking place in straight-line filaments, but as soon as the critical velocity is past the flow has become involved in eddies or vortices, and the exponent of v is at once increased to above 1.70.

The critical velocity may be determined by equating the straight line or viscous flow equation for h_f,

$$h_f = \frac{32\ \mu L v_m}{g D^2} \qquad \text{(Art. 3)}$$

with a similar equation for normal or turbulent flow as:

$$h_f = \frac{0.38\ v_m^{1.87}\ L}{1000\ D^{1.25}} \qquad \text{(Art. 11)}$$

and solving for v_m which will be the value of the critical velocity.

To determine whether the flow in any case is above or below the critical velocity solve for h_f in the above equations and the one giving the higher value is that of the kind of flow existing.

9. Capillary Tubes and Soils

For Capillary Tubes let T_c = temperature centigrade, s = slope, D = diameter of tube, v = velocity. The formula deduced by Poiseuille is

$$v = 52.500\ (1 + 0.03368\ T_c + 0.000221\ T_c^2)\ D^2 s$$

which has been approximately confirmed by other experimenters, and may be assumed to apply to sub-critical velocity flow. The critical velocity varies inversely as some power of the diameter. Experiments (Trans. Am. Soc. C. E., Dec., 1903, Vol. 51, p. 298) have given

$$\text{Critical velocity} = 0.088/D^{0.784}$$

as an appropriate formula, for a temperature of 70° Fahr.

From the above it is evident that sub-critical velocity flow will be encountered in practice only in small pipes, but it appears to extend considerably farther at low than at high temperatures. In a 2-in. pipe with a temperature of 40° F. or 4.4° C. the critical velocity appeared to be about 0.35 ft. per sec.

Flow in Soils. For the flow of water through soils, let T_F = temperature Fahrenheit, s = slope, d_s = effective size of the sand in millimeters, V =

velocity through the soil in meters per day, considering the entire area of the bed as effective in carrying water, and C = a coefficient depending upon the uniformity coefficient of the sand, the shape of the grains, the chemical composition and the closeness and packing of the material, and ranging in value for sands from 370 to 1200, varying inversely as the uniformity coefficients. The Lawrence Experiment Station has derived the formula

$$V = Cd_s^2 \left(\frac{T_F + 10°}{60°}\right) s$$

This is seen to be similar to the formula for small pipes in that temperature plays an important part and that h or s varies as the first power of v.

The Effective Size of a sand or gravel is the size of grain such that 10% of the particles by weight are smaller and 90% greater. The size of a sand grain is determined by the diameter of a sphere of equal volume. The **Uniformity Coefficient** of a sand or gravel is the ratio of that size of grain than which 60% of the sample is finer, to the effective size.

Evidently a high uniformity coefficient indicates a large variation in size of grains, while a coefficient of unity would indicate that substantially all the grains were of one size.

Temperature. In small pipes and in the flow through soils the temperature of the water is a very important factor. For smooth pipes of 2-in. diameter and under, the loss of head has been found to increase about 4% for each 10° fall of temperature from 70° to 40° F. (Trans. Am. Soc. C. E., 1903, vol. 51, p. 290.) Other experiments have shown that near the boiling point the loss of head increases with the temperature. In large pipes the effect of temperature may be safely overlooked, except in cases where great refinement is necessary.

In some weir experiments where the discharge was about 200 cu. ft. per sec. it has appeared that the effect of a change from 76° to 33° F. was to decrease the discharge about 3/4 of 1%. With small weirs, laboratory experiments have shown that the influence of temperature between 32° and 45° F. is greater per degree than higher up the scale. Accurate data covering these points are, however, wanting.

At low velocities in small pipes the loss of head may be less with cold than with warm water, due to the fact that the former does not pass from the condition of viscous to turbulent flow as readily as does the latter and hence the h_f may continue to vary as v beyond the point where its variation with v^2 would give the greater loss.

10. Formulas for Long Pipes

The Chezy Formula. If v is the velocity in the pipe, C a coefficient dependent upon roughness, density, velocity, and diameter, r the **Hydraulic Radius,** namely the cross-sectional area divided by the wetted perimeter, h_f the frictional loss of head in a length L, and if h_f/L is designated by s, the inclination or slope, then

$$v = C\sqrt{\frac{rh_f}{L}} \quad \text{or} \quad v = C\sqrt{rs}$$

in which for new pipes C ranges from 95 to 152 and for old pipes from 60 to 120, the value increasing both with the diameter and the velocity, as shown in the tables herewith.

Values of C in Chezy Formula for Cast-iron Pipes

Diameter of pipe, inches	Velocities in feet per second							
	For new pipes				For old pipes			
	1	3	6	10	1	3	6	10

60	142	147	150	152	....	....	....	....

For steel riveted pipes, see next table. Chezy's formula is also used for conduits and streams but the coefficient C for such cases is generally expressed in terms of r and s (see Art. 15 for formulas of Bazin and Kutter).

Darcy's Formula. The original form of Darcy's equation was $rs = av + bv^2$, where a and b were coefficients. This Darcy later reduced to $\mathbf{rs} = \mathbf{Cv^2}$, where $C = c_1 + c_2/r$, where c_1 and c_2 are constants. For new cast-iron and for wrought-iron pipes of the same roughness, Darcy's vales of these constants are $c_1 = 0.0000773$ and $c_2 = 0.00000162$. The formula then reduces to

Values of C in Chezy Formula for Steel Riveted Pipes

Diameter of pipes, inches	Velocity in feet per second			
	1	3	5	10

48	0.00062	0.00031

$$\mathbf{h_f} = 0.00000642\,\frac{(12\,D + 1)}{D}\,\frac{v^2L}{r} \quad \text{or} \quad v = 394\sqrt{\frac{D}{12\,D + 1}}\sqrt{rs}$$

where D is the diameter of the pipe in feet. For rough pipe Darcy reduced the velocity one-half. Darcy's formula may be transposed to $CV^2 = Ds$, in which case C has an average value of 0.00032 for clean pipes of diameters from 8 to 48 in. inclusive, the variation being only 3% from the mean for all except the 8-in. The preceding table gives more accurate values of C for Darcy's formula in the last form.

Fanning's formula for flow in pipes is

$$h_f = \frac{4\,fL}{D}\,\frac{v^2}{2\,g} \qquad \text{or} \qquad v = \sqrt{\frac{2\,gDh_f}{4\,fL}}$$

where f is a coefficient which ranges from 0.0071 to 0.0028 for new pipes and from 0.0152 to 0.0046 for old ones, the value decreasing as diameter and velocity increase. The other notation is the same as that at the beginning of this article.

Kutter. The Kutter formula was designed for open channels and will be treated under that head. It is sometimes used for pipes, but the results from it, since the coefficients, like those of the Chezy and Fanning formulas, change with the velocity in the same pipe, are usually erroneous, except for a very small range of velocity. For this reason it is not to be recommended for general use in computations for pipes.

11. Exponential Formulas for Pipes

One form of an exponential formula for flow of water in pipes is

$$h_f = \frac{Kv^N L}{D^{1.25}}$$

where the notation is the same as that at beginning of Art. 10, but where the coefficient K and exponent N may vary with the kind and condition of the pipe. To avoid zeros in the coefficient a unit length of 1000 ft. may be taken, when the formula becomes

$$h_f = \frac{Kv^N}{D^{1.25}} \cdot \frac{L}{1000}$$

in which N has a mean value of 1.87 and K ranges from 0.28 to 0.48 with an average value of 0.38 for ordinarily clean pipes. For rough or tuberculated pipes K may become as high as 0.70. The advantage of the exponential formula is that the coefficient for the same pipe is nearly constant and, if the exponent, its range being from 1.70 to 2.00, is properly selected, absolutely so; and the variation in all cases is much less than with other formulas, so that with a few average coefficients for different classes of channels, all hydraulic flow problems may be solved with reasonable accuracy without reference to any tables of coefficients. The foregoing formula with the coefficient 0.38 may be expected to give results within 20% of accuracy for any pipes likely to be encountered which have diameters from 1 in. to 15 ft., except those extremely tuberculated, and with velocities from 1 ft. to 20 ft. per sec. For ordinary cast-iron or riveted pipe with any diameter and velocity, the results may be expected to be within 6% of accuracy.

The exponential formula is derived from experiment in the following manner: Any plane curve passing through the origin of coordinates can be represented by an equation of the form $y = mx^N$, in which m and N may be either constant or variable. If the curve is one of single curvature such that the change of inclination of its tangents either continuously increases or continuously decreases, both m and N become constants. All curves which are loci of equations expressing the relation between velocity and loss of head in flowing water are of this latter class, and consequently $h_f = mv^N$ is a general expression for the loss of head in either a pipe or an open channel. If for any pipe line the values of m and N be determined, the equation of flow in that line is established. Expressing the above equation for logarithmic computations, it becomes

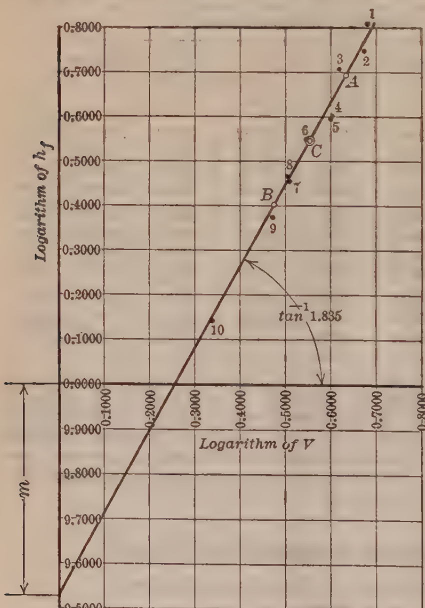

Fig. 15. Logarithmic Plotting

$$\log h_f = \log m + N \log v$$

and considering the logarithms as mere quantities, this is at once seen to be the equation of a straight line in which $\log m$ is the intercept on the h_f axis and N is the tangent of the angle which the line makes with the v axis. Both m and N may be found by determining two points in the line representing the plottings of the logarithms. If it is desired to draw the straight line which most nearly coincides with a number of points, it must pass through their center of gravity and also through the centers of gravity of the two groups into which the center of gravity of the whole divides them. Having the last two points, the equation of the line is readily determined.

The following example will serve to illustrate the process (Fig. 15). The data are from observations on a 12-in. cast-iron water main very carefully laid in a tangent some 3500 ft. long, the loss in 1000 ft. of which was measured.

C = center of gravity or mean point of the whole group
A = center of gravity of part of group above C
B = center of gravity of part of group below C

$C_h = h_f$ coordinate of C, $\quad C_v = v$ coordinate of C
$A_h = h_f$ coordinate of A, $\quad A_v = v$ coordinate of A
$B_h = h_f$ coordinate of B, $\quad B_v = v$ coordinate of B

			Sum = 5.5382		Sum = 5.4687	
			mean = 0.53382 = C_v		mean = 0.54687 = C_h	

$A_v - C_v = 0.63334 - 0.55382 = 0.07952 \qquad A_h - C_h = 0.69282 - 0.54687 = 0.14595$
$C_v - B_v = 0.55382 - 0.47430 = 0.07952 \qquad C_h - B_h = 0.54687 - 0.40092 = 0.14595$

Since $A_v - C_v = C_v - B_v$ and $A_h - C_h = C_h - B_h$, the three points A, C, and B are in a straight line, which fact checks the accuracy of the work.

N = tangent of inclination of line ACB

$$= \frac{A_h - C_h}{A_v - C_v} = \frac{C_h - B_h}{C_v - B_v} = \frac{A_h - B_h}{A_v - B_v} = \frac{0.14595}{0.07952} = 1.835$$

Since $\log m = \log h_f - N \log v$, using the coordinates of C

$$\log m = 0.54687 - 1.835 \times 0.55382$$
$$= 0.54687 - 1.01626 = 9.53061 = \log 0.3393, \text{ and } m = 0.3393$$

The equation for this 12-in. pipe is therefore $h_f = 0.3393\, v^{1.835}\, L/1000$.

Remark: Evidently the v coordinates must be divided between the same pair of observations as the h_f coordinates. The mathematical determination of what group should include a point whose v coordinate is on one side of C and whose h_f coordinate is on the other, depending on whether the point itself is above or below a normal to the line ACB through C. This can usually be established by plotting the logarithms on ordinary cross-section paper, or the observations on logarithmic paper.

To introduce the diameter into the equation, a series of values of m and N for pipes of different diameters must be obtained. The range of N is relatively small, the limits for all reliable pipe experiments on record being from 1.70 to 2.08, and if the pipes are of the same character of surface and alignment the value of n will be constant. It is, therefore, only necessary to consider the variation of m, which depends upon the area of the cross-section or upon D and upon the roughness. Evidently m varies inversely as some power of the diameter, and for $1/D = 0$, $m = 0$ for any velocity, so the curve representing the relation between m and D will be $m = KD^{-x}$. Proceeding in the same manner as before, an average value of $x = 1.25$ will be obtained, and the formula for pipe of the same character as that in the above experiment is

$$h_f = \frac{Kv^{1.835}}{D^{1.25}} \cdot \frac{L}{1000} \quad \text{or} \quad h_f = \frac{0.38\, v^{1.87}}{D^{1.25}} \cdot \frac{L}{1000}$$

for average conditions, and this may be transposed to

$$v = 73.54\, D^{0.668}\, s^{0.535} \quad \text{or} \quad v = 185\, r^{0.668}\, s^{0.535}$$

Scobey's Formula for **Wood-stave Pipe** is of the above form and is

$$v = 1.62\, D^{0.65}\, h_f^{0.555}$$

wherein h_F is loss of head per 1000 ft. The U. S. Dept. of Agriculture Formula (Bulletin 854) for tile drains of clay or concrete, 4 in. to 12 in. diameter, is:

$$v = 138\, r^{2/3}\, s^{1/2}$$

Hazen and Williams Formula. A commonly accepted exponential expression is that known as the Hazen and Williams formula (see Hydraulic Tables, Williams and Hazen, John Wiley & Sons, New York City), which is:

$$V = cr^{0.63} s^{0.54} 0.001^{-0.04}$$

The last term of this formula $0.001^{-0.04}$ was introduced to make the co efficient c correspond in value with that of the Chezy formula for a slope s of 1 ft. in 1000 ft. This formula was originally devised to furnish the basis for the Hazen and Williams Hydraulic Slide Rule by which ordinary problems of discharge and loss of head in either closed or open channels may be readily solved, and from which the above named "Hydraulic Tables" have been derived.

The Hiram F. Mills Formulas. The most scientific and rational formulas yet presented for the flow of water in pipes are those devised by the late Hiram F. Mills, C. E., of Lawrence, Massachusetts, and posthumously published in 1923 through the interest of John R. Freeman, C. E., and Karl R. Kennison, C. E., by the American Academy of Arts and Sciences, of Boston. The Mills formulas are of the form:

$$s = \frac{C_1v + C_2v^2}{r^{1.25}}$$

wherein C_2 is zero for flow below the so-called critical velocity. The expression is quite similar in appearance to the old Darcy formula $rs = av + bv^2$, a form originating with Dr. Young and Prony about the beginning of the 19th century.

The theory of these formulas is that the flow of water takes place throughout a part of the pipe section in approximately parallel filaments, under which condition the loss of head h_f varies as the first power of v, and through the rest under conditions of disturbances inducing impacts which cause the loss to vary as v^2, the latter being considered the probable limiting condition under extreme disturbance. As such maximum disturbances cannot occur in small pipes it follows that the average exponent of v, which is that derived for the exponential formulas, will be smaller for small pipes than for larger ones. Also by reason of the disturbances caused by the roughness of the pipe wall the exponent of v for rough pipes will be more largely influenced by the v^2 condition and the mean exponent will be greater. The exponent of r in the Mills formula corresponds to that of D or r in the exponential formula previously considered.

The flow of water in a pipe or other channel, starting from rest as set forth by Mr. Mills, passes through four different stages or conditions.

First. It starts as viscous flow with the velocity increasing from zero at the pipe wall to a maximum at the center, and h_f varies as C_1v, with C_1 a constant.

Second. A velocity is reached at which the water begins to move at the pipe wall and eddies starting there move out toward the center. The first effect is to reduce the value of C_1, and at the same time a resistance varying as C_2v^2 appears with C_2 increasing from zero, approximately as the ordinates to a quarter ellipse and becoming constant, while C_1 begins to increase from its decreased value.

Third. With C_2 constant, C_1 continues to increase approximately as the ordinates to a quarter ellipse starting from the point of zero velocity until the maximum disturbance of the stream due to eddies has been reached, after which C_1 becomes constant and this constitutes the

Fourth condition, when both C_1 and C_2 are constant with C_1 considerably smaller than C_2.

To provide for all these conditions and the additional effect of temperature, which in small pipes and at low velocities is important, is evidently impossible in a single formula, since for each class of pipe at least four equations would be required, two of which must involve a variable coefficient. Omitting all of the first three conditions, Mr. Mills presents the following equations for the fourth:

For	v above	$r^{1.25}$ s
Seamless drawn brass tubes....	6 ft. per sec.	$= 0.0000593\,v + 0.0000220\,v^2$
Riveted sheet-iron pipe coated with bitumen..............	4 ft. per sec.	$= 0.0000542\,v + 0.0000317\,v^2$
Wrought-iron pipe coated with asphalt....................	4 ft. per sec.	$= 0.0000527\,v + 0.0000252\,v^2$
Tin pipes....................	2.5 ft. per sec.	$= 0.0000398\,v + 0.0000257\,v^2$
Glass pipes..................	2.5 ft. per sec.	$= 0.0000386\,v + 0.0000294\,v^2$
Wrought-iron pipes...........	4 ft. per sec.	$= 0.0000370\,v + 0.0000337\,v^2$
Lead pipes...................	2.5 ft. per sec.	$= 0.0000340\,v + 0.0000264\,v^2$
Galvanized-iron pipes.........	4 ft. per sec.	$= 0.0000318\,v + 0.0000483\,v^2$
Tarred cast-iron pipes.........	2 ft. per sec.	$= 0.0000201\,v + 0.0000414\,v^2$
Bored wooden pipe...........	1 ft. per sec.	$= 0.0000149\,v + 0.0000836\,v^2$
New uncoated cast-iron pipes..	1 ft. per sec.	$= 0.0000144\,v + 0.0000497\,v^2$
Old cast-iron pipes — cleaned..	1 ft. per sec.	$= 0.0000080\,v + 0.0000572\,v^2$
Old cast-iron pipes with thin calcareous deposit..........	1 ft. per sec.	$= 0.0000072\,v + 0.0001121\,v^2$
Old rusty and tuberculated wrought-iron pipes..........	1 ft. per sec.	$= 0.0000032\,v + 0.0001185\,v^2$

For velocities of 6 ft. per sec., where the effect of C_1v is negligible, the pipes are arranged according to resistance, as follows:

Material	$r^{1.25}$ s	Material	$r^{1.25}$ s
Seamless drawn brass....	$0.0000319\,v^2$	Tar coated cast iron......	$0.0000447\,v^2$
Lead..............	$.0000320\,v^2$	New cast iron (uncoated).	$.0000521\,v^2$
Tin................	$.0000323\,v^2$	Galvanized iron.........	$.0000549\,v^2$
Asphalt-coated wrought iron.................	$.0000340\,v^2$	Old cast iron — cleaned...	$.0000585\,v^2$
Glass.............	$.0000358\,v^2$	Bored wooden pipe......	$.0000863\,v^2$
Wrought iron.......	$.0000399\,v^2$	Old cast iron with calcareous deposit..........	$.0001133\,v^2$
Bitumen-coated sheet iron................	$.0000408\,v^2$	Old rusty tuberculated wrought iron..........	$.0001163\,v^2$

The group of tables now presented give:

(a) The loss of head in smooth brass pipes by the Mills formulas, which may be used for all very smooth pipes up to 4 in. in diameter.

(b) The loss of head in wrought-iron pipes by the Mills formulas, which may be used for ordinary pipes up to 5 in. in diameter.

(c) The loss of head in ordinary pipes from 6 in. to 72 in. in diameter by the Hazen and Williams formula, using a coefficient of 100, corresponding to poorly laid cast iron several years old but not badly tuberculated.

For pipes as smooth as those included in (*a*) the coefficient varies from 130 to 150, increasing with the diameter. For ordinary cast-iron pipe when new a coefficient of 120 is reasonable and for riveted steel pipe under similar conditions 110 is recommended. Fire hose ranges from 140 for the smoothest to 89 for unlined linen hose.

Loss of Head in Smooth Brass Pipe

Note. Pipes XIV, XV and XVI were slightly rougher than the others.

The 10-ft.-diameter brick intake tunnel at Detroit gave a value ranging from 80 to 90.

Experiments on a 42-in. cast-iron sewer at Baltimore reported by Keefer and Register (Eng. News-Record, Mar. 1, 1928) wherein the pipe was coated with a layer of slime about 1 in. thick, gave a coefficient of 103 computed for the full diameter and 116 when the diameter is reduced to 40 in. on account of the slime layer.

Experiments by the U. S. Dept. of Agriculture, reported by C. E. Ramser on Flow through the St. Frances Floodway, Arkansas (Eng. News-Record, April 5, 1928), wherein the flow took place through a wooded area generally free from undergrowth, at depths ranging from 4 to 9.5 ft. and with average velocities from 0.4 to 0.62 ft. per sec., give values of the coefficient ranging from 15 to 20.

Experiments by the same personnel on Flows in the Little River Drainage in Missouri (Eng. News-Record, Oct. 12, 1922) give for depths of 4.5 to 5.0 ft. in a floodway obstructed by scattered brush and small tree growths at velocities from 0.5 to 0.75 ft. a coefficient of about 24, and for a floodway cleared of all brush and trees, but not of stumps, for similar depths and velocities the coefficient was about 40.

The rock section of the Chicago Drainage Canal 160 ft. wide and 22 ft. to 26 ft. deep gave $C = 77$ to 97.

Loss of Head in Commercial Wrought-iron Pipe

Discharge and Loss of Head in Pipes

By Hazen and Williams Formula with $C = 100$ h_f in Feet of Water per 1000 Ft. of Pipe.

For new straight cast-iron pipe $C = 130$ to 140, whence the velocity and discharge will be increased 30 to 40% from the above values, for the given h_f.

For badly tuberculated pipe C may be as low as 70, whence the velocity and discharge may be decreased 30% from the above values, for the given h_f.

12. Variations in Diameter, Material and Conditions

Relation of Diameter of Pipe to Quantity Discharged. In terms of C for Chezy's formula

$$Q = \pi/8\ C\ \sqrt{sD^5}$$

in terms of Fanning's coefficient f, $Q = \pi/4\ \sqrt{\frac{2g}{4f} \cdot \frac{h_f}{L} \cdot D^5}$

Approximately for rough pipe $\quad Q = 1000\ D^{5/2}\ s^{1/2}$

and for smooth pipe $\quad Q = 2 \times 1000\ D^{5/2}\ s^{1/2}$

Material. Most pipes experimented upon previous to 1900 were of cast iron. Experiment since that date and others previous thereto indicate that the exponential formulas (Art. 11) may be safely used for wooden stave pipe, and that for riveted steel pipe the effect of rivets and joints is to reduce the discharge from 10 to 12% below that of cast iron when pipes are new.

Roughness. The effect of roughness in a water pipe is in general to retard the flow or increase the loss in head. This is accomplished by reducing the velocity of the water at the surface of contact, thus producing a general reduction in velocity and also causing cross currents or eddies which use up the energy in the stream. Roughness decreases C and increases f and K in the foregoing formulas. It also increases N somewhat in the exponential formula.

Curvature. The effect of curvature is to increase the loss of head. This increased loss is partly due to the cross currents and eddies set up in the bend, but also to the changes of velocity along the stream lines and increased friction along the walls of the channels due to increased velocities over part of the circumference. The loss of head due to a curve may be stated in terms of the velocity head h_v or, better, in terms of the equivalent length of straight pipe which would give the same loss as the curve.

The loss in a curve should be measured as the excess over that in an equal length of straight pipe. An examination of the experiments upon curve resistance by W. E. Fuller, Mem. Am. Soc. C. E. (Jour. N. E. W. W. A., Dec., 1913) has led to the following conclusions:

1. The excess loss of head due to bends is greater for large than for small pipes.
2. For large pipes a 6-ft. radius has given the minimum excess resistance except where very long radii are used.
3. If the radius can be made very long, the least excess resistance will be from the curve of longest radius.
4. For small pipes, with long radii, the total loss of head may be less than that in a straight pipe of length equal to the sum of the two tangents to the curve.
5. Approximate formulas:

For 90-deg. bends of a radius between 1.5 ft. and 10 ft. the excess loss of head due to the curve $h_b = 1/4 \left(\frac{V_2}{2g}\right)$

For tees = bends of zero radii, $h_b = 1\text{-}1/4 \left(\frac{V^2}{2g}\right)$

For 90-deg. bends of 6-in. radius $h_b = 1/2 \left(\frac{V^2}{2g}\right)$

For loss in 45-deg. bends use 3/4 of loss in similar 90-deg. bends.
For loss in 22-1/2-deg. bends use 1/2 of loss in similar 90-deg. bends.
For loss in a Y-branch use 3/4 of loss in similar tee.

The above formulas though convenient to apply are evidently inaccurate because they take no account of differences in radius of curvature.

The following values of curve and special resistance were obtained experimentally from tests of 30-in., 16-in., and 12-in. cast-iron pipes, and the excess

Resistance in Pipe, and Equivalent Loss of Head, Due to Curve or Special Connection

resistance is expressed in equivalent lengths of straight pipe, measured in pipe diameters. (Trans. Am. Soc. C. E. Vol. XLVII, pp. 360 and 205.)

Unfortunately most laboratory experiments on curve resistance appear to have been made with measuring apparatus insufficiently delicate to detect the small differences of loss of head due to the introduction of curves in the experimental lines.

A length of about 100 diameters of pipe seems to be required to eliminate the effect of a curve on the distribution of velocities in a smooth pipe, and a somewhat shorter length as rougher pipe is involved.

Expansions when sudden always produce eddies which increase the loss of head. Consider two sections of a pipe, 1 and 2; 1 to be taken at a point where normal condition of flow exists before expansion and 2 after expansion. If v_1 and v_2 are the velocities and A_1 and A_2 the areas at the two sections then the loss of head due to this sudden enlargement

$$h_{fe} = \frac{(v_1 - v_2)^2}{2\,g} \quad \text{or} \quad h_{fe} = \left[\frac{A_2}{A_1} - 1\right]^2 \frac{v_2^2}{2\,g}$$

According to St. Venant, this quantity should be increased by $v^2/18\,g$, but this correction is so small as a rule that it can be neglected, and more recent experiments indicate that the formula is as likely to give results in excess as otherwise.

Experiments by Prof. T. J. Rodhouse at the Cornell Hydraulic Laboratory in 1905 gave:

$$h_{fe} = k\left[\frac{A_2}{A_1} - 1\right]^2 \frac{v_2^2}{2\,g}$$

wherein $k = 0.967$ for an expansion from 1.069 in. to 2.096 in. and 0.987 for one from 1.5 in. to 2.096 in. in circular brass pipe. A length of 35 diameters of the larger pipe was required to eliminate the effect of the expansion.

Contraction, when sudden, produces an effect upon a stream very similar to that of a sharp orifice; that is, just beyond the contraction occurs the point of minimum cross-section of the stream or the "vena contrata." There result not only the loss of head due to the contraction of the stream, but also that due to the reenlargement of it after passing the "vena contracta." If v is the velocity under conditions of normal flow in the pipe after passing the contraction and C is the coefficient of contraction, the same in this case as for a sharp orifice, then the loss of head due to the contraction is

$$h_{fc} = \frac{v^2}{2\,g}\left[\frac{1}{C} - 1\right]^2$$

According to St. Venant this quantity should be increased by $v^2/18\,g$. Also it may be written $h_{fc} = C_c v^2/2\,g$, where C_c varies from 0.42 to 0.53. A fair assumption to make is $C_c = 0.5$. This may also be taken as the loss of head due to sharp-edged entrance into a pipe. The value of C is probably too high for small pipes and too low for large pipes.

A length of about 30 diameters appears necessary to eliminate the effect of a contraction.

Obstructions. If the sectional area of a pipe be gradually decreased and then gradually increased as in the case of a Venturi meter, the loss of head for moderate velocities is not much increased over that due to normal flow. When the obstruction causes a sudden contraction or expansion of the stream or there is discontinuity of the pipe wall, the loss of head is increased.

The disturbances caused by the various obstructions extend for considerable distances downstream. Those producing symmetrical distortions of the velocity curve disappear sooner than the others.

Valves. The losses due to valves in pipe lines have been investigated with accuracy in only a few instances. From these experiments it appears that a fully open gate valve in a pipe causes a loss of head corresponding to about 6 diameters of length of the pipe.

Siphons. A siphon is a pipe whose center line rises above the hydraulic grade line at some portion of its course and hence operates through a partial vacuum.

The laws governing flow through siphons are the same as those for other pipes, but if the siphon be short, allowance must be made for losses at entry and due to curvature. Unless the velocity is maintained at about or above 2 ft. per sec. air will accumulate at the summit and may materially retard or absolutely check the flow. On this account the siphon should be carefully graded up to a high point at which air can be conveniently removed by an ejector or through a filling chamber from which point the drop should be quite abrupt to the outlet. On account of the tendency of air to expand and separate from the water at low pressure the lift of the siphon should be as low as circumstances will permit, and not above 20 ft. unless an ejector or a high velocity is used.

A siphon installed by George S. Pierson, M. Am. Soc. C. E., of 24-in.-diameter cast-iron pipe about 2900 ft. long with a 20-ft. lift has been in use for many years connecting a distant well with one near the pumping station at Kalamazoo, Michigan.

A 24-in.-diameter spiral riveted pipe siphon installed by the writer at Taughannock Falls, N. Y., in 1904, has an initial lift of 9 ft., a run of 411 ft., with a rise of 6 in. and a drop of 88 ft. to a waterwheel which is supplied through it, and drives a lighting plant furnishing current to the village of Trumansburg. The wheel has a draft tube giving a further drop of 14 ft., and no difficulty has been encountered from accumulation of air when running, the operation head being from 90 to 93 ft.

Flow Through Culverts. Experiments at the Hydraulic Laboratory of the University of Iowa by the Bureau of Public Roads have resulted in the following formulas for the flow through such structures when flowing full (Studies in Engineering Bulletin Univ. of Iowa, Feb. 1926):

Q = discharge in cubic feet per second;
A = cross-sectional area of pipe in square feet;
D = diameter of pipe in feet;
L = length of culvert in feet;
H = loss or fall of head through culvert including velocity head absorbed at entrance;
r = hydraulic radius in feet.

Concrete pipe with square cornered entrance

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1 + 0.31\,D^{0.5} + \dfrac{0.026\,L}{D^{1.2}}}};$$

or for $L = 30.6$ ft., $Q = 4.40\,D^{2.09}\,H^{0.50}$.

Concrete pipe with beveled lip entrance

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1.1 + \dfrac{0.026\,L}{D^{1.2}}}};$$

or for $L = 30.6$ ft., $Q = 4.61\,D^{2.18}\,H^{0.50}$.

Vitrified clay pipe, regular bell upstream

$$Q = \frac{A \sqrt{2\,g\,H}}{\sqrt{1 + 0.023\,D^{1.9} + \dfrac{0.022\,L}{D^{1.2}}}};$$

or for $L = 30.6$ ft., $Q = 5.07\,D^{2.05}\,H^{0.50}$.

Corrugated metal pipe — corrugations 2-3/4 in. apart and 1/2 in. deep

$$Q = \frac{A \sqrt{2\,g\,H}}{\sqrt{1 + 0.16\,D^{0.6} + \dfrac{0.106\,L}{D^{1.2}}}};$$

or for $L = 30.6$ ft., $Q = 3.10\,D^{1.31}\,H^{0.50}$.

Box culverts with square cornered entrance

$$Q = \frac{A \sqrt{2\,g\,H}}{\sqrt{1 + 0.4\,r^{0.3} + \dfrac{0.0045\,L}{r^{1.25}}}}.$$

Box culverts with rounded entrances of 6 = in. radius

$$Q = \frac{A \sqrt{2\,g\,H}}{\sqrt{1.05 + \dfrac{0.0045\,L}{r^{1.25}}}}.$$

Flaring the outlet end of a 36-ft.-long culvert having a rounded entrance by diverging the sides at an angle of 6° 30′ with axis to double area at outlet increased its discharge 60% and gave a discharge 86% above that of a similar culvert without flare and having square cornered entrance.

13. Oil, Sand and Air

Oil Pipe Lines. With heavy viscous oils the loss of head becomes so large that transportation by pipe lines is difficult. Raising the temperature of the oil increases its fluidity, but this is satisfactory only for short lines, because to maintain a sufficient fluidity throughout a long line the initial temperature must be raised to such a point that disintegration is likely to result. Experiments have been tried with oil mixed with water, but cross currents and eddies in the pipe line produce at the discharge an emulsion, from which it is very difficult to separate the water. It is, however, possible by mixing about 10% of water with the oil and forcing it through a pipe line having rifling grooves or guides along its walls, to facilitate the transportation. The rotation of the liquid by the rifling causes the water to form a thin film or sheet between the oil and the pipe. Emulsification does not take place, and practically all the water can be separated by allowing the mixture to stand for a short time in a tank.

The rifling of an 8-in. line used by the Southern Pacific Railway Company consists of six helical grooves in the circumference, making a complete revolution every 10 ft. of axial length. This line was laid with a valley every 400 ft. of length, the depth being equal to the diameter of the pipe, in order to facilitate starting the flow after the line had been out of service and the expedient seems to have served its purpose.

The results of tests made by the Southern Pacific Railroad Company give the following values of K for the formula $h_f = Kv^2L/1000\,D$. (Engr. News, June 7, 1906, and Eng. Record, May 23, 1908.)

	K
8-in. plain pipe carrying oil only	134
8-in. plain pipe carrying 90% oil and 10% water	79
8-in. rifled pipe carrying 90% oil and 10% water	0.95
3-in. plain pipe carrying oil only	284
3-in. rifled pipe carrying 90% oil and 10% water	0.64
Mean of above pipes for water only	0.35

Filter Plant Sludge or Clay Slurry. The losses of head due to pumping sludge from the New Orleans Filtration Plant were investigated by Prof. W. B. Gregory of Tulane University in 1926, and the results were published in Mechanical Engineering, June, 1927.

The loss of head appeared to be substantially constant and independent of velocity at values below the critical velocity and it therefore follows that when such material is to be pumped the most economical rate of flow is at the critical velocity.

Flow of Clay Slurry in 4-in. Pipe

Experiment No.	Per cent solids by weight	Specific gravity of slurry	Critical velocity V_c in ft. per sec.	H_f in ft. of water	H_f in ft. of slurry	Apparent * viscosity μ	Average temperature degrees Fahr.	Corresponding H_f for water, H. and W. formula C = 140
1	18.6	1.13	2.25	5.25	4.65	0.0162	88+	5.18
2	23.4	1.175	3.60	13.00	11.05	0.0251	88+	12.40
3	29.05	1.225	6.00	28.50	23.25	0.0331	88+	31.80
4	32.5	1.255	7.00	48.00	38.25	0.0477	88+	42.20
5	35.3	1.285	8.50	70.00	54.50	0.0572	88+	57.50
6	23.6	1.17	1.5	3.85	3.29	0.0178	65	2.45
7	23.6	1.17	2.0	5.00	4.28	0.0174	65	4.15

* This fluid is not truly viscous.

The approximate composition of the sludge was:

	Per cent
Clay and sand	70.29
Carbonate of lime	23.96
Hydrate of magnesia	2.90
Hydrated oxide of iron	2.32
Undetermined	0.53
Total	100.00

At velocities above the critical the loss of head corresponded closely with that of clear water as given by the Hazen and Williams formula with a coefficient of 140.

Transportation of Solids. The percentage of solid matter that can be transported in flowing water in a pipe after a velocity has been attained sufficient to cause the suspension of the solids, is independent of the velocity. At the lower velocities the solids are rolled or dragged along the bottom with a relatively large loss of head; as the velocity increases they are picked up by the water and retained in suspension. The velocity at which the material becomes suspended is dependent upon the size of the grains and their weight. The velocity at which the material becomes approximately all suspended is the one at which the minimum loss of head will occur; and when the cost of pressure is great compared with the cost of the channel, this will be the most economical velocity to use. If the material varies in the size of its grains the condition of minimum resistance may occur before the heavier particles are in suspension. Ordinarily, however, pressure is of less importance than the line cost, and hence higher velocities will be used in order that the delivery per unit of time may be as great as possible.

The accurate experiments bearing on the subject have been made with sands having an effective size varying from 0.16 mm. to 0.75 mm. For a 1-in. pipe the velocity of suspension for such material is about 3.5 ft. per sec.; for a 3-in. pipe about 4 ft., and for a 32-in. pipe about 9 ft. The loss of head due to the transportation of these sands may be taken as about 25% of the loss due to water alone at the velocity of suspension, for each 1% of sand added to the water. For the higher velocities with fine sands, the resistance appears to increase somewhat more rapidly than with water alone, whereas with the coarser material the increase is slightly less rapid. For average results the loss of head for the mixture may be taken to vary from the velocity of suspension as v^2, until more complete investigation shall discover the true law. As much as 52% of sand has been transported through a 4-in. pipe. (Trans. Am. Soc. C. E., 1906, vol. 57, p. 400.)

Flow of Compressible Fluids in Pipes. When ai · flows along a pipe there is necessarily a fall of pressure due to the resistance of the pipe, and consequently the density of the air decreases and its veclocity increases along the pipe in the direction of motion. The effect of the resistance is to create eddying motions, which, as they subside, give back to the air the heat equivalent of the work expended in producing them. The result is that, apart from conduction through the walls of the pipe, the flow is isothermal.

Flow of Gas in Pipes under Small Differences of Pressure. Let p_1 and p_2 be the absolute unit pressures at the inlet and outlet of the pipe, w_g the weight of the gas in pounds per cubic foot, h_{fg} = head lost in feet of the gas, h_f = head lost in feet of water, and f = coefficient. If $p_1 - p_2$ be small so that the change in density may be neglected, then

$$p_1 - p_2 = w_g h_{fg} = w h_f$$

The law of flow may be expressed by the Fanning formula

$$h_f = \frac{4\,fL}{D}\,\frac{v^2}{2\,g}$$

and f has an average value of $0.0044\,\frac{w_g}{w}\left(1 + \frac{1}{7\,D}\right)$. Or when h is measured in feet of gas the coefficient becomes $f' = 0.0044\left(1 + \frac{1}{7\,D}\right)$. Experiments on compressed air give

$$f = 0.0027\,\frac{w_a}{w}\left(1 + \frac{3}{10\,D}\right) \quad \text{and} \quad f' = 0.0027\left(1 + \frac{3}{10\,D}\right)$$

Head Lost in an Inclined Gas Main. Let h_{p1} and h_{p2} be the heights of water columns at points 1 and 2, z_1 and z_2 be the elevations of the points, w_a the unit weight of air and let the flow be from 1 to 2, then

$$h_{fg} = \frac{1}{w_g}\left\{w(h_{p1} - h_{p2}) - w_a\,(z_1 - z_2)\right\} + z_1 - z_2$$

or

$$h_f = (h_{p1} - h_{p2}) - \frac{w_a - w_g}{w}\,(z_1 - z_2)$$

When Variation in Density is taken into account, the flow of air in a long uniform pipe is modified. Let v_1 be the initial velocity in the pipe whose diameter remains uniform; then the true equation as given by Unwin (Hydraulics, London) is

$$v_1 = \sqrt{\left\{222\,900\,\frac{D}{fL}\,\frac{w_a}{w}\,\frac{p_1^2 - p_2^2}{p_1^2}\right\}},$$

and an approximate formula for ordinary temperature is

$$v_1 = \left(1.132 - 0.726\,\frac{p_2}{p_1}\right)\sqrt{222\,900\,\frac{Dw_a}{fLw}}$$

The **terminal pressure** p_2 in terms of the **initial pressure** p_1 is given by

$$p_2 = p_1 \sqrt{1 - \frac{f \frac{w}{w_a} v_1^2 L}{229\,000 D}}$$

The distribution of velocity in an air main is very similar to that in a water main; that is, it approximates to a cylinder surmounted by an ellipsoid. The ratio of the mean to the velocity at the center is given as 0.873.

14. Flow over Weirs

Sharp-edged Weirs. When an obstruction is placed in an open channel, so that water is caused to flow over it, it is called a dam or weir. If the top of the weir is a thin straight edge, the conditions of flow are similar to those that would exist in an orifice in a thin wall if the side contractions were suppressed and the head fell so low that the water did not fill the orifice to its top. If the portions of the dam near the walls of the channel are raised above the level of the rest so that water does not flow over them, the overflowing jet is contracted at the sides as in the case of an orifice. The general expression for the discharge of water over a weir is

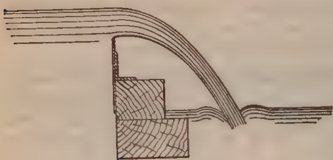

Fig. 16. Sharp-edged Weir

$$Q = 2/3\, CLH \sqrt{2\, gH}$$

wherein H is the height above the crest of the weir to the level of still water and L is the length of the crest over which the water flows. Practically, it is not possible to measure H, but a head h may be observed to the surface of the stream above the curve of depression caused by the weir, and to this the velocity head h_v due to the velocity v_a with which the water approaches the weir, may be added when the result is approximately equal to H. If the velocity of approach is small, h as observed may be treated as equal to H. C is a coefficient which depends upon the height and form of the weir, whether or not there be end contractions, the character of the weir surface and the condition of the water on the downstream side. In weir formulas it is customary to combine one or more of the factors 2/3, C, and 2 g into a single coefficient.

Four Recognized Formulas for the discharge of weirs are as follows, but the first and the fourth are the most important.

The Francis formula

$$Q = 3.33\, LH^{3/2} \quad \text{or} \quad Q = 3.33\, L\, [(h + h_v)^{3/2} - h_v^{3/2}]$$

The Fteley and Stearns formula

$$Q = 3.31\, LH^{3/2} + 0.007\, L \quad \text{or} \quad Q = 3.31\, L\, (h + 1.5\, h_v)^{3/2} + 0.007\, L$$

The Hamilton Smith formula

$$Q = 3.29\, (L + H/7)\, H^{3/2} \quad \text{or}$$

$$Q = 3.29 \left(L + \frac{h + 1\text{-}1/3\, h_v}{7}\right) h + 1\text{-}1/3\, h_v)^{3/2}$$

The Bazin formula

$$Q = mLh\sqrt{2gh},$$

where $m = \left(0.405 + \frac{0.00984}{h}\right)\left[1 + 0.55\left(\frac{h}{a+h}\right)^2\right]$

in which a is the height of the crest of the weir above the bottom of the channel of approach. For weirs with end contractions, Francis concluded that L in the above formulas should be replaced by $L - 0.1\,nH$, where n is the number of full end contractions. This correction has been generally accepted, but it is by no means accurate, and for exact work in measuring water a weir without end contractions is to be preferred. These formulas all apply to a weir with a vertical upstream face, a sharp edge and with free access of air the under side of the overfalling sheet of water.

Rehbock's formula, published in 1912, is based on measurements over weirs ranging in height from 0.41 ft. to 1.64 ft. in a channel 1.64 ft. wide, with heads from 0.03 ft. to 0.75 ft., and is:

$$Q = 2/3\, mLh\sqrt{2gh} \quad \text{where} \quad m = 0.605 + \frac{1}{320\,h - 3} + 0.08\,\frac{h}{a}$$

Hazen's formula for sharp-edged weirs without end contraction (Trans. Am. Soc. C. E., Vol. LXXVII, p. 1289 *et seq.*) is:

$Q = \left(3.27 + 0.5\,\frac{h}{a}\right) h^{3/2}$, and for heads above 0.3 ft. gives results within 1% of those obtained by Francis and Fteley and Stearns.

The Schoder and Turner formula

$$Q = 3.33\,L\left[\left(h + \frac{v_a^2}{2g}\right)^{3/2} + h\,\frac{v_b^2}{2g}\right]$$

wherein v_a is the mean velocity in the channel above the level of the crest of the weir, and v_b is that in the portion below it, is the most accurate yet devised. (Trans. Am. Soc. C. E., Vol. XCII.)

Triangular or V-shaped Weir. This form of weir, suggested by Prof. Thomson of Dublin, possesses the peculiarity that, whatever the heads, the sections of the stream are similar, and hence it may be expected to have a coefficient more nearly constant than the ordinary weir and be particularly well adapted to the measurement of water where the flow varies through a considerable range. The coefficient will vary for different inclinations of the sides of the notch. For a sharp-edged weir in which the sides make an angle of 90 deg. with each other, since $L = 2\,h$, the discharge is $Q = 2.6\,h^{5/2}$.

Prof. H. W. King (Michigan Technic, October, 1916), gives $Q = 2.52\,h^{2.47}$ deduced from a series of experiments covering a range of h from 0.15 ft. to 1.8 ft.

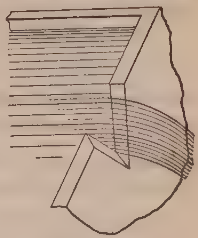

Fig. 17. Triangular Weir

Trapezoidal or Cippoletti Weir. By combining the rectangular notch or weir with end contractions, with the two halves of a triangular weir, it is possible to so proportion the triangular portions that they shall compensate for the effect of contraction and the result is approximately obtained when the inclination of the ends is one horizontal to four vertical. The formula

$Q = 3.367\ Lh^{3/2}$ is commonly used for such a weir without **velocity of approach.** Professor H. W. King recommends

$$Q = 3.34\ Lh^{1.47}\left[1 + 0.56\left(\frac{h}{a+h}\right)^2\right]$$

which takes account of **velocity approach.**

No experiments have been made upon weirs of this type when other than sharp-edged with vertical faces, but the effects of inclination and rounding may be expected to affect them similarly to rectangular weirs.

Rounding the Upstream Corner of the crest of a weir increases the discharge. With flat-crested weirs Bazin found this effect to amount to as much as 13% where the radius of the rounding was 4 in. and the breadth of crest 6.56 ft. Fteley and Stearns, with weirs up to 1 in. in breadth, found the rounding to be equivalent to increasing the head by $h_R = 0.7\ R$, where R is the radius of the rounding.

Inclining the Upstream Face away from the current decreases the contraction and increases the discharge as much as 10% when the slope is one of 45 deg. If the inclination is in the opposite direction, the contraction is increased and the discharge decreased. With a 45-deg. slope, the decrease may be as much as 7%. Inclining the **downstream face** does not materially alter the discharge until the slope becomes at least 3 horizontal to 1 vertical, when the discharge is reduced.

Rounding the Entire Crest reduces the discharge for low heads, but increases it for those wherein the curve of the crest approaches the curve of the natural under side of the sheet. By a combination of a rounded crest and an inclined upstream slope, the discharge may be increased 20% above that of the sharp-edged weir.

Flat Crests decrease the discharge until the head becomes so high that the sheet jumps clear of the downstream corner, when they have no effect. A broad flat crest may reduce the discharge 25% below that of the sharp edge.

The Sheet of Water adhering to the downstream face of a vertical sharp-edged weir has increased the discharge about 28%. The sheet being wetted, that is depressed and the space between it and the weir filled with water, due to the formation there of a partial vacuum, has increased the discharge about 15%. The sheet being depressed, but the space only partially filled with water, has increased the discharge about 6%.

Submerged Weirs. When water on the downstream side of the weir rises above the level of the crest, the weir is said to be submerged. If h_u is the head observed on the upstream side and h is the difference of head on the two sides, the usual formula for the discharge of a submerged weir is

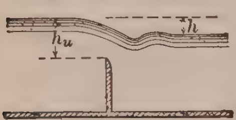

Fig. 18. Submerged Weir

$$Q = CL\sqrt{2\,gh}\,(h_u - h/3)$$

where C for a sharp edge varies from 0.58 to 0.63. On account of the difficulty of measuring h, the head in the lower pool, because of the turbulence there, accurate results with this formula are impossible.

15. Open Channels

Hydraulic Radius or Hydraulic Mean Depth. The Hydraulic Radius, also called the Hydraulic Mean Depth because it is the depth of a rectangle whose area is the same as that of the section under consideration and whose width is equal to the wetted perimeter of the latter, is equal to the area divided by the wetted perimeter and is represented by r. In open channels it takes the place of D in the pipe formulas, and for a circular pipe flowing full or half full is equal to $D/4$. The cross-sections of natural channels, particularly in soft materials, approximate to one or to two parabolic segments. It may therefore be useful to utilize the relation of the area to the arc of the parabola in approximating the hydraulic radius. Let y_1 = semi-width of channel if symmetrical about a vertical, or the distance from the bank to the vertical of greatest depth, d = the greatest depth, S_1 = length of the arc from the surface to the foot of the deepest vertical. The area of the semi-parabola $A_1 = 2/3\ y_1 d$, and the length of the arc when $d < 0.25 y_1$ is approximately $S_1 = y_1 + 2/3\ d^2/y_1$. If the channel is symmetrical, $r = A_1/S_1$, but if the other part be made up of a different parabola, then a similar expression may be written for A_2 and S_2 and $r = (A_1 + A_2)/(S_1 + S_2)$.

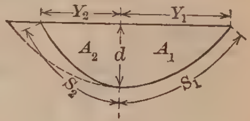

Fig. 19

Long Channels. In the term "open channel" are included all rivers, artificial canals, aqueducts and conduits and, in addition, sewers and pipes of whatever section which run partially full. The force producing flow cannot now be provided for by any external head, but is solely due to the slope or gradient of the channel.

Normal Flow. When the magnitude and distribution of velocities at various sections over a considerable length of the stream are the same, the flow is said to be normal. The curve of the distribution of velocities in a vertical section parallel to the direction of motion through any point of an open channel approximates an ellipse, being tangent to the bottom and with its axis in or near the surface of the stream. Wave action, eddies, etc., cause the velocities near the surface to be decreased, and this effect may extend to nearly half the depth. The actual curve then follows an ellipse halfway to the surface, where it leaves the ellipse and becomes somewhat flattened, giving a maximum velocity in the upper two-tenths of the depth. The mean velocity on any vertical is normally about 0.9 the maximum and occurs about 0.577 d from the surface, where d is the depth of the stream. The loss of head in open channels, probably on account of their greater irregularity, varies as a somewhat higher power of v than in pipes. It, therefore, is possible to use formulas involving v^2 with a less variation in the coefficient than in pipes, though an exponent of 1.9 gives more constant coefficients.

The Chezy Formula is $\mathbf{v = C\sqrt{rs}}$, where v is the velocity, C a coefficient, s the slope and r the hydraulic radius = area ÷ wetted perimeter.

The Bazin Formula is probably one of the best yet devised for the flow of water in open channels, although the same careful scrutiny has not been given to its roughness factors as to those of Kutter. It is

$$\mathbf{v} = \frac{87}{0.552 + \frac{m}{\sqrt{r}}}\sqrt{rs} = C\sqrt{rs}$$

where r is the hydraulic radius in feet and v is the velocity in feet per second. Values of the roughness factor m are as follows:

Very smooth surfaces of cement and planed boards	0.06
Smooth surfaces of boards, bricks, concrete	0.16

For brick sewers and dirty concrete	0.28
Ashlar or rubble masonry	0.46
Earthen channels, very regular or pitched with stones, tunnels and canals in rock	0.85
Earthen channels in ordinary condition	1.30
Earthen channels presenting an exceptional resistance, the wetted surface being covered with detritus, stones or weeds	1.75

Bazin's Formula. Values of C in $v = C\sqrt{rs}$

Hydraulic radius r, feet	(a) m = 0.06	(b) m = 0.16	(c) m = 0.28	(d) m = 0.46	(e) m = 0.85	(f) m = 1.30	(g) m = 1.75

(c) For smooth but dirty brick or concrete.
(d) For ashlar masonry.
(e) For earth canals in very good condition and canals pitched with stones.
(f) For earth canals in ordinary condition.
(g) For earth canals exceptionally rough.

The Kutter Formula, though largely used, is probably not entirely satisfactory for large streams with slight slopes. It depends for its accuracy almost entirely upon the experimental determination of its coefficient of roughness n, which changes for different velocities in the same channel, and great care must therefore be exercised in extending computations beyond the limits of actual experiment. Let r = hydraulic radius, s = slope, and v = mean velocity; then the formula is, for the English system of measures,

$$v = \left[\frac{41.6 + \frac{1.811}{n} + \frac{0.00281}{s}}{1 + \left(41.6 + \frac{0.00281}{s}\right)\frac{n}{\sqrt{r}}}\right]\sqrt{rs} = C\sqrt{rs}$$

For slopes steeper than 1 ft. per 100 ft., the coefficient C remains practically constant for a given n and r and has the values given in the adjacent columns for $S = 0.01$.

When $r = 3.28$ ft. the value of C is independent of the slope and its value is $1.811/n$.

where the coefficient of roughness n has the following values:

Rectangular wooden flume (very smooth)	0.0098
Neat cement, glazed pipes and very smooth iron pipes	.010
Plaster, 1 : 3 mixture, iron pipes in best order	.011
Unplaned timber, ordinary iron pipe	.012
Brick washed with cement, basket-shaped sewer:	
6 by 6.7 ft., nearly new	.0130
6 by 6.7 ft., one year old	.0148
6 by 6.7 ft., four years old	.0152
Brick washed with cement, 9 ft. in diameter:	
Nearly new	.0116
Four years old	.0133
Old Croton aqueduct, brick lined	.015
Sudbury aqueduct	.01
Glasgow aqueduct, cement lined	.0124
Steel pipe, riveted, clean, 1897 (mean)	.0144
Steel pipe, riveted, clean, 1899 (mean)	.0155
Rough brickwork, incrested or tuberculated iron	.015
Brickwork or ashlar in bad condition, rubble in cement in good order	.017
Rough rubble in cement, stone pitching, very firm gravel	.020
Earth of tolerably uniform cross-section, slope and direction, in moderately good order and regimen, and free from stones and weeds; or stone pitching in bad condition	.025
Earth, having stones and weeds occasionally	.030
Gravel in bad condition, earth in bad order and regimen, overgrown with vegetation, and strewn with stones and detritus	.035

Manning's Formula (Trans. Inst. C. E. of Ireland, Vol. 20, 1890) is

$$v = \frac{1.486}{n} r^{2/3} s^{1/2}$$

in which the values of n are very near those for Kutter's formula given above.

The Hazen and Williams formula

$$v = cr^{0.67} s^{0.54} 0.001^{0.04}$$

may be used for open channels with the following coefficients:

For very smooth channels	C = 135 to 140
For ordinary unplaned plank	C = 104 to 118
For ordinay sewer crock	C = 100 to 127
For ordinary brick sewers	C = 100 to 125
For large canals in rock	C = 75 to 95
For ordinary earthen channels	C = 35 to 84
For rough natural channels	C = 30 to 70
For floodways through brush	C = 25 to 40
For floodways through trees	C = 15 to 20

16. Variations in Sections

Roughness. In general, the effects of roughness in a stream bed have been taken care of by coefficients. The action in streams is similar to that in pipes, causing eddies and cross currents which absorb head and so reduce velocity.

Curvature disarranges the distribution of velocities and prevents the continuance of normal conditions of flow. In general, the tendency is for the velocity on the concave side of the stream to decrease, thus causing some of the material in suspension to be deposited. This decrease in velocity on the concave side is accompanied by an increase in velocity on the convex side, giving rise to erosion. In general terms, the conditions of scour will prevail where the hydraulic axis is convergent to the bank, produce fill where this axis diverges from the bank, and cause no action where the axis and bank are parallel; the hydraulic axis is taken as the locus of the center of gravity of the section of the stream.

Principles which govern a stream freely forming its own channel in an alluvial plane are: (1) A plastic mass moving in a resisting medium will assume the form in which it encounters least resistance. (2) The transverse section of a body adjusted to the form of least resistance will have the maximum ratio of area to perimeter. (3) The form of a fluid mass will vary, whenever the direction of movement is changed, by virtue of the unequal inertia of particles in different parts of the mass. (4) The form being unsymmetrical and the direction of movement not a straight line, if the mass is variable the path described by the center of gravity, or the hydraulic axis, will be variable also in position and length. (5) With given limits of mass variation, the vagation of the paths will lie within a zone of certain width.

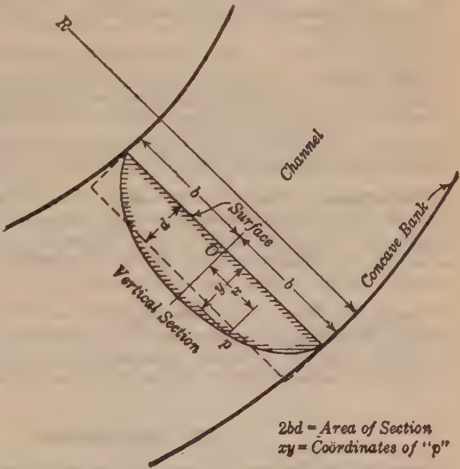

Fig. 20

Thus a river traversing a homogeneous soil will form a bed whose width and depth will be largely determined by the variations in volume, being wider and shoaler as the vagation of the hydraulic axis is greater; narrower and deeper as the volume becomes constant and the vagation of the hydraulic axis becomes less.

Cross-section and Curvature. The relation between the cross-section of the stream and the curvature in soft material when the channel has reached a condition of stability is given by H. C. Ripley, Trans. Am. Soc. C. E., Vol. XC, by the following equations from which the section may be plotted:

For streams where the channel occupies the full width of the waterway:

$$\text{(I)}\quad y = 1.445\,d\left(1 - \frac{x^2}{b^2}\right) + 1.445\,d\left[\frac{17.52}{R}\left(1 + \frac{x^2}{b^2}\right)x\right]$$

For channels not occupying the entire width of the waterway and to channels at harbor entrances created by the action of a single curved jetty:

$$\text{(II)}\quad y = 1.65\,d\left(1 + \frac{x^2}{b^2}\right) + 1.65\,d\left[\frac{26.28}{R}\left(1 - \frac{x^2}{b^2}\right)x\right]$$

Wherein d = mean depth of channel in feet;
b = half-width of channel in feet;
R = radius of curvature of the concave side of the channel, in feet;
x is the abscissa and y the ordinate of a point on the bottom, the origin of coordinates being taken at the center of the channel at the water surface.

When R is less than 40 $\sqrt{\text{area of section}}$ no further deepening of the channel results from increased sharpness of curvature.

When R is greater than about 50 $\sqrt{\text{area of section}}$ the shape of the channel does not conform strictly to that given by the equations.

Formula II is not applicable to straight channels nor to curved ones when R exceeds about 110 $\sqrt{\text{area of section}}$.

On a cross-over bar when the channel is neither on a curve nor in a straight reach the maximum depth is about 14-1/2% less than the computed value.

Formula II gives a width of channel at mean depth about 20% greater than the actual width.

Hence it follows: (1) That every artificial channel, whether it is a flume, an open aqueduct, a ditch or a drainage canal, to discharge the greatest volume with a given slope should have the form determined by formula I both in straight and curved reaches; and (2) That bends in streams when R is greater than 40 $\sqrt{\text{area of section}}$ are constructive bends and tend to stability whereas sharper bends are destructive, tending to shift the channel.

Obstructions. The loss in velocity, due to obstructions, arises mainly in the loss in expansion from the contracted section to the normal section of the stream. Wherever an obstruction occurs, the velocity is increased and the surface level generally lowered. After the obstruction is passed, the velocity decreases and the surface rises to normal.

Change of Section. (See also General Laws under Curvature.) In general a change of section is accompanied by a change in the distribution of velocity. In a stream through a homogeneous alluvial soil, change in the distribution of velocity is accompanied by either erosion or deposition of material.

17. Backwater

Formulas are frequently given for computing the extent and rise of backwater caused by an obstruction in a stream, but in order that a formula may be applicable to such cases as occur in practice it must be extremely complicated. Those usually given consider only a change in depth, without the necessarily corresponding change in width. For practical application, except in the extremely rare case of backwater in an artificial channel with vertical sides, such formulas are valueless. The practical method of solving the problem is to divide the channel in which the backwater occurs into reaches such that both the velocity and the hydraulic radius will be substantially constant throughout each reach, and to compute for each reach, beginning with that next the obstruction, for a mean v and r, the h_f. This h_f when added to elevation of the surface at the downstream end gives the elevation at the beginning of the next reach. By making the several sections sufficiently short, any desired degree of accuracy may be obtained within the limits of the formula used for loss of head.

Bridge Piers. An experimental investigation on models of bridge piers having widths of 6 in. and lengths from 18 to 33 in. in a flume 26 in. wide, the depth of water being about 2 ft., by Floyd A. Nagler, Jun. Am. Soc. C. E. (Trans. Am. Soc. C. E., Vol. LXXXII), has developed the following formula for backwater due to such piers:

Let C = a coefficient;

d_1 = depth of water at point of measurement of velocity of approach above piers in feet;

d_2 = depth of water at point of measurement of velocity of retreat below piers in feet;
h = observed difference of head between water surfaces above and below piers = backwater effect of piers in feet;
K = a coefficient;
Q = flow in channel in cubic feet per second;
V_1 = velocity of approach above piers in feet per second;
V_2 = velocity of retreat below piers in feet per second;
W = unobstructed width of channel at piers in feet.

Then assuming the slope of the channel throughout the area considered to be zero:

$$h = \frac{Q^2}{2g\left[CW\left(d_2 - \frac{0.3\,V_2^2}{2g}\right)\right]^2} - K\frac{V_1^2}{2g}$$

in which C varies from 0.86 for a rectangular pier to 0.94 for a pier with boat-shaped nose and fish-shaped tail.

If there is a perceptible fall in the channel from the point of measurement of d_1 to that of d_2 the value of d_2 must be decreased by this fall, and if there is a rise the value of d_2 must be increased by the rise.

The coefficient K varies with the percentage of the original channel that is obstructed, approximately as follows:

Per cent obstructed..	0	5	10	15	20	30
Coefficient K.........	1.00	1.04	1.27	1.50	1.70	1.93
Per cent obstructed..	40	50	60	70	80	90
Coefficient K.........	2.00	2.03	2.04	2.05	2.06	2.07

Example. Let Q = 19 500 c.f.s.
Area of unobstructed stream = 3680 sq. ft.
Area of obstruction = 351 sq. ft. = 9.5%
Area of clear waterway = 3329 sq. ft.
Depth of channel d_2 = 16.4 ft.

$$V_1 = \frac{19\,500}{3680} = 5.3 \text{ ft. per sec.}$$

$$\frac{V_1^2}{2g} = \frac{V_2^2}{2g} = 0.4362 \text{ ft. and } 0.3\frac{V_2^2}{2g} = 0.131 \text{ ft.}$$

Assume C = .894 from shape of obstruction
K = 1.25 from area of obstruction

Substituting in formula there results:

$$h = \frac{19\,500^2}{64.4 \times 0.894^2 \times 203^2\,(16.4 - 0.13)^2} - 1.25 \times 0.4362$$

$$= 0.677 - 0.545 \text{ ft.} = 0.132 \text{ ft.}$$

Jump. When an obstruction is present in a stream, and the slope is so steep that the velocity v_1 before the obstruction is greater than $\sqrt{gd_1}$, where d_1 is the depth before the obstruction, a jump is likely to occur, producing a depth d_2, and if the velocity head $v_1^2/2g$ be called h, the value of d_2 is slightly less than that given by

$$d_2 = 1/2\,h + \sqrt{h\,(d_1 + 1/4\,h)}$$

and the height of the jump is then $d_2 - d_1$.

Investigations by Prof. S. M. Woodward of the State University of Iowa

(Miami Conservancy District Technical Reports, Part III, Dayton, Ohio, 1917) have developed the following formula for the **hydraulic jump** which is in close accord with the experimental results:

Let d_1 = depth of water above jump;
d_2 = depth of water below jump;
V_1 = velocity of stream before jump occurs.

$$d_2 = -\frac{d_1}{2} + \sqrt{\frac{d_1^2}{4} + \frac{2\,V_1^2\,d_1}{g}}$$

Waves. When the water in a stream passes under or over some obstruction and is then thrown upward, a standing wave is produced. When a stream of high velocity discharges into a large body of water moving with a slower velocity, the curve of heading up does not always extend back till it reaches the free surface of the water, but ends abruptly at the point of change of velocity and a standing wave may be there produced. Under these conditions very little of the velocity head is converted into head of elevation, but is absorbed in impact and wave formation.

Whirlpools, eddies, and waves all indicate a useless expenditure of force and are like to cause damage to banks and bed. Where a minimum of loss of head is desired they should be as far as possible eliminated, which may usually be accomplished by smoothing the channel and removing abrupt changes of section.

18. Transportation of Sediment

Sediment can be transported by a stream in two ways: By being dragged or rolled along the bottom, or by being carried along in suspension. The weight of particles which will be dragged or rolled along by a stream is supposed to vary as the sixth power of the velocity. The experimental data usually quoted to determine the velocity at which different materials are moved were made before the beginning of the last century. These with some more added since by various observers gave a limiting bottom velocity for stability of material as follows:

Material	Bottom velocity, ft. per sec.
Soft earth	0.25
Soft clay	0.50
Sand	1.00
Gravel	2.00
Sea pebbles (1.06 in. in diameter)	2.20
Brickbats (4.76 cu. in.)	2.25 to 2.50
Slate (9.06 cu. in.)	2.75 to 3.00
Broken stone	4.00

Observations made in India show that for any section of channel and character of silt there is a certain **critical velocity** $\mathbf{v_s}$ at which silt is neither picked up nor deposited. If the velocity is increased, scour results; and if it is decreased, silting occurs. This critical velocity is found to depend upon the depth and to be given by the equation $\mathbf{v_s = md^{.64}}$, where d is the depth of the channel and m is a coefficient whose values are given as follows:

For fine light sandy silt of northern India,	$m \doteq 0.82$
For somewhat coarser light sandy silt,	$m = 0.90$
For a sandy loam,	$m = 0.99$
For a rather coarse silt, as débris of hard soils,	$m = 1.07$

The silt-transporting power of a stream is said to vary as $v^{2.56}$. (Kennedy, Proc. Inst. C. E., 1894–5, vol. 119.)

Velocities of Descent of certain fine materials through still water are:

Materials	Velocity, ft. per sec.
Brick clay (mixed with water and allowed to settle half an hour)	0.009
Fresh-water sand	0.166
Sea sand	0.196
Rounded pebbles (size of peas)	1.000

The heads corresponding to these velocities, h_v, may be taken to measure the amount of pressure head h_p acting upward that is necessary to keep them in suspension. If the change of velocity in any vertical is such as to cause the excess of h_p at the lower level over that next above to be equal to or greater than the h_v obtained above for the particular material, there will be no deposition. As the rate of change of velocity is greatest near the bottom, the greatest amount of suspended matter will be found in that region, because material which may settle through the upper layers will have its descent stopped by the more rapidly increasing pressures.

The flow of ground water into a river through its bed aids in suspension by giving an upward velocity to the water near the bottom; and obstructions in the bottom which direct the current upward aid in suspension temporarily; but the main factor in the transmission of suspended matter is the increase of pressure from point to point on a vertical as the velocity decreases. Whenever due to a disturbance of any sort the velocities in a vertical are equalized, the pressures become equalized also and the material deposits.

The Phenomena of Scour, in the case of beds along which the water passes tangentially, are also due to differences of pressure caused by variations of velocity. The velocity in the semi-fluid layers of sediment next the bottom is relatively very low, whereas that in the water just above may be considerable. The pressure in the water is then less than that in the saturated material, and the excess in the latter lifts the particles of it up into the current until the velocity of the latter is reduced to a point where equilibrium is established, or else all the loose materials are carried away, and in either case the scour ceases.

The proportion of silt in various waters, in parts per 100 000 by weight, is as follows, the amounts for the Rhine, Vistula, and Rhone being very exceptional.

Mississippi, near mouth, in flood	175
Mississippi, near mouth, ordinary	67
Mississippi, above Ohio, ordinary	20 to 30
Ohio, at Louisville, ordinary	35
Ohio, at Cincinnati, ordinary	23
Allegheny, at Pittsburgh, ordinary	5
Interior rivers in Illinois, ordinary	1 to 8
Colorado, at Yuma, average annual	560 to 1420
Colorado at Yuma, flood, Jan., 1916	2990
Rhine, Germany, in flood	1000
Vistula, Germany, in flood	2000
Maas, Holland, ordinary to flood	1 to 30
Danube, Austria, ordinary	33
Rhone, France, in flood	2000
Po, Italy, in flood	330
Nile, Egypt, in Flood	150
Ganges, India, in flood	130 to 800
Indus, India, in flood	420
Sutlej, India, in flood	300 to 900
Roorkee, canal, India, in flood	3000
Indian rivers, average for year	61
Yellow, China, normal	400
Yellow, China, average flood	6500
Yellow, China, high flood	9000 to 10 000

Bank Slopes. The angle ϕ at which materials stand when submerged varies considerably. Very light material, as might be expected, assumes the steepest slope when the current impinges against the bank in flowing past. The following are given as results of observations in India.

Alluvial soil, soft rock, and very firm gravel; slope 1/2 horizontal to 1 vertical, or $\phi = 63° 20'$.

Stiff earth or clay, or alluvial banks with stone pitching; slope, 1 to 1, or $\phi = 45°$.

Ordinary earth; slope 1-1/2 horizontal to 1 vertical, or $\phi = 33° 40'$.

Loose earth and soft slippery clay; slopes, 2 horizontal to 1 vertical to 3 horizontal to 1 vertical, or $\phi = 26° 30'$ to $18° 20'$.

MEASUREMENT OF WATER

19. Weight and Volume

The methods of measuring water may be classed as absolute and inferential. The absolute methods are two: by weight and by volume. The inferential methods embrace the nozzle, the Venturi meter, the orifice, the weir, the float, the current meter, the waterwheel, the hydrometric pendulum, coloring matter and chemicals, as well as variations of these methods. In some cases the method may appear to occupy an intermediate position between the two classes, but generally will fall in one or the other.

By Weight. The most accurate method of measuring water is by weight, and when the weight of a quantity of water and its temperature are known, its volume can be readily computed. This method is necessarily limited, by the capacity of weighing apparatus, to moderate or small quantities. The following table gives the volume of 100 lb. of water at various temperatures.

Volume in Cubic Feet of 100 Lb. of Water

Temperature, degree Fahr.	Volume	Temperature, degree Fahr.	Volume	Temperature, degree Fahr.	Volume	Temperature, degree Fahr.	Volume
32	1.6021	50	1.6024	90	1.6098	160	1.6392
35	1.6020	60	1.6035	100	1.6129	180	1.6505
39.3	1.6019	70	1.6051	120	1.6202	200	1.6629
45	1.6020	80	1.6073	140	1.6290	212	1.6709

By Volume. The method ranking second in accuracy is by volume. The volume that can be so handled is limited by the capacity of the measuring vessel or tank, which may vary from a pipette to a reservoir or a natural lake. The accuracy of the observation depends upon the accuracy with which the areas and change of level of the surface are determined. If V = the volume, L = its length, A_1, A_2, and A_c = the areas respectively of the two ends and the mid-section of the body, and A_m = the mean area, then the volume is given by the prismoidal formula $\mathbf{V = 1/6\,L\,(A_1 + 4\,A_c + A_2)}$, and the mean area perpendicular to L is $A_m = 1/6\,(A_1 + 4\,A_c + A_m)$. These formulas apply to the sphere, the hemisphere, any segment of a sphere, a ring or torus, a cone, a pyramid, a wedge, a frustum, a paraboloid, an ellipsoid or any segment of one, and to practically all solids having parallel ends and bounded by plane surfaces.

When measurements are made in tanks with irregular bottoms, the bottom should be covered with water and the difference of elevation of the water surfaces, before and after filling, be measured by means of a hook gage, a point gage, a tube gage, or a scale, depending on the accuracy desired, the devices being here enumerated in the order of their accuracy.

Approximate Volumetric Measurements. The methods under this head include the various water meters in which a liquid fills a space and is then expelled through ports or valves by a piston, as in the water cylinder of a pumping engine — which falls in this class. On account of leakage through the valves and past the piston and the possibility of the space not being completely filled when operating at high speeds, the volume of the liquid does not exactly coincide with that of the chamber, and where exactness is required the relation between the two must be experimentally determined. The amount of liquid discharged may vary from the volume of the chamber by from 1 to 20% of the latter. A device used for measuring water at Lowell early in the last century belongs to this class; it consisted of a large paddle-wheel arranged with its paddles closely fitting a specially prepared channel through which the water to be measured was caused to flow. The paddle, completely obstructing the channel, was driven ahead by the water. The wheel therefore assumed the velocity of the water, and so long as the paddle was in close contact with the sides and bottom of the channel the volume swept through by it below the plane of the water surface measured the quantity of water passing in that time, subject to a correction for leakage past the paddle, which relatively to the total volume could be made very small. A modification of this device has been utilized in Europe at some of the turbine-testing plants, where a very easy-running car, traveling on a track over a channel, carries a screen which can be lowered into the water and which fills the cross-section of the channel. The car is then driven forward at practically the velocity of the current, and the volume swept through by the screen below the water surface measures the water discharged, with a small correction for leakage around the edges. With a sufficiently long channel, the possibilities of accuracy in the apparatus considerably exceed those of any of the inferential or of the other semi-inferential devices.

To this class belong the various automatic flush tanks which are designed to discharge their contents when the water reaches a certain elevation, either by causing the tank to turn on its axis, or by bringing a siphon into action, or by operating valves with the aid of a float. These are sometimes designated as low-pressure meters because they use up or dissipate the major part of the pressure energy of the stream. This class also includes those of the pressure water meters in which there is a definite space filled by the water, whether it is that formed by the displacement of a reciprocating piston, a vibrating disk, or a revolving chamber, in all of which the moving part is essentially a piston. All such apparatus must be calibrated before its indications can be relied upon in cases where exact determinations are essential.

20. Nozzles and Venturi Meters

By the Nozzle. The measurement of water by means of a nozzle requires first an accurate determination of the area of the outlet and of the section at which the pressure is read, and thereafter the observation of the pressure at some point as close as possible to the inlet of the nozzle. This pressure should be observed as communicated through at least four orifices situated 90 deg. apart in a plane perpendicular to the axis of the nozzle. The orifices should be cut with their walls normal to the axis of the pipe where the elements of the interior surface are parallel, or at least the tangents to the elements at the plane of the orifice should be parallel to each other and to the axis of the channel. The edges of the orifices should be smooth without projecting slivers or burrs, and the several orifices should be united to a common equalizing chamber to which the pressure gage is connected. Frequently this chamber is an annular space surrounding the pipe, being made in a special casting designed for the purpose. Fairly good results may be obtained by connecting the gage to a single orifice at the base of the nozzle, but in this case it is important to remove to a considerable distance upstream, ten diameters of the pipe at least, any curvature or obstruction causing an unsymmetrical disturbance of the velocities. In any event a curve should not be within five diameters of the place where the pressure is read, unless a screen or baffle is used to equalize the velocity distribution before the gage is reached. Let A_g = area at the gage section, A_n = area at the nozzle outlet, h_p = pressure head at gage section, h_{vg} = velocity head at gage section, h_{vn} = velocity head at nozzle outlet, Q = quantity of water discharged, v_g = velocity at gage section, v_n = velocity at nozzle outlet, C = coefficient of discharge. When the nozzle is horizontal,

$$h_{vn} = \frac{h_p}{1 - (A_n/A_g)^2}$$

When the center at the gate section is a vertical distance z below the center of the nozzle outlet, h_p in the above equation must be decreased by the distance z, and if the gage section be above the outlet by the distance z, h_p must be increased by z. Then

$$Q = CA_nv_n = CA_n\sqrt{2\,gh_{vn}} = CA_n\sqrt{2\,g\frac{h_p \pm z}{1 - (A_n/A_g)^2}}$$

With a smooth tapering nozzle, 2 in. or more in diameter at its outlet, the angle of convergence between the two sides being from 10 to 15 deg., and a waterway leading to it of such form as to prevent swirls and eddies, and a carefully made piezometer connection having at least four orifices as above described, connected to an accurate gage for measuring the head, the coefficient C may be taken at 0.995 and the resulting measurement may be within 1/4 of 1% of the actual discharge. In ordinary work, however, a coefficient of 0.98 is as high as it is safe to rely upon, and the discharges so computed, with careful observation, should be within 1% of correctness. In smaller nozzles the coefficient will be somewhat lower than in large ones, and may be expected to increase for very large sizes.

If the nozzle outlet is submerged, h_p in the foregoing expressions must be decreased by the depth of water over the center of the nozzle outlet, and in the event of discharge into a vacuum, h_p must be increased by the height of water column equivalent to the measure of the vacuum. (Trans. Am. Soc. C. E., 1891, vol. 23, p. 492.)

By the Venturi Meter. This device consists of a short truncated converging cone united by a short cylindrical or forge section, called the throat, to a diverging truncated cone, the latter being much longer than the former and having therefore a more gradual taper. The pressure head is read through piezometer connections at the inlet of the upstream cone and at the throat, the difference of pressure head at the two points representing the increase in velocity head at the smaller section over that at the larger and the frictional loss between the two. As the upper cone is short, usually not

over two diameters in length, and may be made quite smooth, the latter element is ordinarily negligible. The discharge is computed by the same formula as that of the nozzle when h_p is replaced by the difference of the pressures read at the inlet and the throat. Let A_i = area at inlet to meter, A_t = area at throat, h_{pi} = pressure head at inlet and h_{pt} = pressure head at throat. Then

$$Q = CA_t\sqrt{2g\frac{h_{pi} - h_{pt}}{1 - (A_t/A_i)^2}}$$

The coefficient C has an average value of 0.96 to 0.98 and is increased when the inlet is near a curve over the condition when following a straight pipe. Ordinarily the accuracy of measurement should be within 3%. The loss of head in passing through the meter is usually from 10 to 15% of the difference of pressure head between inlet and throat. A special recording device is furnished with the meter castings by the manufacturers. The commercial size of the meter is that of the inlet, or the same as that of the pipe in which it is to be set. (Trans. Am. Soc. C. E., 1887, vol. 17, p. 228.)

Let d and D be diameters of the throat and inlet pipe in inches, and h the so-called "head on the meter," or $h_{pi} - h_{pt}$, in feet. Then the discharge, in U. S. gallons per 24 hours, is

$$Q = 28276\,C\frac{d^2\sqrt{h}}{\sqrt{1 - (d/D)^4}}$$

In Eng. News, July 31, 1913, Allen Hazen concludes that 0.99 is the usual value of C, and J. W. Ledoux gives 0.97 as derived from tests on 2- and 8-in. throats for high velocities. In Eng. News, Oct. 2, 1913, A. T. Safford gives 0.97 for small discharges and nearly 1.00 for large ones. Tests at Cornell University by E. W. Schoder in 1915 on a 12 by 5-in. meter gave about 0.99 for C when the discharge was about 9000 gal. per minute.

Fire Streams. The preceding table gives the characteristics of fire streams from smooth conical nozzles, as established by the experiments of John R. Freeman, Mem. Am. Soc. C. E. (Trans. A. S. C. E., Vol. XXI). The pressures indicated are those existing while the stream is flowing. For ring nozzles the characteristics correspond to those of the next size smaller smooth nozzle.

21. Orifices

For Small Orifices 1 in. in height or less, the coefficient 0.61 for the discharge from circular orifices and 0.62 for square and rectangular ones, if the head be more than eight times the vertical dimension, will give results sufficiently accurate for ordinary cases. If more accurate gagings are required, the orifices should be calibrated in place by weighing or volumetrically measuring the water discharged under different heads. When the vertical dimension of the orifice is more than one-sixth the head over the top, the variation of pressure between the top and the bottom causes the center of pressure on the orifice to be appreciably below the center of gravity, and the center of pressure at the vena contracta is below that at the plane of the orifice. Let the notation be

A = area of orifice; A_c = area of jet at vena contracta;
C_v = coefficient of velocity; C_c = coefficient of contraction;
C or C_vC_c = coefficient of discharge;
h_b = head above bottom of orifice; h_{bc} = head above bottom of vena contracta;
h_g = head above center of gravity of orifice; h_t = head above top of orifice;
h_{tc} = head above top of vena contracta; h_v = head due to velocity of approach;

L = length of sill of rectangular orifice; v = velocity through orifice;
v_c = velocity through vena contracta; Q = quantity discharged;
R = radius of a circular orifice;
x = width of orifice at any point; x_c = width of vena contracta at any point;
z = height of water surface above any point of the orifice;
z_c = height of water surface above any point in the vena contracta.

The General Formula for discharge per second is

$$Q = Av = A_c v_c = C_v \sqrt{2g} \int_{h_{tc} + h_v}^{h_{bc} + h_v} x_c z^{1/2} \, dz \tag{1}$$

in which, if x_c is not constant, it must be expressed as a function of z. The application of this formula requires the determination of the dimensions of the vena contracta, which is a difficult operation, and therefore the dimensions of the orifices may be substituted for those of the vena contracta and the coefficient of contraction C_c may be introduced, when, since $C_v C_c = C$, the above equation becomes,

$$Q = Av = C \sqrt{2g} \int_{h_t + h_v}^{h_b + h_v} x z^{1/2} \, dz \tag{2}$$

If the orifice is horizontal $h_b = h_t$ and z is constant. For a rectangular orifice in which $x = L$, after integrating,

$$Q = Av = 2/3 \, CL \sqrt{2g} \, [(h_b + h_v)^{3/2} - (h_t + h_v)^{3/2}] \tag{3}$$

The best experiments show the value of the coefficient with full contraction on all sides to be practically constant and for square orifices $C = 0.604$, for circular orifices $C = 0.597$.

If contraction is suppressed on one side by bringing the wall of the channel of approach into coincidence with the plane of the side of the orifice, the contraction on the opposite side is increased somewhat, but not by an amount equal to the original contraction on the side suppressed.

For a rectangular orifice 0.656 ft. high and 2.624 ft. wide with end contractions suppressed, Bazin's experiments give the coeficient C in equation (3) as 0.624, showing about 3% increase of discharge above that for full contraction on all sides.

For square orifices the experiments of Lebros give: Contraction suppressed on one side, C is increased 2.9%. Contraction suppressed on two sides, C is increased 5.25%. Contraction suppressed on bottom, C is increased 3.25%. Contraction suppressed on bottom and one side, C is increased 7.25%. Contraction suppressed on bottom and two sides, C is increased 11.5%.

For circular orifices Bidone deduced the effect of full suppression as increasing C or the discharge 12.8% and partial suppression correspondingly. It is to be noted the suppression at the top would have less effect than at the bottom, and may be taken as increasing the discharge of a square 2.6%. From this it may be expected that the suppression of contraction over the lower half of a circular orifice would increase the discharge about 8%, over the upper half about 5%, and over one side half about 6%.

Stewart's experiments at the University of Wisconsin on 4 ft. sq. submerged orifices and pipes give considerably higher results where contraction is suppressed by a curved entry. See Art. 7.

For the discharge of sluice gates where the bottom and sides coincide with those of the channel, the coefficient for the corresponding orifice may be used provided there is no apron beyond the gate and the discharge is allowed to fall away freely. If there is an apron or chute or continuation of the channel, the friction along it will reduce the coefficient, particularly at low heads. When h_g was about 2-1/2 times the height of the opening, the discharge has been found to be as much as 12% less than for the orifice with full contraction.

22. Weirs

The Weir affords the most commonly used method of measuring the volume of water in moderately large quantities. The standard weir, or sharp-edged weir, consists of a vertical partition across a channel with its top edge horizontal, sharp cornered and narrow enough so that at the heads used the overflowing sheet jumps from the upstream edge clear of the downstream corner. Such weirs may be either with or without end contractions. A weir with end contractions is one whose crest extends only part way across the channel and is terminated by partitions in its plane, with their vertical edges rising above the level of the water on the upstream side. Such a weir may be compared to a rectangular orifice upon which the head has fallen below the top. A weir without end contractions is one which extends entirely across the channel. If a = height of crest of weir above bottom of channel of approach, A_w = area of stream in the plane of the weir, H = height above the crest of the surface of still water upstream from the weir, h = head above crest as observed, v_w = velocity in and perpendicular to the plane of the weir, then the formula for the discharge is similar to that for the orifice and is

$$Q = A_w v_w = 2/3\ CL\sqrt{2g}\cdot H^{3/2} = 2/3\ CL\sqrt{2g}\,(h + h_v)^{3/2}$$

Since $LH = L(h + h_v)$ = area of the stream above the crest level at the plane of still water and CLH is the area in the plane of the crest, the total **head** producing flow is $2/3\sqrt{2g}\,(h + h_v)$. (h_v = head due to velocity of approach.)

The Francis Formula. The coefficient C in this formula was determined experimentally by James B. Francis as about 0.62, and by combining this with $2/3\sqrt{2g}$, the well-known coefficient of the Francis formula 3.33 is obtained. This formula was considered by its inventor to be reliable between heads of 0.5 ft. and 2.00 ft. Later investigators have modified it into the form:

$$Q = 3.33\ L\,(h + 1.4\ h_v)^{3/2}$$

In applying this formula the process is as follows: Having measured the head h at a point above the surface curve to the weir, compute an approximate value of the discharge by the equation $Q_1 = 3.33\ Lh^{3/2}$. Find the approximate velocity at the plane where the head is observed by the equation $v = Q_1 \div L(h + a)$ and the velocity head by $h_v = v^2/2\ g$. Then Q is obtained by substitution in the above formula and should be within 3 to 4% of correctness if the head is not more than 30% of a and has been properly measured, and the sheet is fully aerated underneath.

For weirs with end contractions Francis recommended reducing the length L in the above formula by 0.1 H for each full end contraction. This correction is only an approximation and, for accurate gagings, weirs with end contractions should not be used.

The Machinery Builders Society in October, 1917, in connection with the Testing Code for Hydraulic Turbines, adopted the following coefficients for use with the Francis formula in the form $Q = CLh^{3/2}$ which include the effect of velocity of approach.

Table of Values of C for Various Heads and Heights of Crest a

Head h	Height of crest a, in feet									
	4	5	6	7	8	9	10	12	14	16	20
1.0	3.376	3.356	3.344	3.335	3.329	3.325	3.322	3.317	3.314	3.311	3.308
1.2	3.391	3.366	3.350	3.339	3.332	3.326	3.322	3.316	3.311	3.308	3.305
1.4	3.409	3.378	3.359	3.346	3.336	3.330	3.324	3.316	3.311	3.307	3.303
1.6	3.429	3.392	3.370	3.354	3.343	3.334	3.328	3.319	3.312	3.308	3.302
1.8	3.450	3.408	3.382	3.363	3.350	3.340	3.333	3.322	3.315	3.309	3.303
2.0	.....	3.425	3.394	3.373	3.358	3.347	3.338	3.325	3.317	3.311	3.304

The above coefficients are the averages of values computed by the following three formulas:

(1) Bazin,

$$Q = \left(0.405 + \frac{0.00984}{h}\right)\left[1 + 0.55\frac{h^2}{(a+h)^2}\right]\sqrt{2g}\,Lh^{3/2}$$

(2) Rehbock,

$$Q = \left[0.605 + \frac{1}{320h-3} + 0.08\frac{h}{a}\right]\frac{2}{3}\sqrt{2g}\,Lh^{3/2}$$

(3) Fteley-Stearns,

$Q = 3.31\ L\ (h + 1.5\ h_v)^{3/2} + 0.007\ L$, in which

h_v = head due to velocity of approach.

The formula of Rehbock is based upon rather small scale laboratory experiments, and in the writer's opinion is given undue weight in this connection.

The Bazin Formula has been considered the most accurate one for wide ranges of head, and it has been commonly applied between heads of 0.2 ft. and 6 ft.; it does not require a correction for velocity of approach, as it is based upon the observed head h and not on the **theoretical** or **total** head $H = h + h_v$ as are the others. It applies only to weirs without end contractions and is

$$Q = \left(0.405 + \frac{0.00984}{h}\right)\left[1 + 0.55\left(\frac{h}{a+h}\right)^2\right]Lh\sqrt{2gh}$$

The tables, on pp. 1360 and 1361, give values of Q for a weir 1 ft. long and for various values of h and a. The value of g used in computing these tables is 32.17 ft. per sec. per sec.

Recent investigations indicate that it gives too high values for heads below one foot when applied to truly sharp edged weirs.

When the weir is so high that the velocity of the approaching water is practically zero, Bazin's formula reduces to

$$Q = \left(0.405 + \frac{0.00984}{h}\right)Lh\sqrt{2gh}$$

At low heads, less than 0.2 ft., Bazin's formula gives discharges somewhat too high and the formula proposed by Fteley and Stearns is recommended, which is:

$$Q = 3.31\ LH^{3/2} + 0.007\ L$$

The results by this formula are within 4 to 6% of the experimental values for heads ranging from 0.2 to 0.007 ft., and the actual discharges were generally in excess of those given by the formula. It holds only so long as the sheet jumps free of the crest and the space behind it is fully aerated.

Schoder and Turner Formula. From several series of experiments involving 2438 individual determinations, carried on at the Cornell Hydraulic Laboratory, in which the flow was very accurately measured volumetrically, the range of head covered being from 0.012 to 2.75 ft., and weirs ranging in height from 0.5 to 7.5 ft., and comparisons with the work of previous experimenters, Francis, Fteley and Stearns, Bazin and Rehbock, Professors E. W. Schoder and K. B. Turner derived a more accurate expression for the discharge of a vertical smooth sharp-edge weir than any of the foregoing. Their formula involves both the velocity of approach above the level of the weir crest v_a and that below it, v_b (Trans. Am. Soc. C. E., Vol. XCII, Proceedings, Sept., 1927) and requires the distribution of velocity in the channel of approach to be investigated by current meters.

Discharge in Cubic Feet per Second per Foot of Length over Sharp-edged Vertical Weirs without end Contractions

Computed by Bazin's Formula

The formula is for weirs without end contractions:

$$Q = 3.33\,L\left[\left(h + \frac{va^2}{2\,g}\right)^{3/2} + h\,\frac{vb^2}{2\,g}\right]$$

They also found the effect of a roughening of the upstream face of a weir from the condition of a smooth brass plate to that of a coarse file for a distance of 1 ft. from the crest to be to increase the discharge nearly 2% at a 0.5-ft. head, and to over 1% for a 1.35-ft. head.

The effect of slightly rounding the upstream corner of the weir crest (by about 1/24 in. or 1 mm.) was to increase the discharge 2% for a head of 0.5 ft. and 0.5% for a head of 1.35 ft. A rounding to a radius of 1/8 in. increased the discharge about 3% and to 1/4 in. about 5-1/2% at 0.5 ft. head. In one case the effect of altering the distribution of velocities in the channel of approach changed the discharge as much as 25% for the same head on the weir.

The Flow over Irregular Crests may be computed by multiplying the discharge of a standard weir of the same height and length and at the same head by a factor depending on the form of the crests. The following tables give the multipliers for various forms of weirs (Fig. 22) as determined from experiments upon full-size models at the Hydraulic Laboratory of Cornell University:

Multipliers for Flat-topped Weirs (Fig. 22*A*)

Imperfectly Aerated and Submerged or Drowned Weirs. Bazin recognizes four types of overfalling sheet or nappe.

(a) Free nappe, with the space under the sheet thoroughly aerated, being the condition assumed in the ordinary weir formulas.

(b) Depressed nappe, or the condition when the space under the sheet is partially aerated and the sheet is pressed toward the downstream face of the weir by the atmospheric pressure outside.

(c) Drowned nappe, or that when the space underneath the sheet is entirely filled with water though the surface downstream may be below the crest level.

(d) Adhering nappe, or when at low heads the water flows over the crest and down its lower face in contact therewith, allowing no air to accumulate underneath the sheet.

Experimentally, with a weir 2.46 ft. high and 6.56 ft. long and a head 0.656 ft., Bazin found:

Nappe	Increased discharge of free nappe, Per cent
Depressed	6
Drowned	15
Adhering	28

The effects increase with increasing head, and vice versa.

For Submerged or Drowned Weirs when h_u is the head upstream of the weir and h_l that downstream, Bazin gives the following multiplier to be applied to the discharge over a sharp-edged weir with a free nappe:

$$\left[1.05\left(1+\frac{1}{5}\cdot\frac{h_l}{a}\right)\sqrt[3]{\frac{h_u-h_l}{h_u}}\right]$$

Experiments by the author on a submerged weir with a rounded crest (Type *L*, Fig. 22) showed that until the submergence h_l amounted to 30% of h_u, the reduction of discharge was less than 10%. So long as the overfalling sheet plunges below the water downstream, the following formula may be applied,

$$h^{3/2} = h_u{}^{3/2} - h_l{}^{5/2}/h_u$$

and the resulting value of $h^{3/2}$ used in the ordinary weir formulas.

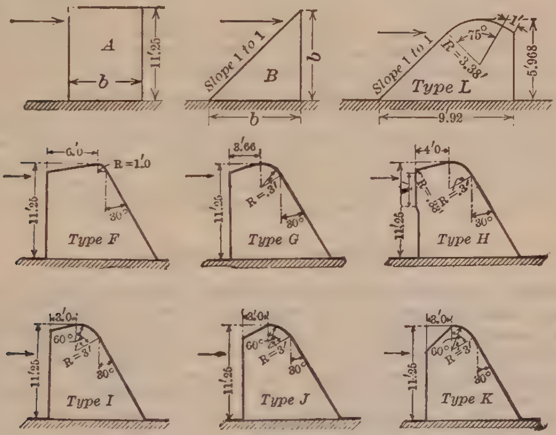

Fig. 22. Types of Weirs and Dams

Measurement of Head. When the head on a weir exceeds 1 ft. the means used for observing the head may cause an appreciable variation in the computed discharge.

The following table gives the percentage variation of heads observed in various ways, from those indicated by a device *A* similar to that used by Bazin:

Variations of Head Observations on Weirs

(Experimental)

A. Head observed by hook gage in pit connected at bottom of channel of approach by 4-in.-diameter pipe flush with wall, 29.88 ft. upstream from weir 6.55 ft. high.

B. Head observed by tape and bob over center of 16-ft.-wide channel 14 ft. upstream from weir 6.55 ft. high.

Head observed by 1-in. glass tube gage connected to 1/4-in.-diameter orifice 6 ft. upstream from weir 6.55 ft. high:

C. In brass plate flush with channel wall 2-1/4 in. below level of crest.

D. In iron cap flush with timber channel wall 1 ft. above bottom of channel.

E. In brass plug flush with face of 2 in. by 12 in. by 18 ft. plank on center line of channel, 3 in. above bottom.

F. Head observed by 1-in. glass tube gage connected to 1-in. pipe with 1/8-in. orifices, 2 in. apart on under side, set transversely across channel 1 ft. above bottom and 10.2 ft. upstream from weir 5.85 ft. high.

G. Head observed by hook gage in barrel connected to five 5/8-in. orifices in weir bulkhead 9-3/8 in. below crest of weir 6 ft. high and 65 ft. long.

H. Head observed by 1-in. glass tube connected to 1-in. pipe with 1/4-in. orifices, 6 in. apart on underside set transversely across channel 8 in. above bottom and 37 ft. upstream from weir 5.2 ft. high.

Variation of Observed Head in Per Cent of A

5.0							−6.10
5.5							−6.74

23. Current Observations

By Floats. In shallow streams approximate discharges may be obtained by surface floats, the mean of whose velocity when multiplied by 0.80 will give the average velocity probably within 10%. For more accurate gagings the **rod float** may be used, and when the conditions of the channel are ideal the accuracy of this method places it next to the weir. Rod floats may consist of tin tubes or bamboo poles loaded with shot, or of wooden rods wrapped at their bottom with sheet lead or otherwise weighted. They should be so loaded as to stand vertically in the water, and the point to which they sink should be marked by a ring of paint. Wooden floats, if to be used in accurate work for more than a very few minutes at a time, should be thoroughly oiled, or coated with a waterproof varnish, to prevent absorption of water and the consequent change of buoyancy. In starting the floats they should be immersed to the submergence mark with the bottom inclined slightly against the current and allowed to swing to a vertical position under the influence of the current while held with the thumb and finger as trunnions whose axis is perpendicular to the current and parallel to the surface. As soon as the float comes to a vertical position it should be released without disturbing its submergence or its motion, and allowed to float far enough to take up the velocity of the stream before passing the point at which the upstream observation is taken. The course selected should be in a straight reach of as nearly uniform depth and section as possible, free from weeds and having a straight channel leading to it.

The cross-section should be accurately determined and a length for the course laid off on the bank parallel to the axis of the current. If the stream is narrow, two cords or wires situated in a vertical plane a foot or more apart should be stretched across at the upper and lower ends of the course, and either one of the wires or a separate line should be tagged at intervals to assist in locating the float. The observer should take the time as the float passes the plane of the wires and the recorder or the starter its location along the tagged line. If the stream is wide, the floats should be observed with a transit whose telescope is at right angles to the course and the position determined by means of the vertical angle to the water surface, the elevation of the telescope axis above the water being measured. Where less accurate results are required a single line or a pair of ranges may be used to locate the upper and lower ends of the course and the position may be estimated. If but a single observer and one or two floats are employed, the time may be best taken by means of a stop watch, but for rapid work a large number of floats may be used and with an observer using an ordinary watch and a recorder, at each end of the course, fully as accurate work may be done. The two watches must be set together and frequently compared during the observations. The floats should be so started as to cover as far as possible the entire cross-section of the channel throughout the course, and where the depth of the cross-section varies, floats of different lengths should be used. It is customary to consider the course of the float as that indicated by the mean of its positions at the upper and lower wires and that its velocity is uniform throughout the run and that the area of the stream is the mean area throughout the course.

The floats should be made to pass as close to the bottom as possible without dragging or striking on obstructions, but it is never possible in ordinary streams to have them run closer than several inches above stream bed. The velocity of the float will therefore be greater than the mean velocity of the water in the whole vertical in which the float travels. The float gives practically the mean velocity in that part of the vertical through which its submergence extends, and may be taken to represent the velocities horizontally for half the distance each way to the next float. When d = depth of water, i = immersion of float, u = mean velocity of water, v_f = velocity of float, then

$$u - v_f\left\{1.0 - 0.116\left[\frac{d-i}{d} - 0.1\right]\right\} \text{and } Q = Au$$

In a rectangular channel 10 ft. deep and 16 ft. wide it was found that float discharges agreed with weir discharges within 2% for ranges of immersion from 60 to 98% of the depth. Double floats and subsurface floats are of little value for measuring water.

By Screen or Diaphragm. This is a special form of float and is mounted on a truck running on rails along a straight and uniform section of the channel and is so devised that it can be quickly lowered into the water and made to occupy nearly the whole area of the channel during the run and be lifted out at the end. A proper distance being allowed for starting and stopping and the screen occupying practically the whole cross-section of the channel, its velocity corresponds very nearly to that of the water. If, however, the screen does not approximately fill the cross-section of the channel the Francis float formula of the preceding paragraph may be applied. As the screen is usually run in a rectangular channel of considerable depth it may be desirable to make a second further application of the formula to cover the spaces between the screen and the side walls by considering the distance from the center of the channel to the edge of the screen as i, half the width of the channel as d, and the first computed u as v_f for each half of the channel. The depth of water then becomes the width. The sum of the discharge as computed for each half then will be the true discharge.

By Current Meter. The current meter consists usually of a revolving device, driven by the current, the revolutions of which bear some relation to the velocity of the water, and are transmitted to some form of a recording or sounding apparatus whereby the number occurring in a given time may be observed.

Two types of meter may be distinguished: the screw or direct acting-meter, and the cup or differential meter. The Haskell, Fteley-Stearns and Ott meters are examples of screw or direct acting meters. The Price meter is the best example of a cup meter, and has been adopted as a standard by the U. S. Geological Survey.

The meter should be rated to determine the ratio between its revolutions and the velocity of the passing water, which rating is usually accomplished by drawing the meter at known speeds through still water, either attached to a truck running on rails over a channel or to a boat propelled at a uniform speed, usually by a person walking along the shore. In gaging, the meter is attached to a line and sunk by a weight, or in shallow water attached to a rod, and held at various points in a vertical line until sufficient observations are obtained to give the mean velocity in the vertical line with the required degree of precision. The meter is then moved to another vertical line and the mean velocity determined there. Since it is not possible to operate the meter close to the bottom, the mean of the velocities indicated by it in any vertical line will be greater than the mean velocity of the water in that vertical line, as in the case of the float, and the same formula may be used for reducing the observations, where v_f becomes the mean velocity determined by the meter; or the vertical curve may be drawn from the observations and extended to the bottom by the eye, when the mean velocity of the water can be found directly with the aid of a planimeter or any integrating or area-measuring process.

As the meterwheel may easily become clogged by weeds or by floating matter getting into the bearings, it should be examined from time to time during a gaging. As soon as a meter is rated, what is known as the hand test should be applied. That is, the instrument is held firmly in the position in which it stands when in operation and the wheel is spun by a single effort of the hand, the length of time that elapses before it ceases its revolutions being observed and recorded. This should be repeated several times, and thereafter before starting a gaging and whenever the meter is taken from the water the hand test should be applied and the result recorded. In this way it will be possible to detect both the existence and time of a change in the rating of the instrument.

Comparisons between meter and weir gagings show them to agree under most favorable conditions for the former within from from 3 to 4%. It is to be noted that during

Resistance of Meters, Cables and Rods to Dragging through Still Water

an observation the meter should be stationary in the current or only moving as impelled thereby. The method of gaging sometimes used in which the meter is moved continuously about the cross-section is entirely untrustworthy.

Cup meters may over-register in considerably perturbed water 25%.

Screw meters may under-register in considerably perturbed water 10%.

The 3/8-in. cable used, 10 ft. 1/2 in. long, weighed 1 lb. 7-1/2 oz. in air and 1 lb. 2 oz. in water and had a 3-strand rope center 3/16 in. in diameter, covered by 6 strands 0.121 in. in diameter, each composed of 6 strands of 0.037 in. in diameter wires on a 1/16-in. rope center.

The 1/4-in. cable used, 11 ft. long, weighed 1 lb. 2 oz. in air, and 15 oz. in water, and had an insulated electric wire 0.038 in. in diameter for a center covered by 6 strands 0.086 in. in diameter composed of 7 wires 0.030 in. in diameter.

By a Waterwheel. Since practically all submerged waterwheels are composed of a series of orifices or nozzles, they may be used for measuring water whenever the discharge through them for any head and number of revolutions is known, as the velocity, and hence the discharge for constant gate, increases as $\sqrt{2\,gh}$, and the speed of the wheel for similar relative discharges must vary as that of the water.

By the Hydrometric Pendulum. This apparatus consists of a metal ball suspended upon a cord. When the ball is lowered into a current the cord is inclined away from the vertical in some relation to the force of the current. With a suitable scale for measuring the inclination, this becomes a cheap but crude current meter.

A method somewhat akin to the hydrometric pendulum is that of the torsion disk. A disk or plate is attached by its vertical edge rigidly to a small rod which is supported in a vertical position by guides and carries a pointer at the top which travels over a graduated arc. A zero reading is taken with the disk out of the water and at right angles to the direction of the current. The disk is then immersed parallel to the current and revolved by means of an arm on the rod above the pointer until the disk is again perpendicular to the current. The variation of the pointer from its first position measures the torsion of the rod, which is itself a measure of the moment of the force of the current on the disk.

By Coloring Matter, Brand, Sawdust, and Chemicals. These materials are deposited in the water and partake of the nature of floats which disperse themselves throughout the whole body of the stream. The various anilines or even ordinary bluing may be used as colors, and are suitable for use not only in open channels and pipes but also in subterranean streams. The observations are ocular. In the case of chemicals, as lithium or common salt, the observations depend usually upon chemical analyses. The latter method is often valuable in determining the amount of water from a particular source that occurs in a mixed stream, as knowing the dilution at inlet and at outlet the added untreated water can be estimated. The use of chemicals for the measurement of water passing through turbine wheels has been very fully developed by B. F. Groat, M. Am. Soc. C. E. (Trans. Am. Soc. C. E., Vol. LXXX). The essentials for accuracy in this process are the thorough mixing of a known solution with the influent water and a sufficiently distributed sampling of the effluent, care being taken that eddy and back currents do not dissipate the chemical into portions of the water that is not utilized in the measurement.

By a Cord. The measurement of surface velocities by the curve formed by a loose cord attached to the two banks and floating in the stream is possible.

By Ripple Formation. Surface velocities may be measured by the ripples formed by two pins allowed to scratch the surface at known distances apart in a line at right angles to its axis. The distance from this line to the intersection of the ripples varies with the velocity.

24. The Pitot Tube

The Pitot Tube is an instrument having two orifices or two sets of orifices one of which may be so directed as to receive the impact of a stream, and the other opening either at right angles thereto, or at some other angle so as to receive only the pressure energy of the water. These orifices are connected to a gage composed of two parallel glass tubes with a scale between or behind them, so that the difference of height of the two columns of liquid supported by the pressures on the orifices may be observed. This difference is then a function of the velocity head of the flowing water. The impact opening may be a hole bored in a piece of small-diametered pipe, the bottom of which is closed, and which is inserted in the stream of water flowing through a conduit or other channel, and the pressure orifice may be an opening in the channel wall normal to its interior surface. Experiment shows that for ranges of

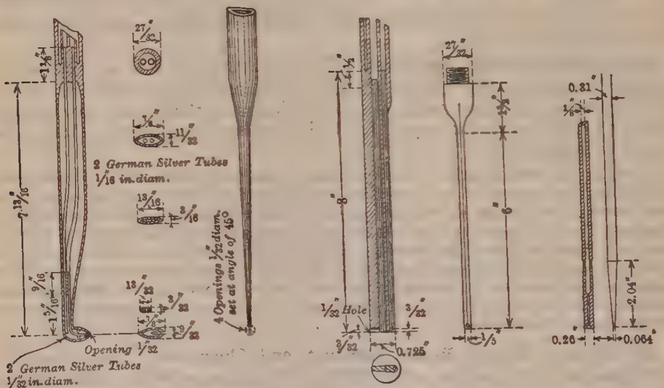

Fig. 23. Details of Pitot Tube

velocity up to 10 ft. per sec. and for pipes of diameters up to 8 in. the indication of a water column gage, when the openings are as last described, appears to give the velocity head at the impact opening within 1 or 2%, assuming the indication of the gage to be $v_2/2\ g$. In large open channels this statement does not appear to hold true and for work in the latter it is necessary that the instrument be rated. This rating may be accomplished with fair accuracy in a manner similar to that of rating current meters. A better rating can be obtained by measuring with the instrument the flow through a pipe, the discharge of which is simultaneously determined volumetrically or gravimetrically. The method of gaging is to locate the impact opening of the instrument successively at different points in the cross-section of the channel and read the indication of the gage, from which the velocity at the several points may be computed and thereby the discharge of the pipe or channel be determined. Since in the case of normal flow in a circular pipe flowing full, the central velocity is about 1.19 times the mean velocity, if the existence of normal flow at the point of gaging is established, the impact orifice of the instrument may be placed at the center of the pipe and the observed velocity divided by 1.19, or multiplied by its reciprocal 0.84 to get the mean velocity of the water. Such a determination when the area of the cross-section is accurately known and the condition of normal flow established should be correct within 3%. If normal flow does not exist but the distortion of the velocity curve is symmetrical about the axis of the pipe, the ratio of the mean to the maximum velocity, sometimes called the coefficient of the section, may be obtained by observations across a diameter and the mean velocity thereafter obtained by multiplying the observed central velocity by the thus obtained coefficient. The accuracy of the results will depend upon the accuracy with which the coefficient has been established, but with careful work should be within 5%. Observations with the Pitot tube in closed channels where the velocity distribution is distorted unsymmetrically as by a curve or gate cannot be relied upon for establishing the mean velocity unless they cover several diameters of the pipe.

The formula for reducing Pitot tube observations is usually misunderstood. It may be deduced as follows for the case of the pressure orifice in the wall of a circular pipe:

h_d = observed difference of head by the gage;
p = pressure head at any point in the cross-section of the pipe;
p_c = pressure head at the center of the cross-section of the pipe;
p_w = pressure head at the wall of the cross-section of the pipe;
v = velocity at any point in the cross-section of the pipe;
v_c = velocity at the center of the cross-section of the pipe;
v_w = velocity at the wall of the cross-section of the pipe.

By Bernouilli's theorem, for all points in a horizontal diameter of the section $p + v^2/2g$ is constant and

$$p_c + v_c^2/2g = p_w + v_w^2/2g = p + v^2/2g$$

The impact opening of the tube receives and transmits the pressure of the stream at that point, plus twice the head to which the velocity is due by the theory of impact, or its gage column represents $p + v^2/g$ for the point at which the orifice is situated. The opening in the wall transmits to its gage column the pressure p_w. Then the difference of the columns of the gage is

$$h_d = p + v^2/g - p_w$$

and for the point at the center of the pipe

$$h_d = p_c + v_c^2/g - p_w$$

But by Bernouilli's theorem

$$p_w = v_c + v_c^2/2g - v_w^2/2g$$

and the gage difference at the center then is

$$h_d = p_c + v_c^2/g - (p_c + v_c^2/2g - v_w^2/2g) = \frac{v_c^2 + v_w^2}{2g}$$

When $v_w = v_c/5$, then $h_d = 1.04\, v_c^2/2g$; and when $v_w = v_c/10$, then $h_d = 1.01\, v_c^2/2g$.

From the foregoing it appears that when the observed differences of head of the instrument with the pressure orifice in the wall of the pipe give the correct mean velocity on the theory that $h_d = v^2/2g$, it indicates the actual wall velocity to be about or less than one-tenth of that at the center. The closest measurement to the wall yet observed in the author's experience was at a point about 3/5 of 1% of the diameter from the wall in a 30-in. pipe, at which point the velocity was about 1/2 that at the center on the $h_d = v^2/2g$ theory. Although it is not impossible to conceive the rate of reduction of velocity between this point and the wall to bring the wall velocity down to 10% of that at the center it is difficult to understand. It therefore seems that the formula must be $h_d = v^2/g$ as theory has indicated, and it then follows that the velocity of the center v_c instead of being twice that at the wall v_w, will be about the $\sqrt{2}$ or 1.414, times v_w.

When the instrument carries its own pressure opening it does not seem possible to deduce its coefficient theoretically for the reason that the pressure orifice is always so situated that the velocity of the water next the instrument is considerably retarded, and hence the pressure increased, in passing from the impact to the pressure opening. Consequently the pressure transmitted is not that corresponding to the velocity to which the impact opening is subjected. The head indicated on the gage will therefore always be less than v^2/g, and as the velocity past the pressure opening is never less than that at the pipe wall, the head on the gage will always be greater than $v^2/2g$. Therefore when, as is commonly the practice, hd is assumed to represent $v^2/2g$, the indication must be multiplied by a coefficient less than unity, usually between 0.7 and 0.9; while using v^2/g, the coefficient of the instrument will be greater than unity.

Practically it is of little importance which formula be used so far as measuring the flow is concerned, as the tube must be rated in any case; but when a study of the laws of flow is involved the use of the correct formula is essential. (Trans. Am. Soc. C. E., vol. 47.)

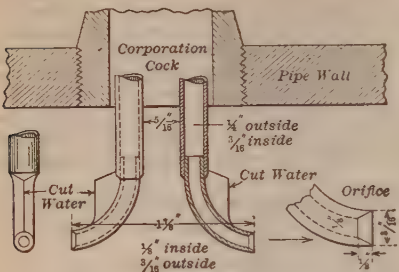

Fig. 24. Cole-Flad Pitometer

A Pitot tube of special form combined with a photographic recording apparatus is known commercially as the Cole-Flad Pitometer. In this instrument the pressure opening points downstream or opposite to the impact opening.

25. Fountain Jets

When water discharges over the horizontal circumference of a vertical pipe, the conditions partake in part of the nature of the flow over a weir and in part of the discharge through a nozzle, at low heads the former and at higher heads the latter predominating, with a range of transition from one condition to the other between. The head on such a device may be most satisfactorily read by an orifice at the center of the pipe directed against the current and located a short distance below the outlet. The head to be used is that measured by a water column attached to the orifice, less the height of the column of water from the orifice to the discharging lip of the pipe.

From a series of experiments made by Lawrence and Braunworth at the Hydraulic Laboratory of Cornell University (see Trans. Am. Soc. C. E., Dec., 1906, Vol. 57, p. 265) in which the pipes had sharp edges tapered on the outside and the head was read as above, the diameters used being 2, 4, 6, 9, and 12 in., the following formulas were deduced, which may be expected to give average results within 5% of the truth:

For Weir Flow, $Q = 8.8\ D^{1.29}h^{1.29}$, which is applicable for heads below $h = 0.028\ D^{1.04}$ with the jet falling free from the pipe; that is, aerated underneath.

For Jet Flow, $Q = 5.84\ D^{2.025}h^{0.53}$, which is applicable for heads above $h = 0.107\ D^{1.04}$. For the range between these two heads the result lies between those given by the above formulas whose lines intersect at $h = 0.045\ D^{1.04}$.

For ordinary computations these formulas, with the same limitations, may be used as:

For the weir, $\mathbf{Q = 8.8\ D^{1.25}h^{1.25}}$

For the jet, $\mathbf{Q = 5.84\ D^{2}h^{1/2}}$

Where D is diameter of jet in feet.

26. Observations of Heads

In Open Channels the most common method of reading head is by a graduated scale upon the face of which the water rises. If this is situated in running water the sides should be tapered to their edges to prevent a depression of the surface due to an eddy at the upstream corner. On account of capillarity the reading will be higher than the true surface of the water and the observer may be expected to read to about one-half the smallest division that is clearly visible. The United States Geological Survey uses for its stream-gaging stations the **ball and chain gage,** which consists of a chain running over a pulley and carrying a ball at its lower end which may be read by allowing the ball to scratch the surface in running water or to be just immersed in still water. The scale is usually horizontal, and a pointer on the chain indicates thereon the position of the ball.

A more accurate apparatus and one which may be readily provided in the field, consists of a plumb bob suspended from a steel tape which is passed over a block cut at the edge to an arc of about 2- or 3-in. radius, having on the top a mark against which the reading of the tape is taken. By fastening an ordinary leveling rod target to the block and causing the graduated edge of the tape to lie next the vernier, very accurate readings of the position of the bob may be obtained. In running water the bob should be allowed to scratch the surface and cause a fine ripple. When the surface undulates, readings of the high and low of the vibration should be taken. In still water the bob may be swung until it barely cuts the surface, or it may be slowly lowered until contact with the water is indicated by the rising of the water to the point due to capillarity. The **point gage** consists of a point attached to a graduated rod sliding past a vernier. It is read similarly to the plumb bob, and is only second in accuracy to the hook gage. The ordinary leveling rod with its upper section fastened to a post and the lower carrying a metal point makes an excellent and easily obtained point gage.

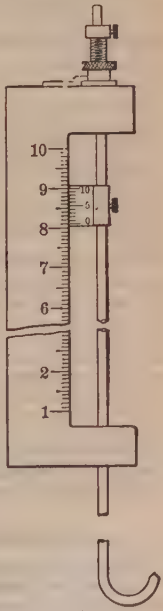

Fig. 25. Hook Gage

The Hook Gage, an apparatus invented by Uriah Boyden, consists of a hook attached to a graduated rod sliding past a vernier, or to a vernier sliding past a fixed scale. The hook is lowered below the surface of the water and slowly raised until its point comes in contact with the surface film of the water when the latter is distorted, and if the point in contact is in the reflection of a light a black spot appears; if in diffused light, a bright spot. In still water the delicacy of the instrument is such that variations of the surface of 1/10000 of a foot may be readily observed. For best results the point of the hook should be a cone with a vertex angle of about 90 degrees.

The Water Column which rises in a glass tube connected to the channel may be utilized for reading head, but in this case the attraction of the walls of the tube for the water causes the liquid to rise higher than the height due to pressure alone. If the tube is less than 0.5 in. in internal diameter this effect must be allowed for in accurate work. Under no circumstances should the height of the column be measured to the intersection of the water and the glass, but a line tangent to the extreme edge of the curve of the meniscus at the center of the tube should be taken. Except on a vibrating column during the rise of the liquid the water meniscus is always concave upward.

The Mercury Column, owing to the lack of affinity between the glass and the mercury, has its meniscus convex upward and should be read on a tangent to the top of the curve. As the specific gravity of mercury is 13.58 at 60° Fahr., one foot of mercury is the equivalent of 13.58 ft. of water.

The Bourdon Pressure Gage, though sometimes used in hydraulic work, is not sufficiently delicate to give satisfactory results except where the pressure to be measured exceeds 5 lb., and is unsuited for determining small differences of pressure.

The Differential Gage is used for measuring differences of head at two points in a stream. This gage consists of two vertical glass tubes connected at one end, with a scale between or behind them, the free ends being connected respectively by hose or pipes to the two points between in which the difference is to be observed. For measuring large differences of head the tubes are connected at the bottom and are then filled about half full of **mercury** or for smaller differences of head, with **carbon-tetra-chloride.** The difference of height of the mercury or tetra-chloride columns, when multiplied by the specific gravity of the liquid used minus one, gives the height of the water column that would measure the difference in pressure head at the two connections to the channel.

For small differences of head the tubes may be connected at the top and the water allowed to rise in the tubes entrapping air above it. Unless the pressure is so great as to compress the air sufficiently to cause its weight to be appreciable, the difference in height of the water columns measures the difference of pressure heads at the connections.

For very small differences the air in the upper portion of the gage may be replaced with oil. If G_o is the specific gravity of the oil and h_u and h_l the height of the upstream and downstream water columns, the difference of pressure head indicated will be $c\ (1 - G_o)\ (h_u - h_l)$ where c is a coefficient less than unity depending on the kind of oil. When a gage of this kind is used it should be calibrated by comparison with a water-column gage to determine the value of c, or better the value of one unit of the scale. For kerosene oil with $G_o = 0.7879$ at a temperature of 60° Fahr., the reading of the gage has been found to be 4.895 times the head; with gasolene having $G_o = 0.7159$ at the same temperature, the multiplication was 3.52; and with ordinary sperm oil it was 9.05. (Trans. Am. Soc. C. E., vol. 47, pp. 78-90, April, 1902.) Carbon-tetra-chloride being only a little heavier than water has also the effect of magnifying the observed reading. When suitably colored by dye to cause it to register on photographic paper it is used in the Cole-Flad Pitometer recording apparatus.

27. Early Methods of Measuring of Water

Before the methods and apparatus above described were introduced the methods of measurement were oftentimes somewhat indefinite. For milling and manufacturing purposes the quantity of water conveyed or to be taken was frequently described as that which will flow through an aperture of a certain area, usually measured in square inches, under a certain specified head, or those existing in the particular structure from which it was to be taken.

An old grant made in the late eighteenth century specified:

> "Three sluices of water to issue out of the canal, each sluice to contain thirty-five square inches, and the bottom of the water in each sluice to be four feet and one-half foot below the top of the water in the canal at its common level."

Later grants from the same source were less specific, usually reading a certain number of "square inches of water" under a certain head, but meaning thereby the amount of water that would flow through an aperture of the named area. Sometimes the word "square" is omitted.

In other localities grants of a certain number of square inches or inches of water to be drawn from a specified or understood dam or flume are common, by which was meant the amount of water that could be drawn with the usual appurtenances through an aperture of the size named from the pond or flume as it existed When the existent conditions at the time of the grant are known the quantity of water so granted is usually not difficult to determine.

Experiments by the writer have shown that the coefficient of discharge for the ordinary apertures with square-edged gates and their accompanying chutes to overshot wheels varied from 0.50 to 0.65 for the type of apparatus commonly in use, depending on the extent of the suppression of contraction by the side walls. Beveling the edge of the gates to an angle of 30 deg. with the horizontal increased the coefficients about 30% where the height of opening was from 1/8 to 1/10 of its width.

Other grants specified sufficient water to propel a **run of stone** under the conditions existent at the site of the grant. The quantity required depended on the head utilized, and the value of a **run of stone** was influenced by the size of stones in use in the particular locality. According to Whitham ("Water Rights Determination," John Wiley & Sons, Inc.) a **run of stone** might vary from 10 to 25 hp. Where the specification includes "the usual machinery connected therewith" as much as 40 hp. per run of stones has been estimated. Whitham finally concludes:

A run of stone in a first-class merchant mill yielding 85 to 100 barrels per day requires 30 to 40 hp.

A run of stone in a second-class merchant mill yielding 50 to 60 barrels per day requires 20 to 25 hp.

A run of stone in a common country grist mill requires 12 to 15 hp.

In the early days of milling when the stones were smaller, the amount of auxiliary machinery used was not so extensive and the flour ground coarser, the power required per run of stone was from 2-1/2 to 6 hp.

Miner's Inch. The measurement of water through apertures was applied by the early Californians in apportioning water for mining uses. Hence came into being the miner's inch as a unit of measurement; it was the quantity of water that would flow through an aperture one inch square in a plank under conditions which varied in different localities, but the head was usually about 6 in.

In California and Montana 40, in Colorado 38.4, and in Arizona, Idaho, Nevada and Utah 50 miner's inches = 1 cubic foot per second.

TURBINES AND WATERWHEELS

28. Classifications

Turbines are of two types, reaction or pressure turbines and tangential or impulse turbines. In the former the wheel is completely filled with water, which acts by its pressure, and in the latter the head is converted into velocity and the wheel should never be filled.

A **reaction** or **pressure turbine** is an assembling of curved channels or nozzles revolving uniformly about a fixed axis, usually either horizontal or vertical, with suitable stationary or movable guides to direct the flow into the revolving channels. The revolving part of such an assemblage is called the **runner** or **wheel.**

Runners are designated as Right-Hand or Left-Hand, according to the direction of their rotation. When the observer stands in the line of the shaft of the wheel with the inlet end toward him, or is looking in the direction along the shaft in which the water flows to enter or leave the wheel, a wheel which appears to revolve in a clockwise direction is Right-hand, and one revolving in a counter clockwise direction is Left-hand.

Turbines are classed according to the direction in which the water passes through them, as: (1) **Outward flow**, or **Fourneyron** wheels. (2) **Inward flow**, or **Francis** wheels. (3) **Parallel** or **axial flow**, or **Jonval** wheels. (4) **Mixed flow**, or **American** wheels. In the last named class the flow is first inward, then axial. When standing still the laws of flow through nozzles apply to this apparatus without modification, but when revolving the centrifugal force of the water inclosed in the wheel complicates the equations.

Nomenclature

b = barometric column of water;
d_i = depth of wheel at inlet;
d_o = depth of wheel at outlet;
e = efficiency of turbine;
e_h = hydraulic efficiency;
h_c = centrifugal head;
h_{ci} = height of center of inlet above tailwater;
h_{eo} = height of center of outlet above tailwater;
h_{pi} = pressure head at inlet;
h_{po} = pressure head at outlet;
H = total head acting;
H_n = head corresponding to a runaway speed of n revolutions;
k_1 = power constant;
k_2 = capacity constant;
k_3 = speed constant;
K = wheel characteristic;
n = number of revolutions per minute;
Q = quantity of discharge per unit of time;
R_i = radius of wheel at inlet;
R_o = radius of wheel at outlet;
u_i = radial component of velocity at inlet of wheel;
u_o = radial component of velocity at outlet of wheel;
U_i = absolute velocity of water at inlet of wheel;
U_o = absolute velocity of water at outlet of wheel;
U_t = absolute velocity of water at outlet of draft tube;
v_i = velocity of wheel at inlet;
v_o = velocity of wheel at outlet;
V_i = velocity of whirl at inlet;
V_o = velocity of whirl at outlet;
V_{ri} = relative velocity of water at inlet;
V_{ro} = relative velocity of water at outlet;
w = weight of one cubic unit of water;
W = power;
ϕ = speed coefficient.

Fundamental Reactions. Bernouilli's equations for the flow through a turbine:

At inlet, $$H - h_{ei} + b = h_{pi} + \frac{U_i^2}{2g}$$

Between inlet and outlet the wheel impresses upon the water a head due to centrifugal force $= (v_i^2 - v_o^2)/2g$, so that within the wheel:

$$h_{ei} + h_{pi} + \frac{V_{ri}^2}{2g} = h_{po} + \frac{V_{ro}^2}{2g} + \frac{v_i^2 - v_o^2}{2g} + h_{eo}$$

and between outlet and tail-water:

$$h_{po} = \frac{U_o^2}{2g} + h_{eo} = b + \frac{U_t^2}{2g}$$

To relate V_{ri} and V_{ro} to U_i, U_o, v_i and v_o, referring to Fig. 26, where

$$AB = U_i \quad ab = U_o \quad AC = v_i \quad ac = v_o \quad AD = V_i \quad ad = u_o$$
$$BC = V_{ri} \quad bc = V_{ro}$$
$$BD = u_i \quad bd = V_o \quad R_i = \text{radius at inlet} \quad R_o = \text{radius at outlet}$$

α = angle between absolute velocity of water and tangent to periphery of wheel at inlet;
β_i = angle between tangent to inlet of bucket and tangent to periphery of wheel;
β_o = angle between tangent to outlet of bucket and tangent to interior of bucket circle;
θ = angle through which the jet is diverted or angle between U_i and U_o.

$$V_{ri}^2 = (v_i - U_i \cos\alpha)^2 + (U_i \sin\alpha)^2$$
$$V_{ro}^2 = [v_o - U_o \cos(\alpha + \theta)]^2 + [U_o \sin(\alpha + \theta)]^2$$

Or otherwise, since the flow is radial, the product of the radial velocity and the area of the circumferential sections of the channels must be constant, whence: $\pi R_i d_i U_i \sin\alpha = \pi R_i d_i u_i = \pi R_o d_o u_o$

or $u_o = R_i d_i u_i / R_o d_o$

The total work done by the water in passing through the turbine is measured by the change in kinetic energy and equals $W = Qw\,(U_i^2 - U_t^2)/2\,g$, and the energy carried away in the water is $QwU_t^2/2\,g$. The work is also equal to $W = Qw\,(V_i v_i - V_o v_o)/g$, and by the aid of these equations all the factors may be interrelated.

When U_0 is radial or axial, as it should be for maximum efficiency, the relations are materially simplified, as U_0 is then equal to u_0.

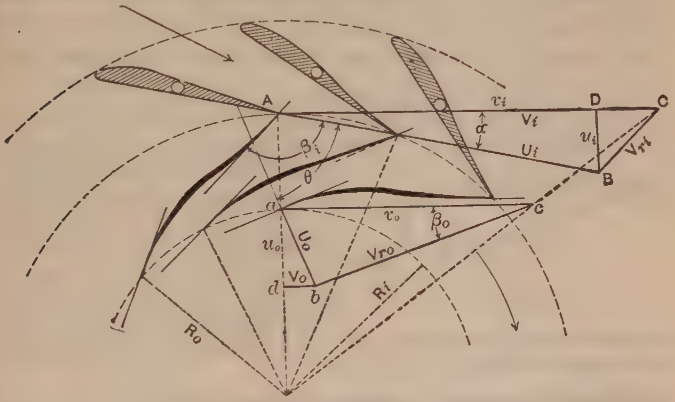

Fig. 26. Turbine Diagram

29. Definitions

The theoretical power of a fall of water is the force, or weight of the water, multiplied by the space passed through, or the height of the fall; when H = the height through which the water falls, Q = the discharge in cubic feet per second, w = the weight of a cubic foot of water, the theoretical horsepower is $= QwH/550$. A turbine wheel converts a part of this theoretical power into effective energy, and the **mechanical horsepower** of the wheel $= Wh_p = cQwH/550$, where c is the efficiency of the wheel.

The Efficiency of the wheel is the ratio of its output in power to the total power of the water and head used. As c is usually about 80%, the horsepower of the wheel $= QH/11$ approximately, or 11 cu. ft. of water per second falling through 1 ft. will yield 1 hp. at the turbine shaft.

The Hydraulic Efficiency of a turbine is the quotient obtained by dividing the change in kinetic energy by the total potential energy of the fall utilized and is

$$e_h = \frac{Qw}{2\,g}\,\frac{(U_i^2 - U_t^2)}{QwH} = \frac{U_i^2 - U_t^2}{2\,gH}$$

This differs from the actual efficiency, and is what would be its limiting value if there were no frictional or impact losses either in the water itself or in the mechanism. The actual efficiency, or the efficiency of turbines as shown at the Holyoke Testing Flume, ranges from 70% to 93%.

The Discharge Q of a wheel varies as the velocity and is therefore proportional to $\sqrt{H}$.

The Mechanical Power of a given wheel varies as the head H and also as the discharge Q, which in turn varies as $\sqrt{H}$. Therefore, the power varies as $H\sqrt{H} = H^{3/2}$.

Unit Power is the power at 1-ft. head = horsepower$_1$ = $\dfrac{\text{horsepower}}{H\sqrt{H}}$, designated HP_1.

The Speed at which a wheel will give its maximum efficiency under a given head depends upon the radius of the inlet circle and the form of the buckets or vanes. For best effect the receiving edge of the bucket must be parallel to the direction of the velocity of the inflowing water relative to the moving vane, and at discharge such that the water leaves either axially or radially.

In Fig. 26, if AB represents in direction and magnitude the absolute velocity of the water entering the wheel and AC that of the bucket, then CB is the relative velocity of the water on the bucket, and the inlet edge should be tangent to it. If the velocity of the water is increased to AD, then for the same bucket the velocity of the wheel must be increased to AE, to keep ED parallel to CB, so that the water may still glide upon the bucket without shock. It follows, then, that for any given wheel a certain fixed ratio must exist between its speed and that of the water, for maximum efficiency. The speed of the water is evidently a function of the head, and hence for every head there is some speed at which a given wheel will yield the maximum efficiency. The best speeds are therefore proportional to $\sqrt{H}$.

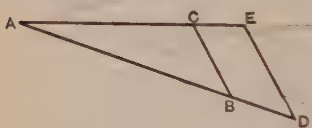

Fig. 27

Unit Speed is the speed of a wheel at 1-ft. head = $n_1 = \dfrac{n}{\sqrt{H}}$.

The Speed Coefficient, usually designated ϕ, is the ratio of the linear velocity of the runner periphery to the spouting velocity of the water under the given head;

$$\phi = \frac{\pi D_1 n}{60 \times \sqrt{2gH} \times 12}$$

where D_1 = outside diameter of runner in inches, measured at center line of inlet.

The Discharging Capacity, and hence the **power** of a wheel, is dependent upon the area of the cross-section of the water passages through it, which are themselves a function of the diameter of the wheel. Therefore in similar wheels the power at a given head will vary as the square of the diameters.

When the performance of a given wheel has been determined for a particular head as to horsepower, discharge and efficiency, the performance at any other head may be computed, and the performance of any similar wheel at any head may be determined with reasonable accuracy by the foregoing relations. By similar wheel is meant one in which all dimensions are in the same ratio to those of the first wheel, all angles being the same.

By changing the form of the vanes or buckets the speed at which the wheel gives its best efficiency may be varied. Starting with a normal speed equal to the tangential component of the velocity of the inflowing water in which case the inlet edge of the bucket would be radial, the speed may be either increased or decreased 25% without appreciably affecting the efficiency. If the speed is increased the bucket tends to become convex toward the incoming water, and is inclined backward toward the outlet; if the speed is decreased the bucket becomes more concave toward the jet and has less backward inclination toward the outlet. The power of a given sized wheel is decreased by varying its speed from the normal, by reason of the resulting contraction of the waterways.

30. Selection of Runners

Type Characteristic. Turbine runners of the same general class may differ widely in their characteristics of speed and capacity, or power, depending upon the size and shape of the blades. In order that runners of different types, or of different manufacture, may be compared on a common basis, a type characteristic has been adopted. *The type characteristic is defined as the speed in r.p.m. at which a wheel would run if it were reduced proportionally in all dimensions so as to develop* 1 *hp. under* 1-*ft. head.* This characteristic is also called the **characteristic speed** or the **specified speed.** It is designated K and is made up of:

(a) A power constant k_1 = horsepower/QH, which is the power of a similar runner using 1 cu. ft. of water under a 1-ft. head.

(b) A capacity constant, $k_2 = Q/D_1^2\sqrt{H}$, which is the discharge of a similar runner of 1-ft.-diameter under a head of 1 ft., where D_1 = diameter of 1 ft.

(c) A speed constant, $k_3 = \sqrt{H} = \pi D_1 n/60\sqrt{H}$, which is the speed of the runner itself under a head of 1 ft. Then

$$\mathbf{K} = \frac{60\,\mathbf{k}_3\sqrt{\mathbf{k}_1\mathbf{k}_2}}{\pi} \quad \text{or} \quad \mathbf{K} = \frac{\mathbf{n}\sqrt{\mathbf{horsepower}}}{\mathbf{H}^{5/4}}$$

For 1-ft. head $\mathbf{K} = \mathbf{n}_1\sqrt{\mathbf{Hp}_1}$ where n_1 = unit speed $= \dfrac{n}{\sqrt{H}}$, Hp_1 = unit horsepower $= \dfrac{Hp}{H^{3/2}}$.

Obviously this characteristic combines the considerations of power and speed and enables a complete comparison to be made between wheels of known efficiency.

The values of K for American, Francis or pressure type turbines vary from 12 to 160, as shown by the table on p. 1379.* For impulse wheels the maximum value is about 6, where a single jet is used. The interval between 6 and 12 is not covered by either the Francis type or a true impulse wheel, though the old Girard turbine would apply between these limits.

The turbines included in the following table are all of recent design and high efficiencies. There are other modern high-efficiency wheels made and the manufacturers listed make other types than the ones shown, but these are all on which data have been furnished to the author.

In general, high values of K indicate relatively " high-speed " wheels, or those adapted for operation under low heads of water. Experience has shown that for any given head there is a limiting value of K beyond which it is impracticable to go, as the resulting speeds would cause pitting of the runner

* The **speed** value used in computing K is that at which the best efficiency is attained by the runner, usually referred to as " best speed " or " normal speed." The **horsepower,** for the sake of definiteness and uniformity in practice should preferable be taken at the actual best efficiency point or gate-opening. However, as this can by arrived at only by a plotting of the test, it has become the practice of most manufacturers to figure K from the full gate horsepower at the best efficient speed. The former method is of course the more conservative, but the latter the more readily applied.

blades and develop excessive centrifugal forces. The limiting values of K as determined by best American practice are approximately:

For heads above 600 ft., $K = 12$ to 25
For heads from 100 to 600 ft., $K = 25$ to 55
For heads below 100 ft., $K = 55$ to 150

Fig. 28 shows graphically the relation between K and H, the curve being an average of the practice of several leading turbine manufacturers.

In using this characteristic K, its value is computed from the requirements of the plant under consideration. If this value falls within the allowable limit for the given head as shown by Fig. 28, the turbine best suited to the place

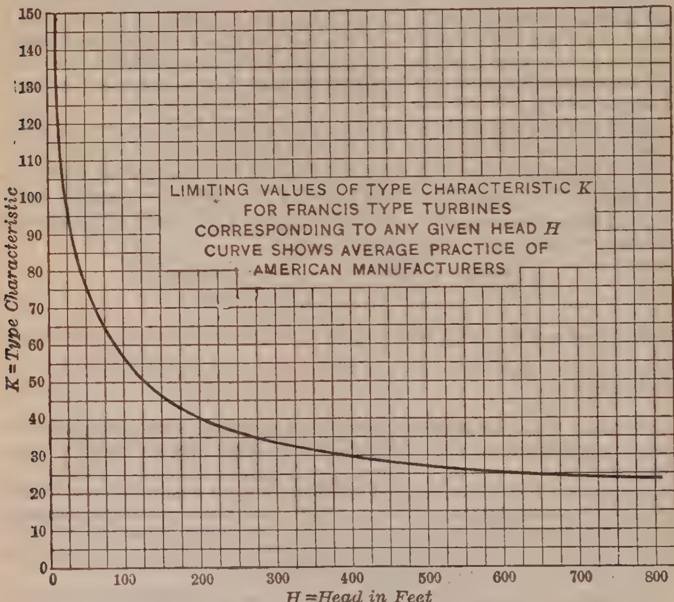

Fig. 28. Limiting Values of Type Characteristic K

will be the one having a value of K nearest that computed. If the value of K computed from the plant requirements considerably exceeds the limiting values, it will be necessary to reduce the power per runner, or reduce the speed, in case this be permissible and K may then be recomputed, using a value of the horsepower equal to the total power desired, divided by the number of wheels assumed, and the runner selected as before. This will be illustrated by several typical examples.

Example 1. "It is desired to install a 60-cycle, 2300-volt, hydroelectric unit, with 450 hp. available under 25-ft. head."

For this low head installation a high-speed turbine (one having the highest permissible value of K) should be used. From the curve (Fig. 28) K_{max} for 25-ft. head is about 95.

Table of Type Characteristics

Manufacturer	Name of runner	K *
Allis-Chalmers Mfg. Co.	Type A	13.55
	Type B	20.3
	Type C	29.4
	Type D	40.7
	Type E	51.7 to 60.5
	Type F	72
	Type G	82
	Type H	92.5
	Type I	105
	Type Nx_1	130
	Type Nx_2	160
Hydraulic Turbine Corp.	Camden, Type 4	53.2
	Camden, Type 8	71.3
	Camden, Type 11	83.5
J. and W. Jolly	McCormack Special	68.2
James Leffel & Co.	Samson-Standard	73.0
	Leffel-Sparks, Type F	81.0
	Leffel, Type Z	105.0
Platt Iron Works Co.	Victor, Type 1	84
	Victor, Type 2	75
	Victor, Type 3	60
	Victor, Type 4	45
	Victor, Type 5	32
	Victor, Type 6	20
	Victor, Type 7	12
S. Morgan Smith Co.	Type E	25.1
	Type F	33.8
	Type G	46.1
	Type H	52.0
	Type K	60.0
	Type N	71.3
	Type O	76.6
	Type R	86.0
	Type S	95.5
Wellman-Seaver-Morgan Co.	Runner No. 42	84.5
	Runner No. 48	71.5
	Runner No. 40	65.5
	Runner No. 11	50
	Runner No. 18	27.2

* K computed using horsepower values at full gate instead of at best efficiency point.

$Hp_1 = \dfrac{Hp}{H^{3/2}} = \dfrac{450}{125} = 3.6$, $n_1 = K/\sqrt{Hp_1} = 95/\sqrt{3.6} = 50$, $n = 50 \times \sqrt{25} = 250$ r.p.m. As this is not a synchronous speed, 240 will be assumed.

Then, $n_1 = \dfrac{240}{\sqrt{25}} = 48$ and $K = 48\sqrt{3.6} = 91.1$.

At least four of the wheels shown in the foregoing table have a K above 91.

The performance of a wheel of given size being known, it is possible to determine the approximate size required to fulfil the assumed conditions, remembering that speed varies inversely with D and power varies as D^2. Or, from such tables as are given on pp. 1382 to 1387 the size under any type that comes nearest to the required conditions may readily be determined.

Thus, from Table (p. 1383) a type of ($K = 92.5$) Allis-Chalmers Co. turbine shows the following performance:

Diameter	$HP._1$	n_1	Q_1	HP.	R.p.m.	Q
30 in.	3.40	50.0	37.4	425	250	187
34 in.	4.36	44.2	48.0	545	221	240

Obviously the required diameter is between 30 and 34 in.

Example 2. Required to develop 6000 hp. at 360 r.p.m. under a head of 125 ft.

$$H.P._1 = \frac{6000}{125\sqrt{125}} = 4.3, \quad n_1 = \frac{360}{\sqrt{125}} = 32.2, \quad K = 32.2\sqrt{4.3} = 66.8.$$

The allowable limit for K at 125-ft. head is only about 50, from Fig. (27*a*).* Therefore, two units will be assumed developing 3000 hp. each.

Then $H.P._1 = \dfrac{3000}{125\sqrt{125}} = 2.145$ and $K = 32.2 \times \sqrt{2.145} = 47.2$, which falls below the limiting value.

Referring to the table on pp. 1385 and 1386 we find that a 42-in. Victor type 4($K = 45$) turbine develops 3026 hp. at 342 r.p.m. under 125-ft. head, and a 42-in. Camden type 4 ($K = 51$) develops 3400 hp. at 365 r.p.m. Both of these wheels very closely approximate the assumed conditions and by a slight modification of the design would be able to meet them exactly.

Example 3. Required to develop 3000 hp. with one hydroelectric unit installed under 900-ft. head.

For economical generator construction, the speed for a unit of this size should not exceed about 450 r.p.m. On this assumption, $n_1 = \dfrac{450}{\sqrt{900}} = 15$ Hp. $= \dfrac{3000}{900\sqrt{900}} = 0.111$, $K = 15\sqrt{0.111} = 5$. As this value of K falls below the minimum of 12 recommended for Francis turbines, the pressureless type, or impulse wheel, should be used.

Assuming 80% efficiency, $Q = \dfrac{3000 \times 11}{900} = 36.6$ c.f.s.

Velocity of free jet $= .97\sqrt{2\,gh} = .97\sqrt{64.4 \times 900} = 233.5$ ft. per sec.

Area of jet $= \dfrac{Q}{V} = \dfrac{36.6}{233.5} = .157$ sq. ft. $= 22.55$ sq. in. Diam. jet = 5-3/8 in.

For maximum efficiency, the peripheral velocity of the runner buckets should theoretically be one-half the spouting velocity of the jet. In actual practice, however, this ratio is taken at about $.47\sqrt{2\,gh}$. $.47\sqrt{64.4 \times 900} = 113$ ft. per sec.

At 450 r.p.m., $D = \dfrac{113 \times 60}{450 \times \pi} = 4.8$ ft. diam. or 57.6 in.

* It will be necessary, then, to use more than one runner. Where it is desired to install only one unit, a multiple-runner turbine may be used. This expedient is, however, being resorted to less and less frequently in best practice and should be avoided whenever possible.

$$\frac{57.6}{5.375} = \frac{10.7}{1} = \text{ratio of wheel diameter to diameter of jet.}$$

This is about the minimum ratio allowable in present practice and it is considered better to increase it to 16 or 18. Assuming 16:

$D = 5.375 \times 16 = 86$ in. A 7-ft. wheel would probably be used. Then r.p.m. $= \dfrac{113 \times 60}{7 \times \pi} = 308$, and the nearest synchronous speed would be 300 r.p.m.

31. Turbine Performances

Variation of Discharge. The quantity of water discharged for an inward-flow turbine is greatest when the wheel is still, and on account of centrifugal force it decreases as the speed increases.

For the other types the discharge is less when still than at a velocity near that giving maximum efficiency, on account of the loss due to shock at entrance, and increases until the wheel gets up to speed; from the maximum it decreases, on account of the interference of the revolving buckets with the stream flowing through to a theoretical zero at a speed of infinity.

Gates. The quantity of water passing through a turbine, and hence its power, may be regulated by opening or closing the gates. In the older turbines, the gate was a cylinder sliding parallel to the axis and reducing the height of the inlet openings. This form is objectionable, as it does not permit the bucket to be uniformly filled at part gate-openings, and the more generally adopted type with recent wheels is the so-called wicket gate, which swings

on a pivot set parallel to the axis of the wheel, and forms not only the gate but the guide for directing the water upon the wheel.

Constant Speed. In the operation of electrical machinery a constant speed is necessary, and hence if the head falls below the normal the turbine must be run at a higher speed than that for which it was designed, in which case the power and efficiency are rapidly reduced and the outlet edges of the buckets are liable to corrode.

If, on the other hand, the head increases, the wheel must run at a lower speed than that for which it was designed, which, though not reducing power and efficiency nearly so rapidly as overspeeding, nevertheless renders the buckets liable to be cut out by the water, particularly if it carry sand or grit.

By **Runaway Speed** is meant the speed at which the wheel would rotate under any given head, with no load; that is, its highest speed, under that head. From this it follows that a wheel with a runaway speed, that is relatively high as compared with the best speed, will fall off in power rapidly as it is overspeeded, and vice versa. For low-speed turbines the runaway speed varies between 1.6 to 1.7 times the best speed and for high-speed turbines is about 1.5 times the best speed. Hence high-speed turbines decrease less rapidly in power when overspeeded than do low-speed ones.

The table given above shows the performance of a pair of McCormack wheels with $K = 68.2$ computed from tests. Other American wheels will give results varying slightly from these figures, which may however be safely used in approximate calculations.

32. Manufacturer's Tables

Manufacturer's Tables. The following tables give the performances at 1-ft. head of various turbines commonly met with. The values have been taken from the makers' catalogs, both old and new, and do not necessarily show the best performances or latest types developed. They are partly intended for reference in connection with old installations and, wherever possible, the date of the catalog from which the tables were taken is shown, to indicate the age of the design.

All values have been computed for 1-ft. head. At any head H:
To obtain horsepower of wheel multiply its tabular horsepower by $H^{3/2}$
To obtain discharge of wheel multiply its tabular discharge by $H^{1/2}$
To obtain speed of wheel multiply its tabular speed by $H^{1/2}$

Turbine Performances at One-foot Head

S. Morgan Smith Company, York, Pa.

From Data Submitted by Maker in 1918

The following table shows the performance of the various types of S. Morgan Smith Company turbines of 30-in.-diameter at 1-ft. head, and the maximum heads under which they are designed to operate. Except for special conditions, sizes are made at intervals of 3 in., as 27 in., 30 in., 33 in., etc. Also for special conditions turbines are designed with characteristics differing from those tabled, but the characteristics must be within certain limits of power and speed, as indicated in the table, according to the head under which the turbines are to be placed.

	Speed	44	54	62	70	76	82	88	99	110	120	....	....	....

For each size the first line gives the horsepower, the second the discharge in cubic feet per second, and the third the speed in revolutions per minute.

Turbine Windage and Friction. The approximate power absorbed by windage and friction in modern turbines in vertical settings may be computed by the following formula:

$$\text{Windage and friction in horsepowers} = 0.000154\ B\ D^4\ n^3;$$

where B = height of gate or guide vane opening, in feet;

D = diameter of wheel at middle of guide vane opening, in feet;

n = revolutions per minute.

33. Tangential or Impulse Turbines

The Girard Turbine may be either radial inward or outward flow, or axial flow. The buckets are so shaped that on leaving the wheel the water has a relative velocity in the direction opposite to that of motion, being received at inlet from a series of nozzles pointed as nearly as may be in the direction of motion. Air is admitted to the wheel to prevent spraying of the jets, and the turbine cannot run submerged. Regulation of speed and power is accomplished by closing part of the inlet nozzles. This motor is very satisfactory for high heads, but its speed cannot be varied appreciably without loss of efficiency unless the head also changes. The efficiencies range 70 to 80%.

The Pelton Turbine is usually mounted on a horizontal shaft and consists of a series of cups which successively receive a jet from one or more nozzles. The jet on striking the cup is divided and turned through nearly 180° and is then discharged with a low absolute velocity. Regulation is accomplished by closing or deflecting the nozzle. The maximum efficiency in this type of turbine occurs when the velocity of the cup V is about one-half that of the jet and when θ = 180 deg., in accordance with the law of curved vanes, and varies from 70 to 85%.

Wheels of the Pelton type are frequently equipped with the Doble nozzle which is closed by a pin or needle moving longitudinally in the axis of the jet from the inside and which may be adjusted to give a symmetrical jet of any effective area from that due to the full nozzle opening to zero. This apparatus affords opportunity for excellent control of the discharge, and hence greatly facilitates regulation without causing a waste of either water or energy.

Waterwheels. This term is applied to the overshot, the breast and the undershot wheels, all of which have become practically obsolete in America. The efficiencies of overshot and breast wheels ranged from 60 to 88%. In these wheels the work was done principally by the weight of the water. The efficiencies of straight-bladed undershots were from 25 to 35%, and for the curved-bladed or Poncelet wheels from 50 to 65%. In these wheels the work was done by the impulse of the stream.

Spiral Wheels are similar to axial-flow turbines except that the runner blades are helical surfaces and they are usually mounted on a horizontal or slightly inclined shaft. For low heads and large quantities of water this form is very satisfactory, efficiencies as high as from 80 to 85% being reported.

PUMPS AND PUMPING

34. Centrifugal Pumps and Screw Pumps

The Work in foot-pounds done by a pump is the product of the weight in pounds of the liquid pumped and the height in feet through or against which it is lifted. The **power** of a pump is the work done in unit time, and the **horse-power** is the work per second in foot-pounds divided by 550, or the work per minute divided by 33 000.

The Centrifugal Pump is essentially an inward-flow turbine reversed, the power being applied to rotate the runner and the water being admitted at the center or eye and discharged at the outer periphery. The earlier centrifugal pumps consisted of a spider made up of three or more arms, either straight or curved, which rotated in a concentric chamber to which water was admitted at the center and discharged at some point in the circumference. The efficiency of this apparatus rarely exceeded 30%, and it was only used for low lifts. By shifting the enclosing chamber so that the area outside the runner increases toward the outlet in proportion to quantity of water that must pass the several sections, by encasing the blades in a revolving shell, Fig. 29, thus reducing the friction of the revolving water on the fixed shell, and by more rational proportioning of the blades and casing, the pump has been greatly improved until its efficiency may slightly exceed 80%, and by passing the water successively through a series of runners any desired lift may be accomplished. As the apparatus contains no valves or parts, it is particularly adapted to the handling of water containing sand or gravel, and of viscous liquids and sewage; and as its discharge is continuous it has an advantage over reciprocating pumps in freedom from water hammer in the suction and discharge pipes.

Fig. 29

In operation it is necessary that the pump, when set above the level of its supply, be primed before it will start, and in such cases a foot valve is advantageous. It does not begin to deliver water until a certain speed of revolution is attained depending upon the height of the lift. When delivery has commenced the speed may be lowered somewhat below this point before it will cease on account of the inertia of the flow when once established, but the conditions of flow are unstable in this region.

As the water passes through the pump, the impeller impresses upon it a head h_c due to centrifugal force; this is equal to the static head that the pump would maintain when running at its normal speed, but at which it would deliver no water were it not that the rotation of the water in the eye of the wheel and in the outer casing has the effect of increasing h_c from 1 to 12%. This increase is greater with vanes having radial

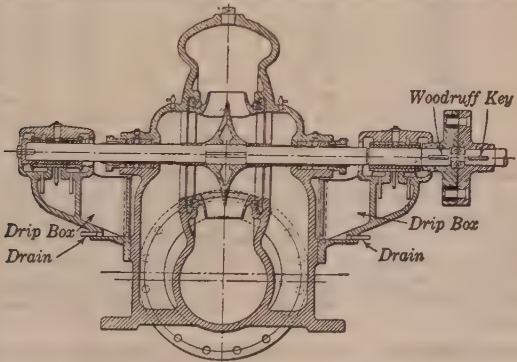

Fig. 30

tips than those which are turned back, and is raised when the wheel is surrounded by a large vortex chamber.

If the head is dropped slightly below the true value of h_c, the discharge will commence, and will continue so long as it remains below this amount. The discharge cannot, however, be reduced below that corresponding to the head h_c after flow has started without danger of its stopping altogether, so the statement is generally made that a centrifugal pump will begin to deliver against a certain head at a certain speed and cannot deliver less than a certain quantity.

Lift for Single-stage Centrifugals. A single-stage centrifugal pump has been made to lift against a head of 936 ft. and such pumps with a lift as high as 350 ft. are in service, but it is usually considered that 100 ft. is the practical limit without a second stage. For higher lifts a series of pumps is used on the same shaft, delivering water from one pump to the next, by which any desired head may be overcome.

The following table gives the approximate average performance of a centrifugal pump so designed that the discharge ceases when the head becomes 50% greater than that for which the pump is speeded.

Average Performance of a Centrifugal Pump

At constant speed					At constant head
Per cent of designed head	Per cent of designed discharge	Per cent of designed brake horsepower or input	Per cent of designed water horsepower or output	Per cent of best efficiency	Per cent of best speed
150	....	....	0	0	81.6

The Suction Lift of a pump is dependent upon the pressure at which the entrained air in the water separates. This separation occurs at lower pressures in rapidly moving than in slowly moving water. The lift also depends upon the velocity in the suction pipe, being less for high and greater for low velocities. The head at which the air separates is usually between 24 and 28 ft. below atmospheric pressure, and 26 ft. may be taken as an average safe value. The velocity effect may be taken as $h = v^2/g$ including inlet losses from the suction basin.

Power and Efficiency. Let Q = volume of water lifted per second, w = weight of a cubic unit of water, g = acceleration of gravity, v = velocity of outer circumference of pump wheel, β_0 = angle which vane makes with outer circumference, u_0 = radial component of velocity at outer circumference, H = total head = height water is raised plus all frictional heads. Then

$$\text{Power required to drive pump} = \frac{Qw}{g} v_0 (v_0 - u_0 \cot \beta_0)$$

$$\text{Hydraulic efficiency of pump} = gH/v_0 (v_0 - u_0 \cot \beta_0)$$

The hydraulic efficiency is the quotient of the gross work done by the pump, divided by the work done on the pump wheel. The speed v_0 required to pump against a given head must increase as β_0 decreases, and it becomes a minimum when $\beta_0 = 90°$. In this case the vanes are radial at the outer circumference, and for perfect efficiency $v_0^2 = 2\,gH$. As the efficiency decreases v_0 must increase so that $v_0^2 = k \cdot 2\,gH$, where k is a coefficient whose value ranges from 1.2 to 1.8.

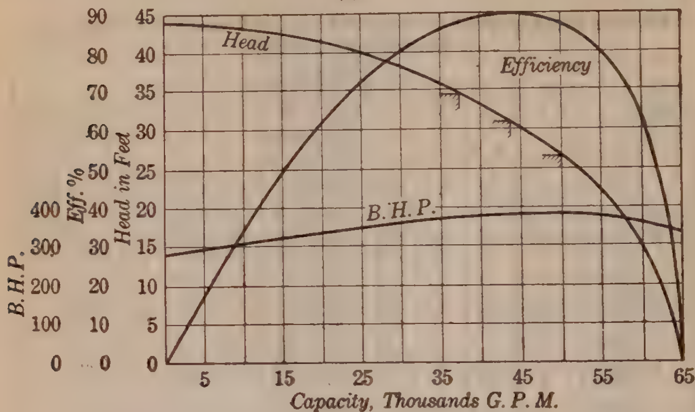
Power = brake horsepower to drive pump shaft. Water = gallons per minute delivered. Speed = revolutions per minute.

Screw Pumps. The screw pump is closely related to the centrifugal but has fewer vanes and hence has larger passages for a given capacity and is in consequence particularly fitted for drainage and sewage pumping where the lifts are low and the liquid pumped liable to contain a considerable amount of floating matter. The range of head is limited to not over 45 ft. Screw pumps now on the market are of two distinct types, one known as the Wood pump, consisting of a series of scoop-shaped buckets arranged around the periphery of a wheel which pick up the water as the wheel revolves very much as the tank of a locomotive is filled when in motion. These pumps are frequently provided with a trash cutter near the inlet of the buckets to prevent large pieces of floating material from getting in and clogging them. The second type has its propeller built on the lines of a screw and thus may be made with much larger passageways and is more closely related to the centrifugal.

(a)



(b)

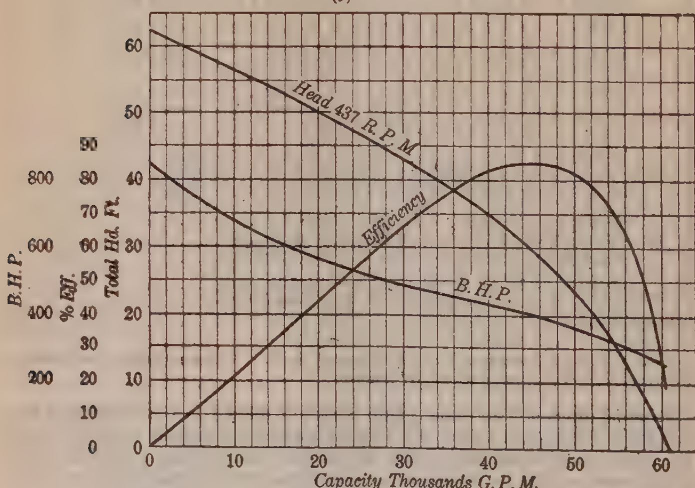


Fig. 31. Curves of Centrifugal Pump and Screw Pump
(a) 42-in. Centrifugal (Allis-Chalmers)
(b) 42-in. Screw Pump (Worthington)

Pumps of both types are built of very large capacities. The efficiencies now obtainable with screw pumps are somewhat lower than those of centrifugals of the same capacity.

The rules of **speed variation effects**, within working limits for centrifugal and screw pumps are:

Head varies as the square of the speed.
Capacity varies as the first power of the speed.
Brake Horsepower varies as the cube of the speed.

The **specific speed**, K_p, of a centrifugal or screw pump is

$$K_p = nQ^{1/2}/H^{3/4} = n/\sqrt{H} \cdot \sqrt{Q/\sqrt{H}}$$

where n = revolutions per minute;
Q = discharge capacity in c.f.s.;
H = head of water pumped against.

Although this expression is somewhat similar to that for the specific speed of turbines, the two equations are not interchangeable.

The **size** of centrifugal and screw pumps is designated by the diameter of the discharge opening.

Figs. 31*a* and 31*b* represent respectively the characteristic performance curves of a centrifugal and a screw pump of the second type designed to meet similar requirements.

Considering the working range of each pump to be from 40 000 to 50 000 gal. per min., the range of **head** is seen to be 11 ft. in both cases, with the **efficiency** of the centrifugal ranging from 89 to 88%, and that of the screw from 83 to 82%. For the centrifugal the **power** required (B. hp.), is nearly constant throughout a wide range and decreases slowly in both directions from a maximum at a discharge of 50 000 gal. at a head of 19.4 ft., while for the screw it decreases rapidly with increase of discharge from the starting point. The **speed** of the centrifugal is given as 225 r.p.m., whereas that of the screw is 437 r.p.m., or nearly twice as great. Both pumps, being motor-driven, are designed for constant speed. The **capacity** of the motor required to start the screw pump with its casing full of water is nearly twice that of the centrifugal.

The **specific speed** of screw pumps is much higher than that of centrifugals.

35. Reciprocating Piston Pumps

Types. Reciprocating piston pumps may be classed as to operation as either single- or double-acting. The former takes water on one stroke and discharges it on the other; the double-acting pump takes and discharges during both strokes. As to construction they are divided into inside-packed and outside-packed pumps, an example of the latter being shown in Fig. 32.

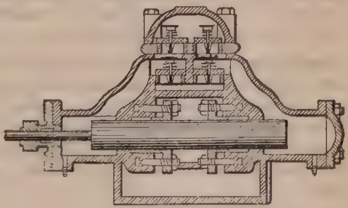

Fig. 32

A continuous discharge from a single-acting pump may be obtained by either of the devices shown in Fig. 33, in which when suction takes place on the upstroke the chamber below the piston is filled with water and at the same time the volume of water in the discharge chamber above the piston is delivered. The volume of the discharge chamber being less than that of the suction chamber, as the piston descends part of the water in the suction chamber is delivered through the discharge chamber and part of it flows into the space above the piston to be delivered on the suction stroke.

Displacement Curves. If the piston velocities as ordinates are plotted to time, or to space passed through by a crank moving at uniform velocity, as abscissas, the area enclosed between the curve, the axis of the abscissas, and a vertical ordinate will represent the displacement of the piston at any time. For uniform effort and uniform flow this displacement should be uniform, but in a reciprocating pump this can only be approximated.

Long Suctions. If the suction of a reciprocating pump is long, even though the lift is low, on account of the variable velocity, a considerable portion of the suction head is absorbed in accelerating the water at the beginning of the stroke. A part of this force is recovered at the end of the stroke as pressure forcing the piston ahead, but unless the head h_f is available at the beginning of the stroke the pump will not lift. If the speed of the piston is such that it moves more rapidly than the inertia of the water can be overcome, the water

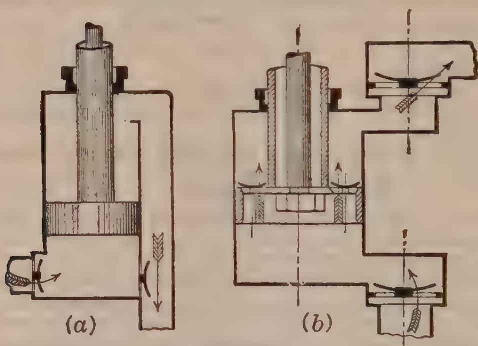

Fig. 33

separates from the piston and may ultimately overtake it, as the latter is retarded in the second half of its stroke, causing severe shock or hammer.

The head at inlet of the suction for a maximum is equal to the depth of the suction opening below the water surface in the suction well plus the height of the water barometer, and the head at outlet is that corresponding to a perfect vacuum less the effective lift of the pump. When, as is usually the case, the pump is located above the level of water in the suction well the head available for producing flow is reduced.

Separation of Air. The suction lift of a pump is dependent upon the pressure at which the entrained air in the water separates. The head at which the air separates is usually taken at about 26 ft. below atmospheric pressure. Separation of air also may occur on the discharge side of the piston during the second half of the stroke when the piston is being retarded due to the velocity previously imparted to the water being so great as to carry it away from the piston.

Air Chambers. To prevent separation an air chamber may be installed on either the suction or the discharge pipe and should be located as near as possible to the pump. The value of the air chamber increases with its size, cross-section being more effective than height. It should be so located that the water is drawn as low as possible without actually emptying the chamber at each stroke.

Flywheel pumps, kind	Ratio of change of air volume in air chamber to volume of	
	1 stroke of piston	1 revolution of pump
Single-acting	0.557	0.557
Double-acting	0.211	0.106
Two double-acting 90 deg. apart	0.048	0.012
Three-throw single-acting 120 deg. apart	0.0032	0.0011
Three-throw double-acting 120 deg. apart	0.0032	0.0011

The duplex pump without a flywheel, if the piston were accelerated uniformly, would give a uniform delivery; in practice, however, the variation is about the same as that of a three-throw flywheel pump.

36. Pumping Engines

Types. Pumping engines are a combination of a pump with a steam engine in a single machine, and the term is usually restricted to machines of at least one million gallons daily capacity. There are four general types:

(a) The Common Duplex Pumping Engine, consisting of two parallel double-acting pumps directly connected to two steam engines, and taking strokes alternately or 90 deg. apart, each engine operating the valves of the other. In this type the length of stroke is variable, and the steam must follow throughout the full stroke, and can be used expansively only by adding a low-pressure cylinder into which it expands continuously during the discharge stroke of the high-pressure cylinder.

(b) The Duplex Pumping Engine with the Worthington High-Duty Attachment, which is a duplex pump having attached to each piston rod a pair of auxiliary cylinders filled with oil and mounted on trunnions through which they are connected to the delivery main. These cylinders rotate in such a manner that at the beginning of the stroke they oppose the movement of the piston and thus prevent racing while the steam follows at full pressure. At midstroke just after cutoff they neutralize each other and toward the end of the stroke assist the movement of the piston when the steam is working expansively. This device enables the steam to be expanded in one, two, or three cyclinders, and thereby increases the economy of operation.

(c) The D'Auria Pumping Engine, in which the use of steam expansively is accomplished by circulating through the frame of the pump a body of water which is acted upon by an auxiliary piston and accelerated during the first half of the stroke, and then acts upon this piston during its retardation in the second half of the stroke.

(d) The Crank and Flywheel Pumping Engine, in which the expansive use of steam is provided for by the inertia of the flywheel.

Performance. The performance of pumping engines is usually stated as **Duty,** which was originally defined as the number of foot-pounds of work delivered for each 100 lb. of coal burned under the boilers. Owing to the variation in evaporative power of coal, and also of boiler efficiency, the coal basis for computing duty is more or less unsatisfactory for accurate work, and a new basis was adopted using an assumed evaporation of 10 lb. of water per lb. of coal, so that duty is also defined as the number of foot-pounds of work delivered for each 1000 lb. of dry steam, this being determined by the amount of water evaporated from and at 212° F. with corrections for moisture in the steam delivered to the engine. On account of the varying dryness of the steam and the condensation between boiler and engine it has been suggested that duty be based upon each 1 000 000 B.t.u. in the steam delivered to the engine and this value is now usually reported, sometimes alone and sometimes with the others. This would correspond to the preceding if the steam were supplied to the engine at an absolute pressure of about 5 lb., corresponding to a temperature of about 162° F. It follows that the duty on the last-named basis will in practice be less than that on the steam basis and usually less than that on the coal basis.

The duty of pumping engines and steam pumps ranges from about 3 to 8 million foot-pounds in the single-cylinder boiler-feed pumps to 160 million foot-pounds in the best high-duty, direct-acting and flywheel pumping engines, and in turbo-driven centrifugals, all on the 1000 lb. of dry steam basis. The coal consumed per horsepower per hour on a basis of 10 lb. of water evaporated per pound of coal may be obtained by dividing 198 by the duty in million foot-pounds.

Duty and Coal Consumption of Steam Pumping Machinery

Kind of pumping machinery	Duty in 1 000 000 ft-lb. per 1000 lb. of dry steam	Pounds of coal per horsepower per hour
Single-cylinder boiler-feed pumps and air pumps	3 to 5	66 to 40
Steam fire engines:		
Silsby rotary	6.5 to 8	30 to 25
Amoskeag	6 to 9	33 to 22
Clapp and Jones	7.5 to 14	27 to 14
High-pressure duplex pumps	15 to 20	13 to 10
Duplex compound non-condensing pumps	25 to 40	8 to 5
Duplex compound condensing engines	30 to 45	6.6 to 4.4
Duplex triple condensing engines	40 to 60	5 to 3.3
Cornish flywheel engines	60 to 70	3.3 to 2.8
Walking-beam compound condensing engines	60 to 85	3.3 to 2.3
Steam turbines and centrifugal pumps	80 to 90	2.5 to 2.2
Worthington high-duty duplex engines	100 to 160	2.0 to 1.25
Compound condensing flywheel engines	100 to 130	2.0 to 1.5
Triple-expansion flywheel engines	110 to 160	1.8 to 1.25
Steam-turbine-driven centrifugals (large)	100 to 160	2.0 to 1.25

Direct-acting Water Motor. When the steam end of a duplex pump is replaced by a similar end with large valve openings, which may be connected to a supply of water under pressure, the device is called a direct-acting water motor or pump. On account of the high frictional losses the device is not so efficient as a turbine connected to a centrifugal or a reciprocating pump. As the apparatus requires little attention, it may be advantageously used as a continuous relay at the end of a long line of pressure pipe to increase the pressure in a following line where a smaller amount of water is needed.

37. Jet Pump and Hydraulic Ram

The Jet Pump. In this apparatus (Fig. 34) a small jet of water at high velocity is discharged through a throat the upstream end of which connects to a suction pipe and the downstream end to the discharge. The velocity of the jet reduces its pressure below that of the atmosphere and thus creates a partial vacuum at the throat into which water from the pump well rises and is then mingled with the jet and carried along at reducing velocity by it. The efficiency of this apparatus is greatest

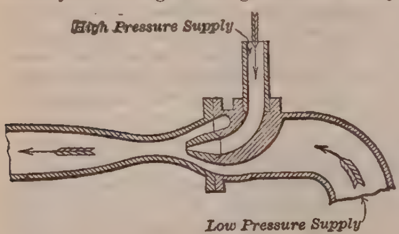

Fig. 34

with a high suction lift and low pressure on the discharge, when it may reach 25 or 30%. When a steam jet replaces the water jet, the ordinary steam injector is obtained in which the vacuum is formed not only by the velocity of the jet but by the condensation of the steam.

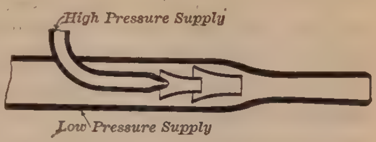

Fig. 35

The water-jet pump may be advantageously used to produce a large discharge through a nozzle at a low pressure for a fountain, or for fire fighting, by means of the apparatus shown in Fig. 35, which is sometimes called an injector nozzle. (Proc. Inst. Mech. Eng. of Great Britain 1879.)

The following table gives the quantity of water at a head of 700 lb. per sq. in. required to deliver through a one-inch nozzle a jet of 150 g.p.m., the head at the nozzle being 100 ft.

Low-pressure supply, Pressure, lb. per sq. in.	60	50	40	30	20	10
High-pressure supply at 700 lb. per sq. in. G.p.m.	3.7	10.9	18.1	25.2	32.4	39.6

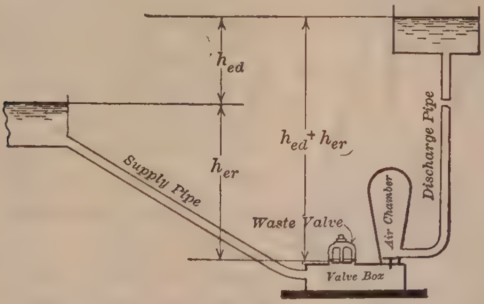

Fig. 36

The Hydraulic Ram (Fig. 36) consists of a drive pipe delivering into a chamber whence the water escapes to waste until the waste valve is closed by the discharging water, and then into the air chamber, in which it compresses the air until the flow stops, when the air expands, closing the valve at the chamber inlet and forcing water up the delivery pipe. When the flow is stopped there is a rebound of pressure toward the inlet. This creates a reduction of pressure and causes the waste valve to drop open and flow is

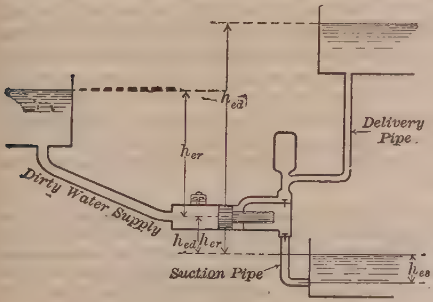

Fig. 37

started again. The apparatus thus intermittently utilizes the momentum in the drive pipe, and the longer this pipe the more work the machine will do.

If h_{er} is the height of the supply reservoir above the ram, the efficiency is $e = Q_d(h_{ed}+h_{er})/Q_s h_{er}$ when a portion of the water used to drive is pumped, the inlet of the drive pipe being taken as the suction inlet. When a separate supply is pumped, as may be done with the machine shown in Fig. 37, $e = Q_d h_{ed}/Q_s h_{er}$. The efficiency decreases as the ratio of h_{ed}/h_{er} increases, and becomes very small for high lifts. The value of e in the above expressions may be as high as 70%. Rankine gives $e = 1.12 - 0.2\sqrt{(h_{de} + h_{er})/h_{er}}$.

38. Pulsometer and Air Lift

The Pulsometer (Fig. 38) has a chamber with two parts, each connected to a suction pipe at the bottom and to a steam pipe at the top with a discharge at the side near the bottom. Steam enters and fills one chamber and then condenses when the steam inlet valve shifts, allowing steam to enter the other chamber. As the steam condenses, a vacuum is formed which lifts water into the first chamber. When the second chamber is filled with steam, the valve shifts again and steam enters the first chamber, forcing out the water through the discharge valves and then condensing again, making the process continuous. Tests of a pulsometer reported by DeVolson Wood, Trans. Am. Soc. Mech. Engs., 1892, vol. 13, p. 211, gave a duty ranging from 9 to 13 million foot-pounds. The apparatus is practically adapted to pumping out cofferdams, on account of the ease with which it can be set up, as it may be simply suspended from a ring at the top and connected with steam, suction and discharge hose lines.

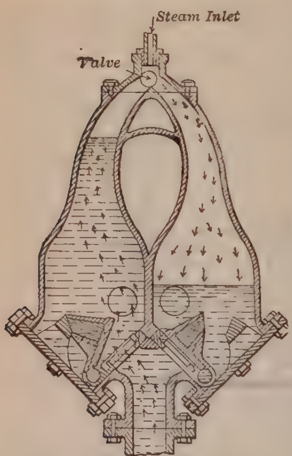

Fig. 38

The Air Lift. This device involves the discharge at the bottom of the well or at least a considerable distance below the water surface, of air into the mouth of the delivery tube. The air as small bubbles mixes with the water, and the specific gravity of the mixture is so reduced that the pressure of the water outside the delivery tube causes the mixture to overflow at the top. Evidently the greater the length of the pipe below the surface the greater the difference between the weight of the columns within and without the tube and the higher the water can be lifted. Generally the depth of submersion is made 1.5 to 2 times the lift.

The air lift is especially adapted to raising liquids from great depths, and is more efficient in handling hot liquids on account of the greater expansion of the air. It is particularly easy to install when the well has sufficient depth below the water surface. The air at entrance should be distributed over the area of the pipe rather than concentrated at the center, and small bubbles give better efficiencies than those which fill the entire delivery tube.

Experimentally the following relations are found to give the best results:

Head in feet	10	20	30	50	100
Qa/Qw	1.0	1.5	2.0	2.5	3.0

Of the indicated horsepower of the air chamber of the compressor the lift under favorable conditions may return as much as 45%, but ordinarily not more than 25 and frequently only 10 or 12%. The duty of air compressors ranges usually from 6 to 40 million foot-pounds, and the duty of the whole plant may therefore range from less than one million to perhaps 20 million foot-pounds as an upper limit. (See Proc. Inst. Civ. Engs. of Gt. Britain, 1900, vol. 140, p. 323, and 1906, vol. 163, p. 353.)

During the operation of the air lift the following equations apply:

a_p = area of eduction pipe, above air inlet, in square feet;
c_e = coefficient of entrance = 0.97. (See Art. 7 of this Section.)
c_p = coefficient due to pipe friction and average slip varying from 0.70 to 0.99;
d = diameter of eduction pipe in inches;
h_l = lift in feet;
h_s = submergence of air discharge in feet;
p_b = barometric pressure on water in well and at upper end of discharge pipe in feet of water;
p_t = absolute pressure at inlet in foot piece in feet of water;
q_b = discharge of air at pressure p_b in cubic feet per second;
q_w = discharge of liquid in cubic feet per second;
u_w = density of liquid pumped;
v_l = velocity of liquid in eduction pipe below air inlet;
W = work output in foot-gallons per second.

$$h_s - \frac{p_t - p_b}{u_w} = \frac{v_l^2}{2g}(1 + c_e) \tag{1}$$

$$\frac{q_b}{q_w}\frac{p_b}{u_w}\log_e\frac{p_t}{p_b} = h_l + \left[\frac{\left(1 + c_p\frac{W}{d}\right)(q_b + q_w)^2 + c_e q_w^2}{2g\,a_p^2}\right] \tag{2}$$

$$\frac{p_b}{q_w\,u_w}\log_e\frac{p_t}{p_b} = \frac{1 + c_p\frac{W}{d}}{2g\,a_p^2}(q_b + q_w) \tag{3}$$

$$\left(1 + c_p\frac{W}{d}\right)(q_b^2 - q_w^2) = 2gh_l\,a_p^2 + c_e q_w^2 \tag{4}$$

Example. To determine the air required to pump water at a rate of 2 cu. ft. per sec. from a well 10 in. in diameter and 330 ft. deep, in which the air pipe inlet is submerged 64.33 ft. and the lift is 25.67 ft., the air pipe being 2-1/2 in. in diameter and passing through the 10-in. pipe.

a_p = area of 10-in. pipe − area of outside of 2-1/2-in. pipe = 0.5 sq. ft.;
c_e = 0.97;
c_p = 0.80;
d = 10 in. − 3 in. = 7 in. = net diameter of 10-in. pipe enclosing 2-1/2-in. pipe;
h_l = 25.67 ft.;
h_s = 64.33 ft.;
p_b = 14.7 lb. = 33.96 ft.;
p_t = 64.33 + 33.96 = 98.29 ft. = pressure of water over air outlet + atmospheric pressure;
q_w = 2.0 cu. ft. per sec.;
q_b = air required in c.f.s. atmospheric pressure.

u_w = density of mixture of air and water $= \dfrac{62.5\,q_w + 0.08\,q_b}{62.5\,(q_w + q_b)}$;

$v_t = \dfrac{2}{0.545} = 3.67$ = discharge in cubic feet ÷ area of 10-in. discharge pipe;

$W = 2 \times 7.48 \times 25.67 = 384.8$ ft. gal. = product of gallons pumped and lift.

Applying equation (4):

$$\left(1 + c_p \frac{W}{d}\right)(q_b^2 - q_w^2) = 2\,gh_l\,a_p^2 + C_e q_w^2$$

and substituting therein:

$$\left(1 + 0.80\,\frac{384.8}{7}\right)(q_b^2 - 2^2) = 64.4 \times 25.67 \times 0.5^2 + 0.97 \times 2^2$$

or
$$44.97\,q_b^2 = 179.88 + 413.2 + 3.88$$

and
$$q_b^2 = \frac{596.6}{44.97} = 13.25 \quad \therefore \quad q_b = \sqrt{13.25} = 3.64 \text{ c.f.s.}$$

If the submergence were not given its proper amount could be computed from equation (3) by determining the value of p_s, the only unknown therein, which can then be introduced in equation (1) to obtain h_s, as follows:

Equation (3)
$$\frac{p_b}{q_w\,u_w}\log_e\frac{p_t}{p_b} = \frac{\left(1 + c_p \dfrac{W}{d}\right)(q_b + q_w)}{2\,g\,a_p^2}$$

Substituting values:

$$\frac{33.96}{2 \times \left(\dfrac{62.4 \times 2 + 0.08 \times 3.64}{62.4 \times 5.64}\right)}\log_e\frac{p_t}{33.96} = \frac{44.97\,(3.64 + 2)}{64.4 \times 0.5^2}$$

or
$$\frac{33.96}{0.706}\log_e\frac{p_t}{33.96} = \frac{254.5}{16.1}$$

$$\therefore \log_e\frac{p_t}{33.96} = \frac{0.706}{33.96} \times \frac{254.5}{16.1} = \frac{180.5}{546.76} = 0.33$$

0.33 being the hyperbolic or natural logarithm of 1.38

$$\frac{p_t}{33.96} = 1.38, \quad \text{and} \quad p_t = 1.38 \times 33.96 = 46.86 \text{ ft.}$$

By equation (1)
$$h_s - \frac{p_t - p_b}{u_w} = \frac{v_t^2}{2\,g}(1 + c_e),$$

and substituting:
$$h_s - \frac{46.86 - 33.96}{0.353} = \frac{(3.67)^2}{64.4}(1 + 0.97)$$

or
$$h_s = \frac{12.90}{0.353} + \frac{13.47 \times 1.97}{64.4} = 36.54 + 0.49 = 37.03 \text{ ft.}$$

This submergence being that given the highest efficiency is about 60% of the total length of eduction, or sum of submergence and lift, and indicates the submergence used in the apparatus as specified was too great for best results.

Davis and Weidner (see Bull. 450 Univ. of Wisconsin) conclude

1. The central air tube pump has the greatest theoretical capacity for a given size of well.

2. The coefficient of pipe friction and slip decreases as the discharge increases, and decreases as the ratio of volume of air to volume of water increases.

3. The coefficient of pipe friction and slip varies with the length of pump, but seems to be independent of the percentage of submergence and of the lift.

4. The length of pump, the percentage of submergence, and therefore the lift remaining constant, there is a definite quantity of air causing the maximum discharge. This quantity of air for maximum discharge, as also the ratio of volume of air to volume of water, differs for different percentages of submergence and lift, the length of the pump remaining constant.

5. The length of pump remaining constant, the maximum output (e.g., foot-gallons) occurs at about the same percentage of submergence for all rates of air consumption, being at from 61 to 65% for the pump used in the Wisconsin experiments. At other submergences the output varies as the ordinates of a parabola having a vertical axis. Under these conditions the lift does not remain constant as the percentage of submergence varies.

6. The length of pump and percentage of submergence remaining constant, and therefore constant lift, the efficiency increases as the input decreases, that is, the highest efficiencies are obtained at the lowest rates of pumping.

7. By varying the percentage of submergence, and therefore the lift, the length of pump remaining constant, the maximum efficiency is obtained at approximately 63% submergence for all rates of input or discharge.

8. The lift remaining constant, the efficiency increases as the percentage of submergence increases, for all rates of input and all practical percentages of submergence.

9. With the same size and type of pump, the percentage of submergence remaining constant, the efficiency increased as the lift increased for the small lifts experimented on, that is, up to about 24 ft. From a theoretical study, however, the indications are that a point will be reached from which the efficiency will decrease as the lift increases.

10. Other conditions remaining constant, there is no advantage to be gained by introducing compressed air above the surface of the water in the well.

11. The type of the foot-piece has very little effect on the efficiency of the pump, so long as the air is introduced in an efficient manner and the full cross-sectional area of the eduction pipe is realized for the passage of the liquid. Anything in the shape of a nozzle to increase the kinetic energy of the air is detrimental.

12. A diverging outlet which will conserve the kinetic energy of the velocity head increases the efficiency.

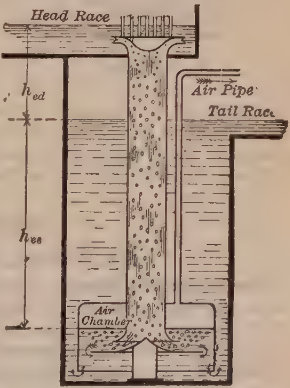

Fig. 39

The Hydraulic Air Compressor. This apparatus (Fig. 39) is practically the reverse of the air lift. Water is caused to pass vertically downward through a tube or shaft at a moderately high velocity, and by means of small pipes or an open surface at the top opportunity is given for the water to absorb as much air as possible. At the bottom the water is discharged against a considerable head and is made to pass underneath a collecting hood which is connected with a chamber for storing air. The reduction of velocity at outlet causes the water to release a portion of the entrained air, which rises through the collecting hood and passes to the air chamber under a pressure equal to h_{es} the head of water above the free surface underneath the hood.

The velocity at which bubbles of air separate themselves from running water is about 0.75 ft. per sec., and the flow down the tube or shaft must exceed this. Experimentally a velocity between 12 and 16 ft. per sec. gives the best results. (Eng. and Min. Jour., Jan. 19, 1907.)

39. Miscellaneous Pumps

The Archimedean Screw has been largely used in Holland against heads not exceeding 10 ft. It consists of an inclined shaft carrying one or more helices of considerable diameter, which are rotated with little clearance in a circular or semicircular channel connecting head and tail water. The angle of inclination of the channel should be less than the angle of the helix so that the water always tends to run down the helix and up the channel. The best angle for the helix is found to be between 30 and 40 deg., and an efficiency of 75% has been reported.

The Scoop Wheel is used for drainage pumping, and consists of a series of flat vanes revolving in a curved channel, and is practically a reversed undershot waterwheel. It may be used for lifts as high as 6 ft. and has been constructed to deliver 160 cu. ft. per sec. An efficiency of 70% is claimed under favorable circumstances.

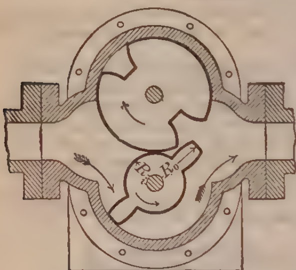

Fig. 40

The Positive Rotary Pump (Fig. 40) is intermediate between the centrifugal and the reciprocating piston type. It has long been familiar in the Silsby fire engine, where both the steam and water ends are of this class. The same construction is used in the ordinary rotary blowers for delivering free air. The chief objection to this pump is the difficulty of keeping the revolving pistons tight. Like the centrifugal it requires no valves, and like the reciprocating pump is positive in action. The discharge of such a pump per revolution is $\mathbf{Q} = \pi \mathbf{d}(\mathbf{R_i}^2 + \mathbf{R_0}^2)$ where d = axial length of the piston, or distance between crowns, R_i = radius of piston hub, and R_0 = radius of piston tip. The discharge as computed from this formula must be reduced for leakage past the pistons.

WATER POWER

40. Power, Slope, and Discharge

The Power of a Stream is the product of the fall H and the weight Qw of water flowing per second, Q being the discharge and w the weight of a cubic unit of water. When H is feet, Q cubic feet per second, and w pounds per cubic foot, then **work per second in foot-pounds = QwH** and **horsepower = QwH/550.** Assuming a plant to deliver 80% of the power of the stream the horsepower developed at the wheel shaft is simply $QH/11$. Assuming an efficiency of generating apparatus of 90%, since 1 kilowatt = 1.34 horsepower, the electrical output at the station switchboard is $QH/16$ in kilowatts. Since a stream of water flows continuously, its power should be stated on the basis of 24 hours per day and 365 days in a year, and a horsepower year is $24 \times 365 = 8760$ horsepower-hours, or 525 600 horsepower-minutes, or 31 536 000 horsepower-seconds.

The International Advisory Committee on Rating of Rivers (1928) recommended that:

1. The **Kilowatt** be adopted as the unit of power to be used in rating rivers.
2. The **full power of the river** and **gross head** be used as a basis for rating rivers.
3. The **flow duration curve** and also the **month of occurrence** of minimum flow are desirable as a basis for rating rivers, and where this information can not be given there should be supplied: (a) the minimum flow and its occurrence; (b) the flow which is available for six months of the year; and (c) the **arithmetic mean flow.**

In ordinary industrial operations it is usually estimated that a plant will operate during 310 days in a year and from 10 to 16 hours per day, depending on the character of the industry. The number of horsepower-hours in a year required for each horsepower capacity is therefore from 3100 to 4960. If the water which would flow during the remaining 14 to 8 hours and the remaining 55 days can be stored for use during the time the plant runs, the capacity of the plant per hour for the tunning time will be from 8760/3100 to 8760/4960 or from 2.83 to 1.76 hp. per horsepower of average stream capacity. In using the term horsepower in connection with water-power development the unit of time upon which it is based should be stated, and when no unit is designated 24-hour 365-day power should be understood. Evidently a stream will yield twice as much power on a 12-hour basis as it will on a 24-hour basis if the flow of the other 12 hours can be stored.

The Slope. The distance through which the water falls vertically per unit of horizontal distance traveled is sometimes called the slope per unit of distance, and is for uniform fall the tangent of the inclination of the water surface from the horizontal. Since the slope of natural streams is ordinarily small, the inclined length and the horizontal length practically coincide.

In ordinary natural streams, except in the vicinity of an obstruction, the low-water slope is greater than the flood slope. For streams with nearly vertical side-walls, the reverse will ordinarily be true. Upstream from and in the vicinity of a dam over which the water flows, the flood slope will be greater than the low-water slope, except in channels which enlarge their cross-section very rapidly by overflowing extensive flats as the water rises. Generally for the estimation of power the natural slope may be taken as practically the same at all times unless the location is upstream from an obstruction which may cause the water to back up from below against the base of the dam without causing a similar rise above its crest.

Backwater. The distance upstream to which the backwater effect of a dam or other obstruction extends in an ordinary stream will be greater at low water than in time of flood.

The Discharge or Runoff of all streams varies from day to day, month to month, and year to year, and bears some relation to the rainfall on the drainage area. This relation is by no means a simple one, and stream-flow measurements are essential to the reliable determination of the flow, unless a comparison can be made with the known discharge from a similar watershed similarly located; and even then great care must be taken in estimating to allow for the influence of a range of hills if one exist between the two basins considered, as greater precipitation and hence greater runoff may be expected on the windward side of a summit of land than on the leeward side.

The water that falls on the surface of the earth is partly evaporated by the direct rays of the sun and partly by the aid of vegetation, partly absorbed by the soil to reach the streams through their banks and beds, and partly flows away over the surface. The quantity of discharge of a stream is therefore dependent upon both the rainfall and the evaporation, and ordinarily amounts to the surface runoff plus the subsurface flow, and of this discharge the continuous as distinguished from the intermittent flood flows, when corrected for the effect of visible storage in ponds and lakes, represents the subsurface supply, or the percolation, which generally ranges from 25 to 60% of the total supply, being greater on flat, sandy, and porous drainages than on steep, impervious ones.

Occasionally it happens that percolation from an area whose surface is tributary to

one stream is delivered by underground strata into another, but such conditions are relatively rare. It will be found that whereas the percentage of rainfall appearing as runoff is greater for precipitous and rocky drainages, the amount of the runoff that can be utilized for power will be greater from flat, sandy areas.

Runoff Data. The most useful as well as most accurate data available for American conditions are those of Desmond FitzGerald, obtained at Boston on the Sudbury and Cochituate watersheds. (Trans. Am. Soc. C. E., 1892, Vol. 27, p. 253.)

The Sudbury watershed has an area of 75.199 square miles, is hilly, with steep slopes having some large swamps within its borders, and the material is costly unmodified drift. The Cochituate watershed has an area of 18.87 square miles, with flat, sandy slopes and the surface mostly modified drift. The two are adjacent to each other.

The records of the Sudbury watershed are given in more detail than those of Cochituate, and the more important data are in the following table:

When the rainfall is high, a greater portion appears as runoff and when low a less percentage than the mean, since the vegetation takes its share before the water gets away, except in severe storms, and when there is little rain during the growing season vegetation takes nearly all. With rainfall records as a basis and the data of FitzGerald's experiments, it is possible to estimate with a fair degree of accuracy the annual runoff of streams in the humid portions of the United Stations, and also to approximate the low-water flow, particularly if cognizance is taken of the character of the surface and the influence of the vegetation on the evaporation.

In working from rainfall to runoff it is to be noted that a given amount of precipitation concentrated in a few sharp showers will appear to a larger extent as runoff than the same amount falling during the same period in a more continuous but mild storm. Also when the soil, of a clayey nature, is baked by a drouth and vegetation is drooping, a larger proportion of the precipitation will run off than when the soil is slightly moist and vegetation thriving. Rain falling at night contributes more to the runoff than that falling in the daytime by reason of the direct evaporation in the latter case by the sun's rays, and a mild shower falling on a hot surface may be almost wholly evaporated without the aid of vegetation. Rain falling on frozen ground appears almost wholly as runoff. The water which runs off over the surface reaches the streams within a few hours, but the subsurface flow is likely to continue for at least two weeks under ordinary conditions before it all appears in the open channels.

41. Rainfall in the United States

The table on the following pages, compiled from the records of the U. S. Weather Bureau, gives the normal monthly and annual precipitation in inches at 190 places in the United States, as established from records prior to 1922. In the arid regions, the minimum annual precipitation may be as low as 25% of the normal, but in the humid portions, while records as low as 40% occur, an annual minimum less than 50% of the normal is rare. The terms Rainfall and Precipitation are usually synonymous, meaning the vertical depth of rain and melted snow.

42. Percolation and Runoff

Percolation, or subsurface runoff, varies greatly with the character of the soils and their covering. The accompanying data, from both European and American sources, gives the percolation in percentages of the rainfall:

	Per cent
Sand, bare	65 to 85
Ordinary ground, bare	29 and 29.2
Ordinary ground, cultivated, no crops	36
Loam, bare	33
Peat, bare	44
Sand, with grass growing 6 months	14
Loam with grass growing 6 months	1.3
Peat with grass growing 6 months	14.6 and 8.7
Ordinary soil with sod	33
Bare ground	45
Bare ground covered with 1 cm. sand	82
Bare ground covered with 1 cm. straw	94
Bare ground covered with 5 cm. dry leaves	93
Bare ground with grass growing	−34*
Meadow grass, short	0 to 1.15
Meadow grass, long	0 to −100*
Beans and peas	5
Clover	−12*
Indian corn	40 to −50*
Wheat	25
Rye	40 to 18
Oats	38
Potatoes	40
Ash forest	37
Alder forest	43
Beech forest	44
Elm forest	50
Maple forest	57
Oak forest	58 to 70
Vineyards	66
Mixed forest	74
Norway spruce forest	91
Pine forest	93
Fir forest	94

These data so far as they deal with crops and forests must be accepted as giving only relative relations. It is, however, safe to say that the percolating runoff from evergreen forests will be about twice that from deciduous forests and three times that from cropped areas during the growing season.

* Water in excess of rainfall taken from subsurface runoff of adjacent areas.

Normal Precipitation in United States

From Beginning of Records to 1920 or 1922. (U. S. Weather Bureau)

Evaporation and Reservoirs. The final runoff of a stream is also affected considerably by the extent of water surface from which evaporation may take place. The evaporation from water surfaces in the United States varies from 18 in. to over 100 in. annually, being greatest in the arid regions and least at high altitudes in the north. For water-power calculations in the humid portions, the evaporation during the summer months is usually all that needs to be considered, as at other times it is insignificant, or else a portion of flow is necessarily wasted. During summer in the northern states this evaporation may amount to about 60% of the annual rainfall in open country, but where the surrounding shores are forested and the water surfaces narrow so as to be little exposed to wind the evaporation is much less.

The evaporation, particularly from water surfaces, is considerably influenced by the wind, as shown by the following observations:

Wind velocity in miles per hour	0	5	10	15	20	25	30
Relative evaporation	1.0	2.2	3.8	4.9	5.7	6.1	6.3

The aquatic plants exercise a considerable influence upon the evaporation from water surfaces. From experiments made under the direction of the author, it appears that the bulrushes, like long grass, exhale much more moisture than would be evaporated from open water, whereas the pond lily exhales considerably less, the common arrow-leaf occupying an intermediate position.

Runoff from Typical Streams in various parts of the United States has been shown in the preceding pages with other appurtenant data.

In applying the data of this table to cases not therein included, cognizance must be taken of both the rainfall and the topographical conditions of the watershed to which it is applied.

43. Flood Discharge of Rivers

The flood discharge of a stream will be greater per square mile for small drainage areas than for large ones on account of the greater intensity of precipitation on the former in time of storm. Although many flood formulas for computing the runoff per square mile in time of storm have been suggested, the data in the following table of observed flood flows in rivers of the United States as established by the Hydrographic Branch of the U. S. Geological Survey will be found, for those rivers, much more valuable and useful than any formula can ever be.

In using this table to estimate flood flows the character of the drainage area must be carefully considered together with the rainfall conditions. The ordinary storm rate of precipitation in the humid regions is less than 0.4 in. per hour. Excessive rates are from 0.4 to 0.7 in. per hour, but on rare occasions extreme rates of 2 in. are recorded for periods of about an hour over areas of 20 to 100 square miles. In the arid regions, as much as 17 in. in 24 hours has been recorded over a considerable area. The average slope of the watershed and that of the stream itself also influence the maximum discharge, as also whether the ground be frozen or not.

Maximum Rate of Discharge of Streams in the United States

44. Storage of Water

The Mass Diagram. To determine either the amount of storage necessary to utilize at an average or variable rate of consumption the entire flow of a stream or any part of it, or the amount of water that can be continuously utilized from a stream, the flow for a considerable period being known, the most simple process is by the aid of the so-called mass diagram. The reliability of this process depends upon the completeness and accuracy of the information as to the runoff of the stream. A comparison of the runoff data of the Ohio, Tennessee, Sudbury, and Colorado rivers by John C. Hoyt in Eng. News, April 23, 1908, Vol. 59, p. 459, shows that a single year's record is entirely insufficient for reliable prognostication and that five-year periods in the humid sections usually give mean results within 10% of the normal average, but may be in error as much as 30%, and in the arid region in error from 4 to 88%. Ten-year averages in the humid region are usually accurate within less than 10%, but on the Colorado the error ranged from 1 to 48%. It may therefore be concluded that at least a five-year record should be secured or a much longer one constructed from rainfall data, to obtain results of reasonable accuracy in the humid regions, and that a prediction of runoff in the arid region should be adopted with extreme caution.

Having the desired record, the beginning for purposes of computation may advantageously be taken at the last of the latest low-water month of the earliest year, but such a starting point is not essential. The diagram is usually constructed with a time unit of one month, although when only a part of the flow is to be stored a weekly unit may be preferred. The record should be arranged chronologically in a table, and after each item the sum of it and all the preceding items should be entered. These sums then represent the total quantity of water that has been discharged by the stream at the end of any period since the beginning of the tabulated observations, and may be expressed in cubic feet per second, or any other convenient unit. With unit of time as the abscissa and total discharge as the ordinate, the mass curve is plotted, and if the lowest possible line is drawn tangent to the curve at two points an ordinate to

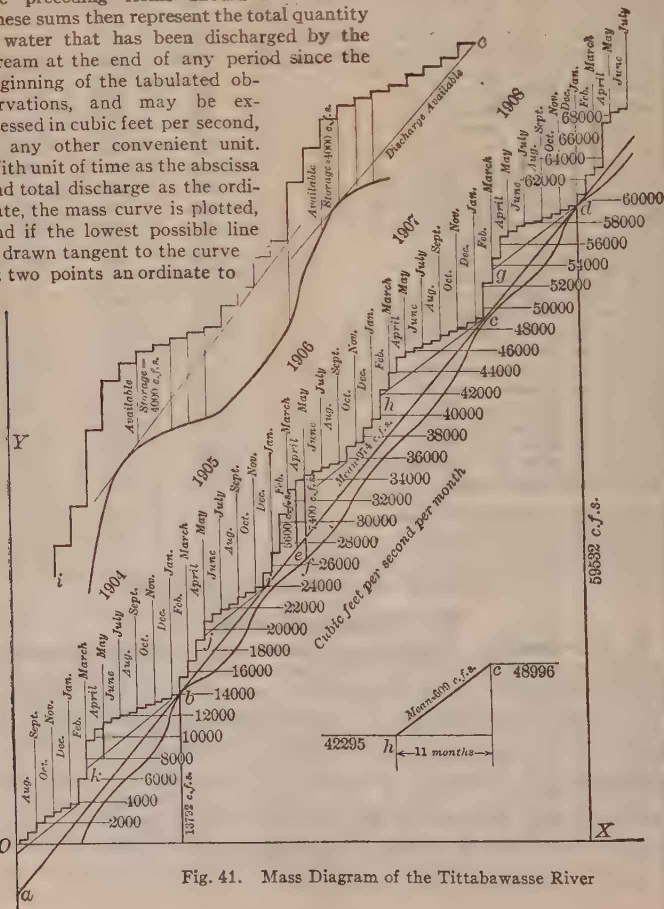

Fig. 41. Mass Diagram of the Tittabawasse River

this line will represent the maximum quantity of water that could have been used from the stream for the period between the ordinate considered and the intersection of the tangent with the axis of abscissa, assuming the quantity to be used uniformly during the period and a similar use to continue indefinitely. This ordinate divided by the time above included will then give the quantity to be so used per unit of time. The amount of storage required to equalize this flow will then be represented by the maximum partial ordinate between the tangent and the curve.

Fig. 37 shows a mass curve for a river in Michigan. In this case, for the sake of distinctness, the mass data have been plotted as a stepped curve rather than as a smooth one, the discharge being in cubic feet per second per month. When this is done it must be remembered that the ordinates considered are always those to the right-hand end of the step. The tangent line *bd* shows the average daily available yield to be, by the ordinate at *d*, 59 532 cu. ft. per sec. divided by the time from the last of December, 1903, to January, 1909, inclusive, about 61.2 months, or 974 cu. ft. per sec. The partial ordinate between the point *e* on the tangent and the right end of the step of the mass curve for April, 1906, gives 5605 cu. ft. per sec. for one month, or $5605 \times 60 \times 60 \times 24 \times 30 = 14\,528\,160\,000$ cu. ft. as the storage required to provide a constant flow of 974 cu. ft. per sec.

If instead of a constant use a variable one is desired, a mass curve of the variable use should be plotted in the same manner as the original diagram, but this variable flow curve must be of such dimensions that it falls either below or is tangent to the original mass curve. Such curves will usually have an opposite phase to the mass curve and hence must fall below or tangent to the line *bd*, as shown by the lower sinuous curve of the figure. The storage required to provide a supply of the nature represented by this curve is shown by the partial ordinate at *f* between the consumption and the mass curves to be 7400 cu. ft. per sec. for one month, or 19 180 800 000 cu. ft.

If it is desired to determine the amount of storage necessary to develop continuously a less quantity than the total flow of the stream, draw from the low points of the mass curve a line having an inclination parallel to the mass consumption line for the quantity desired. In the figure the lines *dg*, *ch*, *bk*, etc., represent such consumption lines, and the maximum storage required for the corresponding uniform consumption is represented by the partial ordinate for May, 1904, between the consumption line *bk* and the mass curve. The intersection of the consumption line, with the vertical of the mass curve, indicates the time when storage should have begun, in the particular year, to yield the consumption represented by the line, and the ordinates between consumption and mass curves represent the amount of water in storage at the time shown by each ordinate. The triangle in the lower right of the figure shows the rate represented by the lines *dg*, etc.

To determine the equalizing value upon the flow of the stream of a given amount of storage, plot downwards from the mass curve for the six high months of each year the magnitude of the storage in the unit of the diagram. Join the points so located in each year by a curve as in the upper diagram of the figure, in which *ic* is an enlarged representation of the mass curve from *i* to *c*, and from each of the succeeding low points of the mass curve draw a tangent to the curve just located. The minimum inclination of such tangents which do not cut the mass curve will give the rate of consumption that may be uniformly utilized with the storage in question. This method fails when the storage considered is so great as to exceed the maximum partial ordinate between the tangent *bd* and the mass curve, as in that case the storage could not be filled by the stream between dry periods.

Corrections for Evaporation. When from the amount of storage needed as shown by the mass diagram and a study of the topography of the watershed the area of water surface of the required reservoir is determined, the evaporation may be compiled and the net yield of the stream determined. A corrected mass diagram may then be constructed for more accurate computations.

Bank Storage. The visible capacity of reservoirs is very materially augmented in sandy or gravelly districts by the water held in the adjacent ground between the high and low water planes. The volume of such storage is dependent on the slope of the natural water table and on the proportion of voids in the soil. The former can frequently be determined by observations on wells in the territory affected, and the latter for the most porous soils may amount to 40% of the total volume, but for ordinary sands and gravels may be safely taken at about 20%. For clay it is inconsiderable, probably about 3 or 4%, and for loam about 10%. Sandstone rocks take up about 15% of their volume of water, limestone 5%, shales 4%, and granites 1%. The difficulty of estimating the value of bank storage lies in the uncertainty as to the actual character of the strata below the surface. The water stored in the ground is given out much less rapidly than that from an open reservoir, and hence is of little value for sudden fluctuations of draft, but in a long gradual lowering of the surface of the reservoir will add materially to the quantity available.

Emptying of Reservoirs. The time required to empty a pond or reservoir between known levels through a certain opening, or over a weir of known dimensions, is obtained from the general formula

$$t = \int_{H_2}^{H_1} \frac{A_r}{CA_0 \sqrt{2\,gh}}\,dh \tag{1}$$

in which A_r is the area of the reservoir at any elevation and A_0 is the area of the orifice through which discharge takes place, while H_1 is the elevation of the water surface, H_2 a lower elevation, h the height of the water surface above the center of the orifice, and C the coefficient of discharge. If A_r is variable it must be expressed in terms of h. When A_r is constant and $H_2 = 0$ this becomes $t = 2\,A_r \sqrt{H_1}/CA_0 \sqrt{2\,g}$, which is twice the time required for the same quantity to be discharged under a constant head H_1. For a weir, the expression for weir discharge is substituted for that of the orifice in the denominator of (1).

(a) In practice the area of reservoirs will be variable, and where definite information as to the relation between Ar and h is not available the reservoir volume may be assumed as semi-parabolic in longitudinal section and parabolic in cross-section and plan. With X as the length, Y as the half width, and Z as the depth, the area of the surface is 4/3 XY and the area at any elevation is $A = 4/3\ X_1Y_1Z/Z_1$ where X_1, Y_1 and Z_1 apply to the original surface considered. If a is the height of the center of the orifice or of the crest of the weir above the reservoir bottom $Z = h + a$ and $Ar = 4/3\ X_1Y_1\ (h + a)/Z_1$, which may be substituted in (1) before integration. (b) Another assumption which may be made is that X is directly proportional to Z, which is equivalent to saying that the reservoir has a uniform slope lengthwise. In this case $Ar = 4/3\ X_1Y_1\ (h + a)^{3/2}/Z_1^{3/2}$. (c) If it is assumed that Y also varies directly with Z, or that the sides of the reservoir slope uniformly to the center, which is, however, a condition never met with in natural ponds, then $Ar = 4/3\ X_1Y_1\ (h + a)^2/Z_1^2$. Of the above assumptions that under (b) is the most likely to conform to natural conditions, except where the reservoir has silted considerably, when assumption (a) will be more accurate. It may be added that since 4/3 X_1Y_1 in cases (a), (b), and (c) gives the area of the pond surface, if this is known it may be substituted at once for Ar, when the only assumption involved is that of the form of the vertical sections.

The time required to empty a vessel of rectangular cross and longitudinal section is twice that required to discharge its volume at the initial head. The time required to discharge one-half the contents of such a vessel into one of the same size and shape with their bottoms at the same level is equal to the time required to empty the vessel under the initial head.

The time required to empty a wedge-shaped vessel with parallel ends, vertex down, or a right paraboloid of revolution, vertex down, or any vessel in which the areas at different heights vary as the first power of their distance above the bottom is 4/3 of that required to discharge its volume under the initial head.

For a pyramid or cone with vertex down the factor is 6/5.
For a bottom hemisphere 7/5.
For a sphere 8/5.

When the reservoir is of irregular shape so that the foregoing assumptions are not sufficiently accurate, recourse must be had to Simpson's Rule and the distance $H_1 - H_n$ through which the water falls may be divided into an even number n of equal spaces and the area of the surface A_r at each of the so located positions determined by survey or computation from the known shape of the reservoir, calling them $A_{r1}, A_{r2}, A_{r3} \ldots . A_{rn}$. The approximate time required then is:

$$t = \frac{H_n - H_1}{3\,CA_0\sqrt{2g} \times n}\left[\frac{A_{r1}}{H_1^{1/2}} + 4\left(\frac{A_{r2}}{H_2^{1/2}} + \frac{A_{r4}}{H_4^{1/2}} + \frac{A_{r6}}{H_6^{1/2}} + \ldots \frac{A_{rn-1}}{H_{n-1}^{1/2}}\right) + 2\left(\frac{A_{r3}}{H_3^{1/2}} + \frac{A_{r5}}{H_5^{1/2}} + \ldots \frac{A_{rn-2}}{H_{n-2}^{1/2}}\right) + \frac{A_{rn}}{H_n^{1/2}}\right]$$

where H_1, H_2, etc., are the heights of the surfaces.

The volume, V, discharged may be similarly obtained from:

$$dV = -A_r\,dH, \text{ whence } V = \int_n^1 A_r\,dH, \text{ or approximately:}$$

$$V = \frac{H_1 - H_n}{3n}[A_{r1} + 4(A_{r2} + A_{r4} + \ldots A_{rn-1}) + 2(A_{r3} + A_{r5} + \ldots A_{rn-2}) + A_{rn}]$$

For a prismatic tank of rectangular section, the volume varies as the head and the time required to empty portions of it varies as the square root of the head, whence the last quarter will empty in half the time and the last one-ninth in one-third of the time.

For a wedge-shaped vessel the volume varies as the square of the remaining head and the time varies as $h^{3/2}$.

For the time required to empty a pond over a weir from a head on the weir of h_1 to a head h_2 the equation is

$$t = 2\frac{A_r}{CL}\left(\frac{1}{\sqrt{h_2}} - \frac{1}{\sqrt{h_1}}\right)$$

the weir discharge being represented by $Q = CL\,h^{3/2}$, C being considered constant.

45. Auxiliary Steam Plants

Desirability. When sufficient storage cannot be economically secured to equalize the flow sufficiently to yield the required quantity of power, the deficiency may be made up by a steam plant. It is to be remembered that a steam plant depreciates about as fast when idle as when running, and that the interest charges are to be carried during the whole year. When operation, interest, depreciation, and maintenance of a steam auxiliary are capitalized it will often be discovered that storage would have been a better investment.

Capacity. The capacity of a steam plant necessary to make up the deficiency of flow is best determined by the use of a diagram of graded discharge, as in Fig. 42, in which, with the time unit as the abscissa, the discharges, either natural or equalized by storage as the plan may be, as ordinates, are plotted, not chronologically but in the order of their magnitudes from least to greatest. A horizontal line drawn through the diagram, whose ordinates represent the desired total capacity, limits between itself and the curve the total amount of water that must have been replaced by auxiliary power, and for each month the amount is given by its individual partial ordinate between the capacity line and the curve.

Operation of Combined Steam and Water Plants. When a steam auxiliary is used, it will usually be advantageous to run it continuously during the periods when it must run at all and use the water power to provide for the fluctuations, if the size of the pond at the plant permits this without wasting water. For the reason that a steam plant when idle is radiating heat, and hence not only wasting interest and depreciation charges but also a part of the fuel cost, it is better to let the water power lie idle while the pond fills up, as by such procedure nothing is lost, the full value of the water being utilized. On this account the importance of a large pond at the station is apparent.

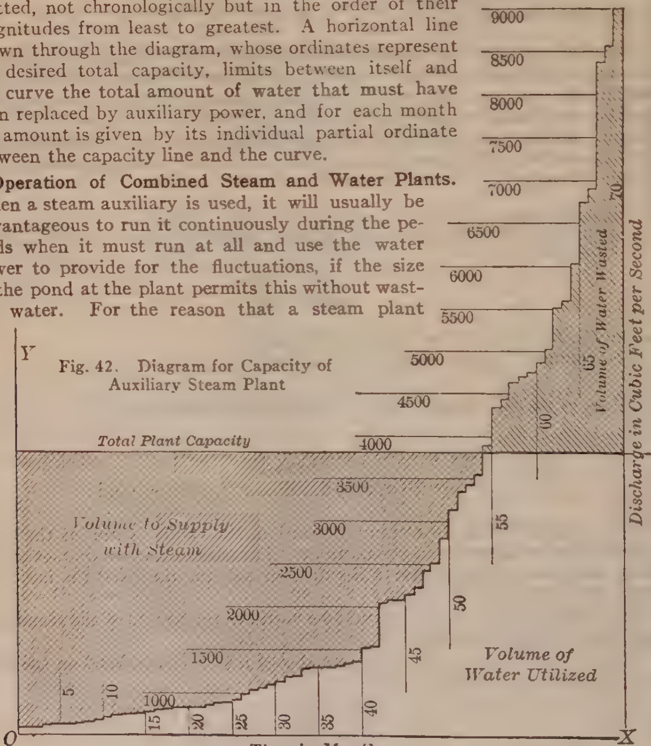

Fig. 42. Diagram for Capacity of Auxiliary Steam Plant

46. Design of a Power Plant

Power House. The Power House should be so located as to be protected from floating ice and other debris. When situated in a gorge, the position should be such as to permit a maximum of sunlight to reach the building. The intakes, whether direct to the wheelpits or to a closed flume or pipe line, should be so located that debris will readily pass by them. If water is flowing over the spillway or through the waste gate, these structures may be advantageously put near by, in order that they may be controlled to keep the intakes clear.

To avoid ice troubles the intake to the wheelpits or closed flumes may best communicate directly with the pond, rather than with a canal or head race, and a curtain wall may wisely be carried a few feet below the water surface at the entrance. To facilitate inspection the entrance to the wheelpits should be provided with easily operated gates.

See paper by Benj. F. Groat in Trans. Am. Soc. C. E., Vol. LXXXII, for special construction to divert ice.

Wheelpit. For low and moderate heads, up to 40 or 50 ft., the open wheelpit is to be preferred to the closed flume or pipe line. Of this head 20 ft. may be covered by the draft tube. Vertical wheel and umbrella type generators give higher efficiencies than horizontal shaft installations, due mainly to the reduction of bearings. The passages leading to the wheels should be so designed that the water is never retarded in its velocity as it passes toward the wheels but if possible is gradually accelerated. The losses between head and tail water in the best-designed plants, excluding the turbine loss, is about 4% of the total output for plants with heads below 20 ft., and may frequently amount to 12%. For higher heads the percentage is less, as there is little change in the rack losses and friction in flume, wheelpit, and draft tubes, while the power increases with the head. For approximate calculations a uniform loss of 1 ft. may be taken for all heads.

The **Draft Tube** should expand gradually from the outlet of the wheel until an area of outlet is attained such as to require a velocity through it a little greater than that of the water into which it discharges.

Draft Tubes may be classed as **Straight**, having the sides parallel, i.e. cylindrical, **expanding** when they form the frustum of a cone; **spreading** when they terminate in a trumpet mouth discharging radially around the full circumference; and **elbow** when the stream is turned within them, through an angle usually 90 deg. The straight draft tube is to be found only in old installations.

The proper design of the draft tube is one of the most important features of a hydraulic power plant as it may affect the efficiency and output of the turbines from 5 to 10% on low heads.

W. M. White, M. Am. Soc. C. E., has determined by very careful experiment the form assumed by a circular jet striking a flat plate perpendicularly and flowing off along it in all directions. (See Journal Assoc. Engr. Socs., Aug., 1901, and Trans. Am. Soc. Mech. Engrs., Vol. 43, May, 1921.)

It may therefore be expected that the form of draft tube that would offer the least resistance to the discharge of water through it would be of such form as that shown in Fig. 43. Such a tube, however, would not produce a regain of the velocity head,

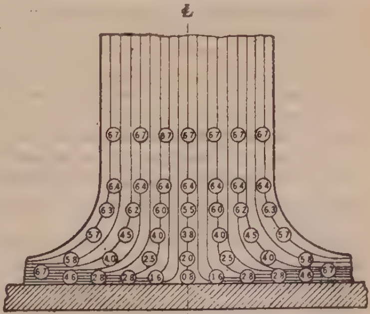

Fig. 43. Section of jet impinging on plate. Figures in circles indicate velocities. After White.

which is normally high at the outlet of the wheel. Therefore an advantage may be obtained by expanding the jet as it falls and the limiting angle of inclination of the sides of the tube has been found experimentally to be about 8 deg. from the axis when the jet is under less than atmospheric pressure and about 11 deg. when it is under atmospheric or greater pressures.

The hydrucone, Fig. 44, designed by Mr. White, embodies these conditions, its outlet being shaped similarly to the jet profile and water being discharged horizontally in all directions from the plate below its outlet.

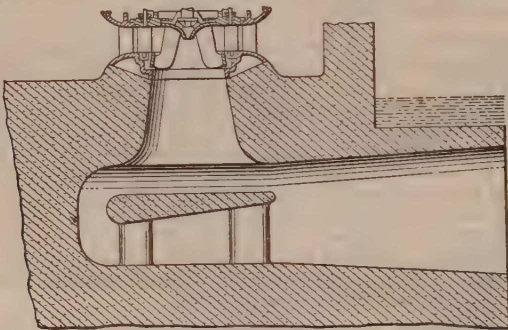

Fig. 44. White's Hydrucone

This device utilizes to some extent the centrifugal force of the discharging water and on tests has increased the efficiency about 6% over the best obtainable with the ordinary form of tube.

The same principles may be utilized in the design of an **elbow** draft tube by considering the flow through it to represent that through a circle whose diameter is the radius of the jet, as in Fig. 45.

The water passing through the circle whose diameter is *od* will be one-fourth of the total of the jet whose radius is *od* and, when the filaments have become parallel along the plate as at g' c', occupies the circle whose diameter is *oc* and would pass through the portion of the circle *vcw* covered by the arc *acb* if properly directed. But as some of the water in the circle *od* falls outside of the quadrant *oacb* it cannot follow the lines *oa* and *ob* but must be brought to the plane *ab* by paths bounded by some such lines as *oea* and *ofb*, and *ab* becomes the chord whose arc is the required width of the draft tube. If there is to be no further lateral expansion of the jet after passing the arc *acb*, then the direction of the outside filaments must be changed to tangency with the sides *am* and *bn* and this may be well accomplished by allowing a greater spread to the jet before it reaches *acb*; for this design curves such as *oka* and *ojb* give good results.

As the water is assumed to be traveling in the direction *oc* when it reaches *ab* it follows that to pass this plane it must be accelerated or else the chord *ab* must be extended to a length equal to the arc *acb*, giving the plan of the tube a form represented by the semicircle *pkojq* in which the filaments of water will have directions in planes indicated by the arrows. The line *pq* then becomes the horizontal projection of the throat of the draft tube and may fall anywhere between *t* and *c*. Experiment indicates that the area of the throat should not be greater than that of the jet at the plane where its curvature begins. Beyond the throat the tube may be caused to expand vertically along a line $g'r'$, making an angle with the bottom of the tube of not to exceed 22 deg., but better, not over 16 deg., until an area of tube is reached giving the desired outlet velocity.

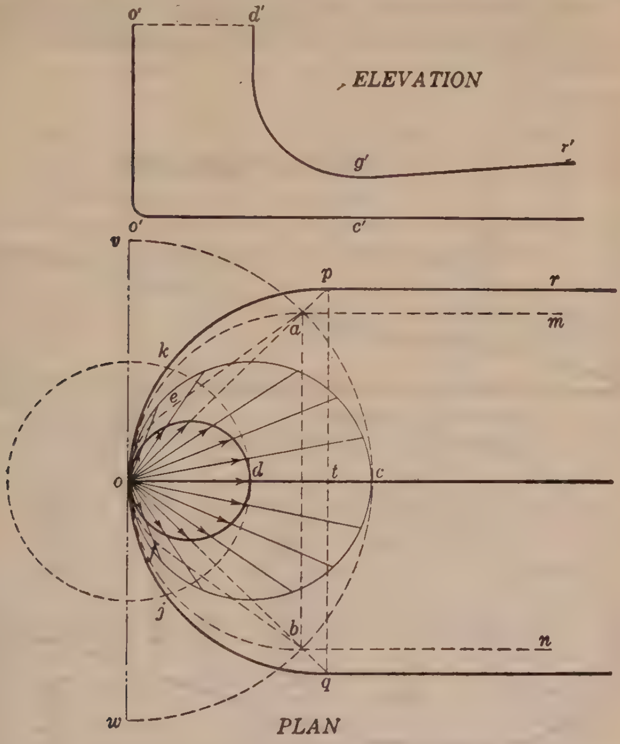

Fig. 45. Draft tube diagram

Having a tube of the general design just outlined, the jet being expanded from the outlet of the wheel downward (Fig. 46), it may be found that the width is too great for the space available; in this case the floor of the tube may be rolled up at the sides giving a U-shaped section having the same area as the original full-width one as shown in the lower half inverted plan. The length of the horizontal part of the tube must be increased to give the area at bb_2 that existed at rs in the full-width tube. The top of the upturned portion is represented by the broken line $a'm'j'b'$ in elevation and its boundaries by $ambb_2g_2a$ in the lower half inverted plan. The tube may be given a partial **spreading** characteristic by moving the center o downstream a short distance and raising the curve $a'm'$ to allow discharge into the upper projections of the tube directly from the whole of the upstream half of the descending jet. A tube of the latter type gave the highest efficiency of those tested for the Alabama Power Company at the Alden Hydraulic Laboratory, Worcester, Mass.; the report was published in Trans. Am. Soc. C. E., Vol. LXXXVII, pp. 892-926. For **spreading** draft tubes it is advantageous to insert a steep cone extending up the axis nearly to the outlet of the wheel.

The height of the draft tube, that is, the distance from the outlet of the wheel to the level of tail water, may theoretically be 34 ft., less the head corresponding to the change of velocity from the top of the tube to the outlet.

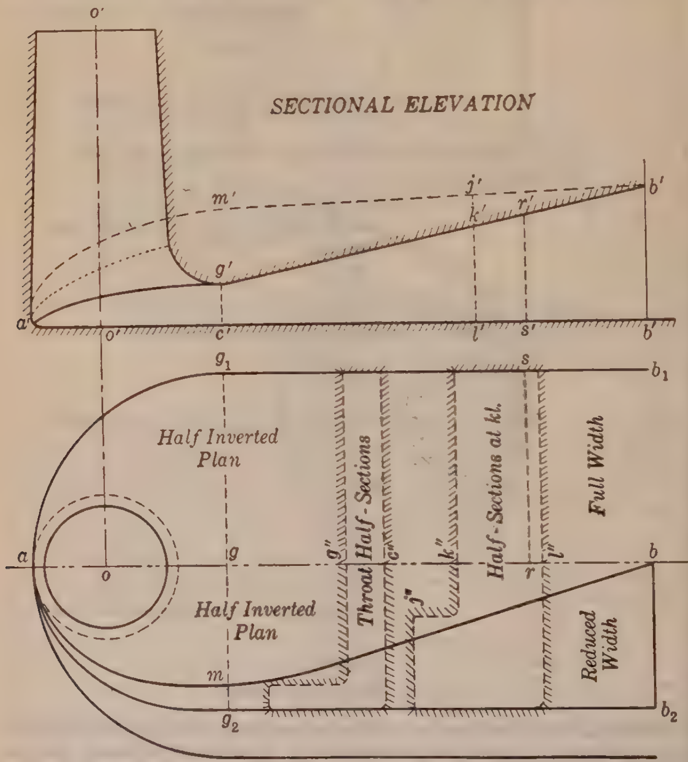

Fig. 46. Elbow Draft Tube

On account of the tendency of water to vaporize as it approaches the condition of flow in a vacuum it is found inadvisable to utilize this full height in the draft tube. In general practice a height of 20 ft. is found satisfactory with an upper limit of 24 ft., or possibly 26 ft. if the turbine will always run at or near full discharge.

Head or Fall Increasers are devices connected with the draft tube to increase the discharge by reducing the tail-water pressure. The most effective device of this kind appears to be that designed by Clemens Herschel, which is an application of the principle of the Venturi tube through the throat of which water is passed from the pond drawing into itself through apertures in the throat, water discharged by the wheel. (See Eng. News, Vol. 59, June, 1908, p. 635.)

Another device has involved the surrounding of the discharge from the wheel in the vertical part of its course with a stream from headwater.

By the introduction of a jet from headwater at the bottom of a curved draft tube the author has increased the output of a plant in flood time between 5 and 6% and by a utilization of the flow over the dam, if adjacent to the power-house, a considerable further advantage can be secured. The author's tests were made with the flow into the elbow at the center of the bottom of the draft tube. It has since been found to be more effective when introduced at the sides. Tests by the Power Corporation of Canada wherein the flow was introduced at the sides and somewhat above the bottom, showed increases of power as high as 30% due to the ejector flow.

The Generating Unit. In the earlier installations horizontal-shaft generators were largely used, either belted or geared to the turbines, or driven directly from a shaft on which several turbines were mounted. Tests of such installations have shown them to be considerably less efficient than the vertical-direct-connected units, and the multiple-wheel unit, whether vertical or horizontal, is not now looked upon with favor except under very special conditions.

The direct-connected unit requires that both turbine and generator shall be adapted to the same speed of rotation.

In selecting machinery the best speed of rotation is one slightly less than one-half the so-called spouting velocity, or velocity due to the head, but by specially designed wheels this can be increased as much as 50%, giving a fairly wide range of generator speeds from which to select.

The table on the following page gives data as to the vertical waterwheel generators, developed by the Allis-Chalmers Manufacturing Company, and may be taken as fairly representative of the machines of other manufacturers.

Current. Except where current is to be used in the immediate vicinity of the plant or for arc lighting or electric railway service, direct-current generators are not commonly used in the United States. For incandescent lighting, 3-phase 60-cycle alternating-current generators have a preference, but for power work 25- or 30-cycle machinery is considered more satisfactory. The current is frequently generated at about 2300 volts pressure, and is transformed upward to the line voltage for transmission. The line voltage may be anything between 440 and 150 000 volts; the higher the pressure the more power can be delivered over a given size of conductor, and consequently the low voltages are only used in local distribution or inside buildings.

Bearings. The bearings should be accessible at all times, and in the case of a vertical-shaft installation the entire load may be wisely concentrated on a single thrust bearing of special design. Such bearings may be placed either above or below the generator, and according to the loads to be carried may be of the simple plate type, roller bearings, the Kingsbury or the Spring bearing, or for very heavy loads the oil pressure bearing.

Of these the **plate bearing** consists of two plates, the lower of which is supported in a fixed position while the upper is fastened to the shaft and revolves with it, resting upon a film of oil between it and the lower plate, both plates being immersed in a bath of oil. Such bearings are satisfactory for speeds encountered in low-head plants.

The **roller bearing** consists of two plates as above with the film of oil replaced by a cage of rollers, either conical and of considerable length, or cylin-

				10 000	144	242	280 000

drical and of length not greater than their diameter. The plates and rollers of this bearing are all immersed in an oil bath.

The **Kingsbury bearing** replaces the cage of rollers with a series of segments or shoes supported by a pivoting surface near one end and slightly beyond the center of gravity in the direction of rotation. This causes the space between the segment and the upper plate to be more open at one end than the other so that a wedge-shaped film of oil is drawn in by the revolving disk. The parts of this bearing are immersed in an oil bath and the bearing operates satisfactorily under surface pressures of 400 to 500 lb. per sq. in. in high-speed turbine installations.

The **spring bearing** introduces a series of spiral springs fixed on the lower plate and carrying above them a rubbing plate which takes the load of the upper plate on a film of oil. On account of the ready adjustment of the springs to irregularity of load the bearing can be made of smaller diameter than the others and hence occupies less space. Like the preceding, the parts are immersed in a bath of oil.

The **oil thrust bearing** provides for the introduction of oil under a high pressure to a chamber in the plates near the shaft from which it flows out between the plates, insuring complete lubrication. The loads carried depend upon the pressure of the oil which is circulated by a positive piston pump. These bearings are used for the heaviest loads and the highest speeds, and are particularly adapted to steam turbine work.

The Exciter may be most economically driven from the main turbine shaft, but in many plants an independent exciter driven by a separate wheel is installed. After the plant is once started, and as long as it continues in operation, the excitation may be provided by a motor generator or rotary converter transforming the alternating current of the main generators into direct current for their excitation. The economy of this is slightly less than that of the separate exciter so far as operation is concerned, but when interest is considered may prove more economical, so that a single separator exciter may be provided to excite the first machine of a series and the rest be operated from the main current as above indicated. The exciting power usually ranges from 0.5 to 3% of the power at full load, being nearly constant in amount whether the main generator is loaded to full capacity or not.

The Switchboard should be so located as to enable the operator to command a view of the machines which he controls, and should have the following instruments: (a) On generator panel, 1 voltmeter, 1 ammeter for each phase, 1 frequency meter and 1 field ammeter. (b) On feeder panel, 1 wattmeter. (c) On exciter panel, 1 voltmeter and 1 ammeter. (d) On a bracket 1 synchroscope when more than one generator is installed. To which are added the several switches and connections, and for studying the station output an integrating wattmeter should be placed on the main circuits.

The Governor for turbines operates upon the gates and must be capable of exerting a large amount of power at times. This is usually accomplished by a piston driven by oil which is maintained at a high pressure in a reservoir with compressed air by the aid of a force pump operated from the turbine shaft. The action of the piston is controlled by valves moved by the governing mechanism proper. For less rapid operation governors depending on simple mechanical friction are utilized, but these governors are not sufficiently delicate for combined lighting and power loads. In governing impulse wheels, less power is needed, and the nozzle is frequently deflected away from the bucket without altering the flow. In the Doble Nozzle a tapered pin is pushed forward through the center to close and pulled back to open, either operation requiring a relatively small amount of power. The governor should be so located as to be under the eye of the attendant at the switchboard, unless a second attendant is available to look after it.

The usually accepted equation for determining the torque T of the regulating shaft resulting from the operation of the gates, is:

$$T = \frac{C \times \text{horsepower of turbines}}{\sqrt{\text{head}}}$$

Where C has a maximum value of 50 and a minimum of 25.

For low-head open-flume plants the percentage temporary change in speed for load thrown off is given by:

$$d = 81\,000\,000 \frac{(\text{Hp.}) \times t}{WR^2 \times (\text{r.p.m.})^2};$$

d = percentage change of speed;
Hp. = maximum horsepower of turbine;
t = time in seconds occupied by governor in moving gates through their range;
W = weight of rotating parts;
R = radius of gyration of rotating parts;
r.p.m. = normal revolutions per minute.

Remote Control. By the use of special apparatus designed by either the Allis-Chalmers or the General Electric Company the operation of water power plants may be controlled from a distance so that a single operating crew may handle several plants and the apparatus may be in part operated by a float so as to be thrown on and off as the pond rises and falls.

Crane. As this piece of apparatus is only used occasionally, it may wisely be of the hand-operated type where first cost is an item of importance. Cranes operating with chains are preferable to those using cable for power-house work.

The Racks. The loss of head through the racks is of considerable importance, particularly in low-head plants, and may be considerably reduced by using lenticular or fish-shaped rack bars. A platform from which to rake debris from the racks and a chute or other device for removing it is important.

47. Operation of Plant

The Load Factor of a plant is the ratio of the average to the maximum load carried. For economical operation this should be brought as near unity as possible, and it becomes good policy to sell the output at a low rate during the low-demand hours to stimulate consumption at such times.

In ordinary plants supplying municipal, domestic, manufacturing and commercial service the load factor is usually between 40 and 50%, which means that for a large part of the time the plant runs at part capacity, but late in the afternoon it has for 1 or 2 hours a peak load of nearly the maximum amount, the actual maximum covering only a few minutes. The result of this is that such a plant must be designed to deliver very much more than the average capacity of the water utilized. Usually the machinery installed is made capable of delivering the entire daily output in from 6 to 8 hours.

The Plant or Capacity Factor is the ratio of the average load to the rated capacity of the plant.

The Diversity Factor is a term used to indicate the diversity of uses in which the output is absorbed and may be defined as the ratio of the sum of maximum demands of the subdivisions of the load to the maximum demand of the whole system, measured at the point of supply.

The Connected Load is the combined continuous rating of all the receiving apparatus on the customer's premises connected to the system.

The Demand Factor is the ratio of the maximum demand to the total connected load.

The Power Factor of a plant is the ratio of the effective power in watts to the volt-amperes, all measured at the switchboard. The existence of a power factor, which is peculiar to alternating-current installations, is due to the fact that there usually exists in a line an induced current which neutralizes in part the power current. The effect of the induced current may be reduced by special expedients, but with ordinary motor loads is likely to cause the power factor to drop to 0.85, and in some distributions it may fall as low as 0.30. The power factor is determined by the load and not by the generating apparatus, and so far as the latter is concerned should be taken as unity unless otherwise specified.

Except as the efficiency of the generator may be affected by a change in power factor, there is no effect upon the input to the generator, hence the turbine requirement is always based on the kilowatts delivered and not on the volt-amperes.

Regulation. If the speed of the generator changes, the voltage or pressure changes and the brilliancy of illumination and power of the output varies. Reducing speed reduces voltage, and vice versa. To maintain constant speed with a varying load requires a reduction or increase of gate opening, and where the wheels are supplied through a pipe line, a consequent change in velocity and pressure through the conduit.

Water-Hammer and Surge Tanks (see Warren, Trans. Am. Soc. C. E., Vol. LXXIX, p. 238). When power plants are supplied through long pipe lines it becomes necessary to provide against the water-hammer and surges occurring when the wheels are stopped and started if by manipulating gates. In plants using impulse wheels this is sometimes met by deflecting the nozzle so that the jet passes off the wheel when the latter is to be stopped and thus the flow of water is not interfered with, but water is wasted.

The magnitude of the water-hammer and surge increases as the rapidity of the stoppage or start of the flow. The **maximum hammer** occurs when the time t of closing the gate is instantaneous or less than the critical time $\frac{2L}{a}$, where L is the length of the pipe in feet and a is the velocity of vibration along the pipe in feet per second.

Then
$$h_h = \frac{av}{g} = \frac{145\,v}{\sqrt{1 + \frac{Kd}{Eb}}} \tag{1}$$

where h_h = head due to hammer, in excess of static head, g = the acceleration due to gravity, v = mean velocity in pipe in feet per second, d = inside diameter of pipe in feet, b = thickness of pipe wall in feet, K = modulus of elasticity of water in compression, taken as 42 400 000 lb. per sq. ft., and E = modulus of elasticity for material of pipe in tension, taken as 4 000 000 000 lb. per sq. ft. or 28 000 000 lb. per sq. in. for steel plate. Then

$$a = \frac{4660}{\sqrt{1 + \frac{Kd}{Eb}}}$$

For **ordinary water-hammer** that is, when the time of closing is greater than $\frac{2L}{a}$ the equation is:

$$h_h = \frac{Lv}{g\left(t - \frac{L}{a}\right)} \tag{2}$$

To counteract or reduce the hammer, standpipes or surge tanks are connected to the pipe line at or near the lower end.

For the **maximum surge** S_{max}, in a standpipe or surge tank either in starting or stopping the plant, the equation is:

$$S_{max} = H_f \left[1 + \frac{1}{2\,me} m' \left(\pi - \cos^{-1} m \right) \right] \tag{3}$$

where $m^1 = \frac{m}{\sqrt{1 - m^2}}$ and H_f = total loss of head in feet between feeding reservoir and standpipe, $m = \frac{H_f}{2\,Q} \sqrt{\frac{A_t\, g\, A_p}{L}}$ wherein Q = steady discharge in cubic feet per second, taken before gate starts to close or after gate is fully open and flow established. A_t is the area of the standpipe or surge tank and A_p the area of the pipe line, both in square feet. e = Napierian logarithmic base = 2.718.

In starting, S is measured from the water surface under static conditions and in stopping from a distance below this equal to H_f.

The foregoing equations do not take into account the effect of the operation of the waterwheel governor.

The following table gives a comparison of Initial Velocity, Time of Closure and Pressure rise by various authorities. See Kerr, Trans. A. S. M. E., Vol. 51, No. 6.

Initial velocity, ft. per sec.	Closure intervals 2 L/a	Rise in pressure in feet		
		By de Sparre-Gariel formulas	By R. S. Quick chart	By Gibson's arithmatical integration
10	10	51.8	51.8	51.5
9	9	51.8	51.8	....
8	8	51.8	51.0	....
7	7	51.8	51.0	....
6	6	51.8	51.2	....
5	5	51.8	53.8	54.1
4	4	58.2	59.6	....
3	3	66.5	67.4	68.0
2	2	77.7	78.5	....
1	1	93.3	93.2	93.26
0	0	0.0	0.0	0.0

To determine the **economical size** of penstock or pipe line the following formula may be used:

$$d = \sqrt[6]{\frac{3250\ QI}{C^2\ PB}} \tag{4}$$

wherein I = income in dollars per year per foot of head, C = the coefficient in the Chezy formula, $V = C\sqrt{rs}$, P = percentage return on investment including profit, depreciation, maintenance and taxes, and B cost of pipe in place per foot of diameter per foot of length, other symbols as before.

Differential Surge Tanks. From formula (3) it is evident that an increase in the area of the standpipe or surge tank reduces the surge, but for economic reasons it is not usually possible to make this area very large and often not so large as is desirable. To overcome this situation the differential surge tank has been introduced, which consists of a standpipe of about the same diameter as the pipe line, freely connected to it, and a storage tank of larger dimensions surrounding the standpipe and connected to the pipe line by a restricted passage (see Johnson, Trans. A. S. M. E., Vol. 30, p. 443, and Trans. Am. Soc. C. E., Vol. LXXVIII, p. 760), the whole being in such a condition that with a heavy surge water may overflow the standpipe into the surge tank whence it flows back to the pipe line through the restricted passage unsynchronously to the surges in the line itself.

48. Testing Code for Hydraulic Turbines

(Abstract)

(Approved by Machinery Builders' Society, Oct. 11, 1917)

Introduction. This code is intended to apply to acceptance tests of hydraulic machinery.

Efficiency of the plant takes account of all losses of energy between head water and tail water outside the plant as far as, or through the switchboard.

Efficiency of the machinery takes account of all losses of energy between the water in the wheelpit and tail water and as far as the generator terminals or switchboard.

Efficiency of the turbine takes account of all losses of energy between the water in the wheelpit and tail water and as far as the coupling on the turbine shaft. Losses through racks, in intake to penstock and in penstock shall not be charged against the turbine, nor shall the head necessary to discharge the water from the end of the draft tube. The net or effective head acting on the turbine shall be measured from a point near the intake to the turbine casing in turbines equipped with casings, or from a point immediately over the turbine in turbines having an open flume setting, to a point in the tail-race, and a correction for the velocity head required to discharge the water into the tail-race shall be added to the tail-water elevation; and a similar correction applied at the intake to encased turbines. The power developed by the turbine shall be taken as the mechanical power delivered on the turbine shaft and transmitted by the turbine shaft to the generator or other driven machine or system.

General. When the contract calls for the performance of the guide vanes, runner, draft chest and draft tube only, the velocity head at entrance to the casing shall be excluded, and the pressure shall be measured by piezometers so connected to the casing as to avoid velocity effects, instead of at entrance to the casing.

Apparatus shall be inspected before, during and after tests.

Testing apparatus must not interfere with operation of unit under test, which shall have been operated under load for at least 3 days prior to test.

Leakage of air into wheel or draft tube or of water out of wheelpit or penstock must be prevented or measured and allowed for.

Tests should not be made when variations of load exceed 3%; of head 2%, and of speed 1%, above or below the average of each.

Important instruments shall be installed in duplicate and calibrated before and after test.

Power Output. Power output may be measured by the electrical generator, or by a Prony brake or Dynamometer. If by a generator, the latter must be tested either in the shop or in the field and its efficiency curve established for the range covered by the tests, in accordance with the Standardization Rules of the Am. Inst. E. E. of September, 1916. The output of the wheel then is the kilowatt output of the generator divided by its efficiency and reduced to horsepower, the exciting current not being charged against the turbine. If the exciter is driven from the turbine, then its output similarly computed shall be added to that of the main generator.

When a dynamometer, either of the Prony brake, friction disk or other type is used, the dynamometer is to be so arranged as to avoid imposing either end thrust or side thrust on the turbine shaft and bearings, or to avoid adding any friction load which is not measured, and the brake must be capable of operating with the weighing beam floating free of the stops during the entire duration of a run.

Power Input or Water Horsepower. The turbine shall be tested, if possible, under the effective head stated in the contract, and at the speed specified in the contract.

Variation of 10% in head may be allowed if the speed is adjusted to correspond according to the law that

Speed varies as $h^{1/2}$
Power varies as $h^{3/2}$

Errors in adjustments of speed to head may be corrected for up to 2%, on the basis of test curves of the same or a similar turbine. The hydraulic equivalent of the speed is equal to the specified speed multiplied by the square root of the ratio of the effective head existing during the test to the specified effective head. The hydraulic equivalent of the horsepower is equal to the specified horsepower, multiplied by the three-halves power of the ratio of the effective head existing during the test to the specified effective head. Tests shall not be run when the head differs from the specification by more than 10%, or when the total draft head approaches within 5 ft. of the height of the barometric water column.

For turbines having closed casings the head is to be measured by at least two, and when possible not less than four piezometers connected to a straight portion of the penstock near the turbine casing intake, and by two or more board, rod or float gages in the tail-race, placed at points reasonably free from local disturbances.

The conditions of measurement, including velocity distribution, length of straight run of penstock, and conditions of piezometer orifices shall be such that no piezometer shall vary in its readings by more than 20% of the velocity head from the average of all the piezometers in the section of measurement. The piezometer orifices shall be flush with the surface of the penstock wall, the passages shall be normal to the wall, and the wall shall be smooth and parallel with the flow in the vicinity of the orifices. The piezometer orifices shall be approximately 1/4 in. in diameter.

The effective head on the turbine is taken as the difference between the elevation corresponding to the pressure in the penstock near the entrance to the turbine casing, and the elevation of the tail water at the highest point attained by the discharge from the unit test, the above difference being corrected by adding the velocity head in the penstock at the point of measurement and subtracting the residual velocity head at the end of the draft tube. The velocity head in the penstock shall be taken as the square of the mean velocity at the point of measurement, divided by 2 g; the mean velocity being equal to the quantity of water flowing in cubic feet per second, divided by the cross-sectional area of the penstock at the point of measurement in square feet. The residual velocity head at the end of the draft tube shall be taken as the square of the mean velocity at the end of the draft tube, divided by 2 g;

the mean velocity being equal to the quantity of water flowing in cubic feet per second, divided by the cross-sectional area of the penstock at the point of measurement in square feet. The residual velocity head at the end of the draft tube shall be taken as the square of the mean velocity at the end of the draft tube, divided by 2 g; the mean velocity being equal to the quantity flowing in cubic feet per second, divided by the final cross-sectional discharge area of the closed or submerged portion of the draft tube in square feet.

For turbines set in open flume, the head is to be measured by board, rod or float gages, located above the center of the turbine, and by board, rod or float gages in the tail-race, all gages being placed at points reasonably free from local disturbances, and not less than two gages being installed in the flume and not less than two in the tail-race.

Such gages are to be free of velocity effects, and if this is not obtainable when the gages are set in the open channel, they shall be placed in properly arranged stilling boxes.

The effective head on the turbine is to be taken as the difference between the elevation of the free water surface immediately above the center of the turbine, and the elevation of the tail water at the highest point attained by the discharge from the unit under test, the above difference being corrected by subtracting the residual velocity head at the end of the draft tube, computed as in the previous case.

Quantity of Water. The quantity of water discharged from the turbine is to be measured by weir, current meter, Pitot tube, screen or diaphragm, or by the chemical method, in accordance with the methods described in Arts. 22, 23 and 24 of this section.

When the quantity of water is measured by weir, weirs with suppressed end contractions shall be used.

The weir or weirs shall if possible be located on the tail-race side of the turbine, and care shall be taken that smooth flow, free from eddies, surface disturbances or the presence of considerable quantities of air in suspension, exists in the channel of approach. To insure this condition the weir should not be located too close to the end of the draft tube, and stilling racks and booms should be used when required. The channel of approach should be straight, of uniform cross-section and unobstructed by racks and booms, for a length of at least 25 ft. from the crest. The racks should be arranged to give approximately uniform velocity across the channel of approach. The uniformity of velocity should be verified by current meter or otherwise.

When the discharge is measured by current meter, observations shall be taken by two different types of meter, one type having preferably such characteristics that it will slightly over-register under conditions of turbulent or oblique flow, and the other type having characteristics such that it will under-register under similar conditions. The true velocity obtained by reducing the meter readings on the basis of their still-water ratings may then be taken as a weighted mean between the two series of observations.

The point method of observation shall be used and sufficient points shall be obtained to enable both vertical and horizontal velocity curves to be plotted for all portions of the section of measurement. The average velocity shall be determined from these curves by planimeter.

When the Pitot tube method is used, the Pitot tube shall be located in a straight run of penstock or conduit, at a distance equal to at least ten pipe diameters from any upstream bend and at least five diameters from a downstream bend. When the observation is made in a circular pipe or penstock, at least two Pitot tubes shall be arranged to traverse two relatively perpendicular diameters, but in the case of very large penstocks or those having unsymmetrical flow. Pitot tubes shall be arranged to traverse completely or partially the intermediate diameters, giving traverses at 45-deg. intervals.

When the screen method is used, the length of run of the screen shall be sufficiently in excess of the portion used for measurement to provide ample space for starting and stopping the screen so as to insure uniform conditions over the measured portion of the run. In determining the discharge the velocity of the screen shall be multiplied by an area intermediate between the net immersed area of the moving screen and the average area of stream cross-section of the portion of the channel traversed. The variation of the level in the flume shall be observed during the course of the run and the average elevation shall be used in determining the area.

When the chemical method is used, samples shall be taken from points distributed over the entire sampling section.

SECTION 14

WATER SUPPLY

BY

ALLEN HAZEN

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

COLLECTION OF WATER

Much of this material was originally prepared by the author's partner, the late George C. Whipple, M. Am. Soc. C. E.

COLLECTION OF WATER

1. Intakes

Intakes are structures built out into a body of water for the purpose of drawing water for use. The position of intakes is often affected by considerations of local pollution when sewage is allowed to flow into the same body of water from which the supply is taken. This is commonly the case in cities located upon rivers and great lakes. The depth of intake is frequently a matter of importance where water of different qualities is to be obtained at different levels. There are three type of intakes: (1) Unprotected intakes, (2) Submerged intakes, (3) Exposed or tower cribs.

Unprotected intakes are used for small supplies. The pipe is allowed to terminate at the desired point, sometimes being protected by a coarse screen. A fine screen is not permissible because it will be clogged by matters carried by the water.

A Submerged Crib is a structure built on the bottom or built at the surface and sunk to the bottom of the lake or river from the interior of which the water is taken. It serves the purpose of roughly screening the water and also of protecting the end of the intake pipe from damage. The opening is frequently covered by a rack of wooden bars spaced an inch or so apart. Sometimes a steel or brass screen is used in addition to the rack. Exposed or **tower cribs** are structures built on the bottom of the river or lake and extending above high water. They are frequently provided at different levels with ports controlled by gates, and screens may be located in their interiors. Tower cribs have many advantages for large supplies. The ports may be closed and the water pumped out of the intake pipe and everything inspected for tightness and condition. Screens in them may be reached for cleaning and repairs. Tower cribs require excellent foundations and they must be built strong enough to withstand ice pressures. In cold climates they are used only for large supplies. In warmer climates where ice pressure is not effective they are also used for small supplies.

Intake Pipes or Conduits are the connecting channels between the intakes and the shore. Intake pipes up to 36 in. in diameter are generally of cast iron. From 48 to 72 in. in diameter the most common material is steel pipe. For larger intakes tunnels driven under the bed of the lake reaching from the shore to the bottom of an exposed crib are most common.

☞ Long intakes in lakes should be of ample size to avoid friction and excessive suction on the pumps. Short intakes in sediment-carrying rivers should be smaller with velocities to prevent them from filling up with silt. Where pipe is laid on the bottom of a lake or river a channel should be dredged for it so that the top of the pipe is well below the natural bottom, but such dredging may be omitted in lakes deeper than about 30 ft.

Cast-iron Pipe for intakes is commonly of a special type. From four to eight 12-ft. lengths of ordinary pipe are joined in the ordinary way and then a special joint is used (Figs. 1 and 2) which is made flexible with a turned spherical casting moving in a bed of lead which has been run inside of an enlarged bell. Such joints, well made, give a considerable amount of flexibility while remaining nearly water-tight. The pipe is put together above water and gradually lowered to position, the flexible joints making this possible.

(a) (b)

Fig. 1. Special Joints, Cast-iron Pipe

Where the water is not too deep to allow a diver to work comfortably, the flexible joints are sometimes omitted and flange joints bolted together by a diver are used. Numerous other kinds of joints are also used.

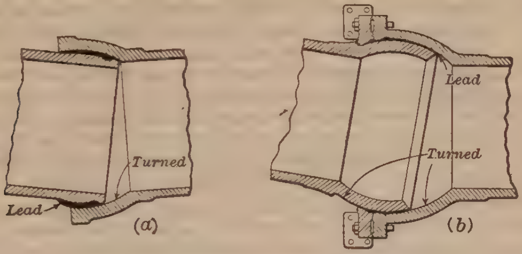

Fig. 2. Special Joints, Cast-iron Pipe

Trouble from leaks in intake pipes has frequently been experienced where the water through which they passed was subject to pollution. Where the intake passes under highly polluted water it is safer to have it below the bed of the river or lake, well covered with sand or other protecting material.

Steel Pipes for intakes are laid in much the same way as cast-iron pipes. Flexible joints are riveted to the ends of the steel pipes where required (Figs. 3 and 4), but the length of steel pipe between such joints may be greater, as steel pipe is stronger than cast-iron pipe. Steel pipe is frequently designed to fit closely the contour of the bottom and it can then be put together with flange joints bolted up by a diver.

The difficulty of making such joints with divers increases rapidly with the depth. Up to 30 or 40 ft. there is but little difficulty. Beyond this depth the difficulty increases and the joints practically become impossible before 100 ft. of water is reached.

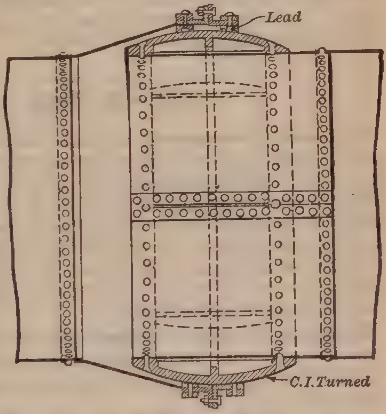

Fig. 3. Flexible Joint of Rochester Steel Pipe

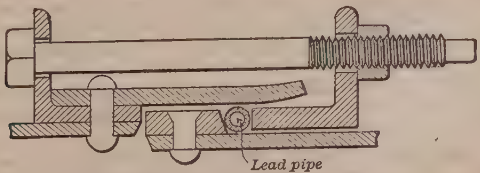

Fig. 4. Flexible Joint of Erie Steel Pipe

Tunnels under lake or river bottoms are most safely and cheaply driven in rock. Intakes under the lakes at Cleveland and Chicago have been driven in clay. The greatest difficulty has been from marsh gas contained in the clay, which comes into the tunnels during construction, forming an explosive mixture. There has been great loss of life and property from accidental explosions. Where clay is free from marsh gas it is a good material to tunnel through. Tunnels may be driven through sand and gravel, but with greater difficulty and expense. Air pressure must always be used corresponding to the distance that the tunnel is below the surface of the water. The length of time that men can work under pressure decreases rapidly as the pressure increases, so that such tunnels cannot be driven at too great a depth. The ordinary limit is 60 or 80 ft. and about 100 ft. is the extreme limit.

Anchor Ice is troublesome in northern climates in the case of intakes taking their supply near the surface or in shallow water. Much trouble has been experienced from this cause. A steam boiler furnishing steam to be taken to the seat of trouble through a hose is the most effective means of maintaining the supply.

Pumping Stations are commonly at the shore end of an intake pipe or tunnel. The pumps must be so placed as to be able to take water at the lowest water level and they must also be protected from water during the highest floods. In the case of rivers having a wide range of water level the protective structures are frequently very expensive.

2. Data of Yield and Storage

Impounding Reservoirs are artificial lakes built on upland streams for the purpose of storing freshet flows for use during those times when the natural flow of the stream is insufficient to maintain the supply. Impounding reservoirs are formed by the construction of a dam, preferably across a narrow valley at a point where there is an enlargement of the valley above to give large storage capacity. A reservoir on a tributary is substantially as useful in maintaining the supply as a reservoir on the main stream, up to the point where the reservoir on the tributary can be filled from bottom to top by the runoff of an ordinarily dry year.

Storage and Yield. To estimate the yield of an actual reservoir, or of a reservoir to be built, or to estimate the size of reservoir required to develop a given output, the best starting point is a record of the flow of the stream feeding it.

The **storage ratio** is the net available storage divided by the mean flow for one year. The **percentage yield** is the percentage of the mean flow that can be made available for use when needed.

From the flow record make a mass diagram by the method described in Sect. 13, Art. 44. Assume a rate of draft and find the maximum depletion that would have occurred at that rate during each year. These maximum annual depletions form a series. The series may be examined by probability methods, and the amount of storage that will be exceeded on 5% of the years may be accepted as practically sufficient. The calculation is repeated for other rates of draft until enough points are found to make a storage diagram which will serve as a basis for the calculation.

95% Dry Year Used. The 95% dry year is used as a basis for municipal water supplies. It is defined as the year of such dryness that 5% of the years are drier and 95% of the years are wetter than it. The drier years are the years that require more storage. For the 5% years that are drier than the normal less than full supply will be available. On Eastern data about 94% of the full supply on an average will be available in these drier years.

For extra conservative estimates, a 98% dry year may be used. This in a general way will call for 14% more storage. If the 99% dry year were used, 25% more storage would be required.

American cities have experienced moderate water shortages at intervals, and building storage that will be used less than once in twenty years is only warranted where the cost of storage capacity is unusually low.

Probable Error. The probable error (due to variation in annual quantities) in the mean flow of a stream is found by the formula

$$\text{Per cent of probable error} = \frac{67.5 \text{ Coefficient of Variation}}{\sqrt{T}}$$

T being the number of years in the record. Thus, for a 30-year record on an Eastern stream having a coefficient of variation of 0.25, the probable error is 3%; and for a Western stream a 20-year record with a c. v. of 0.70, the probable error is 10.6%. The errors in gaging must also be considered. No estimate can be more accurate than the data on which it rests, and available data do not often permit precision.

Data for Other Streams. If the record of the stream for which an estimate is to be made were sufficiently long and accurate, no other data would be needed for computing storage; but in most cases records are short or absent. A good short-term record is useful but the probable error is large. It is best to give weight to available records of flow and storage of other streams as similar as may be to the one for which an estimate is required.

Rainfall. Runoff comes from rainfall and follows it. Rainfall data are more abundant than runoff data. With meager runoff data there is a temptation to try to find relations between rainfall and runoff and to build up theoretical runoff tables and use them as a basis of estimate. Something can be done but great skill is required, for the relations are exceedingly complex and depend upon unknown and only partly known factors. Years ago when runoff data were less common there was more need of such expedients. Now, the records of the U. S. Geological Survey are numerous and widely distributed. These and other gagings will nearly always serve as a safer starting point.

Size of Catchment. In general runoff is proportional to catchment area and the required storage for a similar development will be in the same ratio. No doubt there will be small differences in special cases but in the absence of clear proof of difference the assumption is at least approximate that variations are in direct proportion to area. Areas high in elevation usually produce more water proportionately than low ones.

Cycles. A close study of rainfall data discloses cycles. Corresponding cycles in runoff are to be expected. As a practical matter not much attention need be given to them. But if a short term record is used, get the record of the nearest stream for which the data have been kept for a long time, and from it find whether the short term period has been unusually dry or wet. Numerical corrections for such differences are difficult, but a general idea of relative conditions is obtained.

Daily and Annual Storage. The required storage is made up of two parts: (1) daily storage required to balance fluctuations of flow within a single year; and (2) annual storage required to carry over surplus of wet years and make it available in dry years.

Methods of collecting, combining and stating the results are given in Transactions, Am. Soc. C. E., 77, p. 1539, 1914; but since that publication more data and some improvements in methods have become available and are used in preparing the tables that follow.

Practical Procedure. The mean flow and other data to be described are obtained for each stream flow from its record. With these data at hand, an estimate of the mean flow is made for the given stream. The required storage or the available output may then be computed with the aid of the tables that follow.

The mean annual flow is conveniently expressed in inches of runoff. To find the mean flow in gallons, multiply the area in square miles by inches of runoff and the product by 47 581 to obtain the mean flow in gallons per day, or by 17 380 000 to obtain the mean flow in gallons per annum.

Owing to the variations in flow and the irregularity of the variations, the whole of the mean flow of a stream can never be utilized. Some of it will be lost in flood flows. The more storage provided, the higher the percentage of the mean flow that can be utilized.

Three tables are given showing the storages required to yield various percentages of the mean flow for different parts of the country and with different degrees of development. These are followed by Tables 4 and 5, giving statistics of actual water supplies and stream flows for comparison and to aid in selecting the proper starting points for the estimate.

Table 1 is for streams north of the Potomac and east of the Alleghanies, and for low developments with not more than 50% of the mean flow utilized. In this table the second line of classification is according to ground storage.

Ground Storage. Ground storage is an important element in stream flow. Streams having extensive deposits of sand and gravel on their catchment areas have better maintained flows than where the materials are impervious. Ground storage may amount to several inches of runoff. Where ground storage exists, artificial storage may be less, and vice versa.

Ground storage is best expressed as day's supply at the rate of draft and represents the reduction in needed artificial storage below the amount otherwise required. This is called ground storage, but in reality it represents all the variations that there are from whatever cause; and seasonal distribution of rainfall, snow conditions and other matters contribute to a total of which ground storage is usually the largest element. Table 4 shows the computed ground storage in days for a number of actual supplies. In Table 1 four grades of ground storage are shown. In judging of the amount of ground storage in the absence of definite data, a stream that goes dry in droughts has no ground storage; one that has very well maintained flows in droughts has abundant ground storage.

Table 1 may also be used for streams on the western slope of the Alleghanies and on the South Atlantic Coast, but with less confidence, and greater variations from it must be expected. It should not be used for any other part of the country. For corresponding low developments in the West, data are not available to permit general statement, and local data must be studied by the mass diagram method.

Table 2 is for high developments, where more than 50% of the mean flow is made available, and when the reservoir will not refill in dry years and stored water must be carried over from year to year. In this table the second line of classification is the relative variation in annual flow. Some streams vary from year to year much more than others, and the amount of storage is dependent more upon this characteristic than any other. The coefficient of variation is the best index of this variation and is used as a basis for classification.

Coefficient of Variation. To compute the coefficient of variation, make a table of annual flows in any convenient units and find the mean. The difference between each term and the mean, without regard to sign, is the variation. Each variation is squared and the sum of the squares is found. Divide this by the number of terms less 1. The square root of the quotient is the **standard variation.** The **coefficient of variation** (c. v.) of annual flows is the standard variation divided by the mean.

The coefficient of variation of annual flows should be calculated for each record of ten years and over that is to be used. It is well to take into account records of neighboring streams, and it will be safer to use the indications of good long-term records of neighboring streams than a value derived from a short-term record of the stream under consideration.

For streams having coefficients of variation under 0.50, use Table 2. This applies to all that part of the United States east of the Mississippi River and also to Oregon and Washington. It also applies to eastern Canada. It is not recommended that a value below 0.20 should be used for any estimate; and the table shows no lower values. North of the Potomac and east of the Alleghanies values from 0.20 to 0.25 prevail. South of the Potomac the values are somwehat higher. West of the Alleghanies they increase more rapidly.

If ground-water storage is indicated, deductions from the storage shown in the table may be made in the same amounts that would be used in classifying the stream under Table 1. The last column shows the deduction for thirty days' ground storage. Other amounts are in proportion.

Table 3 is for streams having coefficients of variation above 0.50. These are most common in that part of the United States west of the Mississippi River excepting Oregon and Washington. Storage equal to ninety days has been added in this table to cover the seasonal distribution of rainfall and runoff which is usual in the western part of the country.

Table 4 shows data of mean flow, coefficients of variation in annual flows and ground storage for selected streams.

In making estimates, all local data should be examined. Unless local data are very good and records of 20 years and upward are available, it will not pay to make mass diagrams. More reliable estimates will be reached by the shorter process of mean flows and coefficients of variation and by the aid of Tables 1 to 3.

Table 5 shows statistics of runoff and storage for some of the more important municipal water supplies in the United States.

Example. Compute the storage required to develop 35 million gallons of water per day from an area of 48 square miles of mountain country with little ground storage, the mean runoff being assumed from data for neighboring areas to be 25 in., and the coefficient of variation in mean annual flow to be 0.20.

The mean annual flow is $48 \times 25 \times 17.379 = 20\,855$ m.g., or 57.1 m.g. per day. The required delivery, 35 m.g.d., is 61% of the mean flow. As this is more than 50%, Table 2 is used. Under c.v. = 0.20, 60% and 65% of mean flow available call for storages of 0.31 and 0.35. By interpolation 61% calls for 0.318 of the mean annual flow. $0.318 \times 20\,855 = 6632$ m.g. This is the required storage. To this must be added an allowance to cover loss by evaporation, by a method to be explained below.

From the same area for a first installment of 20 m.g.d. equal to 35% of the mean flow, Table 1 is used. No ground storage assumed. Storage required, 0.128 of the mean flow, or 2669 m.g. An allowance for evaporation must be made.

Evaporation. The loss of water by evaporation from the surface of the water in the reservoir must be allowed for, except that when the records of flow upon which the estimate is based represent conditions after reservoir construction, no correction is necessary.

(1) Where the evaporation from a water surface is greater than the rainfall, compute the yield for the full capacity of the reservoir and deduct the net loss by evaporation, computed as a draft, which is the amount by which evaporation from water area is greater than evaporation from land area. The net loss in runoff is equal to the evaporation from water surface plus runoff from land surface less rainfall. The net loss in inches is applied to the average water area, and this for practical purposes may be taken as 0.9 of the area at the flow line of the reservoir. The amount so found is to be deducted from the computed daily capacity of the source.

Example. What will be the average daily loss by evaporation from a reservoir of 850 acres, where the rainfall is 28 in., the runoff is 8 in., and the evaporation from the water surface is 40 in.?

The net loss in inches is $40 + 8 - 28 = 20$. 20 in. in depth on 0.9 of 850 acres is $20/12 \times 0.9 \times 850 \times 325\,851 = 415$ m.g. per annum or 1.14 m.g. per day.

(2) Where the average rainfall is greater than the evaporation from a water surface, proceed as follows:

(a) From the natural mean flow deduct the estimated loss by evaporation computed as under (1) to obtain the mean flow after development.

(b) From the reservoir capacity deduct an amount sufficient to equalize the evaporation loss throughout the year calculated for a dry year. An allowance ranging from 6 in. in depth over the area of the reservoir for northern New England and New York to 8 in. in the latitude of Philadelphia and to 12 in. or more on the south Atlantic slope and increased 50% or more for shallow reservoirs with high water temperatures in summer. The adjusted values for mean flow and storage are then used in the calculation.

Economical Development. The economical development of a catchment area is reached when the dam has been built so high that the cost of making it higher is more than the value of the additional water secured. The height of dam corresponding to economical development may increase with the demand

for and value of water, and this often leads to raising dams. On the other hand, full probable economic development of any supply that is utilized should be taken into account to the end that partial developments first made may be arranged to be increased without too much difficulty.

In a general way, in the northeastern states the economical limit is reached by the storage of an amount equal to at least half the mean annual flow, and not greater than the mean annual flow, and when between 75% and 90% of the mean flow is made available for use. If water is low in value and conditions of storage difficult, the limit will be lower. Where water is especially valuable and the site is favorable for cheap storage, additional amounts may be advantageous.

In the western states more storage is required and the proportion of the mean flow that can be used is less. Storages, of three times the mean annual flow are not uncommon.

3. Effects of Storage

Storage in an impounding reservoir may have important effects on the quality of the water, both for good and for harm. By reason of the opportunity given for sedimentation, storage tends to remove suspended mineral matter such as silt and clay and thus clarifies the water. Bacteria are also reduced in number by being carried to the bottom with the sediment, by natural death, by the destructive action of sunlight and by the effect of other organisms, so that the sanitary quality of the water is improved. Colored waters stored for long periods in impounding reservoirs tend to become bleached. On the other hand, storage offers exceptional opportunities for the growth of algae and protozoa which give rise to objectionable odors and tend to increase the turbidity and sediment present in the water. At the bottom of large reservoirs also decomposition of organic matter may take place, with the production of foul gases and of carbonic acid. One result of this is that the water is more liable to attack lead pipes.

Period of Storage. The normal period of storage of large reservoirs is expressed in days and is taken to be the capacity of the reservoir divided by the average daily flow through it. This expression is useful for comparing different reservoirs, but it means little as far as indicating the length of time that the water is actually stored on account of the variations in volume of the water entering the reservoirs. For example, in a reservoir that has a normal period of storage of thirty days there may be one or more times each year when the stream flow is sufficient to displace all the water in the reservoirs in two or three days. Furthermore, the water entering a reservoir at one end reaches the outlet at the other end not always after the displacement of all the waters, for, by reason of difference in the density of water due to difference in temperature, the action of the wind, etc., part of it may cross the reservoir in a period much shorter than that required for displacement; so that even in a reservoir that has a normal storage period of thirty days the actual time of transit of water from the inlet to the outlet may be reduced to a period of a few hours. For this reason storage reservoirs cannot be depended upon alone to protect the water supply from a sanitary standpoint.

The period of storage is based on the entire capacity of the reservoir, while the storage ratio is based on net available storage that can be drawn for use. Many reservoirs have dead water below the intakes, and the two terms, while similar, must be clearly distinguished.

Horizontal Currents Induced by the Wind. Wind blowing over the surface of a body of water causes a movement of the surface water in the same direction. The velocity of such induced currents of water varies according to the intensity and duration of the wind. Experiments made at Lake Erie have shown that for winds blowing in one direction for at least ten hours the velocity of the surface water is from 3 to 7% of that of the wind. For winds blowing long from one direction this per cent increases. The depths of such induced currents or the velocity of currents below the surface are not well known, but the former are doubtless 10 to 20 ft.

Stagnation. The lower portions of deep reservoirs are not affected by wind action, and during certain periods remain stagnant. Where the volume of water is large and the reservoir is clean, the dissolved oxygen in the water during the stagnant period is sufficient to take care of organic changes and keep the water sweet. This is true of such reservoirs as Ashokan and Kensico Reservoirs of New York City and of Wachusett Reservoir of the Boston

* Natural lakes raised and controlled.

Note. There are impounding reservoirs of considerable size not in the above table at Forth Worth, Texas, Decatur, Ill., Scranton, Johnstown and Altoona, Pa., Waterbury, Conn., Lynn and Pittsfield, Mass., and no doubt at many other places.

Metropolitan district and a few others. In smaller and shallower reservoirs the stagnant waters usually become foul in taste and odor, due to putrefaction after the oxygen originally contained in the water is exhausted.

Water of better quality may be drawn from such reservoirs by intakes located near the surface, but even such intakes draw some water from a depth, and more or less bottom water is usually mixed with the surface water and tends to impair its quality.

Turnovers. Once in the spring and once in the fall there takes place a thorough mixing of the top and bottom waters. This is due to the change in temperatures. During warm weather the top water is warmer and lighter than the bottom water. During cold weather it is colder and lighter. In both cases when the maximum density of water at a temperature of 39° F. is reached, overturning takes place. A strong wind will bring about overturning before the complete temperature adjustment is reached. Following the spring and fall turnovers, the water has increased color, taste and odor, and becomes objectionable in quality for a time, followed by gradual improvement.

If there are deposits of organic matter at the bottom of a reservoir bacterial putrefaction will take place at the bottom during the period of stagnation. The oxygen will become exhausted and the water impregnated with carbonic acid, sulfureted hydrogen, carbureted hydrogen, and compounds of ferrous iron and organic matter. Crenothrix and fungi may develop. During the following periods of circulation this stagnant water becomes mixed with the rest of the water in the reservoir and may temporarily increase its color. The ferrous iron becoming oxidized tends to act as a coagulant and thus to exert a purifying effect and facilitate subsequent filtration and decolorization.

During the period of circulation the spores of various algae and other organisms are distributed through the water together with food for their growth, and under the influence of sunlight in the upper layers they grow and remain near the surface by reason of gases evolved during the process of growth. Diatoms, in particular, are likely to be abundant in large impounding reservoirs after the spring and fall "turnovers."

Organisms. Some of the most troublesome forms of algae, such as Anabaena, occur only during hot weather. They seldom develop when the temperature is less than 65° or 70°, although in the fall they may linger in the water even though the temperature is lower than that. It is because of the lower summer temperature that algae growths are less prevalent in England than in America.

The organisms growing in reservoirs are both animal and vegetable. The latter, by the aid of sunlight, break up carbonic acid forming carbon and organic matter, which is the basis of their structure, exactly as do plants growing in air. Other very small organisms of the animal type feed upon the vegetable organisms, and larger ones upon the smaller, and as a result there is a series of organisms up to and including the fishes and other forms of aquatic life.

Organisms grow in all waters exposed to sunshine but the strength of the growths depends upon many conditions, among which may be mentioned temperature, the amount of food supply, represented by mineral matters in the water, and wind action. The latter is quite important because wind keeps the water in agitation and renders it unfavorable for the development of many kinds of organisms.

Organisms by their growth, and especially by their death and decay, have a profound influence upon the quality of water obtainable from reservoirs.

In some cases a moderate control of organisms may be secured by the use of copper sulfate, but such control usually serves to change the kind of growth rather than to reduce its total amount. Filtration of water containing growths of such organisms is the only adequate treatment. Strong growths make the filtration more difficult and expensive and they are therefore undesirable even where the water is filtered.

In the tropics and warm climates growths are most troublesome, and in cool northern latitudes they are less important.

Soil Stripping. In order to prevent the growths of algae reservoir sites are sometimes cleaned by removing the vegetation and top soil. This practice has been followed extensively in Massachusetts reservoirs. It results in a temporary benefit, but ultimately deposits of material occur on the bottom that contain as much organic matter as that found in the soil, and the advantage of stripping is lost. The organic matter that has the greatest effect on the quality of impounding waters is derived from grass, weeds and other vegetation on the reservoir site. This should be removed by cutting and burning just before the reservoir is filled. For the sake of appearance and to prevent growths of water weeds and filamentous algae the shores of the reservoir from 2 to 5 ft. vertically above the high-water mark and for 10 to 20 ft. or more below, according to circumstances, should be cleared of stumps and roots. Elsewhere the stumps should be cut to 12 in. or less above the mean surface of the ground.

Drainage of Swamps. The color of a stored water may be sometimes reduced by draining swamps on the catchment area. This also tends to reduce the danger of the reservoir becoming seeded with algae. The advantage is less where the water is to be purified.

Penetration of Sunlight into Water. On account of the rapid absorption of the sun's rays by water, the disinfecting effect of sunlight and its bleaching action on the coloring matter are limited to a shallow layer near the surface. In clear water there is little bleaching effect below a depth of five feet, and in turbid waters the effect of the sunlight may be felt only a few inches. For this reason growths of organisms are much less likely to occur in turbid, silt-bearing waters than in clear waters.

4. Ground-water Supplies

Ground Water is that part of the rainfall that has accumulated in the ground, either in soil or in rock. Its upper surface is called the water table, or the ground-water level. The water is actually present in the pores of the soil or granular rock or in fissures, crevices and seams. These may be considered as underground storage reservoirs.

Classification. The water in the ground, above an impermeable stratum, and relatively near the surface, is termed the upper ground water, and wells for obtaining it are called shallow wells. Water taken from beneath an impervious stratum is termed artesian, or deep-seated water, and wells for taking it are artesian wells, or deep wells. Originally the term " artesian " was applied only to deep-seated water that was under a sufficient head to cause it to flow naturally to the surface without pumping. All ground water is derived primarily from the rainfall. Geologically there are three principal classes of ground water, namely, those occurring in underlying stratified porous rock covering large areas, those occurring in old lake or river beds, and those occurring in deposits of sand and gravel, that is, in the drift.

Ground-water supplies are obtained from (1) sand and gravel deposits; (2) sandstone rock; (3) limestone rock. In the first two cases the water is present in the pores of a more or less homogeneous material. In the last it is present in caverns and fissures, usually extending indefinitely into the limestone rock, and replenished by surface waters that flow into them or by ground waters from sand and gravel deposits above the limestone. Water from either sand or sandstone is well filtered and of good hygienic quality. Water from limestone is often surface water that has flowed simply through a limestone cave and may be of inferior hygienic quality.

Percolation is the downward flow of rain water through the ground under the influence of gravitation and capillarity. It varies in amount according to the rainfall, porosity of the soil, temperature, etc. Under specially favorable conditions, illustrated by the sands of Long Island and the sand dunes of Holland, percolation may amount to from 30 to 60% of the rainfall. With less pervious material, such as is found in the South and Middle West, percolation may be as low as 10 to 20%.

Velocity and Direction of Subterranean Flow. The slope of the water table can be determined by measuring the elevation of the water in a series of bore holes, enough measurements being made to determine not only the amount of slope but also the direction of greatest declivity. The direction of flow is the direction of greatest declivity. The velocity may be estimated approximately from the slope for clean sands and gravels where samples can be secured, by making mechanical analyses and determining the average effective size of the material; but such calculations, based upon conditions largely unknown, are to be used with caution. The formula for the flow of water through sand is given in Art. 11.

Measurement of the Velocity of Flow of Ground Water. The actual velocity of ground water may be measured by introducing a solution of salt into one of two wells and noting the time required for its flow to the second well, the time being determined by making frequent analyses of the water. A more accurate method is that of Professor Slichter, who used an electrical device by which the conductivity of the water in the lower well and in the ground between the two wells could be determined. Ammonium chloride or some other electrolyte was placed in the upper well and the time required for it to flow to the lower well was determined by noting the increase in conductivity of water. Ground water in sandy soils often has a velocity of 5 to 10 ft. per day, although velocities of 50 ft. or more per day are not unknown. The deep-seated water found in underlying rock often moves with extreme slowness. In some cases calculations have shown the velocity to be as small as 10 ft. per year.

Quantity of Underground Flow. The quantity of underground flow is obtained by multiplying the velocity by the area of the cross-section under consideration and by the percentage of voids in the material. These usually are from 30 to 40% in natural gravels and somewhat less in sandstones.

Flow of Water into Wells. If a well is sunk into the ground water and pumped, the surface of the ground water adjacent to the well will be depressed and assume a form similar to that shown in Fig. 5. The shaded area is commonly called the cone of the depression, and the area within which the water table is appreciably affected is termed the **circle of influence.** If pumping were continued and the ground water received no acquisitions, the circle of influence would widen without limit. Usually a ground water has a natural slope and a flow in a definite direction, so that, when the circle of influence has broadened until the ground-water flow tributary to the area equals the amount of water pumped, a condition of equilibrium is obtained. The curve assumed by the water table near the well is parabolic in form. Formulas have been worked out to show the relations existing between the various elements of the problem, but they are valuable chiefly as

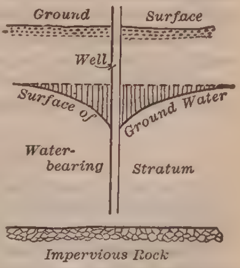

Fig. 5. Ground Water

indicating relative conditions caused by drawing down the water table to different depths. They cannot be depended upon to determine with any degree of accuracy the capacity of a well or the radius of the circle of influence, except in special cases where unusual attempts have been made to determine the values of the constants involved.

Interference with Wells. Wells placed in the same stratum near together mutually interfere according to the size and spacing of the wells, the radius of the circle of influence and the lowering of the ground-water table. As an illustration of this interference Slichter has given the following example. If in place of a 6-in. well that has a radius of the circle of influence of 600 ft., and a lowering of 10 ft. in the water table by pumping, there were two 6-in. wells 200 ft. apart, the yield of each would be 85% as much as a single well. while if there were a number of wells 100 ft. apart the yield of each would be only about one-third as much as that of a single well of same size.

Tests of Wells are frequently carried out by putting down test wells and pumping them for a limited period. Such tests have little value beyond showing the perviousness of the material about the test well. If there is water in the underground reservoir, water can be pumped at any rate at which the well is capable of taking it from the reservoir as long as the supply lasts. This may be a day, a week, a year, or permanently, according to the supply. Actual use through dry periods is usually the best test. Wells extending below sea level, as on Long Island and in New Jersey, may draw fresh water in excess of their permanent capacity for several years, while sea water is gradually filling the voids previously occupied by the fresh water.

Yield of Ground Water. The yield of ground-water collecting works depends upon the size of the catchment area, the rainfall, percolation, etc., and also upon the efficiency of the devices employed for collecting the flow. The conditions governing the amount are the same as those governing surface flow with storage. It is always difficult and frequently impossible to estimate the amount of underground storage utilized by the works and for this reason close estimates of yield can seldom be made. Where the underground storage is very large, as on Long Island, a development as high as could be obtained from corresponding surface sources is secured and in that case a yield of 900 000 gallons per square mile per day is obtained.

Conditions on Long Island are exceptionally favorable for the collection of ground water. In other localities where the rainfall is the same the safe yield might not amount to 500 000 gallons per day per square mile. In some parts of the country the safe yield is as low as 100 000 gallons per day per square mile. It is seldom that more than about 3 million gallons per day can be economically obtained from sand or sandstone at any one place, and often the limit is as low as one million gallons or less. When larger quantities are required it is customary to have several stations with pumps operated separately or by power transmitted from a central station.

Temperature of Ground Water. One of the advantages of a ground water supply is its cool and equable temperature. In the case of ground water found in the drift the ordinary temperature of the water is usually not far from the average temperature of the air in the same place.

5. Wells and Pumping

Ground water is made available for public water supplies by large dug wells, driven wells, infiltration galleries, and springs. There are three principal types of driven wells, that is, shallow, tubular wells; deep, bored wells in soft material; and rock wells.

Wells of Large Diameter. The chief advantages of the well of large diameter are, the storage that it affords and the possibility of placing the pumps at a low level and short suction pipes. The effect of the size of the well on the yield is comparatively small. Large wells are useful where the pumping is variable and especially in cases where the ground water flows through fine material with low velocity. Dug wells avoid the clogging that occurs in driven wells located in iron-bearing sands. As the cost of large wells increases rapidly with the depth, they are seldom made more than 50 ft. Large wells vary in diameter up to 50 or 100 ft. They are commonly lined with brick, concrete, or masonry, openings being left for the entrance of water. They are covered to exclude light and dirt. The capacity of large wells is sometimes increased by driving small wells or galleries horizontally into the ground, or by sinking vertical wells in the bottom of the large well.

Shallow, Tubular Wells. The ordinary driven well consists of a wrought-iron or steel tube, 2 to 8 in. in diameter, with a strainer near the bottom. It is forced into the ground by a hammer or by the use of a falling weight or with the aid of a jet of water carried through a small pipe to loosen the material in advance of the point. The strainers may be merely holes or slots in pieces of brass pipe, or larger holes in the pipe, covered with brass gauze. Porcelain strainers and tile wells also are used. The use of different metals in a strainer is objectionable, as it gives opportunity for galvanic action, causing corrosion and clogging. The size of the openings must be adjusted to the texture of the soil. They must be small enough to prevent the entrance of any large quantity of sand but large enough to reduce the entrance velocity to a point where the friction will not be excessive, that is, less than about 0.2 ft. per second.

Tube wells usually afford only a limited space for the entrance of water, and as the rate of flow, depending upon the fineness of the material, is usually slow, a great number of wells must be used to obtain a considerable supply of water. It is common to connect such wells up in batteries extending in lines across the valley or strata from which water is to be obtained.

Three methods of connecting up such batteries of wells may be mentioned. First, **direct connections;** where the tops of the wells are connected with a suction pipe laid on the surface of the ground or a short distance below it, extending to the suction end of the pump. This method of connection is common, but with it any air that leaks into the wells and to the suction pipe is carried to the pump and must be handled with the water and frequently interferes with the operation of the pump, and any fine sand that enters the well with the water is also carried forward to the pump, and if a reciprocating pump is used it scores and wears the moving parts and its efficiency is rapidly destroyed. In the second or **siphon method,** independent suction pipes are run down inside each well. For instance, 4-inch suctions are used in 8-in. wells. The suction pipes must be carried below the lowest level from which water is to be drawn. The suction pipes are connected to the main suctions outside the well, and the best arrangement is to carry that pipe to the bottom of a large receiving well near the pumping station as Fig. 6. The pipe then acts as a siphon, and is limited in its draft to about 25 ft. The suction pipe must be graded to a summit just outside this well and the air that would otherwise accumulate at this point must be removed by an air pump. The sand is carried into the large suction well and deposits on its bottom. The pump suction in the large well draws water free from both air and sand. The third or **pumping method** may be used where the material is deep and coarse enough to permit fewer and larger wells to be used. A centrifugal pump with vertical shaft is placed in each well. Such pumps have the motors above the surface of the ground with long shafts reaching to the pumps below the lowest water in the well and throw water to the surface where it may be carried off under pressure to storage tanks or to a central pumping station. This method in general is not applicable to wells in fine-grained materials, but may be extended somewhat to finer materials by the use of larger wells surrounded with specially prepared material brought in or put around the well as it is placed, or prepared from the natural material by a construction pump introducing a strong back and forth current which churns out the finer material and leaves the well surrounded with only the coarser parts of the natural material.

Suction lines for wells on either the first or second system must be made and maintained air-tight and the joints must be made more carefully than are required for ordinary water pipes. Flange pipes with rubber or other compressible gaskets have been widely used. In other cases bell and spigot joints have been made tight by the use of lead wool, which has the advantage over poured lead in that the whole mass of the joint may be calked and made tight, as distinguished from a poured joint where the influence of calking only extends back a quarter of an inch or so, leaving a small annular space which will be certain to leak after the 1/4 in. tightened by calking has been loosened by a number of small movements due to temperature changes or settlements.

Conditions of obtaining underground water vary greatly in different parts of the country and it is not possible to lay down general rules that will apply in all cases. Many cases are found which seem to differ widely from what may be regarded as usual over average practice.

Deep, Bored Wells. Deep wells in soft material are bored. The loosened material is brought up by the use of a water jet or sand bucket; such wells are usually cased. Wells are bored in rock by the use of a cutting drill which is raised, revolved, and let fall with a blow. Where strict artesian conditions prevail a casing is put down to the impervious stratum.

Infiltration Galleries. Infiltration galleries are closed conduits of masonry, wood, iron, brick or vitrified pipe, laid with numerous small openings to allow the inflow of water. They serve the double purpose of collecting the ground water and conveying it to the pump well. To prevent the entrance of fine material through the openings the latter are surrounded on the outside with graded gravel and sand. Infiltration galleries are placed at right angles to the general line of flow of the ground water, although sometimes they are placed near the shores of streams. In the latter case, as the bed of the stream is generally covered with silt, the greater proportion of water is derived from the land side. The attempt to use the bank of the stream as a filter and collect the stream water in a filter gallery beside it has been frequently attended with failure.

Pumping is required to utilize most ground waters. It is possible to lift water by a suction pump not more than 25 ft., and special effort should be made to locate the works so that water can be obtained without more than this amount of suction.

An air pump on the suction pipe frequently facilitates pumping with high lifts and long suction lines. An air chamber is placed on the suction just before connection is made with the pump, and the air that leaks into the system is separated and removed by an air pump, so that the main pump always draws water without air.

A Deep-well Pump is a small pump of peculiar construction lowered through the pipe to the bottom of the well and operated by a connecting rod reaching to an engine above the surface of the ground.

A Screw Pump is a screw propeller, or a series of them, placed in the pipe and lifting the water in the well by being revolved rapidly, motive power being applied to the shaft above the surface of the ground.

Fig. 6

The Air Lift is a process of taking water out of wells by the pressure of compressed air. The well is extended in depth to a considerable distance below the water level. Compressed air is carried to the bottom of the well through a small pipe and allowed to escape. The air mixes with the water in the discharge pipe, which must not be too large in diameter. The column of mixed material is lighter than solid water, and it becomes higher in proportion until water mixed with air overflows at the surface into a separating device.

All three of these means of getting water out of deep wells are of very low efficiency from a mechanical standpoint. The expense of lifting water from wells 30 to 50 ft. deep frequently exceeds the cost of pumping it afterwards against a much higher lift.

Hardness is common in ground waters. Waters obtained from sands and gravels free from lime, as in New England, Long Island, and parts of New Jersey, are soft. The glacial drift from central New York westward contains lime, and waters obtained from it are hard. The hardness depends more upon the fertility of the overlying soil than upon the amount of lime in the sand, because rich soil produces carbonic acid, which is taken up by the water as it passes through the soil and this promotes the solution of lime. Waters from limestone rock are always hard.

Among the largest ground-water supplies in the United States may be mentioned the Brooklyn Works, and other supplies upon Long Island for suburbs of New York, and the works at San Antonio, Houston and Galveston, Texas; Memphis, Tenn.; Lowell, Mass.; Camden, N. J.; Jackson, Michigan; and Jacksonville and Miami, Florida. Ground-water supplies have advantages for small works and a large majority of all public supplies are of this character, although the aggregate amount of water produced is much less than from surface supplies. Ground-water supplies are also largely used by industries and for domestic purposes.

6. Tests for Potable Water

Sanitary Inspection. No surface water is entirely without danger of infection. The closer the proximity of the source of pollution to the intake of the waterworks, the greater is the danger, although it is a question of time of flow rather than distance of flow. The population on catchment areas may be classed as, urban (population above 4000 per sq. mile), village (population between 4000 and 1000), and rural (population below 1000). The figures are best expressed in population per square mile of drainage area as above.

Sanitary regulations for the prevention of contamination of water supplies are in force in many states. The guiding principle should be: to make the sewage pass through the ground and not over the ground, and if this cannot be done, to remove it from the catchment area or purify and disinfect it. In considering the danger of privies located in proximity to watercourses, the character of the soil and the slope of the surface should be taken into account, and also the method of cleaning. Cases of typhoid fever or dysentery existing on a catchment area should receive special consideration.

Water Analysis. A complete water analysis consists of four sections, physical, chemical, bacteriological, and microscopical. The standard methods of analysis are given in " Standard Methods for the Examination of Water and Sewage," American Public Health Association. (Fourth Edition may be obtained from the Secretary of the A. P. H. A., Boston, Mass.) The standard method of expressing the results of chemical analysis is in parts per million by weight, which is practically equivalent to milligrams per liter. To change such results to " parts per 100 000," divide by 10; to " grains per

U. S. gallon," divide by 17.1; to "grains per Imperial gallon," divide by 14.3. Bacteria and microscopic organisms are expressed in "number per cubic centimeter." The expression "degrees of hardness" usually refers to "grains per gallon." Degrees of hardness on Clark's scale are "grains per Imperial gallon." On account of the variety of conditions there are no accepted standards of purity to either chemical or bacteriological analysis.

Samples of Water for physical, chemical, and microscopical analysis should be collected in clean, glass-stoppered bottles holding two quarts or a gallon. Bacteriological examinations demand special sterilized, glass-stoppered bottles holding at least two ounces. Bottles may be sterilized by heating in an oven for one hour at 160° C. Bacteriological examinations must be ordinarily made within six hours after collection, and the sample must be packed in ice for transportation. Tests for gases, such as dissolved oxygen and carbonic acid, should be made at the time of collection of the sample. Chemists usually prefer to furnish their own bottles.

Turbidity is caused by clay, silt, microscopic organisms and other fine particles. A perfectly clear water has a turbidity of zero. Turbidities higher than 2 to 5 parts per million are noticeable in drinking water and are objectionable. Turbidities as high as 50 or 100 make a water "muddy." In the Mississippi River and elsewhere in the South and Middle West, below the region of the glacial drift, turbidities of 2000 or 3000 are not uncommon. The turbidity of a river varies more or less directly with the stream flow.

The Standard of Turbidity is a water which contains 100 parts per million of silica in such a state of fineness that a bright platinum wire 1 mm. in diameter can just be seen when the center of the wire is 100 mm. below the surface of the water and the eye of the observer is 1.2 meters above the wire, the observation being made in the middle of the day in the open air, but not in sunlight, and in a vessel so large that the sides do not shut out the light so as to influence the results. The turbidity of such a water is 100. For actual use a standard suspension is prepared from a diatomaceous earth, to contain 1 gram of silica per liter and have a turbidity of 1000. From it silica standards are prepared by dilution with distilled water. For turbidity readings below 20, gallon bottles of clear white glass are used and smaller bottles for higher turbidities. The turbidity of a sample of water is determined by comparing it with these standards, looking through the bottles sidewise and noting the distinctness of some object, such as a series of ruled parallel lines, seen through them, or looking at a black surface while standing with back to the light.

For field use the U. S. Geological Survey turbidity rod consists of a rod with a platinum wire, 1 mm. in diameter near the end, projecting at right angles about one inch. At the other end of the rod, at a distance of 1.2 meters (about 4 ft.) is placed a wire ring through which the observer looks when making the examination. The rod is graduated, so that the distance from the wire to any mark indicates the turbidity when that mark is at the water surface and the wire just disappears from view. This graduation is determined by experiment.

The Color of water is caused chiefly by organic matter derived from decayed vegetation. Swamp waters are usually high colored. Ground waters are usually colorless. The color of the water in large lakes is usually below 10. River waters are colored in proportion to the area of swamps on the catchment area. If the color is as high as 20, water will look unsightly in a porcelain bathtub or in a glass on a white tablecloth. Higher colors are objectionable and warrant purification of the water.

Color is Measured by comparing the sample of water with artificial standards by dissolving platinum and cobalt chlorides in distilled water. The unit of color is that produced by one part per million of metallic platinum. In the field the glass disk method of the U. S. Geological Survey is used. Disks of colored glass, standardized against the platinum solution, are placed at the end of a metallic tube, comparison being made with the sample placed in a similar tube.

Odor. Fishy, grassy, and aromatic odors are caused by microscopic organisms such as Asterionella, Anabæna, Synura, and are due to oily secretions. Moldy and musty odors are due to decomposing organic matter. Peaty odors are due to the same substances that give water its color. Ground waters sometimes have sulfurous odors, due to dissolved gases.

Hardness is caused by carbonates, sulfates, and chlorides of calcium and magnesium. Hard water destroys soap. It has been estimated that the loss due to waste of soap for domestic purposes amounts to ten cents per million gallons for each part per million of hardness. This is based on average conditions and a use of 100 gallons per capita daily. A hardness of ten parts per million is practically unnoticeable, and it requires a hardness of 20 or 30 parts per million to produce curdling with soap. Water may be called hard if the hardness is above 100; very hard, if above 200; and excessively hard, if above 300. Hardness is due to the solvent action that water containing carbonic acid has on soil containing lime. Sewage pollution increases hardness. For temporary hardness see Art. 7.

Chlorine in water represents salt and may be due to sewage pollution, or to proximity to the sea, or, in the case of deep wells, to deposits of salt. The normal chlorine in waters decreases from the seacoast inland, and normal chlorine maps have been prepared by the U. S. Geological Survey for New England, New York, and New Jersey. Sewage pollution is indicated by excess above the normal. If the chlorine exceeds 15 or 20 parts per million it is apt to cause corrosion in boilers and plumbing fixtures. Chlorine is not removed by filtration or by any artificial process.

Iron in water is apt to cause trouble if present in quantities of more than 0.3 to 0.5 part per million. It is usually present as carbonate or hydrate, occasionally as sulfate, and often in organic combination. Manganese causes similar trouble but is less common.

Dissolved Gases. Carbonic acid is exceedingly soluble in water, but is easily reduced in amount by exposure to the atmosphere. Oxygen also dissolves readily in water, but the amount that can be present depends upon temperature and pressure. In winter waters normally contain nearly twice as much dissolved oxygen as in summer. (See Art. 3.)

Microscopical Examinations are required in studying the algae and protozoa in connection with the subject of odors. The method is in general that of concentration by filtration through a small sand filter in a glass funnel and examination of the concentrate with a microscope that magnifies about 100 diameters. Special cells are required, but the operations are not difficult.

Bacteriological Examinations require special methods and the use of sterilizers, incubators, and delicate pieces of apparatus. Several days are required for making the tests. The reports usually give the number of bacteria per cubic centimeter and state the presence or absence of the colon bacillus (B. coli) in 0.1, 1.0, and 10.0 cu. cm. of the sample.

Ground waters contain very few bacteria, seldom more than 100 per cu. cm. Surface waters often contain bacteria in large numbers, several hundred and sometimes many thousands per cubic centimeter. In silt-bearing streams the numbers vary approximately with the turbidity. Pollution generally causes an increase in the number of bacteria. Lake waters generally contain fewer bacteria than river waters. Most of the bacteria found in water are probably harmless. High numbers, however, are objectionable, because among them some objectionable species are more likely to be present. Filtered waters contain few bacteria, and the reduction in the number of bacteria by filtration is commonly taken as an indication of the efficiency of the process. The germs

of typhoid fever, Asiatic cholera, dysentery, etc., may exist in water, but there are no reliable methods for detecting their presence, although certain recent methods are promising. The *bacillus coli communis*, commonly referred to as B. coli, is a constant inhabitant of the intestines of man and warm-blooded animals. It can be detected in water with comparative ease, and its presence is often taken as an indication of fecal contamination.

The Typhoid Fever Death Rate of a community is the number of deaths per year from typhoid fever per hundred thousand. In cities possessing satisfactory water supplies the rate is not often above 10, but typhoid fever is carried in other ways, and higher rates with good water sometimes occur. The substitution of a filtered water, or other pure supply, for a polluted water usually reduces the typhoid fever death rate.

7. Water for Boilers

A Steam Boiler requires good water as much as it does good coal. Bad boiler waters cause corrosion, scale, foaming, overheating, and leaks, resulting in loss of heat, increased labor of attendance, increased cost of operation and repairs, a shortened life of the boiler, and increased danger of explosion. All natural waters are more or less corrosive. Magnesium chloride and other salts cause corrosion, especially when concentrated in a boiler. Galvanic action sometimes causes corrosion. Local corrosion is termed "pitting" or "grooving."

Boiler Scale is formed by the precipitation from the water of the carbonates and sulfates of calcium and magnesium, together with smaller amounts of other salts and suspended matter. Calcium carbonate is quite insoluble after its extra molecule of carbonic acid has been driven off by heat; calcium sulfate becomes almost insoluble above 250° F.; magnesium carbonate is changed to magnesium hydrate and precipitated. Besides these, boiler scale often contains iron, silica, alumina, organic matter, etc. Carbonates often separate as soft mud which is comparatively unobjectionable; they may also form a hard scale. Sulfates always form a hard scale. Calcium sulfate precipitates in a compact, crystalline form, removed by hammering and chipping. It may happen that different kinds of scale occur in the same boiler, due to the different temperatures of the sheet in different parts and to the circulation of the water. The scale in the tubes is often different from that on the sheets.

Hard Waters invariably form scale, and comparatively soft waters may also do so if the boiler is used too long without being emptied. Concentrated soft waters are almost as bad in their effects as water naturally hard. The greater the hardness, however, the more troublesome the waters. **Foaming** is caused chiefly by an excess of alkaline salts, which cause the water to form suds, as if soap had been added. This makes a boiler unmanageable and affects the quality of the steam. If grease is present in the water the sludge or scale may become very sticky. In this condition it adheres tenaciously to the plates and causes overheating, which usually occurs in spots.

The **care of a boiler** has very much to do with the effects of hard waters. The frequent blowing off of a boiler tends to reduce the amount of sludge, and to that extent is advantageous, but in the process of blowing off only a part of the water is removed. Better results are obtained by allowing the boiler to cool, emptying it and cleaning it if necessary. Corrosion due to gases can be eliminated to some extent by allowing a thin scale to form in the boiler.

Boiler Compounds are often employed as a remedy and have their legitimate use. In serious cases of acid corrosion, lime or caustic soda may be used with advantage. Nothing will effectually prevent the precipitation of calcium carbonate, but the use of soda will cause some of the calcium sulfate to settle as carbonate instead of sulfate, thus making the character of the scale less objectionable. To prevent adherence of the scale to the boiler shell many substances have been used, such as potatoes, kerosene, and all sorts of nostrums, organic and mineral. Most of these are practically worthless. Of the boiler compounds more commonly sold none have given more general satisfaction than those which have soda and some form of tannic acid as primary constituents. Tannic acid has a slight action on the iron of the boiler, and is reasonably efficient in preventing scale from sticking, while if properly used its action on the iron is not serious.

One gallon of hemlock extract with two gallons of water and three pounds of soda ash forms a good compound. Hemlock extract costs from 3 to 5 cents a pound in barrel lots and soda ash costs less than 2 cents a pound. Tri-sodium phosphate is also used with excellent results with many waters.

Chemicals for Water Softening. The following table gives the number of pounds of commercial lime (85% available) and soda ash (58% Na_2O) which are required to remove each part per million of the substances mentioned in the first column from one million gallons of water.

	Lime	Soda ash
Free carbonic acid	12.5	
Free sulfuric acid (as H_2SO_4)		9.03
Alkalinity (in terms of $CaCO_3$)	5.5	
Incrustants (in terms of $CaCO_3$)		8.85
Magnesium	22.9	

Temporary Hardness is that part of hardness (Art. 6) due to carbonates. It produces scale in boilers, but is partly removed by boiling, so that treating the water before it goes to the boiler reduces the amount. In most waters the temporary hardness is equivalent to the "alkalinity." Sulfates and chloride of lime and magnesia produce hard scale in boilers and are not removed by boiling. They comprise the permanent hardness, or incrustants and ordinarily are equal to the difference between the alkalinity and the total hardness. For purposes of water softening it is necessary to know the total hardness, the alkalinity or acidity, the amount of magnesia, and the free carbonic acid.

Red Water Troubles. This term is used to designate the troubles that grow out of distributing water that corrodes iron. The red water is caused by the iron which is first taken into solution by the water and afterwards deposited by oxidation. Waters that do this are called active. Active waters also attack lead pipes and may poison those who use water drawn through them.

Active waters may be made quiet by a number of methods, among them removal of free carbonic acid by aeration and treatment with caustic soda, soda ash or lime to neutralize acids and increase alkalinity.

Hard waters in which the hardness is largely alkalinity or temporary hardness are usually quiet even if they contain considerable free carbonic acid, while soft waters of low alkalinity are active even with minimum quantities of free carbonic acid.

Soft waters that are yellow from swamp drainage are especially active by reason of organic matter and acids. Such waters require coagulation, filtration, aeration and frequently a lime treatment, which make them harder but less active.

The "pH" value of a water represents the composite effect of its acid and alkaline constituents, both mineral and organic. It is easily determined by the use of special equipment and in conjunction with knowledge of alkalinity and free carbonic acid serves to indicate corrosive properties.

To be completely quiet waters with alkalinities below 50 p. p. m. must have a pH above 8 which requires practically complete elimination of carbonic acid. With higher alkalinities waters may be quiet with lower pH values and some free carbonic acid. The pH, however, must remain above 7 to be quiet with alkalinities as high as 300 p. p. m.

Soft waters relatively free from carbonic acid are actually distributed by many water works plants with pH values of about 7, and while not entirely quiet some activity is tolerated in preference to a further increase in hardness. Values below 7 are undesirable in all cases. This is a relatively new subject. Conditions are improving and there is room for further improvement.

PURIFICATION OF WATER

8. Auxiliary Processes

Water Purification is frequently spoken of as " filtration," but the processes employed are much broader than are properly covered by the word " filtration," and include such auxiliary processes as aeration, straining, coagulation, disinfection, and sedimentation.

The Capacity of purification works must be sufficient to meet the requirements at the maximum rate of use, and it is usually necessary to provide reserve parts so that the full supply may be maintained while cleanings, repairs, etc., are carried out. As a general rule the capacities of purification plants should be 50% greater than the greatest expected annual rate of use, but the ratio varies according to circumstances.

Aeration consists in bringing water into intimate or violent contact with air for the double purpose of introducing oxygen and of removing objectionable gases. Aeration is used as a preliminary treatment in all cases where oxygen is deficient in the raw water. Oxygen is very easily introduced. Water falling in drops through a height of two or three feet will take up more than half the quantity of oxygen that it will take up by the fullest exposure. The fall of water over a dam, or the play through a jet of a fountain, will serve to fully aerate it as far as introducing oxygen is concerned.

More vigorous aeration is required to remove the gases or substances that produce tastes and odors resulting from the growth and decay of organisms in quiet water in the light. Sufficient aeration greatly reduces or removes these tastes and odors.

There are many kinds of aerators, but those that throw the water upward through numerous small jets are most efficient. For raw water the jets must not be so small as to clog rapidly and must be arranged to be easily cleaned. The best dispersion is obtained when the water is revolved by guides as it approaches the jet. The spacing of the jets must be arranged to properly disperse the water so that it will have ample contact with new air. Two types of aerator that have been successful are shown in Fig. 7.

Filtered water is sometimes aerated to remove carbonic acid and tastes and odors. Effluent aerators are not subject to clogging and may have more numerous and smaller jets. In some recent designs effluent aerators are combined with filter regulators arranged to use for aeration that part of the necessary maximum head not required at the moment.

Screens are used for removing dead leaves, sticks, etc. Stationary inclined screens raked off at intervals are most commonly used. Revolving screens of various types are used for closer screening. Screening through brass wire cloth with as many as 60 meshes per inch is used in paper mills. Screening as a preliminary to filtration is advantageous within certain limits, but close screening is unnecessary.

Coagulation consists in the addition of some substance to the water that reacts with substances in the water, producing a flocculent precipitate which surrounds minute suspended particles in the water and draws them together into aggregates that can be removed by subsequent processes which would not serve to remove the individual particles. Coagulation is an essential part of the treatment of (1) all waters containing large amounts of very finely divided mineral matter, or turbidity, and (2) all waters highly colored by vegetable stain. It is also frequently used for other waters, but is not necessarily essential.

Dry Feed. Coagulants were formerly dissolved, making standard solutions which were fed through adjustable orifices at the desired rates. These devices have been mainly replaced with dry feed machines in which the pulverized coagulant is fed by controlled screw feeds or other devices at the

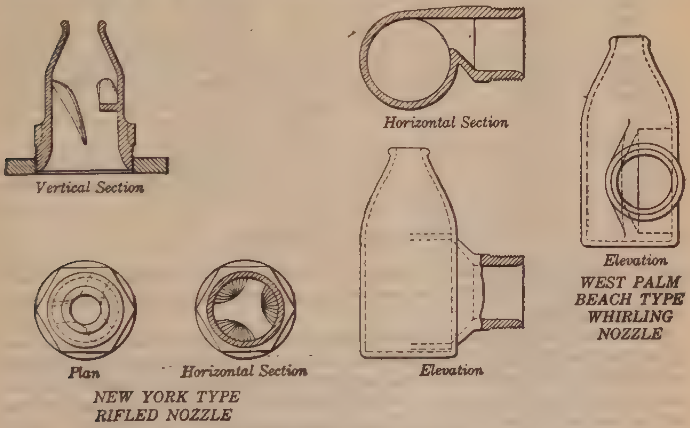

Fig. 7. Aerator Nozzles

desired rate into a dissolving chamber through which an unmeasured quantity of water flows on its way to mix with the main body of water.

Sulfate of Alumina, commonly called alum, is the most widely used coagulant. It is clean to handle, easily dissolved, and efficient in its action. It requires lime or other alkalinity to decompose it. In most cases sufficient lime is present in the water treated. Otherwise lime or soda ash must be added. The approximate quantities of sulfate of alumina (17% Al_2O_3) required to coagulate waters of various degrees of turbidity and color, and the alkalinity required to react with them are given in the table on p. 1470.

Ferric Salts have sometimes been used as coagulants. They are nearly equivalent in action to sulfate of alumina but less convenient to apply and have been used much less widely.

Ferrous Sulfate or Copperas is extensively used as a coagulant for hard waters. It is cheaper than sulfate of alumina and equally efficient in removing turbidity, but requires a more alkaline water. For this reason it is always necessary to use lime in connection with it, and the amount of lime must be closely adjusted to the chemical condition of the water.

Copperas cannot be successfully used except with adequate chemical supervision. The process is therefore preferred principally in large plants where continued close expert supervision can be given. By a judicious regulation of the amount of lime it is possible to partially soften hard waters by this treatment.

Softening. Water is softened for municipal use by two processes: first, conversion of incrustants to temporary hardness by treatment with nine

Turbidity	Alum		Alkalinity necessary for reaction, p. p. m.
	Grains per gallon	Pounds per million gallons	
0	0.50	72	5
50	1.00	143	9
100	1.35	193	12
200	1.78	254	16
300	2.05	293	18
500	2.50	357	22
700	2.87	413	25
1000	3.32	474	30
1500	3.90	557	34
2000	4.40	628	38
Color			
50	1.00	143	9
100	2.00	286	17
200	4.00	572	35

Different kinds of turbidity and color vary considerably in the amounts of coagulant that they require, so that figures varying considerably from the above average will be found. Deep reservoir waters containing iron in solution are more easily coagulated. It is well to keep the alkalinity of the treated water as high as 10 or 12 parts per million to guard against corrosion of metals.

At some large filter plants alum is manufactured from bauxite.

pounds of soda-ash per million gallons for each part of incrustants to be converted. This is a relatively expensive process often omitted and seldom carried to completion.

Second and more important, temporary hardness or carbonates are removed by adding lime to the water, followed by mixing and agitation and by settling and filtering. The added lime takes up the carbonic acid, which holds the lime in the water in solution, and the added lime, together with that in the original water, is precipitated. This is known as the Clark process. Some of the magnesium is also precipitated under favorable conditions. The dose of lime is in proportion to the carbonic acid and does not bear a quantitative relation to the softening effected. A small amount of coagulant aids and is usually added.

Water that has been softened by lime must be **recarbonated** to restore the natural balance of lime and carbonic acid before filtration and use. Products of combustion are cleaned by washing with water in a coke tower and then passed through the water before filtering. Otherwise the filter sand " grows," that is to say, the sizes of the grains are increased by deposits and there are objectionable deposits of crystalline calcium carbonate in valves, water meters, and other parts of the distribution system.

Among important municipal softening plants may be mentioned those at Grand Rapids, Mich., Columbus, Ohio, and Tampa and Miami, Florida. Partial softening is also carried out with lime treatments of river waters at St. Louis, New Orleans and elsewhere. Many railroads have softening plants for their locomotives.

Softening water by lime under certain conditions results in **sterilization** of the water. The results are fully equal to those obtained with chlorine and no other treatment is necessary where lime is used.

The **cost of softening** with soda-ash and lime is more expensive than ordinary filtration. At Columbus, Ohio, the operating costs are about $20 per million gallons for a reduction of 200 parts of hardness, or about 10 cents per million gallons for each part of hardness removed.

The **zeolite** process consists in passing hard water through a material that has the capacity of temporarily absorbing the hardness from the water. The material is regenerated by passing a salt solution through it. Almost complete softening can be obtained. The process is too expensive for municipal plants, but is frequently advantageous for boiler feedwater, water for laundries, and in hotels or houses for water for domestic purposes.

Disinfection consists in the addition to the water of some substance to kill objectionable organisms in it, which substance must be so adjusted as not to be injurious in the other uses to which the water is put.

Liquid Chlorine. Chlorine gas furnished liquefied in steel cylinders has come into general use as a sterilizing agent. It has completely displaced the hyperchloride of lime previously used for the same purpose and is so cheap and satisfactory that the rival processes of ozone treatment and ultra-violet rays have not found extended use.

The chlorine is fed out through an automatic control apparatus, is dissolved in a relatively small quantity of water and this water is afterward mixed with the main flow. Gravity apparatus is best but it can be applied under pressure with special equipment. Chlorine may also be applied directly as a gas to the water by the use of so-called diffusers. Chlorine is very poisonous and destructive and the equipment is best placed in small rooms having an outside door only, entirely separated from other parts of the waterworks plant.

Water after being mixed with the chlorine should be kept by itself as in a pipe or compartment or a reservoir for 15 minutes or more during which the chlorine has a chance to act upon the water without dilution. If the treated water is at once discharged into a large reservoir the effect is largely lost.

The required dose depends upon various matters and especially upon the amount and character of the organic matter in the water treated. Organic matter absorbs chlorine and the dose must be sufficient to satisfy, first, the organic matter and afterward to leave an amount sufficient for sterilization. The size of the dose is determined by noting the excess of chlorine after the period of treatment and this is regulated to an amount shown by experience to be satisfactory under local conditions.

Application of Chlorine to Raw Water. This is commonly practiced where no filtration is used. Excellent results have followed the use of chlorine where filtration was not practicable, but over-confidence in the method has sometimes led to unfortunate results. The sterilization is incomplete when the water is turbid or contains floating organic matter. A water ordinarily treated with success may occasionally change its character and fail to respond, as, for instance, at a time of the sudden rise of a river in a flood or the agitation of a lake by a sudden high wind.

The **application of chlorine to water before filtering** is occasionally used. It requires a relatively large dose because of the impurities in the water. When used in advance of filters, tastes and odors resulting from by-products of the action of chlorine on certain impurities may be eliminated through the biological action in the sand beds, but an excess of chlorine will sterilize the filter sand and reduce its biological action with unfortunate results. In general, such application should be made only where there are large settling or coagulation basins between the point of application and the filters.

Application to Filter Effluents where the raw water is polluted is almost universal. The filtered water receiving the chlorine has less organic matter than raw water and the amount is less variable, and the required dose is smaller and the action more efficient and reliable.

Tastes and Odors from Chlorine Treatment. Chlorine in itself has a taste and odor. If the water passes through reservoirs or long pipes after being treated and before being used it will tend to the elimination of chlorine. It is usually possible to operate satisfactorily. Some kinds of organic matter when present in the water form compounds with the chlorine having stronger and more disagreeable tastes and odors than were the original substances or the chlorine that is added. Phenol compounds in waste products of some industrial establishments are incredibly potent and are not removed by ordinary filtration processes.

Dechlorinizing Processes. A considerable excess of chlorine may be used to permit a stronger reaction and the excess afterwards removed by aeration to drive it off, or by the addition of sulfur dioxide or thiosulphate of soda to absorb it with the formation of harmless products. These methods have been occasionally recommended for special cases but are not at present in common use.

Sulfate of Copper. Sulfate of copper is extensively and successfully used to kill algae and other organisms growing in the light in impounding reservoirs. The common method of application is to drag bags of the material through the water by boats until dissolved. It is also used to treat water in swimming pools. It is added continuously by dry feed to aqueducts or by immersing containers with a hole in the bottom to varying depths in flowing streams or inlets to reservoirs, the rate of solution varying with the depth of immersion. In reservoir treatment the chemical should be distributed as uniformly as possible by triangulation of the surface or by parallel paths first in one direction and then at right angles. Large reservoirs (30 billion gallon reservoirs have been treated) should be subdivided and the volume of each section determined and the chemical apportioned accordingly. Fast launches are used for such service. In the winter period it has been applied through holes in the ice, but distribution is difficult and considerable skill is required. Dosage depends upon the organism present which should be determined by microscopical examination since all forms are not amenable to treatment. Happily the taste- and odor-producing organisms are usually readily destroyed. Usual dosage varies from 1 to 3 lb. per million gallons. In absence of exact information 2 lb. is a safe quantity to use. Dosage in winter is usually double that required in the summer. Fish are rarely killed if the chemical is properly distributed and the organisms are not allowed to accumulate to heavy amounts before treatment. The treated water should not reach the consumer under two days, in order to allow the disagreeable odors produced by treatment to escape from the water. A distribution reservoir should be by-passed or turned out of service. If it has several days' storage capacity, the upper half only may be treated and the treated water allowed to gradually displace the untreated.

Attention is called to the increasing use of chlorination to control algae. Many of those forms not readily destroyed by copper sulfate succumb to chlorine. Particularly is prechlorination used to lighten the load on filter plants and lengthen runs, to prevent growths in sedimentation basins and swimming pools. Dosage varies from 0.5 to 1 or 2 parts per million.

9. Sedimentation

Sedimentation consists in taking water through basins in which the velocity of flow is reduced to a point that permits the heavier suspended matters to settle to the bottom by gravity. Sedimentation is widely used as a preliminary process and is the cheapest way of removing those relatively large particles that will settle out in a moderate length of time. **Baffles** consisting of light dividing walls separating one basin into parts through which the water passes successively, increase the efficiency by preventing the partially cleared water from mixing with uncleared water. Too many baffles increase the length of the horizontal courses and the velocity to a point where deposition of the finest particles is prevented. **Cleaning** is usually accomplished hydraulically, by opening a gate and flushing out the sediment. To facilitate this, drains are built, and the whole bottom slopes to them. Jets of water from hose are used to facilitate the movement.

Sedimentation was formerly used as the principal process in clarifying water from many turbid rivers. Under the most favorable conditions the results reached fell short of present standards for public water supplies and sedimentation as an independent process has almost entirely disappeared. Sedimentation basins today are usually also **coagulating basins** and the determination of size and other conditions depends upon the time required for the chemical reactions to be completed. Chemical rather than physical conditions control, but a coagulating basin must also be a sedimentation basin, and if it is well designed for this it will make for better results in the process as a whole.

Basins may be large open basins with masonry floors and walls, cut up into units to facilitate cleaning. Vaulted covers like those used for sand filters and reservoirs have the advantage of keeping out wind action which is occasionally disturbing. Natural basins of larger size are sometimes availed of.

Time Required for Reactions. Some chemical reactions take place promptly when the chemicals are applied. In such cases moderate sized basins suffice. In other cases and especially in the coagulation of soft waters by aluminum sulfate a very considerable period of time may be required for complete coagulation. There has been a tendency to increase basin sizes for such waters. Basins holding several days' supply work where those holding a few hours' supply are unsatisfactory. If the period is too short the water passes to and through the filters before the chemical reactions are complete. The reactions may be finished in part in the filter sand and in part in the pipes of the distribution system; in the latter case with the formation of objectionable deposits. This is called secondary coagulation. Such deposits are usually colored red by iron taken up from the pipes even though the bulk of the material is white aluminum hydrate. These deposits are stirred up in the pipes at times of extra draft of water and give rise to conditions similar to those caused by active waters and noted under the heading "Red Water Troubles."

In the Intermittent System of operation a basin is filled and allowed to stand and then drawn off. In the **continuous system** of operation water flows constantly in at one end and out at the other.

The Efficiency of a Basin depends upon its area and upon the system of baffling employed. A deep basin is not more efficient than a shallow one of the same area, but a certain depth is necessary in order to hold an accumulation of sediment and to prevent the velocity of flow through the basin from becoming too great to permit full deposition. As a rough rule the depth may be one-sixtieth of the average course that the water will follow when baffled.

Settlement of Particles in Still Water at 50° F.

Kind of material	Diameter of particles in mm.	Rate of settlement, mm. per second
Coarse sand....	1	100
	0.20	21
Fine sand.....	0.10	8
	0.06	3.8
	0.04	2.1
	0.02	0.6
Silt...........	0.01	0.15
Coarse clay....	0.001	0.0015
Fine clay......	0.0001	0.000015

Bacteria and other organisms settle more slowly if at all because their specific gravity is so near to that of water. The rate of settling is greater as the temperature is higher. Twice as much water can pass through the basin with the corresponding results in summer as in winter. The limit of size of particles removed by settling basins can be computed approximately (Trans. Am. Soc. C. E., vol. 53, p. 45) as follows:

The Diameter of Particles in millimeters, such that 75% will be removed with continuance of operation, may be computed by

$$d = 0.0027\,f\,\sqrt{\frac{\text{million gallons daily}}{\text{area of basin in acres}}}\,\sqrt{\frac{60}{t+10}}$$

in which f is a factor depending upon the arrangement of basins and baffling. Use 1.73 for a basin with one inlet and one outlet well separated; 1.41 for two basins through which the water passes successively; 1.22 for a well-baffled basin or other specially good arrangement. $f = 1.00$ is a theoretical limit not reached in practice. In the last term t is temperature in degrees Fahrenheit. For comparisons use $t = 50$ in all cases. The rule does not apply for separations above 0.05 millimeter. It is not precise, but it affords a convenient basis for comparing sedimentation and coagulating basins.

In a general way basins holding six hours' supply, well baffled, in connection with mechanical filters, remove particles more than 0.02 mm. in diameter. Sedimentation basins for sand filters, 24 hours' supply, remove particles more than 0.007 mm. At Washington, D. C., in a succession of three reservoirs holding a week's supply, particles larger than 0.003 mm. are removed.

The Amount of Sediment removed in settling basins at St. Louis amounts to 12 cu. yd. per million gallons; with less turbid waters it is much less. For the Hudson at Albany only about 0.15 cu. yd. is removed.

Scrubbers, or preliminary filters, are rapid coarse-grained filters or their equivalent. Substantially they take the place of sedimentation basins, doing the same work but doing it more quickly and in less space, though usually at greater cost.

It is easy to design a scrubber that is efficient in operation. It is difficult to design one that can also be economically cleaned and kept continuously in efficient working order. From the standpoint of design and construction the cleaning devices are the most important parts of a scrubber. The object of scrubbers is to lighten the work of the filters to which the water is subsequently applied and especially to increase the length of run of the final filter. They are most useful for waters that are highly polluted or difficult to treat, and add to the certainty and reliability of operation.

The size of particles in millimeters, such that 75% will be removed by a scrubber or preliminary filter of sand or gravel 40 in. deep, may be computed by

$$d = 0.0003\,\sqrt{\left\{\begin{matrix}\text{effective size of}\\ \text{sand or gravel}\end{matrix}\right\} \times \left\{\begin{matrix}\text{rate of filtration, mill}\\ \text{gallons per acre daily}\end{matrix}\right.}\,\sqrt{\frac{60}{t+10}}$$

The scrubbers and preliminary filters that have given most satisfactory results are cleaned and operated practically as mechanical filters, but with simpler arrangements.

10. Sand for Filters

A Filter consists of a horizontal layer of sand through which water is passed to underdrains beneath, together with the containing structure and all auxiliaries. Filters act primarily as strainers, the interstices between the sand grains being small and serving to stop all particles too large to pass through them. They also serve to purify the water in other ways. Filters are classified as mechanical filters, sand filters, intermittent filters, and special kinds of filters according to the construction, rates at which they are operated, and the methods used for cleaning.

The Sand for filtering purposes is best clean quartz sand, free from gravel and large particles, and also free from excessive quantities of fine particles and dirt of every description. The presence of a small amount of fine material often aids the action of filter sand. For filtering river waters and any waters carrying carbonic acid, filter sand should be free from lime, as otherwise the water will be hardened. Waters containing less carbonic acid, such as lake waters, will not dissolve lime and sand containing lime may be used.

The Size of Sand Grains is determined by sifting through a set of rated sieves. About 110 grams of moist sand are put in a small iron dish and dried over a lamp. After cooling, 100 grams are put in the coarsest of a set of sieves, and the sieves are put in a mechanical shaker. A definite number of turns found by experience to be sufficient, is given. The shaking is not continued until no more passes, but only until the amount passing is small, so that doubling the number of shakes would not greatly change the result. The sieves are then taken apart, the material that has passed all the sieves is first put upon the pan of the scale and weighed, then the material remaining on the finest sieve is added to it and again weighed. The process is repeated until all the material is on the scale, when it should equal the original weight. The percentages finer than the sizes corresponding to the several sieves are then plotted on a diagram, from which the required data are taken.

The Effective Size of sand is that size such that 10% of the sand grains by weight are finer than it. The size of a sand grain is always taken as the diameter of a sphere of equal volume.

The Uniformity Coefficient is the ratio between the effective size and that size such that 60% of the sand is finer than it.

In rating sieves an ordinary sand is put upon them and the shaking is performed with the usual number of revolutions. The sieves are then taken apart, each sieve is taken separately, and is given a further slight shaking. A small additional amount of sand passes. The grains so passing are substantially larger than all the grains that have previously passed and smaller than those that remain. This small quantity of sand represents the size of separation of the sieve. A certain number of sand grains are counted out and weighed on an assay balance and the average weight is obtained. The diameter is obtained by the formula

$$\text{D in mm.} = 0.9\sqrt[3]{w} = \sqrt[3]{\frac{6}{\text{Sp. Gr.} \times \pi}}\sqrt[3]{w}. \qquad w = \text{weight in milligrams.}$$

There is but little difference in the results of using round-grained and sharp-grained sands, and between grains of different shapes, but the rating is best carried out with various representative sands. Rating of sieves once made does not change appreciably with use until some openings become enlarged or some wires become broken. When this happens the sieves should be at once replaced. When a set of sieves is rated a lithographed sheet is made for plotting the results, in which one line represents each sieve in the set. The best results are with a mixed plotting, partly logarithmic and partly natural, laid out so that normal sands plot as nearly straight lines. On this system accuracy is obtained with a smaller number of sieves. Enough sieves so that each has a size of separation not more than twice as great as the next below will suffice, except where the uniformity coefficient is under 2. In that event one intermediate sieve should be used between each two.

The following represents approximately the relation between commercial brass wire cloth and the sizes of separation:

Meshes per inch	200	140	100	50	40	30	20
Separation in mm	0.10	0.13	0.17	0.33	0.48	0.63	0.95

Owing to variations in weaving, individual sieves will vary 15% either way, and no sieve should be used without rating. In selecting wire cloth make sure that the spacing of the wires is even and that the number of wires per inch in one direction is not more than 10% greater than the number in the other direction Coarser sieves are best of brass plates perforated with round holes and rated in the same way as wire cloth sieves.

Sieves are now manufactured of standard wire cloth and may be purchased with the size of each sieve stated in millimeters. These sizes usually relate to the average size of opening and this differs from the size of separation which is based on the actual average diameters of particles which do and do not pass. For the coarser sieves it is about 10% less and for the finer sieves the variation is greater and not in any constant proportion. All sieves should be rated before being used for analysis of filter sand, and the size of separation must always be used and not the average size of opening.

Turbidity of Sand is the measure of clay in it. Put 10 grams of moist sand into a glass vessel holding one liter and fill with clear water. Agitate vigorously until all fine matter is in suspension. Allow to settle one minute, take the turbidity with a rod. Multiply the turbidity so found by 100 to obtain the parts per million of turbidity in the sand. The weight of clay is from one-half to two-thirds the turbidity, depending upon the size of the clay particles. Turbidity of sand prepared from stock containing clay should always be taken, but when there is no clay in the stock it is unnecessary to do it. At the Washington filtration plant the turbidity of the filter sand was not allowed to exceed 4000 in parts per million, or 0.4%, corresponding to about 0.2% actual clay.

11. Use of Filter Sand

Loss of Head is the frictional resistance of the sand to the passage of water. It is measured by the vertical distance between the level of the raw water over the sand and the level of the water in a small standpipe connected with the drains below the sand. Filters are provided with loss-of-head indicators. For any given condition of the filter bed the loss of head is directly proportional to the rate of filtration. The loss of head is made up of two parts, the frictional resistance of the clean sand and the resistance due the accumulation of dirt on the surface of the filter. The initial loss of head is that at the beginning of a run, but even this is more than for clean sand because there is some dirt on the surface from the very start.

The Frictional Resistance of sand to water when closely packed, with the pores completely filled with water, and in the entire absence of clogging, is indicated by

$$v = cd^2 \frac{h}{l} \left(\frac{t^\circ + 10^\circ}{60}\right)$$

where v is the velocity of the water in meters daily in a solid column of the same area as that of the sand, or approximately in million gallons per acre daily; c is a factor depending upon the uniformity coefficient, the shape of the sand grain, the chemical composition, the cleanness, and closeness of packing, commonly varying from 600 to 1200 for new sand and from 400 to 800 for old sand; d is the effective size in millimeters; h is the loss of head; l is the thickness of sand through which the water passes; t° is the temperature (F.).

Accuracy depends more upon good work in determining d, the effective size in millimeters, than upon any other matter. The formula applies to filter sands with uniformity coefficients less than 3, but also less closely to those with uniformity coefficients to 6, and even 10. It does not apply to coarse gravels in which the viscosity of water is no longer controlling.

Required Head in Feet for Clean Sand One Foot Thick
$c = 800$, $t = 50°$ F.

The adjacent table covers the ranges most commonly used in filtration. It applies to clean sand with no surface clogging. For thicker sand layers the head is greater in direct proportion.

Rate of filtration, million gallons per acre daily	Effective size of sand, millimeters			
	0.20	0.30	0.40	0.50
3	0.09	0.04	0.02	0.01
5	0.15	0.06	0.04	0.02
10	0.29	0.13	0.07	0.05
20	0.59	0.26	0.15	0.09
60	1.76	0.78	0.44	0.28
125	....	1.62	0.91	0.59

Preparation of Filter Sand. Occasionally natural sand is found suitable for use in filters, especially sea sand. Most bank and river sands require treatment. Coarse particles are removed by screening. Fine particles are removed by washing. If the stock contains clay it must first go through a pug mill or otherwise be agitated to break up all the lumps of clay and loosen the particles from the sand grains. It is then passed through a washing box in which the sand moves horizontally and the water vertically at a rate corresponding to the rate of settlement of sand grains of the size of the required separation. The washed sand is drawn off with but little water. The box should have one square foot of area for each cubic yard per hour to be handled.

Filter sand can be prepared from a great variety of raw stocks. The essential requirement is that the stock contain a sufficient proportion of sand grains of the right size. To find the amount of filter sand that can be prepared from a given raw stock make a mechanical analysis of it and find the percentages finer than the desired effective size and 60% line. The difference between these percentages multiplied by 2 is the theoretical amount of filter sand that can be obtained. Actually from 75 to 95% of this amount should be obtained by a suitable plant.

Stock can be **screened wet** under a spray of water to exclude particles larger than about 3 mm. in diameter. If finer screens are used wet they become clogged and the process stalls.

In preparing sand for mechanical filters where the uniformity coefficient must not exceed about 1.6, it is frequently necessary to make finer separations. Any desired separation such as 1 mm. or 1.2 mm. may be made by drying the stock in a furnace and sifting it completely dry and still warm through screens of appropriate size that are mechanically agitated. Such sand must usually be subsequently washed to remove the excess of fine particles.

It will not often pay to work stock from which more than 10% of fine material must be removed because of the difficulty of washing, nor stock that has more than 50% of gravel to be excluded.

The size of separation in sand washing depends principally upon the area of the boxes containing the mixed sand and water to which the mixture is coming, and from which the sand is drawn to the bottom, while the dirty water overflows, and upon the volume of water, taken always as the volume of the waste that overflows at the top. The approximate size of separation such that 75% of the particles of that size will be retained may be computed by

$$D \text{ in mm.} = 0.0065\, f\, \frac{\text{gallons per minute of water overflowing}}{\text{square feet of box area}}$$

in which f ranges from 3.0 for ordinary single boxes to 1.5 for specially designed boxes with water entering steadily at the bottom and overflowing at well-distributed points at the top. The rule does not apply for sand grains less than 0.10 mm. in diameter.

Voids in filter sand range from 35 to 45%, according to the uniformity coefficient and the method of packing. Close packing is obtained with sand either perfectly dry or saturated with water. Sand packed moist always has more voids and settles from 4 to 8% when it is filled with water. Voids in sand are determined by driving a cylinder of sheet iron into the sand in the filter, carefully cutting away the adjoining material with a mason's trowel, and taking out sand equal to the exact contents of the cylinder. The sand is dried, weighed, and the volume of the solid particles computed, taking into account the specific gravity, which for nearly all filter sands is 2.65. This is compared with the volume of the cylinder.

Results obtained by filling voids of dry sand with water are invariably too low because all the air is not driven out, even when filled in the most careful manner, from below.

Gravel is required in filter construction, usually in several sizes, prepared by screening. Crushed rock is used where gravel is not available. Gravel, especially in finer grades, is often obtained as a by-product from the preparation of the filter sand. Gravel should always be washed free from sand, clay, and fine particles. Where the water contains carbonic acid it is preferable free from limestone.

Washing and Handling Sand. Filter sand is commonly handled and washed hydraulically. Water through a jet under a hundred pounds pressure passes through an open space and enters a throat a little greater in diameter than the jet and carries with it sand loosened by water which surrounds the space. The mixture of sand and water will flow as a liquid through pipes to the washers and from the washers to the points where it is stored.

One volume of water is required to take up one volume of sand to make slush, which slush has about 60% of the solid sand and a specific gravity of 1.59.

Ejectors form the basis of the washing and transporting system of sand filters. They are also used with mechanical filters for the occasional sand handling and washing that is required. With a pressure of 100 lb. on a 0.7 in. jet discharging through 50 ft. of 3-in. hose to 4-in. main pipes, 10 cu. yd. of sand per hour can be lifted vertically about 50 ft. or carried horizontally 700 ft. or any proportionate combination of the two. The ejector tables given herewith permit calculations to be made for other pressures and quantities and pipe sizes.

12. Sand Ejectors

The Resistance to be overcome in the discharge piping is made up of actual lift and friction. For the lift, multiply the actual lift in feet by the specific gravity of the mixture. For friction of sand and water in 3-in. and 4-in. pipes, compute the friction for water alone, and add 3.5 ft. per thousand for each per cent of sand in the mixture. For 6-in. or larger pipe add 2.5 ft. and for 2.5-in. hose, add 4.5 ft. per thousand. These figures will be close enough for velocities 5 ft. per second or over. Sand and water mixtures will flow well at all velocities above 5 ft. per second and fairly well from 4 to 5 ft. per second. Between 3 and 4 ft. per second there will be more friction than calculated and some stoppages; and below 3 ft. per second sand and water mixtures will not flow.

Cubic yards per hour

$$= \frac{\text{Per cent sand} \times \text{velocity} \times \text{diameter}^2}{137.5}$$

Hydraulics of Ejector. The best form of throat is one approaching the shape of a Venturi meter. The calculations in this section are for a throat of this shape but somewhat worn by use and not quite in the best condition. With a carefully turned new throat the results may be higher and with worn throats lower. With the best size and shape of throat for any given condition, the tables in this section show the approximate relations. Fig. 8 shows the working parts of a sand ejector, and Fig. 9 shows the method of use in connection with the sand washing equipment and storage of clean sand.

P = proportion of jet pressure developed in discharge	0.50	0.37	0.28	0.20	0.14	0.10
T = ratio of diameter of throat to diameter of jet	1.22	1.44	1.65	1.88	2.12	2.38
V = ratio of velocity in throat to velocity in jet	0.73	0.58	0.49	0.43	0.38	0.35

The formula $(P + V)T^{1.5} = 1.65$ applies to well-shaped Venturi throat ejectors throwing sand. The best results are obtained when $QV = 0.9$ with 5% or 10% variation either way, and within this approximate range $PQ^2 = 0.65$. This is the most convenient equation for comparing efficiencies.

The slush will not enter at a velocity of more than about 40 ft. per second, and at such a velocity wears out the parts rapidly, and with high pressures this compels the use of throats slightly larger than computed as most efficient. The above proportions are suitable for pressures up to 150 lb., and may be used for all lower ones without material loss in efficiency.

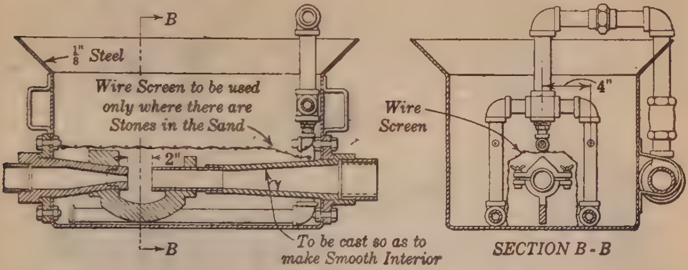

Fig. 8

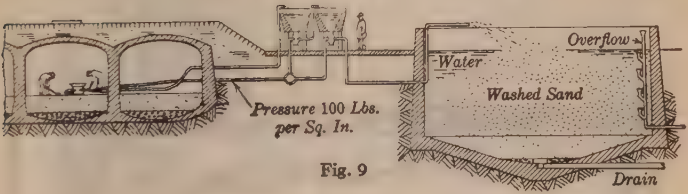

Fig. 9

13. Mechanical Filters

Mechanical filters are filters operating at a high rate with mechanical appliances for cleaning the sand without removing it from the filter. The filter tank containing the sand was formerly of wood or sometimes of steel, but reinforced concrete is now used almost exclusively. It is essential that the filter tank should be air-tight as well as water-tight, to prevent the entrance of air from the outside in the last portion of the run. Fig. 11 shows the arrangement of one mechanical filter in a group of such filters, Fig. 10 shows the arrangement of filters in the group and the main connections but does not indicate the extent of the coagulating basins.

The Sand is commonly from 30 to 36 in. deep, and with effective sizes ranging from 0.35 to 0.50, commonly about 0.40 mm. The uniformity coefficient should be as low as possible and must not exceed 1.6. Sand with high uniformity coefficients is separated into coarse and fine parts in the act of washing, and full filtering efficiency cannot then be obtained. The sand is supported at the bottom by layers of gravel, which must be heavy enough and open enough to allow the wash water to pass without lifting.

The Strainer System serves the double purpose of introducing wash water to wash the sand with a reverse current and of carrying off the effluent. In order to serve its purpose of carrying off the effluent the frictional resistance of the system must not exceed one-fourth the frictional resistance of the sand at the beginning of the run. Otherwise the near parts of the filter would operate at higher rates than the remote parts.

The fundamental requirement of the strainer system when used for washing is that it shall give an equal dispersion of wash water over the whole area of the filter. There is a tendency for the sand to lift at one place. When this happens the pressure on the strainers at that place is reduced and there is a tendency for all the wash water to go

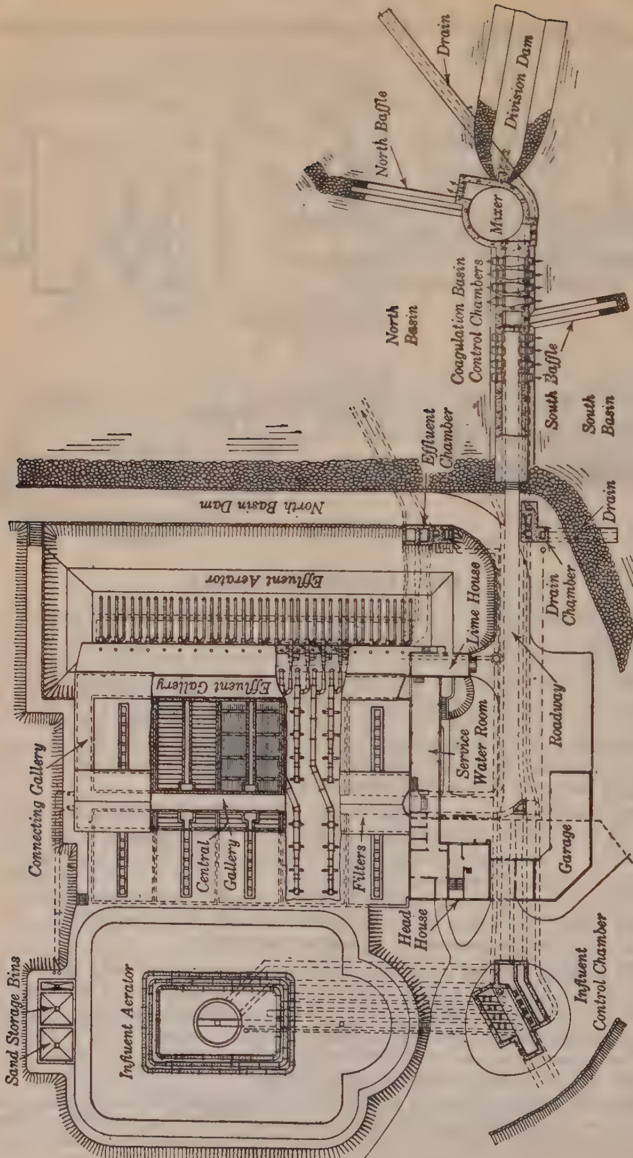

Fig. 10. Layout of a Mechanical Filter

out at one place. This is controlled by putting restrictions on the outlets having resistance at the rate of use greater than the resistance offered by the sand, so that these throats control the position of overflow of the water. The throats must be small enough to give the desired rate of wash with a frictional resistance that will insure the even distribution of the wash water, and large enough so that it does not exceed the economical head applicable to this purpose. The area of main drains should equal twice the area of all the throats supplied by them, and lateral piping should have 2-1/2 times the area of all the throats supplied. In a large filter the ratios should be a little higher.

In a typical design for a mechanical filter, the wash water is supplied at a minimum

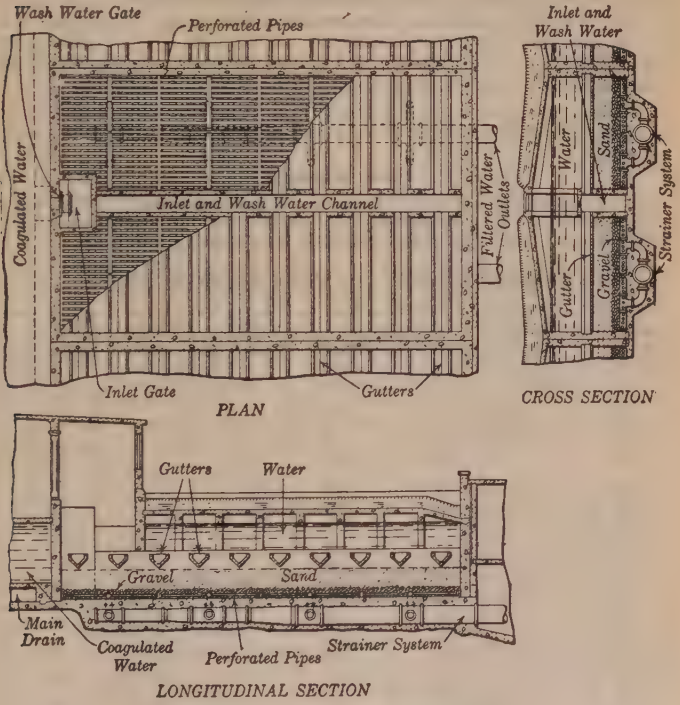

Fig. 11. One Unit of a Mechanical Filter

head of 10 lb. or 23 ft. measured from the level of the gutters, of which 3 ft. are required to lift the sand, 8 are consumed in pipe and gate losses and 12 are effective on the openings in the perforated pipes. For a rate of wash of 26 in. per minute and a coefficient of discharge through the openings of 0.65, the required area of holes in the aggregate is equal to 0.2% of the filter area. To correspond with this and to keep the friction of the pipe system to a proportionate amount, the main drain must equal 0.4% in a small filter or 0.5% in a large one, and the laterals and intermediate piping must equal about 0.6% of the filter area. If these pipes are too small, the distribution of wash water will be bad. In filtering at the ordinary rate which is about one-eighth of the above stated rate of wash, the loss of head, varying approximately with the square of the quantity, will be about 4 in. for the entire pipe system from the gravel to the regulating apparatus.

Mud Balls. Mud balls are accumulations of dirty sand on the bottom of the filter just above the gravel, resulting from settling of caked sand from the top of the filter at the beginning of the wash. Mud balls were prevented in early designs of circular filters by revolving rakes. In other cases air washing, that is to say, blowing air into the bottom of the filter through a separate system of pipes, has been used to break up mud balls. They may be sometimes broken up and pulled out by wire nets on long poles drawn through the sand while the filter is being washed. A relatively high rate of wash is favorable to keeping a filter clear of mud balls, but going too far results in loss of fine sand grains and changing the character of the filter sand. Under any conditions some mud balls accumulate in the bottom of the filter and tend to reduce its efficiency. It is recommended that all the sand be removed from the filter and washed with close screening annually to keep it in good order.

Washing. As a general rule that rate of wash that will expand the filter sand by about 30% is sufficient and, on the other hand, will not wash out too many

Filter Washing

Table showing the rate of wash in inches per minute required to lift the sand in a mechanical filter at various temperatures and with several sizes of sand and to give various degrees of expansion of the sand in the filter during the wash.

$$\textbf{Basis: Rate} = 30d^{1.5}\,(1 + 0.06\%\ \text{expansion})\,\frac{t+30}{80}$$

of the fine particles and change the character of the filter sand. The rate required to produce this result depends, among other things, upon the grain size of the sand and upon the temperature of the water, the required rate being higher in summer and lower in winter and higher as the filter sand is coarser.

Viscosity is the dominant element in the conditions that determine the rate of filter washing; but the phenomena come in a middle ground of change, corresponding to that observed above the critical velocity of flow of water in small pipes, and the conditions deviate materially from those of viscous flow.

Under these conditions no simple formula can be found, but within certain limits the empirical formula used in preparing the table given herewith is a close approximation. It must not be extended to conditions far different from those indicated.

As a general rule the rate of washing that gives 30% expansion is believed to be sufficient and best adapted to average conditions.

Gutters to carry off the wash water should not be less than 12 nor more than 18 in. at their edges above the surface of the sand. The eddying action of the water entering them reduces velocity, and the size of the gutters must be larger than is computed by the usual hydraulic formulas.

Regulating Apparatus. The regulating apparatus for rate control is now almost always of the Venturi type arranged so that change in rate as the filter becomes clogged is automatically met by opening the control gate to maintain the desired rate. In a few recent designs, aerator nozzles are attached in such a way that an automatic apparatus sends as much of the filtered water as possible through them, thus utilizing the surplus head of the filter for aeration.

Loss of head ranges from 2 ft. or less at the beginning of a run to the limit that is allowed, which may be anything from 4 to 10 ft. With the loss of head limited to 4 ft., no suction exists in the filter, and the whole operation is said to be performed by a positive head. With loss of head going to 6 ft. and over the outlet pipe acts as a draft tube and produces suction in the filter in the latter part of the run. This is known as negative head.

Negative head is efficient in making a filter operate, but practically its action is limited because with it air is extracted from the passing water which fills the voids in the sand and soon cuts off the suction. The first foot of negative head is only a little less useful than the last foot of positive head, but each additional foot utilized yields a smaller return than the last. The full effect of negative head may be utilized by putting an air chamber on the outlet pipe and pumping the air from it in the latter part of the run, thereby making the full negative head available.

The Frequency of Washing depends upon the character of the water and especially on the size and manner of operation of the coagulating basin, and commonly ranges from 8 to 48 hours. Washing requires about five minutes and the auxiliary operations more than as much more. From 2 to 5% of the water filtered is required for wash water.

The Rate of Filtration is generally 2 gal. per square foot per minute, equal to 125 million gal. per acre, or 117 cm. per square meter, per day, 347 sq. ft. of filter pass water at the rate of one million gallons per 24 hours.

Leaks Along the Sides. One of the commonest causes of inferior work in mechanical filters is the passage of unfiltered water through a space between the filter sand and the filter walls and this water mixes with the water which has passed through the sand and impairs the quality of the effluent.

As the filter run progresses, and head increases, the sand is compressed. Most of the compression is vertical, but some of it is horizontal. The horizontal compression opens a crack between the caked sand and the filter wall and the crack may pass unfiltered water while it is still too small to be observed. Dirty filter sand compresses more than clean sand and with old filter sand there is more deterioration in quality than with new sand. This used to happen with sand filters but for many years a design for the sides at the bottom has been used which prevents it. The same method unfortunately cannot be applied to mechanical filters because it would leave an unwashed strip around the edge; but roughening of the filter walls and the use of narrow offsets or ledges is advisable.

The erroneous idea has often been expressed that the filter sand or the sediment layer on its top "breaks" under pressure as the loss of head increases. The effect has been widely observed, but the true explanation less often recognized.

14. Sand Filter Beds

Sand Filters differ from mechanical filters in that the rate of filtration is much lower and the filter is cleaned when dirty by scraping off the surface layer of dirty sand, which is washed and ultimately replaced. The sand should have an effective size between 0.25 and 0.35 and a uniformity coefficient not exceeding 3.0. Many old filters had sands with uniformity coefficients up to 5, but such sand is much more difficult to keep in good order. Sand suitable for sand filters is more cheaply obtained than sand with a low uniformity coefficient required for mechanical filters.

The Gravel is commonly placed in three layers. The lowest layer is 7 in. thick and has 3/4-in. to 2-in. screens with an effective size of about 20 mm.; the second layer 3 in. deep, 3/8 to 3/4 in. screens with an effective size of about 8 mm.; and the top layer 2 in. deep, with an effective size of from 2 to 3 mm.

Underdrains must be designed so that, at the proposed rate of filtration, the frictional resistance of the whole system will not be more than about one-fourth of the frictional resistance of the sand when clean. Otherwise when the filter is started that part of the filter near the outlet would do most of the work.

Underdrains for Sand Filters

Rate of filtration, million gallons per acre daily	5	6	8	10	15
Average resistance of clean sand in feet	0.150	0.180	0.240	0.300	0.450
Total allowable friction and velocity head in underdrainage system	0.037	0.045	0.060	0.075	0.112
Approximate ratio of filter area to area of main drain	5100	4700	4200	3800	3200
Approximate maximum velocity in main drain (varying somewhat with size)	0.90	1.00	1.18	1.34	1.68
Approximate maximum velocity in laterals (varying somewhat with size)	0.55	0.61	0.72	0.82	1.04

Masonry covers are usually provided for sand filters. In the north they are necessary as a protection from cold winter weather which would interfere with sand cleaning operations. Open filters were formerly used in warmer climates but covered filters have proved to be more advantageous in most places in the United States where sand filters are used. The net height inside the masonry structure is 12 ft. to accommodate the filtering materials and give convenient headroom for cleaning operations.

Filters are built in units ranging from an acre in the largest plants to half an acre and less in small ones. There must be enough units so that one unit can be out of service at any time for cleaning. As resanding operations frequently run through several weeks there must also be enough units so that the supply can be maintained with two units out for such periods.

Maximum Areas of Filter Beds Drained in Square Feet

Automatic controllers are sometimes used on the outlets of sand filters, but as the change in loss of head is slow, hand control in connection with adequate devices for indicating at all times the rate of filtration and loss of head is sufficient.

The Period of a sand filter is the time between cleanings expressed in millions of gallons per acre. That is to say, if a filter operates 20 days at a 5-million rate the period is 100. The average period for a plant is found by dividing the number of million gallons filtered in one year by the total number of acres of filter surface cleaned.

Periods are increased by drawing the water off when the loss of head has reached the allowed limit and raking the surface of the sand and then proceeding. It does not usually pay to rake more than once in one period. Thorough sedimentation lengthens the period. The application of coagulant lengthens it if applied sufficiently long before filtration, but with a short period of settling after application it shortens it. Preliminary filters lengthen the period. Periods commonly range from 50 to 200. If they average less than 50 there is something wrong with the arrangements.

The Loss of Head in sand filters is commonly limited to 4 ft., but this is arbitrary and losses up to 5 or 6 ft. are sometimes permitted. The **rates** employed with sand filters filtering river waters without preliminary chemical treatment are about 3 million gallons per acre daily. For lake and reservoir waters rates twice as high are used. For filtering river waters with preliminary chemical treatment and settling when the water requires it, corresponding rates can be used.

Cleaning. At the end of a period the dirty sand to a depth of from 1/2 to 1-1/2 in. is removed. It is best shoveled to movable ejectors throwing the water through the piping system to sand washers outside. Scrapings are repeated for a considerable period, averaging 2 years, when washed sand is restored bringing it back to the original level. Cleanings in very cold weather may be done with the dirty sand piled up on the surface of the filter, where it remains until spring. The quantity of water under pressure required for handling and washing sand is commonly from 0.4 to 1.0% of the quantity filtered.

An old filter is commonly more efficient within limits than a new one, and the water filtered during the last part of the period is frequently better than in the first part. It has sometimes been recommended that the first water from sand filters be wasted. It is better practice, however, to start the filter at a lower rate, at which the first effluent will be good, and gradually increase the rate after processes of purification become established.

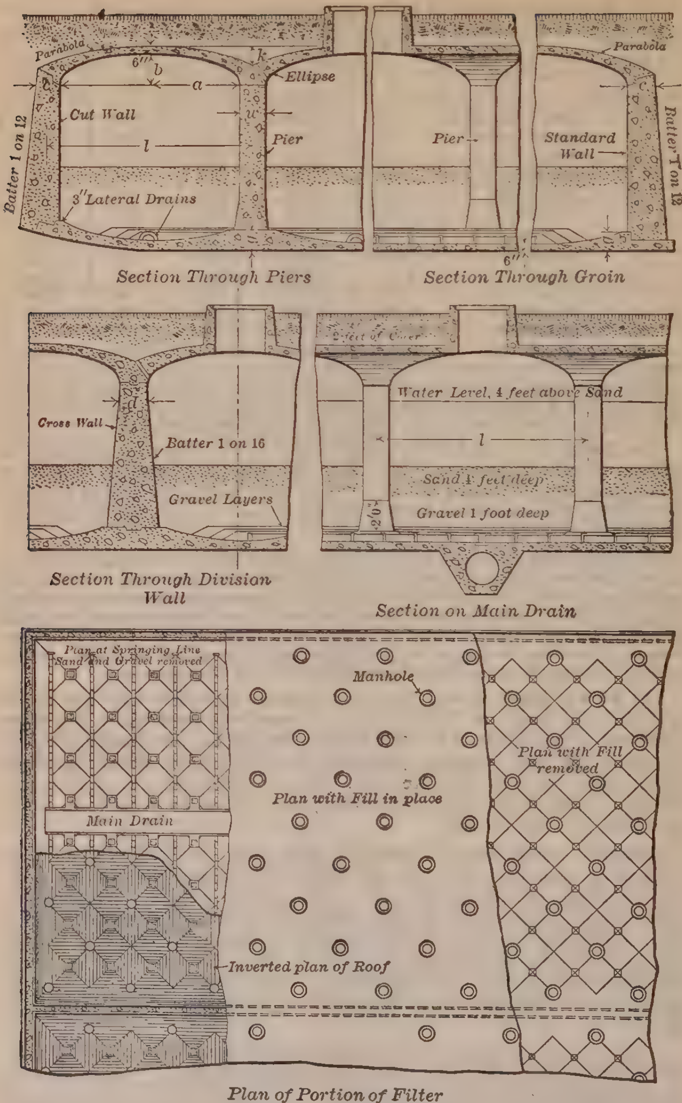

Fig. 12. Slow Sand Filter with Groined Roof

15. Results of Purification

The Cost of installing filters at post war prices may range from $20 000 to $60 000 per million gallons daily capacity, figures between $30 000 and $40 000 being most common. As the filters must usually be 50% greater in capacity than the average output, the cost based on the average output will be correspondingly greater. Operating costs range from $2 to $4 per million gallons and less for sand filters treating clear waters to $6 or $8 per million gallons for mechanical filters with turbid and colored waters. The whole cost of filtration, including both operating expenses and interest and depreciation charges on the capital, commonly ranges from $12 to $20 per million gallons.

Sand filters are often more expensive to build but cheaper to operate than mechanical filters. Lake waters are cheaper to purify than river waters, and reservoir waters are intermediate. Large amounts of color and turbidity add to the cost of treatment. Softening is more expensive than ordinary filtration.

In filtering river waters 99% removal of bacteria is commonly obtained. The efficiency is usually somewhat higher in summer than in winter. Growths of bacteria in the underdrains occasionally occur. These have no hygienic significance but reduce the percentage of apparent removal. These are most likely to occur in filters operating at low rates. Nearly all of the remaining bacteria are now removed by disinfection with chlorine. Purification as practiced does not absolutely remove infection, but it reduces the risk to one so extremely small that it may be considered negligible. Experience with filtration extending over half a century has shown that well-designed, well-constructed, and well-operated filter plants can be relied upon to furnish a safe and acceptable supply of water.

It is good practice to select a raw water for filtration as free from pollution as possible and to take all reasonable precautions to prevent the increase in pollution of existing supplies.

Intermittent Filters are sand filters in which the oxidizing action of the air is more important than the straining action of the sand. They are built of coarse sand with large underdrains freely open to the outlet and with no controlling or throttling devices. Water is applied generally once a day and generally for a period of not more than 12 hours. It is essential that the water on the filter should be drawn down, leaving the surface entirely exposed for some time before the next application of water. This fills the pores of the filtering material with air and the water next filtered is brought in contact with this air. The oxidizing action of an intermittent filter is similar to the oxidizing action of an intermittent filter or sprinkling filter which is used for treating sewage.

Intermittent filters are used for treating badly smelling waters, especially from shallow reservoirs and reservoirs that have at times high temperatures, as in the tropics. Such waters may contain large quantities of organic matter and be incapable of being filtered satisfactorily by either mechanical filters or sand filters of the ordinary type. The rate of filtration depends upon the amount of organic matter in the water, and may be from 3 to 6 million gallons per acre per day. Cleaning the sand is done by the same methods as those used for sand filters.

DISTRIBUTION OF WATER

16. Systems of Distribution

A Waterworks System must secure its supply when and where it can be gotten, and must deliver it when and where required by its customers, or "takers." Waterworks structures are required to collect the water; to hold it from times when it is available until it is required; to pump it to a higher elevation; to convey it from the point where it is available to the points where it is required, and to allow the water to be measured and controlled at all points. Water is required by the takers at very unequal rates, following the requirements and emergencies that arise in their business or domestic uses, and the fundamental requirement controlling the design of works is to secure the ability to supply water wherever and whenever required and in whatever reasonable amounts may be needed.

The Distribution System includes all the main pipes and lateral pipes, the standpipes and distributing reservoirs, gates, meters, all services and connections as far as owned by the water department within and near the area that is actually served with water. The piping in a distribution system must be designed so that water can be supplied to any point at any time at the greatest rate at which water may be fairly demanded at that place.

Gridiron System. This is a system in which all pipes are connected with all other pipes at street intersections, so that in case of a fire at any point water comes to that point through pipes from all directions. This arrangement is more advantageous in supplying water for fire protection than the branching system, which would be sufficient and often best for supplying water for all purposes except fire service. The gridiron system is practically universal in American cities.

An economical system for the distribution of water for routine uses only would consist of a system of branching pipes, each branch being made sufficiently large to supply the water to the territory served by it at the time of day when use is greatest.

High-service Systems. Where there are considerable parts of a city where the ground is high, so that the service and pressure used in most of the area do not suffice to supply them properly, it is common to cut them off and make special high-service systems for them. Each high-service system has its own distribution and distributing reservoir (or else direct pumping), and it is to be considered as if it were an entirely separate system of waterworks. Water is commonly taken from the low-service mains, and those mains must be large enough to supply the high service water in addition to their other functions. In all other respects they may be treated as if the high service did not exist. In nearly all cases water is pumped specially into the high-service pipes.

The Direct Pumping System is used in the middle states and in general wherever the ground is flat. With it there is no distributing reservoir, but water is pumped into the pipes at all times as needed. Pumps of special design are required for this service. When but little water is used the pump must go slowly and automatic regulators must close the throttle so that it will not go too fast and increase the pressure. When water is to be used rapidly the pump must increase its speed and deliver the increased volume of water at full pressure.

Pumps operating on this system are not as efficient as pumps operating at constant speed with a distributing reservoir connected with the system. The pumps must have much greater capacity than where there is a distributing reservoir. The capacity of the pumps must always be equal to three times the average annual rate of consumption, and in small works the capacity of the pumps must be four or five or more times as great. In general the capacity of pumps must be sufficient to maintain the fire service and the domestic service at the same time. It is further good business when possible to have one pumping unit in reserve beyond this capacity.

Reservoirs with Direct Pumping. Wherever the water is filtered or ground water obtained there is a limit to the rate at which pure water can be provided in emergency, and it is commonly necessary to have water during large fires at a greater rate than can be furnished by the filters or wells. To meet this condition pure-water reservoirs at the pumping stations are provided. The size of reservoir is to be determined by the same considerations that determine the size of an elevated distributing reservoir. With a reservoir of this kind kept ordinarily full or nearly full the supply works may operate at a continuous rate throughout the twenty-four hours, and there will always be a reserve of pure water that can be pumped as fast as the pumps can take it in case of fire or other emergency. Such reservoirs are always covered.

Auxiliary Fire Service Systems consist of high-pressure pumping station and pipes laid in central portions of cities where the greatest values of property subject to fire hazard are concentrated. These pipes are built to withstand pressures up to 300 lb., and are connected with hydrants of special design and painted some other color than the hydrants connected with the ordinary pipes. The pumps may be operated by gas engines, electricity, or by other power. Such systems are used only in case of fire. In case of need the pumps are started and the pressure is raised on the system to such a point that efficient fire streams are obtained by attaching lines of hose to the hydrants. No steam fire engines are used.

Salt Water is sometimes used and is believed to be more efficient in extinguishing fires than fresh water. It also results in more damage to goods and property not destroyed by fire with which it comes in contact. Otherwise water is taken from the nearest lake, river, or reservoir or from the ordinary water mains. Where auxiliary fire systems are used there is obviously less demand upon the regular supply system for fire service, and its capacity for rendering fire service may therefore be reduced somewhat. Frequently more money is spent on auxiliary fire service systems than would suffice to reinforce the regular waterworks system to the extent that good service could be obtained from it.

Increased Pressure for Fire Service is obtained in some direct pumping systems by having additional boilers kept under steam and turning on more steam when a fire alarm is sounded. By this means the pressure throughout the city is increased and hose streams are obtained from hydrants without the use of fire engines. This system is much used with direct pumping in the middle states. It is best adapted to small places. The expense of the system and the disturbance that comes to the distribution from increasing the pressure in the whole city are too great in large cities where fire alarms are sounded frequently.

17. Water Consumption

Per Capita Consumption is the amount of water used per day for each person living in the city or area supplied on the basis of the annual average figures. In other words, it is the whole quantity of water supplied in gallons in one year, divided by 365 and divided by the total population of the district supplied with water. Domestic and public purposes will usually take from 50 to 70 gal. per capita daily, a little more where water is very cheap, and a little less where it is comparatively dear. To this must be added industrial uses which include railways, shipping, etc. Industrial uses are very variable and are sometimes larger than domestic uses. In hot, arid climates much water is used for irrigation and lawn sprinkling.

Maximum Monthly Rate of Consumption. During that month in the year when the consumption is highest, from 10 to 25% more water is used than the average for the year. In some cases 40% more water is used.

High monthly rates of consumption are usually associated with either a very dry period, with more than the usual sprinkling of streets and lawns, or an exceptionally cold month, with a continued draft of water through many services to keep exposed and imperfectly protected pipes from freezing. Where services are metered the excess consumption in cold weather largely disappears. It is cheaper to cover the pipes or otherwise to protect them from freezing than to pay for the water that it is necessary to allow to run in order to protect them.

Maximum Weekly and Daily Rates. There will be some weeks and some days when the quantities will considerably exceed the average for the maximum month. Generally a maximum daily consumption of 10 or 15 gal. per capita in excess of the average for the maximum month must be expected.

Hourly Fluctuations in Flow. Water is required primarily for domestic and manufacturing purposes, and for these purposes is required in quantities that are fairly well determined and at times that do not vary very much from day to day. The greatest normal use of water is in the morning hours. The afternoon use is a little less. The night use of water is comparatively small.

Leakage goes on all the time. The ordinary range from 25% above to 25% below the average covers the fluctuations for 12 hours per day. On an

average the output will exceed 40% above the average 3 hours per day, 50% above the average 1 hour per day and 60% above the average 15 minutes per day, and 80% above the average very rarely. On Sundays and holidays the fluctuations are less than on business days. For unmetered systems the percentage fluctuations are smaller and the above figures for per cent may be used as per capita variations, i.e., 40 gal. per capita daily above the average will be exceeded 3 hours per day. Pipes for distribution with no fire service should have a capacity of 70% above the mean to meet peak loads.

Waste of Water. The amount of water that must be supplied at the source is always greater than that actually needed for use. There is leakage from the main pipes, and from the service pipes, and from a considerable percentage of the plumbing fixtures in the houses and other buildings, and water is allowed to run uselessly from many openings. It is mainly for this reason that there are such great differences in the per capita consumption in American cities.

Waste from Service Pipes. Bad plumbing and the unnecessary draft of water from fixtures are best checked by putting meters on the services and adopting a schedule of rates by which the payments of takers are dependent upon the amount of water passing through the meters. If the water that is wasted is paid for at a fair price, then the water department has no occasion to object to the waste. The waste beyond the meter becomes entirely a matter for the taker to consider.

Loss of Water by Leakage from Mains is best detected by dividing the system by closing the valves into comparatively small sections and by supplying water to each small section in rotation through a meter. Meters may be put on the mains temporarily or permanently for this purpose.

It is often possible to shut all the gates on a section and maintain the supply to it through a line of fire hose, connecting one hydrant inside the area with another hydrant outside, a meter being placed in the line of hose.

By opening and closing gates, a number of adjoining sections may be tested with the same equipment and in the course of a short time. Tests of this kind are best made between midnight and five o'clock in the morning, when the normal use of water is at a minimum and there are practically no fluctuations in the rate of draft. Such tests show the relative tightness of different parts of the system, and the lengths of pipe where the greatest leakage occurs are then to be dug up and repaired or replaced with pipes that do not leak.

Amount of Growth to be Anticipated. In designing pipe lines, it is necessary to anticipate growth to a certain extent in order to avoid the necessity of duplicating the lines at an early date. On the other hand, anticipating future growth to an unreasonable extent results in burdening present takers with the cost of facilities provided for the future to an unreasonable extent. In general, all new pipe lines should be designed to serve a population 50% greater than the present population, and in cases of special difficulty, where an additional line would be specially difficult or expensive, a greater growth than this should be anticipated.

Increasing the diameter of the pipe 1% increases the carrying capacity 2.63%, and increases the cost of the pipe from 1 to 1.5%, according to the size and class of pipe and the conditions under which it is laid. On this basis adding 1% to the investment adds from 1.75 to 2.63% to the carrying capacity, $100 invested now in increasing the size of the pipe adds as much to the capacity as from $175 to $263 invested in a new pipe line at some time in the future if the new line is of the same size as the present one. $100 invested now at 5% will amount to $175 in 11 years and $263 in 20 years; at 4% the increase will be reached in 14 years and 25 years, respectively. In general these represent economical limits of time to be anticipated.

As a general rule design should be made for ten or fifteen years only where the growth is over 3% per annum or where money is hard to get, and design for twenty or twenty-five years where growth is under 2% per annum or where money is obtainable at a low rate, and also in all cases where pipe is less than 12 in. in diameter or where pressure is light. There are many exceptions to this rule under peculiar conditions and it must be applied with caution.

18. Fire Protection

The Requirements of Fire Service vary greatly. In European cities, with fireproof buildings, but little water is required for the extinguishment of fire. In tropical countries, where buildings are widely separated and represent but small value, and often in wet climates, it does not pay to furnish fire service. It is better to let buildings burn now and then than to provide long and larger pipes and other equipment that would be required for fire service. In American cities wooden construction is common and wooden floors are used in many buildings having brick walls. A large pipe capacity is required to provide the water which is required for extinguishing fires in such buildings.

The Amount of Water required for extinguishing fires is not very large in the aggregate, but when fires occur it is wanted at a high rate, and pipes must therefore be provided of large capacity to meet this demand. Pipe sizes required for fire protection in American cities are always larger than those required for other uses, and the size of pipe to be selected within the area of the distribution system, and between it and the distributing reservoir or pumping station where direct pumping is used, is mainly controlled by questions of fire protection.

Water Required for Fire Service. The amount of water to be provided for fire service depends upon many matters; among others, the size of buildings, the materials and methods of construction; upon how near the buildings are together; the pressure at which the water is available; upon whether auxiliary fire systems are available; upon how great a loss of life and property might result from a bad fire, and upon the cost of making a given quantity of water available and the financial ability of the system or community to pay for doing it.

For Average American Conditions, take the square root of the population in thousands and this indicates the rate in millions of gallons of water per day at which water should be provided for fire service.

For example: If the population is 9 thousand allow water at a rate of 3 million gallons per day for fire service. If the population is 25 thousand allow 5 million gallons per day, and if 100 thousand allow 10 million gallons of water per day.

The pipes must be designed large enough so that the quantity of water for fire service will be available even though the fire occurs at a time when water is being used at a high rate for other purposes. It is not necessary to assume the extreme maximum rate of draft for other purposes; some chances can be taken. To find the required capacity add, first, the average annual rate of consumption; second, 40 gal. per capita to cover ordinary fluctuations; third, the amount of water allowed for fire protection.

Concentration of Water for Fire Service. In the case of cities up to 100 000 inhabitants it is generally necessary to provide pipe capacity so that the whole amount of water provided for fire protection can be delivered with some loss of pressure in the neighborhood of the closest, largest, highest and most valuable buildings, and at each of such points if there are several; elsewhere piping capable of delivering smaller quantities varying with the kind and value of construction and the proximity of the various buildings.

Population That Can Be Supplied by Pipes of Various Sizes

* Gallons daily $= 140$ pop. $+ 1\,000\,000\sqrt{\text{Pop. in thousands}}$.

† V = velocity, feet per second.

This table may be used as a very general guide. With high per capita consumption and bad fire conditions the sizes should be increased. Under opposite conditions they may be reduced. It will often pay to make pipe sizes a little smaller in the distribution and larger in the supply mains without changing the total capacity of the system.

A Standard Fire Stream is one flowing 250 gal. per minute through a smooth nozzle 1-1/8 in. in diameter, with a pressure at the base of the tip of 45 lb. Such a stream is effective to a height of 70 ft. above the ground or with a horizontal carry not exceeding 63 ft. When fed through the best quality 2-1/2-in. rubber-lined hose the hydrant pressure required to throw such a stream taken while the stream is running is as follows:

Feet of hose	= 50	100	200	400	600
Pounds per square inch	= 56	63	77	106	135

The hydrant pressure is less during the fire than at other times, because more head is lost in friction in the pipes, and the ordinary pressure must be greater to insure standard conditions during the fire. The best hydrant pressure for general use is considered to be from 80 to 100 lb., but as other conditions are frequently controlling, fire service must be largely adapted to what is available.

The best statement of the hydraulics of fire streams and nozzles is in a paper by John R. Freeman, Trans. Am. Soc. C. E., vol. 21, p. 303.

Pressure for Domestic Service Only. At the street line 20 lb. per sq. in. will raise water to the upper floor of three-story residences and allow a fair service, but generally 40 lb. per sq. in. is the least allowance for fair domestic service. For business blocks and higher buildings higher pressures are needed; 60 or 70 lb. per sq. in. is not too much to give fair service in mills and business blocks that are not especially high. High steel buildings generally pump their own water and no effort is made to supply them without such pumping.

Pressure for Fire Service. If steam fire engines are used and depended upon as in many American cities, the only requirement for pressure is that during fires and with the heaviest draft the pipes shall have sufficient capacity to supply water to the steam fire engines and at the same time retain as much pressure as is needed for domestic service. If the pressure is higher, hose streams can be obtained from the hydrants without the use of the fire engines. The additional pressure to permit this to be done is very desirable. A pressure of 70 lb. during fires is the lowest pressure that permits effective hose streams to be obtained for use on buildings of moderate size. If only residences are involved, 50 or 60 lb. will give fair streams. In business districts with large buildings better hose streams are obtained with higher pressures, and in general the higher the pressure the better the fire service. 100 lb. gives a good working service without steam fire engines. Higher pressures up to 150 lb. and more are available in some cities.

19. Reservoirs and Standpipes

Distributing Reservoirs are connected immediately with the distribution system and as near as possible to the center of population supplied. Their function is to take water when it comes and to make it available when it is needed. They are especially to maintain the service at times of fire and on other occasions when water is drawn rapidly. Frequently they also serve the purpose of allowing the pumps supplying the service to be shut down during certain hours of the day or at night, thereby economizing labor. This is especially the case in small plants. **Open reservoirs** with earth embankments or masonry walls have been frequently used. Ground waters and filtered waters always deteriorate in quality in such reservoirs, owing to the growth of certain organisms in the sunlight. **Covered reservoirs** are always to be preferred for distributing reservoirs. Roofs are sometimes used to exclude the light and keep the water from deteriorating. A light roof not necessarily water-tight serves this purpose.

Masonry Covers for distributing reservoirs are often used. At Washington, D. C., Springfield, Mass., Cleveland, Ohio, and elsewhere, groined arch construction has been used. Floors to carry the weight of the roof and distribute it over the whole base are built as inverted groined arches. The piers are of concrete, as thick as 12% of the span on centers, and not more than 12 times as high as thick. If the reservoir is deep, large piers will be required to meet this condition, and the span of the arches is increased to correspond. The roof is of groined arch vaulting without reinforcing. The outside walls, with a minimum thickness of about 12% of their height at top and 16% at bottom, are braced at the bottom by the floor blocks and at the top by the roof blocks, and are calculated as reinforced beams, with breaking moment at about 43% of the distance from the bottom to the top, equal to $4\,h^3$, h being the height of the wall in feet. In deep reservoirs economy is secured by carrying the floor on a slope of about 1 in 6 to the raised base of the walls, thereby reducing the height of the walls. The masonry is backed up by solid earth embankment, and 2 ft. of soil is placed over the top to keep frost from the masonry. Ventilators are provided to allow the passage of air as water rises and falls in the reservoir. The top is covered with grass and shrubbery, but trees or any plants with strong heavy roots should not be planted.

Overflows should invariably be provided for distributing reservoirs and should have sufficient capacity to discharge all the water that the pipes or pumps are capable of bringing to them. Many reservoirs have been lost and great damage done by failure to provide sufficient overflow capacity.

The cost of covered masonry reservoirs under conditions of 1927 in a general way would range from $15 000 to $25 000 per million gallons capacity according to size and conditions of construction, with small reservoirs costing considerably more.

Capacity of Distributing Reservoirs. With the water coming to the city through a gravity line at a steady rate, a storage of about 0.15 of one day's supply serves to balance all the fluctuations in hourly consumption, not including fire drafts. With a pumping system where all the pumping is done during the day a reservoir should hold at least one day's supply. Considerations of fire service frequently determine the size of reservoirs, so that in addition to meeting the ordinary service, drafts amounting to not more than one-quarter or one-half of a day's supply can be made to maintain full fire service for a period of two, four, eight, or some other number of hours, depending upon the size of the city and the amount of property that is to be protected.

The Elevation of distributing reservoirs is a matter of great importance, as it controls the pressure of water in the entire distribution system. Reservoirs have been generally built at levels to give necessary pressures at the time that they were built and in the district to be served. As time has gone on larger buildings and higher buildings and buildings upon higher ground have been erected, and there is demand for, and need of, more pressure than is available. This sometimes involves the abandonment of old reservoirs and the construction of newer ones at higher levels. Abandonment of distributing reservoirs because of insufficient elevation has been common.

Standpipes are elevated reservoirs built of sheet steel entirely above the surface of the ground, and are commonly used where the desired water level is a considerable distance above the surface of the ground. The limitations of steel construction do not in general allow standpipes to be used in large works. Roofs should be provided on all standpipes holding waters deteriorating in the sunshine, that is, in general, for ground waters and filtered waters.

Reinforced concrete standpipes have been used, but it has been found hard to keep them in good order under frost action. Towers of masonry are frequently built about standpipes for ornamental purposes, and to protect them from wind pressure, and to make very tall standpipes small in diameter safe.

Elevated steel tanks with spherical bottoms, supported on steel trestles, have largely displaced standpipes in recent years. They have the advantage that the whole of the water is available and that, for the same effective storage, the weight on the foundation is less. The East Providence, R. I., tank holding one million gallons with a flow line 205 ft. above the ground built in 1904 was the first of a great number of such tanks. The largest tank of this kind at Charleston, S. C., holds two million gallons, with a flow line 115 ft. above the ground.

The accompanying table shows dimensions and relative costs of a number of sizes.

The ratio of height to diameter may be varied within limits. A shallower tank of larger diameter maintains pressure better as water is drawn, but will usually cost a little more. The figures for cost are intended to give relative costs for tanks erected, including foundations on average hard soil at current prices in 1927, the steel work alone costing about 8 cents a pound.

Wooden tanks are frequently used in railway supplies and in industrial operations, but are seldom to be recommended for public water supply.

20. Cast-Iron Pipes

Cast-iron pipe is one of the oldest and most generally used materials in waterworks construction. It is made in lengths of 12 ft., but the smallest sizes are also made in lengths of 16 ft. and 16.4 ft., the latter being 5 meters on the metric system.

At present it is mainly used in sizes from 6 in. to 36 in. Four-in. pipe is now little used, and sizes above 36-in. under pressure in city streets are too hazardous because of the great damage that results from sudden breakage. Designs and specifications have been adopted by the American Water Works Association for four classes of pipe, called A, B, C and D, intended to serve working pressures up to 100, 200, 300 and 400 ft., respectively. Actually the smaller sizes of each class are tougher and stronger than the larger ones. In practice, B pipe is commonly used from 6 in. to 20 in. or 24 in., and C pipe for the larger sizes to 36 in. Each length of pipe is tested in the foundry under a pressure far above working pressure, but this does not prevent a small percentage of pipes from breaking in service.

Among the common causes of breakage are the weight of fill over the pipe, settlement, unequal support, unbalanced pressures at bends and temperature changes. The jar from a passing heavily loaded truck may be the last straw. Breaks are nost common where there are rocks, large boulders or other unyielding substances in the material under and near the pipe, and are less frequent in soils of clay and even grained sand which yield slightly under pressure.

The weight of the earth above the pipe results in pressures and stresses, that can be avoided only in part by careful backfilling. In deep cuts and other difficult places large pipe of any kind should be surrounded with concrete.

Coating. Cast-iron pipe is usually coated by dipping in coal tar at a temperature of about 300° F. Redistilled coal tar of good quality is to be used. With continued heating it loses its more volatile parts and becomes brittle. To prevent this a heavy oil obtained in the distillation of the tar is added to the dipping tank from time to time.

Cement-lined Pipe is cast-iron pipe lined with a layer of cement mortar which is poured soft into the rapidly revolving pipe in which it distributes it-

self before it hardens. The cement layer should not be too thin, usually not less than 1/4 in. Natural cement alone, or mixed with portland, seems to have an advantage over portland cement for this purpose. Because of the greater smoothness of the cement lining there is no loss in capacity even as compared with new unlined pipe. Such pipes are not subject to corrosion and retain their carrying capacity better than tar-dipped pipe.

Pipe is now being made and sold with thinner linings, and the manufacturers report difficulty in getting lining as thick as 1/4 in. that will not crack. Very thin lining is undesirable from the standpoint of permanency. Linings from 1/4 in. to 1/2 in. thick have been successfully used in some jobs.

Delavaud or **centrifugal** pipe is made of cast iron distributed by special machine on the interior of a rapidly revolving mold so that the material is spun as it solidifies into a pipe. The unit strength of the material is greater than of ordinary cast iron and the pipe walls are thinner. The outside diameter is made of standard dimensions. Such pipe is sold by the foot and the cost at present is about the same as ordinary cast-iron pipe.

Depth of Cover. In the latitude of New York and Philadelphia pipe is laid with a cover of about 4 ft. of earth, but large pipe, that is, pipe 2 ft. in diameter and over, may be safely laid with a little less cover than smaller pipe. In the latitude of Boston, Albany and Chicago the depth of cover is increased to 4-1/2 or 5 ft. Further north still greater depths of cover are required. In the latitude of North Carolina and south it is only necessary to give the pipes sufficient cover so that they will not become exposed in the street, or, in other words, to protect them from physical injury aside from frost. In city streets a minimum depth of 30 or 36 in. is recommended in all warm climates. Shallower pipes are broken by excavation and traffic in city streets. In countries where there is no frost main pipes outside the city are sometimes laid on top of the surface of the ground. In other cases they are just covered with soil.

The former arrangement leaves them open to inspection for leakage. The latter arrangement protects them against excessive heat. The cost of pipe laying is greater as the cover is greater.

Cost of Cast-iron Pipe. Cast-iron pipe is sold by the net ton. The maker guarantees the weight. Pipes underrunning the standard weight by more than a certain percentage (the percentage depending upon the diameter and class of pipe) are rejected, and pipes overrunning the standard weight by more than a certain percentage are accepted, but the weight beyond the allowed excess is not paid for. From 1875 to 1909 the price of cast-iron pipe in the northeastern states ranged from $17 to $35 per net ton. The average price was not far from $25, and this was approximately the selling price in 1909. Prices of over $30 per ton ruled in 1875, 1880, 1883, 1884, and 1907. Prices under $20 ruled from 1895 to 1898 inclusive. In 1917 to 1926, the ordinary range was between $50 and $70 per ton. In 1927 it fell somewhat and $40 is a representative figure. Current quotations should be consulted in the engineering papers.

Maximum Bends in Cast-Iron Pipe Joints

Size of pipe in inches	Bend in one joint	Deflection of 12-ft. length, in inches	Approximate radius in feet of curve produced by succession of joints
4	4°	10.0	170
12	3°	7.5	230
16	2° 41′	6.8	260
20	2° 9′	5.4	320
24	1° 47′	4.5	390
30	1° 26′	3.6	480
36	1° 12′	3.0	570
42	1° 2′	2.6	660
48	0° 55′	2.3	750

Special bends are used for shorter curves than those in the table. Specials are all castings other than straight pipe in 12-ft. lengths. Bends, reducers, increasers, crosses, tees, branches, are some of the common forms of specials. Standard designs and weights for all the more frequently used specials have been adopted by the New England Water Works Association and the American Water Works Association.

The weight of specials in long lines of supply pipe in the country is less than 1% of the weight of the pipe. In the distribution system in villages and small cities the weight of the specials will average 2-1/2% of the weight of the pipe. In city work, with short blocks and many obstacles to be passed, specials will average 4% of the weight of the pipe.

Specials cost twice as much per pound as straight pipe, or a little more.

Joints in cast-iron pipe were formerly made with lead and this still remains an important joint material. The following table shows proper dimensions and weight of lead joints. The lead is melted and poured into the joint between temporary gaskets and is then calked with a tool to take up the shrinkage of the material as it solidifies. The effect of the calking only extends a short distance; and that part of the joint depended on for tightness is not more than 1/2 in. deep. Back and forth temperature movements will loosen this in time and result in small leakages.

Joints are made deeper where the pressure is high, and not so deep where it is light. Workmen often make the joints heavier or lighter than specified. Some lead is oxidized in melting and pouring, and otherwise wasted and lost. Variations in the diameter of bell and spigot make a difference in the amount of lead. A small fraction of an inch variation makes a large percentage difference in the amount of lead required. For good management find out how much lead is required, and require inspectors to hold the dimensions of bells and spigots to the design, and the workmen in the trench to the depth of joint required, and investigate closely any large discrepancy between the computed and required amounts of lead.

Amount of Lead Required for Joints

Dimensions in inches				Lead required, pounds per joint

36	D	1.58	625	7500	18.28	19.24	20.88	23.78

A lead joint tight for its whole depth and therefore more reliable and free from leakage may be made by calking lead wool into the joint with a pneumatic tool in thin layers. The cost is greater and such joints are used only in places of special difficulty.

Leadite and Lead-Hydrotite are proprietary mixtures, of which sulfur is the most important element, and are often used in place of lead. They are cheaper and do not require calking. The joints leak slightly when first made but later become tight.

Cement Joints are widely used, especially on the Pacific Coast and their use is extending in Texas, Florida and elsewhere. They are cheap and satisfactory and when well made remain permanently tight. Ordinary portland cement is mixed with very little water and calked in layers with a tool, as hard as lead is calked. Pipes laid with cement or leadite joints may be stiffer than pipe laid with lead joints, but extended experience shows sufficient flexibility to meet practical conditions.

Leakage in pipe should always be tested under full working pressure. If it is practicable to hold the trench open so long it is best to make the test before the trench is backfilled, and to calk all joints showing leakage until they are tight. It is impossible to keep lines of cast-iron pipes permanently tight. The expansion and contraction from temperature changes are accompanied by a slight slipping of the lead on the iron at each joint; settlements cause movements in the joints.

With well-tested work under average conditions in a waterworks system a leakage of three gallons per 24 hours per lineal foot of lead joint under a pressure of 100 lb. per square inch may be anticipated. On this basis the leakage per thousand feet of pipe in gallons per 24 hours will be as follows:

Inches diam..	6	8	10	12	16	20	24	30	36	48
Gallons......	500	650	775	900	1200	1500	1800	2200	2600	3400

Lines of pipe when first laid should have less leakage, and those that have been down for many years may be expected to leak more. It will pay to dig up pipe and calk joints whenever and as far as the value of water saved during an assumed period of five years exceeds the cost of locating and stopping the leakage.

Cost of Cast-iron Pipe Laid. The table in this section shows the approximate cost of pipe of all the sizes and thicknesses in most common use, laid under average conditions. These prices include the cost of the pipe, specials, lead, and all costs of laying, assuming 3% of the trench rock excavation; pipe $40 per ton and labor 50 cents per hour. The column for country work may be used for outside pipe lines where there is no special difficulty. The column for village and suburban work includes taking up and replacing oiled macadam pavements. The column for city conditions includes taking up and replacing concrete or asphalt pavements.

In Congested Districts of cities where there are many existing pipes, conduits, sewers, and other structures to be met and passed, the cost per foot may be increased very greatly above the figures given, which are intended to cover only ordinary city conditions. Many local conditions affect the cost of the work, and prices fluctuate, and the costs will often be found differing considerably from those given, which are intended to represent average conditions, and to show approximately the relative cost of pipe of different sizes and the thicknesses under ordinary conditions of use.

21. Steel Pipes

Steel pipe is used principally in long supply mains, leading from the source of supply to the city. It is not generally adapted to use in city streets or in the distribution system.

Steel pipe is generally cheaper than cast-iron pipe in sizes 36 in. in diameter and upward. It has occasionally been used for 30-in. pipe and is seldom to be recommended for smaller sizes.

Riveted Pipe. The older lines of steel pipe were all riveted. Generally the sheets of steel are 7 ft. or 8 ft. wide, and are bent so that one sheet goes entirely around, forming one section of pipe. Four of these sheets are riveted together in the shop, making a length of pipe 28 to 30 ft. long. This is tested for tightness and dipped in protective coating, and then shipped to the place where it is to be used.

The circular seams may be single riveted. The longitudinal seams which alone are required to carry the stress due to the pressure of the water are double riveted, in all cases, except where the pressure is very low.

In-and-out courses are used, alternate rings being larger and smaller. **Taper lengths** are also used in which one end of each pipe is smaller than the other end and will slip into the large end of the next length. Pipes have also been made with all the lengths the same size fastened together with butt straps on the outside, but as this is a more expensive method it has not been often used.

Lead Joints have been used in Australia on long lines at Coolgardie and Sydney. Cast-iron or steel sleeves are used in making them. The lead acts as an expansion joint and each length of pipe is free to expand and contract with the temperature changes, the steel slipping over the lead to permit this.

Continuous Riveting has been used in nearly all American steel pipe lines; that is, each length of pipe in the field has been tightly riveted to its neighbors. Practical experience with the system of construction has been satisfactory.

Temperature Stresses. Under conditions in the northern states the temperature of water and consequently of the pipe will range from 32 to 75 or 80° F., or for average conditions the range is about 45°. The pipe must be held so that it will not move with expansion and contraction. Under these con-

ditions the change in temperature, which tends to expand or contract the pipe, uses all its force in putting it under stress. The stresses thus produced may range from nothing at the low temperature to the maximum amount in compression at the higher temperature, or from nothing at the higher temperature to the maximum amount in tension of the lower temperature, or they may be divided, coming partly in tension at the lower temperature and partly in compression at the higher temperature. This depends on the temperature at which the pipe is laid and finally connected up. Under the most unfavorable conditions the stresses produced by temperature in this climate are about 9000 lb. per sq. in., and as this comes well within the strength of the steel no difficulty is occasioned by them. Ordinarily they are less than this.

Anchorages are built to keep the pipe from moving at all free ends and at all sharp bends. These anchorages are formed by riveting angle irons to the steel pipe, usually four angles being attached to one 30-ft. length, with a sufficient number of rivets to hold the temperature stresses, and these lengths of pipe are surrounded with concrete reinforced with steel rails of such a shape as to be capable of withstanding the computed amount of stress. In some lines anchorages have been omitted and expansion joints provided at all gates, ends, and other places when continuity of riveted connection cannot be maintained. The temperature push or pull on the anchorage in tons of 2000 lb. for steel pipes of various diameters and thicknesses is shown in the last column of the preceding table.

Gates and Steel Pipes. Flanged gates are usually considerably smaller in diameter than the pipe (Sect. 7, p. 693) and are bolted on one side directly to a flange on the steel pipe and on the other to a nipple connected with the steel pipe through a sleeve with lead joints. In this way the gate is protected from temperature stresses of the steel pipe, and on the other hand is held from being moved by unbalanced water pressure as is the case where lead joints are used on both sides. It is usual to build anchorages on the steel pipe on either side of gates or otherwise the two ends of the steel pipe may be held from movement by an enclosing steel and concrete structure.

Lock-bar Steel Pipe is made by upsetting the edges of the plates and connecting them by a lock bar in the shape of an H going over the opposite edges and being forced down over them by hydraulic pressure. This takes the place of the riveting in the longitudinal joints. The circular joints may be made by riveting or otherwise as for riveted pipe. While double riveting develops only about 72% of the strength of the steel plate, the lock bar is capable of developing 100%. Owing to occasional defects in material or workmanship on the lock bars, in making calculations it is recommended that only 90% of the strength of the plate should be used for lock-bar pipe. Two sheets of steel each 30 ft. long are joined with two bars at their edges to make a 30-ft. length of pipe. The circular joints between these lengths are usually riveted in the field. Thus far lock-bar pipe has been made from plates ranging from 1/4 to 7/16 in. in thickness.

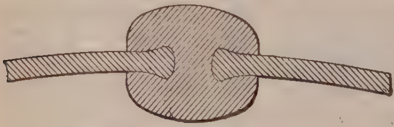

Fig. 13. Lock Bar for Steel Pipe

Welded Steel Pipe has been made possible by the progress in welding in recent years, and its use is extending. The greatest problem is to make a weld without changing the temper of the steel resulting in brittle material in the space between the heated metal in the weld and the cold metal a short distance from it.

Carrying Capacity of Steel Pipe. The steel sheets are much smoother than the interior surface of cast-iron pipe; and for this reason lock-bar steel pipe is found to carry appreciably more water than cast-iron pipe. Welded pipe is believed to be equivalent to lock-bar pipe. In riveted pipe the projecting rivets and rough edges at the joints increase the resistance. To make it comparable with other kinds of pipe the diameter must be increased by at least 4%.

The Diameter of Steel Pipe, either riveted or lock-bar, can be made of any required dimension. In this respect it differs from cast-iron pipe, which is commonly made only of the sizes for which the foundries have molds. The diameter should always be specified as the smallest diameter of the smallest ring, where the rings are not all of the same size.

Weight of Steel Pipe. The finished weight of steel pipe per lineal foot, either riveted or lock-bar, including the excess weight of plates rolled so that the thinnest points in the plate will be approximately of the nominal thickness, and including the laps, rivets and lock bars, material in the joints and coating, may be found approximately by the formula:

$$\text{Weight in pounds per foot} = (12.5 \times \text{diameter} \times \text{thickness}) + 10 \text{ lb.}$$

in which diameter and thickness are to be taken in inches. The weights of commonly used sizes are given in the table in this section. Welded pipe is not quite as heavy.

Thickness of Steel Pipe. The required thickness is computed by

$$\textbf{Thickness in inches} = \frac{\textbf{Diameter in inches} \times \textbf{pounds pressure}}{\mathbf{2 \times 16\,000} \times \textbf{efficiency of joint}}$$

To the thickness thus computed it is customary to add something as an allowance for weakening of pipe by corrosion. In other words, make the pipe heavier so that it may rust to a certain extent and still have needed strength. The strength of the metal with open-hearth steel under standard specifications is taken at 16 000 lb. per sq. in., which allows a factor of safety of about 3-1/2. The efficiency of the joint may be taken at 55% for single-riveted pipe, 72% for double-riveted pipe, with the best spacing of rivets, and at 90% for lock-bar pipe. Welded pipe should be as strong as lock-bar pipe.

In the steel-pipe table in this section are entered under lock-bar pipe and double-riveted pipe separately, first, the gross pressures, in pounds per square inch, that can be carried by pipe of various dimensions without making deduction for water ram and for deterioration, and second, the fair safe working pressures after making reasonable allowances for water ram and corrosion under average conditions.

Proper allowances for water ram and for corrosion necessarily vary with local conditions. Generally speaking, where great variations in rates of flow are to be expected and where a great deal depends upon the continuous service of a pipe, thicker pipe should be used, while under conditions of steady flow and where pipes are in duplicate or otherwise safeguarded thinner pipe may be used.

Depth of Cover for Steel Pipe must not be excessive or the weight of the earth will flatten and deform it. A slight flattening is **not** objectionable, as it does not cause the pipe to leak and does not greatly reduce its carrying capacity.

The table, in this section, shows the greatest depth that should be placed over various sizes and thicknesses of pipe under average conditions. In bad trenches and slippery material keep the depth of cover somewhat less than indicated. With firm material carefully placed around the pipe and well rammed on the sides a somewhat greater depth of cover for short distances may be permitted. If it is necessary to cover the thin pipe to a greater depth it may be stiffened by angle irons riveted to it at frequent intervals. A more substantial result is obtained by surrounding the pipe with concrete.

Cost of Steel Pipe. The relative cost of steel pipe laid complete under average conditions is shown in the table, p. 1505. The costs represent generally those in the northeastern states in the years 1925-27. They include pipe excavation and average amount of water in trench, and of rock excavation, anchorages, brook crossings, etc., but do not include river crossings or special and unusual obstacles or difficult conditions. Steel pipe has often been placed under contract at a price per foot laid, including the pipe and laying, but rock, valves, river crossings, and all other auxiliary works are usually paid for separately.

Bends in Steel Pipe are usually made by cutting off some of the plates at the joint. Both horizontal and vertical bends are made in the same way. It is easier to lay out the work if the horizontal and vertical bends are made in separate joints, but in case of need they can be combined.

The amount of bend that can be made in one joint depends upon the size and thickness of the plate. With 5/16-in. plates bends up to 5° in one joint are easily made; with 3/8-in. plates 4°, and with 7/16-in. plates 3°. Sharper bends are made when necessary but it is harder to calk them tight. With crooked lines the lengths of pipe may be cut, one bend made every 15 ft. or every 7-1/2 ft. With sharper bends special arrangements are made.

It is better to make all bends in steel pipe of steel plates riveted up, rather than of castings, and in case of sharp bends the pipe should be anchored on both sides, to carry the resultants of the temperature stresses.

Cement Lining in Steel Pipe. Steel pipe has been sometimes lined with cement mortar 2 in. thick or less to insure permanence. Where this is to be used the pipe has usually been surrounded with concrete on the outside for stiffness.

Coatings for Steel Pipe are more important than coatings for cast-iron pipe, because the steel is thinner and if unprotected may rust through more quickly. **Asphalt** was used for some of the earlier lines. Asphalt is entirely stable in a dry atmosphere, but it is quickly oxidized and becomes brittle when kept under water. Asphalt coating on steel pipe has actually become brittle and pulverized and has ceased to act as a protective coating in periods usually not exceeding ten years. Coatings made from the residues from the distillation of petroleum have frequently been sold as asphalts. **Redistilled coal tar** used on cast-iron pipe has usually been more durable than the asphalts and special preparations used on the earlier steel pipes. Part of the Rochester pipe line, 1893, was dipped in equal parts of coal tar and asphalt. At Springfield, the 42-in. pipe line, 1909, was dipped in coal tar alone.

The Life of steel pipe seems to be limited in general by perforations of the plate which start with imperfections in the steel and first show after a considerable number of years.

External Corrosion of Steel Pipe. Occasionally soil conditions are found that corrode steel pipe. Where sea water penetrates the soil in which the pipe is laid corrosion must always be anticipated. Corrosive conditions may not be apparent as the pipe is laid, but become known long afterward when the pipe begins to leak. They are not common and are usually localized in peaty areas or where there is corrosive mineral matter in the soil.

Leaks in Steel Pipe. When steel pipe is corroded either naturally or by electrolysis, the result is a small hole or perforation in the pipe. If the pipe is under moderate pressure there will be a small leakage through this hole which may go on unnoticed for a long time. If the pressure is high and the pipe is surrounded with soil containing gritty material, an eddy will be formed on the outside that will rapidly enlarge the hole after a material flow is established. Such perforations are usually stopped without shutting off the water pressure by first driving in a wooden plug and afterward covering with a steel cap with a gasket held by a hoop extending around the pipe and drawn up by a turnbuckle. Recently electric welding has replaced the hoop and turnbuckle. In a few cases it has been necessary to dig up lengths of old pipes in corrosive ground and repair them in this way or replace them. Where such conditions exist the pipe should be surrounded with concrete or otherwise adequately protected from external corrosion.

Concrete Pipe. Concrete pipe made by the Lock Joint Pipe Company coming into use in recent years is in many respects similar to cement pipe that became common about 1870. In the modern pipe a shell of steel welded to bells and spigots at its ends is lined and surrounded with reinforced concrete. The reinforcing in the concrete is planned to carry its share, often the largest part, of the pressure. The steel drum is depended on for tightness. The cement lining on the interior is relied on for durability and smoothness. Such pipe is usually made near the place where it is to be used, but cast in standard molds and with equipment furnished by the manufacturers. Such pipe is used only in large sizes, generally 24-in. and over. For very low heads the steel shell is generally omitted.

Wood-stave Pipe. Wood was one of the earliest materials used for water pipes. Old methods limited its usefulness, and other materials have largely superseded it. Recently methods of manufacture have been developed and it is again finding increased use. It has been largely used in cantonments for somewhat temporary service under war conditions. Decay is less rapid in pipe laid in impervious soil and under pressure that tends to keep the wood constantly saturated with moisture. If laid in loose ground, or in any situation which permits the material of the pipe to become dry at times, it will rot.

Wood pipe may be either " machine made," in sections running up to 20 ft. or more in length, shipped to the work to lay; or "continuous," built up of staves and banded in the trench. Tightness in the longitudinal joints is secured by grooves and beads on the edges of the staves, pinched into tight contact by the bands. Tightness in transverse joints is obtained by the use of metal plates set into the joints. Properly built and placed, wood-stave pipe gives good service at moderate pressure within the elastic limit of the bands.

For small sizes, up to 24 in. machine-made pipe is usually used. For larger sizes the pipe is built continuously in the trench.

Wood-stave pipe will carry as much water as cast-iron pipe when new and as it is not subject to tuberculation, when old, it will carry more than iron or steel pipe of equal age.

Pressure Tunnels. There comes a time in the growth of a large city when it is difficult to lay enough pipes in congested streets to meet growing demands. Under New York City a concrete lined pressure tunnel, varying from 15 ft. to 11 ft. in finished diameter, has been driven deep in the rock under the entire length of the city connected with the main pipes at intervals and taking the place of an enormous extension of the pipe system. A duplicate tunnel in sizes up to 21 ft. is being planned for early construction. Similar tunnels have been proposed for several other cities.

22. Gates and Gate Valves

Gate Valves are placed at intervals on all pipe lines of considerable length. In city streets four are placed at each intersection, one on each line of pipe. Outside the city valves are placed less frequently, and are best placed on summits where the pressure is least. The gates serve the purpose of facilitating tests of the pipe and shutting off portions of it for repairs in case of emergency.

Gates Smaller than the Pipe are often used on pipes 30 in. in diameter and over, connection being made by reducers on either side. The cost is less and the smaller gates are operated more quickly and easily. There is a little head lost, and the smaller the gate the more head is lost. This is controlling in determining how much smaller than the pipe it is best to make the gates.

Loss of Head in Gates with Taper Cone Connections

Diameter of gate, in.	Diameter of pipe in inches						
	30	36	42	48	54	60	72
20	1.57	3.47	6.59	......	......	......	......
24	0.65	1.57	3.07	5.40	8.72	......	......
30	0.15	0.52	1.14	2.09	3.47	5.40	11.45
36	......	0.15	0.44	0.91	1.57	2.51	5.40
42	......	......	0.15	0.40	0.75	1.25	2.83
48	......	......	......	0.15	0.35	0.65	1.57

The figures given are in velocity heads (or in feet, when the velocity in the main pipe is 8.03 ft. per sec.). They may also be taken as tenths of feet when the velocity in the main pipe is 2.54 ft. per sec.

Basis. Loss of head in a gate, 0.15 velocity head. Loss of head in cones, 0.20 of the amount that the velocity head at the throat is greater than the velocity head in the pipe.

The actual amount of head lost in a gate depends upon the form of gate, and considerable variations are to be anticipated with gates of different designs. The amount lost in the cones depends upon the taper design and smoothness of the surfaces, and considerable variations either way are to be anticipated.

Generally 24-in. gates may be used on 30-in. and 36-in. pipes, 30-in. gates on 42-in. and 48-in. pipes, and 36-in. gates on 60-in. and 72-in. pipes; but if head or elevation is very valuable the gate should be one size larger than above indicated.

The Cost of Standard Double Disk Gates with bronze working parts of the best and most permanent design varies with market conditions. The following are given as relative representative prices, including gears where needed, but not including by-passes. These prices are not very different from those which ruled in fair-sized contracts in the year 1927.

Connections and Accessories of Gates. Gates are furnished with either flange or bell ends at about the same cost. Bell ends are generally used in pipe lines in street work; flange connections are used in gatehouses, pumping stations, and about filter plants. **Gate Boxes** are metallic boxes covering the wrench connection and gate, extending to the surface of the ground, with an expansion joint to protect them from damage by frost and with a removable cover to allow the gate to be opened from the surface with a suitable wrench by removing the cover.

Manholes of masonry are often built about gates of special importance, large gates, and gates operated by gears, especially when located under pavements or in other places not easily accessible. It is not necessary to build

Cost of Double Disk Gates

* Geared.

such manholes about small gates nor about gates on supply mains outside the city, because such gates can be readily and cheaply dug up in the infrequent cases of access to them being necessary.

Gears are used on large gates and gates under heavy pressure. In general 36-in. gates, 10 lb. per sq. in. working pressure; 30-in. gates, 50 lb. per sq. in. working pressure; and 20-in. gates, 150 lb. per sq. in. working pressure, are the smallest gates to be geared. **Spur gears** are used on gates set vertically and opening upward, and **beveled gears** on gates set horizontally and opening sideways. The latter are to be used wherever the vertical space is not sufficient to put in the spur-geared gates.

By-passes are provided in many cases on large gates operating under heavy pressures. These are built into and form part of the main gate. A small gate on the by-pass is opened to equalize the pressures in the pipe on either side of the gate before the main gate is opened. This allows the main gate to be opened with less effort than would otherwise be required.

Hydraulically Operated Gates in which the screws of the ordinary gate are omitted, have hydraulic cylinders provided with plungers attached directly to the moving parts. A small control valve allows high-pressure water to act on one side or the other of the plunger, opening and closing the gate. The cost is about twice that of ordinary gates. Gates should not be placed where they cannot be inspected and tested and kept in good order. They are especially useful for gates that have to be opened and closed frequently in pumping stations and about filter plants. Oil may be used in place of water in such gates. The oil is pumped by small electrically operated pumps in a closed system and no outside storage is required. Pressures may be higher and the cylinders and working parts correspondingly smaller and less expensive than those designed for ordinary water pressure. Such equipment is not frozen.

Counter-weights provided for large gates placed vertically facilitate operation and prevent the danger of accidental closing of an open gate.

Electrically Operated Gates are furnished with electric motors, geared to the working parts. They must be provided with reliable equipment to shut off the current before the gate reaches the end of the run to prevent jamming. Good automatic equipment has been developed, and such gates have advantages for throttling when frequent small changes in position are required.

Butterfly Gates open like a damper turning on a shaft running through the middle of the pipe. They are made in large sizes and designs have been perfected that close almost watertight. There is great variety in the design of large gates and much special equipment has been built.

Gates for Throttling Rapid Flow. When a gate controls the flow of water into a masonry chamber, iron pipe or other enclosed passage, and when the velocities of discharge correspond to heads above atmospheric pressure, there develops a condition of chattering or making and breaking of vacuum with vibrations that rapidly destroy both the gate and the chamber walls below it. The best remedy is to secure ventilation by giving ample independent air passages terminating below the gate and extending upward to the open air above the highest water level.

Sluice Gates are of simpler construction, arranged for being built into masonry of reservoirs and other structures, and for holding water against moderate heads only. There is great variety in the design of sluice gates. They are usually cheaper than standard gates, and for the services to which they are adapted are fully as satisfactory.

23. Auxiliaries

Air Valves are small valves attached to pipes for the purpose of automatically letting out air. They are placed on summits only. Automatic air valves need only to be placed on summits of cast-iron pipe lines where the pressure is light and variable, that is, on summits nearly up to the hydraulic grade line. On all summits where the water is under considerable pressure it is sufficient to put on a petcock or a larger valve to be opened while the pipe is being filled and which can be closed at all other times. As air is more soluble in water under pressure there is no danger of the separation of air at summits under considerable pressure, and should air be accidentally introduced to them it would be slowly dissolved and removed by the passing water. As a general rule air valves with a diameter of one inch for each foot in diameter of the water pipe are sufficient. The air valves must be protected from frost by specially constructed housing to insure their being in readiness to act in winter.

For Steel Pipe air valves are also required to let air into the pipe rapidly in case of need, as the pipe is not strong enough to support itself against outside pressure with a vacuum in the inside. A break in a pipe at a low point, allowing the water to run out rapidly, would cause a vacuum in higher parts of the pipe, which would cause the pipe to collapse. Consideration of this feature has led to placing air valves for automatically admitting air on summits of steel pipe. Generally the air valve for this purpose should have a net area equal to one sixty-fourth the area of the pipe.

Air valves are to be insisted upon in all steel-pipe lines, but it must be remembered that they are called upon to act very rarely indeed, and for this reason a defective valve or arrangement may be used without the discovery being made that it is defective, and the fact that a simpler or cheaper type of air valve has been used in certain cases where there have been no breaks and consequently no demand that has taxed its capacity is not to be taken as an indication of the sufficiency of that particular design.

Blow-offs are small pipes attached at low points for the purpose of drawing off and wasting the water contained in the pipe during times of inspection and repair. Blow-offs are usually much smaller in diameter than the main pipe. The necessity of blow-offs depends upon the character of the water and the service of the pipe.

Manholes consisting of saddles attached to the pipe and removable covers capable of being bolted securely to the frame are placed on steel pipes at distances ranging from 1000 to 2000 ft. apart, to allow the pipe to be entered during construction and afterward for inspection and repair. In some cases manholes have been placed on cast-iron pipes, although most lines have been built without them.

Twin Lines of pipe are used in places of special danger. Either line will maintain at least a partial supply in case of break in the other. In case twin lines are long, there should be cross connections with gates so that in case of a break in either line a section only can be cut out, the flow at other points continuing through both lines. With this arrangement, the amount of water flowing through the system will be more than would flow through one line only.

The Cost of Twin Lines with cross connections is from 30 to 50% greater than the cost of a single line of pipe of the same strength and capacity. Where no other purpose than safety is secured by dividing the flow, it is generally better to spend the added money, or a part of it, in strengthening one line and making it secure beyond question rather than dividing it between two smaller lines. River crossings, lines over coal fields, where there are sure to be settlements, and other points of special hazard are best crossed with twin lines. Three lines of pipe cost from 60 to 80% more than one line of equal strength and capacity.

Tubercles in Cast-iron Pipe. The carrying capacity of cast-iron pipe is reduced in course of time by the growth of tubercles upon the interior of the pipe. In a general way the capacity of the pipe, other things being equal, is reduced from this cause by as much as one per cent per annum. In small pipes the deterioration is more rapid. Generally the deterioration is less rapid with clear lake waters and more rapid with turbid river waters, and especially waters carrying organic matter. Filtered river waters act more nearly like lake waters.

Tubercles can be removed by sending an instrument driven by the water pressure through the pipe. This instrument is called a "go-devil." Scraping off the tubercles in this way increases the carrying capacity of the pipe. After the pipe has been scraped tubercles grow more rapidly than before, so that the remedy is a temporary and not a permanent one. When the pipe is once scraped it is usually necessary to scrape it again, and the process becomes an annual one, or the period may be even shorter.

Effect of Cleaning upon the Quality of the Water. The corrosion and tuberculation of iron pipes always adds iron to the water, and this iron gives it a color, tends to deposit, and is objectionable. Scraping the pipes frequently increases the rate of tuberculation and increases whatever objection there may be to the iron in the water from this source.

Hydrants are attached to pipes in a distribution system to allow water to be drawn for fire purposes. Hydrants have 4-in. connections to allow them to be connected with steam fire engines and 2-1/2-in. connections for hose connections. A hydrant having one 4-in. and two 2-1/2-in. connections is a common arrangement. The water is commonly shut off from the hydrant by a 6-in. gate valve at the bottom; closing this shuts off water from all connections. Hydrants are also made in which the different connections can be shut off separately. The cost of hydrants varies from $50 to $125 according to size, type, and the way in which connection is made with the pipe. Hydrants are commonly placed at intervals of 200 ft. where buildings are large, close together, and inflammable, and further apart elsewhere, but in no case more than 500 ft. apart.

Domestic Meters are small instruments set on the service pipes of the takers to measure and record all water drawn through them. The most commonly used meters in the United States are disk meters, consisting of an oscillating disk in a case moved by the water and communicating the motion which represents a certain volume of water to a gear train which indicates the amount on a dial. Another type of meter called a Rotary meter has advantages for certain services and is sold at a somewhat higher price.

Water meters are least accurate with the smallest flows. It is comparatively easy to make a meter that is accurate with large flows. Meters that are accurate at such flows often fail to register very small flows, especially after they have been some time in use. In testing meters therefore it is necessary to pay particular attention to low rates of flow, as otherwise small leakages which when sufficiently numerous would sap the system may fail to be registered by the meters.

Current specifications require domestic meters to register 90 per cent of a flow of 1/4 gal. per minute. This is a relatively low standard and should be insisted upon. With reference to complete accounting for water it is desirable that meters should register much lower flows and more rigorous specifications should be used as rapidly as the advance in the art makes them practicable.

The Cost of Meters varies with market conditions. In a general way the following have been about representative costs in the year 1927.

Cost and Discharge of Domestic Meters

Nominal size inches	Approximate relative cost of disk meters	Manufacturers' rating, gallons per minute	Moderate rating of disk meters with loss of head not exceeding 5 lb.			
			Gallons per minute	Velocity in pipe of exact diameter	Million cubic feet per annum running all the time	Relative capacity
5/8	$ 10	20	7.11	7.44	0.50	1.0
3/4	15	34	12.09	8.78	0.85	1.7
1	22	53	21.33	8.72	1.50	3.0
1-1/2	40	100	42.67	7.45	3.00	6.0
2	80	160	71.1	7.26	5.00	10.0
3	120	315	142.2	6.46	10.0	20.0
4	200	500	213.3	5.45	15.00	30.0
6	400	1000	426.7	4.84	30.00	60.0

A capacity of 10 for a 2-in. meter is taken as the starting point for this table, and in case of revision, is a better starting point than the capacity of the 5/8-in. meter.

Disk Meters of different makes vary in frictional resistance. The figures given in the preceding table should be approximately reached by any standard make. **Rotary meters** differ much more in frictional resistance than disk meters. In some makes resistance would be from 50 to 100% greater than given in the table for disk meters. Other makes have less resistance than shown in the table. **Inferential** or **current meters** have considerably less frictional resistance than disk meters, the results differing widely for different designs.

The Load Factor of a meter is the percentage which the average sales from it are of the capacity shown in the next to the last column of the preceding table. Thus a 2-in. meter recording 40 000 cu. ft. per annum is said to have an 8% load factor $\left(\frac{40\,000}{5\,000\,000} = 0.08\right)$. Meters of the smallest size, 5/8 in., are large enough to give service under ordinary conditions to practically all private houses, and will normally be used on from 90 to 98% of all services. The average load factor on 5/8-in. meters in an average system will be between 1 and 2%. Much slippage or loss of water passing without registration is inevitable because of the low load factor. Smaller meters, if made, would not deliver water fast enough. The 3/4-in. meters used on large houses are in an intermediate position. In all other cases meters are best placed of the smallest size that will give the discharging capacity actually required by the taker. If rigidly held down by this rule an average load factor of all meters 1 in. and over of 15 or 20% may be realized. If the rule is less rigidly enforced lower load factors will result and more water will pass without registration. In general, any meter 1 in. and over with a load factor below 8% should be at once replaced with a smaller one. **Protector meters** and **compound meters** are used where large capacity is essential and where ordinary use results in a very low load factor.

Classification of Services was adopted by the New England and American Water Works Associations to secure uniformity in statistics and rates. Three classes are used with an optional fourth class.

1. Domestic, all using less than 820 gallons per day, equal to 10 000 cu. ft. per quarter or 300,000 gallons per annum.
2. Intermediate.
3. Wholesale or manufacturing, all using over 8200 gallons per day, equal to 100 000 cu. ft. per quarter, or 3 000 000 gallons per annum.
4. Large, optional, if used applying to takers using over 82 000 gallons per day, or 1 million cu. ft. per quarter, or 30 million gallons per annum.

Statistics for 33 Completely Metered Systems for 1915

	Per cent of number of takers	Average daily sales per service in gallons	Per cent of total sales in gallons
1. Domestic	95.17	159	38.4
2. Intermediate	4.37	1 750	19.6
3. Wholesale	0.46	35 700	42.0

Systems vary greatly in sales to takers of the several classes, and especially in sales to large takers.

The Resistance, in all meters, increases nearly as the square of the quantity of water passing. Resistance is added intentionally by makers of meters to prevent them from being used for flows so large that the meter would not be durable.

The use of meters on domestic services is the most efficient means of preventing useless waste of water through leaky plumbing fixtures. The growth in the use of meters during the last years has been very rapid. Many cities sell water only by the meter and the system promises to become as universal as in the sale of gas and electricity.

Water Not Accounted for. In completely metered systems the total quantity of water registered by meters of the takers is always much less than the total output. The loss is made up of: (1) leakage from the street mains; (2) leakage from service pipes and abandoned services; (3) under registration of meters; (4) loss by seepage and evaporation from service reservoirs; (5) water used for special purposes not metered, such as fires, sewers, flushing, etc. With present American methods there are but few systems so tight and well managed that 85% of the water is accounted for. The average is probably under 80% but there are some systems where no more than 60% or even 50% can be accounted for. The records of 27 completely metered systems for the year 1915 showed an average loss equal to 130 gallons per service daily.

The Venturi Meter, invented by Clemens Herschel, consists of contraction of the pipe through the throat of which the water flows at an increased velocity. As the vecloity increases the pressure decreases. A differential gage connected at its two sides with the water at the entrance and throat of the meter indicates the rate of flow. A mechanical integrating device shows the total amount of water which flows through the pipe. There are several devices for accomplishing this, but the principle of the meter in all cases is the same, see Sect. 13, Art. 20. With a good registering device the results are accurate within 1 or 2%. Attachments are made by which the rate of flow is shown by a pen on a chart, the paper being replaced daily or weekly, so that a permanent record is made not only of the rate of flow at all times but also of the total discharge since a specified date.

Venturi meters should be placed on all important supply lines to show the quantity of water used. In connection with the pumps they serve to show the amount of water actually pumped, and form a basis for computing the slip of the pumps and to show any falling off in the efficiency. They are especially useful on the outlets of distributing reservoirs and elsewhere, where they show at all times the actual rate of consumption, the fluctuation at different hours of the day, and the rate of flow during the early hours of the morning when there is but a small amount of use and the bulk of the flow usually represents leakage, and they also serve to show when fire drafts commence and end and how much water is used during fires and at what rates.

Service Pipes extend from the main in the street to the limits of the street. The same pipe usually extends within the taker's property, but he pays for and owns all beyond the street line or curb line. A majority of works furnish the service pipe to the property line without cost to the taker. A considerable variety of materials have been used and choice will frequently be controlled by local conditions and the quality of the water. With lead, copper or brass pipe the size of meter may correspond with the diameter of the pipe, but iron pipe should always be larger than the meter. The service cock, tapped into the street main, may be smaller. A flexible connection between the tap and the service pipe, most often a lead gooseneck, is necessary to prevent damage from temperature change and settlement.

Cement Lined Pipe has come into use rather recently, is economical, of excellent quality and general application. Galvanized pipe should be bought larger than would otherwise be used and the lining can be done with simple equipment by the men employed in laying pipe working on rainy days. The mortar is drawn into the pipe by a follower which regulates its thickness and leaves it smooth. Short nipples must be used to bring the lined barrels of the pipes close together at the ends. Such pipe is not corroded and will retain its carrying capacity indefinitely. Rarely where the soil conditions are bad must the pipe also be surrounded with cement mortar as it is laid.

Galvanized pipe of steel or, better, of genuine wrought iron, is widely used and gives good service where the water is hard and therefore quiet. With soft active waters such pipe deteriorates rapidly and should not be used.

Copper tubing has recently become available with convenient and reliable joints and has the advantage of strength and flexibility and of furnishing its own gooseneck. Such pipe is permanently free from corrosion and may be laid no larger than the size of meter to be served by it.

Brass pipe is made in wrought iron pipe sizes with screw joints and fittings and is not subject to corrosion.

Lead and lead-lined service pipes have been used widely in the past and there are great numbers of such services in use. Lead is permanent and its capacity is not reduced by corrosion but it is attacked slowly by soft active water, and because of lead poisoning, can be safely used only for waters demonstrated to be without action on it.

Goosenecks and Flexible Devices. Where stiff pipe is used, such as steel or iron either lead-lined or unlined or brass pipe, it is customary to use a gooseneck, i.e., a short piece of lead pipe, or to use two or more 1/4 bend fittings, to avoid fracture of the service pipe by temperature stresses. Some water companies using steel pipe have systematically omitted these provisions for many years without apparent ill effects. With waters which attack lead it is better not to use even these short goosenecks.

On an average from 5 to 7 people are served per service (more in very large cities) and there is one service for every 50 ft. of main pipe. For statistical purposes the number of services should correspond with the number of live accounts, abandoned or dead services and services placed in anticipation of business not being counted.

24. Electrolysis

Electrolysis in Cast-iron Pipes is caused by stray return currents of electricity from various sources especially from trolley cars. These stray currents find their way into water pipes through the soil or through service pipes or hydrant connections or gas pipes or telephone conduits or any other metallic structures coming in contact with the water pipes or the services connected with them. Such currents flow in the pipes, leaving them at points near the power stations, or go through other metallic conductors to the power station.

Destruction of a Pipe by electrolysis occurs in two ways: (1) By a current collected by the pipe, following it for a distance and then leaving it in moist soil, the electrolysis occurring at the point where the current leaves the pipe; (2) by the flow of electricity in the pipe, a part of which leaves the pipe at lead joints or other points of extra resistance, coming back into the next length of pipe. These two kinds of electrolysis, while having the same effect on the pipe, are to be sharply distinguished. Electrolysis of the first kind may be corrected in great measure by connecting the pipe system with the negative poles of the dynamos at all power stations. This has the effect of taking the return current out of the pipes directly through a copper wire and avoiding the necessity of currents leaving the pipe in moist ground on the return journey. This method of treating the electrolysis question was proposed in the early days of electrolysis and used to a considerable extent. The principal objection to it is that it produces electrolysis of the second kind. This system is openly followed in some works, and is actually followed by unknown and indirect connections in others.

In cast-iron pipe lines the lead joint is a point of high resistance. The temperature of the melted lead is not sufficient to burn off the tar coating, and actual metallic connection is not made in all cases. The electric current goes through the soil around the joint in sufficient quantity to produce electrolysis on one side of the joint. This takes place in wet soil only. Dry soil is a non-conductor. When electricity makes a passage it goes through the water contained in the pores of the soil, and not through the soil particles. Water is a non-conductor, but it becomes a conductor when mineral substances are dissolved in it.

Leadite and cement joints are non-conductors and cast-iron pipe laid with them cannot carry current. A single insulation joint will be jumped by current with the production of local electrolysis, but if the whole pipe system is insulated at every joint, it becomes non-conducting and there will not be enough flow of electricity to do damage.

Electrolysis of the interior of pipes is extremely rare, because the water used for public water supply is not sufficiently mineralized to act as a conductor. If the water in the soil outside the pipe were equally pure from an electrolytic standpoint there would presumably be little trouble from this kind of electrolysis.

Electrolysis occurs because the ground water contains mineral matter and salts which increase its conductivity. The mineral matters in ground water may result from many sources, among them: (1) From cesspools and similar sources, which are known to increase the chlorine contents of ground water to from 10 to 100 times the natural amounts, in villages and cities, and to less extent in rural districts; (2) urine of horses falling on public roads; (3) sea water brought by the rain, this being a matter of importance only when pipes are not very far from the ocean; (4) solution of mineral matters from the soil.

Insulation Joints are joints made of some non-conducting material to prevent the flow of electricity in pipes. Such joints have been made by driving wooden wedges between the spigot and bell of the cast-iron pipe in place of the lead. To be effective they must be repeated at short intervals, as the electric current will jump a number of such joints, passing through the surrounding moist soil and causing electrolysis at each of them.

Electrolysis of Steel Pipe. The riveted joints of steel pipe are almost perfect conductors of electricity. There is no evidence that a current flowing in a steel pipe injures it in any way as long as it does not leave the pipe. An electric current flowing in steel pipe and leaving it results in electrolysis at the point where it leaves the pipe.

Steel pipe is best protected by finding where the current tends to leave it and giving ample copper connections at those points to carry off the current. Sometimes the connections can be made to parts of the electric system that will absorb the stray current. In the absence of other opportunity old rails or any convenient form of old iron buried in the neighborhood of the pipe and in the direction of flow of current and connected to the pipe by liberal copper wires soldered or welded at both ends will take the major part of the corrosion and protect the pipe.

DAMS

1. Masonry Dams

Foundations of high masonry dams should be only on rock, which should be stripped and all loose or soft rock removed and the rock below thoroughly explored by core borings. If the rock is horizontally-bedded limestone or shale, mud seams may be a source of great danger by permitting sliding of the dam even when such seams are very thin. The igneous rocks frequently have small open seams which are not dangerous but permit leakage. This may usually be stopped by one or two rows of vertical holes drilled along the upstream toe and grouted with neat portland cement or by excavating a trench in the rock along the upstream toe and filling it with concrete. The whole foundation should be thoroughly washed; if it is smooth it may be roughened by chipping or blasting a fresh surface. (See Sect. 10, Art. 30.) If the rock is sound and so treated and the masonry begun by applying first a layer of rich mortar or grout to the clean fresh rock surface as good a joint is obtained as the joints between subsequent lifts of masonry above. Drains may be laid on the bed-rock and led out to the downstream toe to care for any slight seepage that otherwise might produce uplift, and a system of interior drains may relieve pressure both on joints and within the masonry above the base, but such drainage is seldom so sure to be effective that the internal stresses due to water pressure can be neglected.

Rubble Masonry. From the earliest times to the beginning of the present century rubble has been most frequently used for masonry dams. It is probably much better than the more expensive cut stone because of the better bond obtained. In the New Croton dam, one of the best examples of the rubble masonry type, the method of building was as follows: The derrick stones, limestone quarried near site, 15 to 50 cu. ft. in volume, were picked up by the derrick and, while suspended, fins, sharp corners, and edges were sledged off, and the stones thoroughly washed with a hose and then swung to place and lowered into a thick bed of mortar. Each stone was then picked up and examined for perfect bedding and at the same time spalls were packed into the mortar bed where it was thick enough. The stone was placed a second time and men with pinch bars worked it to a firm bed, being careful to move it only horizontally and not to rock it; sometimes the stone was removed and placed several times before the bedding was satisfactory. The vertical joints were then filled with hand rubble, consisting of spalls, well wetted and laid with soft mortar. On account of the irregular shape of the derrick stones the vertical joints averaged about 12 in. in width. The cut-stone facing was kept about one course above the rubble work, and shearing planes were prevented by allowing the hearting rubble to bond between the courses. The resulting proportions were: derrick stones 50%, spalls 26% and mortar 24%. In the Wachusett the proportions of the granite rubble were: derrick stones 54%, spawls 17%, and mortar 29%.

Cyclopean Masonry is rubble in which concrete is used in the place of mortar. Joints are correspondingly thicker. As portland cement became of better quality and cheaper, and skilled labor became dearer, cyclopean masonry began to replace rubble for masonry dams. In the case of several dams built between 1900 and 1910, the general method of constructing cyclopean masonry was as follows: One bucket or more of soft concrete was dumped, making a bed, say 1-1/2 ft. deep, on which large stones from 10 to 50 cu. ft. in volume were set by derrick as closely as their irregularities would permit. These settled into the bed, and were not usually picked up by the derrick again, as is the practice in bedding large rubble in mortar. Into the spaces between the derrick stones, averaging from 1 to 2 ft. in width, soft concrete was dumped and as many spalls as possible, from 1/4 to 1 cu. ft. in volume were forced into it. Care was always taken to prevent the formation of shearing planes by keeping a large part of the derrick stones projecting above the general level to form a bond with future work. In Ashokan dams 25% and in Kensico dam 27% of the total mass was composed of derrick stones.

Concrete Masonry. At present (1928) the use of concrete masonry for dam construction is almost universal. This is because of the development of machinery and methods which usually make a cubic yard of concrete cheaper than any other masonry and also shorten the time of building. However, the day of rubble and cyclopean masonry has not entirely passed because the design of a dam and materials of construction should always be the best adaptation to local conditions and there will still be masonry dams which can be more cheaply and more satisfactorily built of rubble and cyclopean masonry. It has also become almost standard practice to build concrete dams as a series of detached piers, each alternate block being brought up with forms surrounding its four sides and the intermediate blocks poured between upstream and downstream forms. Concreting is usually done in from 4-ft. to 8-ft. lifts. It is still the practice, wherever possible or convenient, to use plums in the concrete either in the form of large derrick stones or one-man stones well embedded in the concrete with special care that they project from each lift into the next above.

Temperature Cracks. It is observed that all straight dams and most curved dams in localities having considerable range of temperature have developed cracks which open in winter and close in summer. The question of temperature cracks has received much study, but the total knowledge derived is still meager. It seems to be fairly well established that temperature cracks in large masses of masonry are widest at the surface, becoming gradually narrower with penetration; that in the latitude of New York they disappear from 10 to 20-ft. depth depending on exposure, character of masonry, and whether the masonry was laid in warm or cold weather, so that if the dam is less than 20 or 30 ft. thick the cracks extend through. At the New Croton dam liquid dye was run into cracks and later the surrounding masonry was removed. All cracks were found to have the same general profile at their bottoms, as indicated in Fig. 1. In general the cracks formed a vertical plane located without regard to joints, passing, in some cases, through headers within two or three inches of their edges. Thermophones were placed in the masonry of Boonton and Kensico dams as they were built, and observations were made for a period of several years in each case. In the Boonton dam many instruments became unreliable so that complete laws could not be deduced; in Kensico dam the readings for nearly all positions were maintained for a period of four years. It was observed that the temperature at any point began to rise as soon as the concrete was placed and rose various amounts depending on the temperatures of the air and foundations, the mass of the concrete, the rate of placing the masonry, the distance to the nearest exposed face, the exposure of that face, and possibly upon the brand and content of cement used and the wetness of the mix. The time required to reach the

Fig. 1

maximum temperature depended on the same factors. The time required for dissipation of the heat generated by the reactions of the cement and water depended primarily upon the distance from an exposed face, the exposure of that face and the temperature difference inside and outside the dam.

The measurements at Boonton dam indicated the conclusion that a range of 130° F. in the atmosphere reduces to a range of about 70° F. 2 to 4 ft. below the surface of the masonry, with a gradual but slower decrease of range with greater depths, also a reduction in range of 10° F. per 1-3/4 ft. of depth.

The last measurements in Kensico dam, made in 1917 when the heat of setting practically had been dissipated, indicate that with a range in mean atmospheric temperature of 73° F. the range in temperature R in the masonry for depths in the masonry from 0 to 40 ft. may be approximately expressed by the formula $R = 48 - 12.3 \log_e D$ where D = distance from nearer face; which face had a sunny exposure. Measurements were taken at elevations where thickness of masonry ranged from 45 to 90 ft. and where D was always equal to or less than 1/2 such thickness.

Expansion Joints. It is now (1928) the universal custom to provide contraction joints at intervals of from 30 to 60 ft. normal to upstream face of gravity dams. The treatment of these joints is not standardized. Various devices which have been used for water stops are illustrated in Figs. 2 and 39.

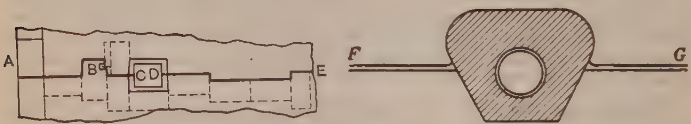

Fig. 2. Two Types of Expansion Joint

AE, Fig. 2, shows the joint in Kensico dam. $ABCDE$ is the trace of vertical planes of weak bond, made so by building first one side of precast concrete blocks, coating it with soft pitch, and later pouring the adjacent block against it. At B a sheet of copper 1/16 in. thick was placed across the joint with its two edges embedded in the concrete on either side in such a way that it will be bent but not ruptured by the movements of the concrete. At Ashokan the joint is the same except that there is no copper strip. CD is an inspection well. FG, Fig. 2, shows the water stop used at Jordan dam, Alabama. It consists of a block of high-melting-point pitch located across the construction joint. In the center of the pitch is a pipe running from top to bottom of the dam into which a second small steam pipe may be inserted to melt the pitch. The same devices as illustrated in Fig. 39 for water stops in aqueducts are used for dams

Waterproofing and Drainage Galleries. Watertightness in dams is desirable because water in penetrating increases the stress and may reduce the strength of the masonry. To construct a nearly vertical wall over a hundred feet high perfectly watertight is a matter of great difficulty. The method most commonly depended upon previous to 1905 was to make the water face of cut stone and point its joints very carefully with rich portland cement mortar, so that if the stone is impervious the leakage may be reduced and the downstream face will be practically dry. The following notes taken from published comments give the extent of leakage in some of the dams treated in this manner. The Lake Cheesman dam under a head of 212 ft. shows no sign of leakage and is entirely free from the appearance of seepage. The Sodom dam shows a few damp spots on humid days only. The Furens dam in France, under a head of 154 ft., showed only a few damp spots. The old Bear Valley dam, which for the greater part of its height is less than 8 ft. thick, showed only sweating under a head of about 50 ft. There is a growing practice of providing a drainage system in the masonry a short distance from the upstream face. In the Ashokan and Kensico dams there are drainage galleries 5 ft. by 7.5 ft., large enough for inspection, one near the top and the other near the base of the dam, connected by inclined drainage holes 16 in. in diameter. These drainage holes are formed in blocks of porous concrete 3 ft. by 3 ft. in plan set about 15 ft. from the upstream face and 12 ft. apart along the axis of the dam. The water face of the Mouche dam was given 3 coats of hot pitch and then whitewashed. The upstream face of the Urft dam was waterproofed with a plaster coat of cement 1 in. thick, on which a coat of asphalt was applied; against this, to hold it in place, a 3-ft. wall of masonry was built, backed by an earth embankment, and drainage pipes were placed in the masonry downstream from the asphalt coating. The upstream face of the Sand River dam, South Africa, was treated as follows: soap and alum washes were applied to the faces with a flat brush, the soap solution being at 212° F. and the alum at 60° to 70° F. The washes contained 1 lb. soap to 1.6 gal. water and 1 lb. alum to 9.6 gal. water. Three coats of each were used. Non-overflow dams in northern climates should have dry downstream faces because of frost action which will cause spalling of the face if water is present in the pores of the masonry. If for this reason or any other it is desirable to have a perfectly dry downstream face some method of waterproofing the upstream face is warranted. Usually the expedient of interior drainage is more satisfactory than attempting to waterproof the upstream face. If the dam is important or its failure would be accompanied by disaster, no reduction of cross-section should ever be made on account of a possible reduction of stresses on account of waterproofing for no waterproofing has been devised which is sure to be and always remain 100% perfect.

Essential details of notable precedents are given in the following condensed statements, where the numbers in parentheses refer to corresponding numbers within small circles on the cross-sections in the figures. Where height and width are given, the width is the base width corresponding to that height. Of all structures dams are probably most governed by precedents in their design and method of construction.

Straight Masonry Dams without Overflow (Fig. 3)

(1) Gros-Bois, France. 1830–38. 1805 ft. long, 21.3 ft. wide at top. Founded on soft. rock. When filled slid 2 in. Reinforced by 11 buttresses 37 ft. thick at bottom and 13 ft. thick at top. 96 ft. high; 52.5 ft. wide.

(2) Lozoyoa, Spain. About 1850. 238 ft. long; 105 ft. high; 128 ft. wide. Wall of cut stone backed by rubble masonry, partly covered on back face by sloping bank of gravel. Top width 21.98 ft.

(3) Habra, Algiers. 1856–71. Rubble masonry. 1082 ft. long. Top width 14.1 ft. Rock poor and porous. Mortar, natural hydraulic lime and fine clayey sand. When filled leaked badly, later leakage practically ceased. Failed 1881 during flood which overtopped dam; 300 ft. carried out down to base. About 400 lives lost. Repaired 1883–87. Profile was much changed and strengthened. 124.2 ft. high; 89.2 ft. wide.

(4) Cágliari, Sardinia. 1866. Granite, rubble, hydraulic mortar. 345 ft. long. Top width 16.4 ft. Height 70.5 ft. Width 52.4 ft.

(5) Boyd's Corner. New York City water supply. 1866–72. Cut-stone face, concrete heart (large plums in lower half). Concrete weighed 133.25 lb. per cu. ft. Length 670 ft. Top width 8.6 ft. Earth embankment upstream side 20 ft. wide on top, 4 : 1 slope. 27 000 cu. yd. masonry. Height 78 ft. Width 57 ft.

(6) Poona, India, 1868. Uncoursed rubble founded on rock. Length 5136 ft., of

which 1453 ft. is waste-weir, 11 ft. below top of dam. Alignment is several tangents. Reinforced by heavy buttresses at intersections. At first masonry showed signs of weakness. Reinforced by earth bank on lower face. Top width of bank 60 ft., height 30 ft. 360 000 cu. yd. masonry. Cost \$630 000. Height of masonry dam 100 ft. Width 60.7 ft.

(7) Tlelat, Algiers. 1869. 325 ft. long. Top width 13.12 ft. Height 68.9 ft. Width 40.3 ft.

(8) Djidionia, Algiers. 1873–75. Resultant said to be outside middle third. Top width 13.12 ft. Height 83.7 ft. Width 52.4 ft.

(9) Bouzey, France. 1878–81. 1700 ft. long. Red-sandstone foundation pervious. When filled dam slid 1 ft. Reinforcement at toe added 1888. Failed 1895, upper 33 ft. overturning for length of 558 ft. 150 lives lost. Height 84.5 ft. Width 57.3 ft.

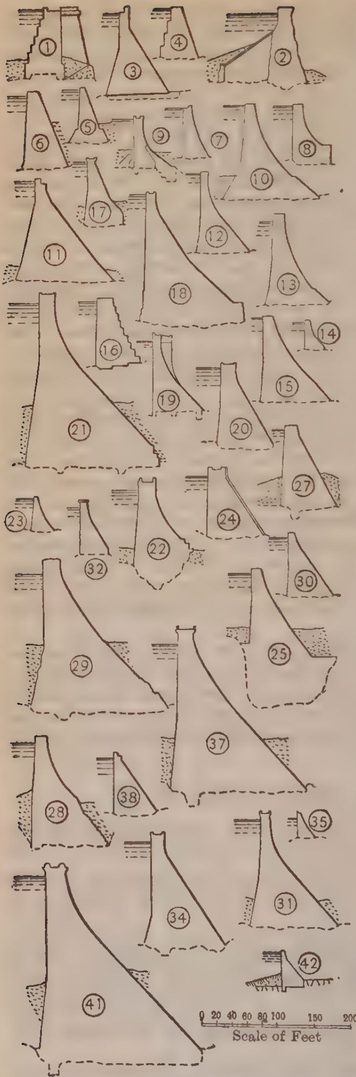
(10) Gran-Cheurfas, Algiers. 1882–84. Rubble. 508.4 ft. long. Top width 13.12 ft. Partially failed when filled 1885; immediately repaired. Height 131.2 ft. Width 134.5 ft.

(11) Lagolungo, Italy. Genoa water supply. 1883. Raised 10 ft. 1903. Top width 8.2 ft. Height 145.9 ft. Width 140 ft.

(12) Vingeanne, France 1885. Top width 11.48 ft. Height 113.8 ft. Width 80.1 ft.

(13) Hamiz, Algiers. 1885. Rubble. 532 ft. long. Top width 16.4 ft. Height 124.6 ft. Width 91.2 ft.

(14) Bridgeport, Connecticut. 1886. Gneiss rubble. Rosendale 1 : 2 mortar. 640 ft. long. Top width 8.0 ft. Base length 50 ft. Height 45 ft. Width 29.5 ft.



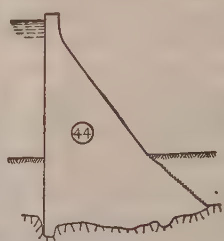


Fig. 3. Straight Masonry Dams without Overflow

(15) Tansa. Bombay water supply. 1886–91. Total length 8800 ft. 1650 ft. of dam is waste-weir, 3 ft. below top of dam. Uncoursed rubble masonry. Stones, hard

trap or greenstone. Cement, hydraulic lime burnt from kunkur nodules. Masonry 408 520 cu. yd. Reported to be watertight. Cost $988 000 by contract. Designed strong enough to permit height to be increased 17 ft. Height 118 ft. Width 99.8 ft.

(16) Tytam, China. 1887. Granite ashlar and concrete. Intended for 20 ft. higher. Present crest width 21 ft. Height 95 ft. Width 63.4 ft.

(17) Sodom. New York water supply. 1888–93. Coursed rubble on solid rock. Faces cut stone; beds perpendicular to faces. Mortar, 1 portland cement to 2 sand. 500 ft. long. Top width 12 ft. 35 887 cu. yd. Cost $366 499. Maximum progress 3000 cu. yd. per month. No leakage except slight sweating at joints. Height 94.7 ft. Width 53 ft.

(18) Periyar, India. 1888–97. Faces uncoursed syenite rubble; heart concrete; hydraulic lime. Situated in jungle. Unskilled labor. 1231 ft. long. Top width 12 ft. 185 000 cu. yd. masonry. Upstream face plastered with hydraulic lime and sand 1 : 1. Height 183 ft. Width 135.5 ft.

(19) Mouche, France. 1885–90. Rubble, 134.2 lb. per cu. ft. 1346 ft. long. Top width 11.5 ft. Given three coats hot pitch on upstream face, then whitewashed. Height 101.5 ft. Width 66.5 ft.

(20) Titicus. New York water supply. 1890–95. Rubble rough-coursed, cut-stone faces; beds perpendicular to faces. Mortar, 1 portland or natural cement to 2 sand. 534 ft. long. Top width 20.7 ft. Maximum progress 5700 cu. yd. monthly. Cost $933 065. Height 109 ft. Width 75.2 ft.

(21) New Croton. New York water supply. 1892–1907. Rubble faced with ashlar. Part cyclopean. Length 1200 ft. Top width 18 ft. Rock in greater part of dam 185 lb. per cu. ft. 855 000 cu. yd. masonry. Maximum progress 5700 cu. yd. monthly. Height 238 ft. Width 185 ft.

(22) Burrator, England. 1893–96. Granite blocks bedded in rich concrete. Cut-stone face. Joints pointed and caulked with neat cement mortar. Length 361 ft. Top width about 18 ft. Cost $495 700. Height 77 ft. Width 63 ft.

(23) Indian River, New York. 1898. Top width, 7 ft. Length 207 ft. Height 47 ft. Width 33 ft.

(24) Assuan, Egypt. 1898–1902. Granite rubble laid in 1 : 4 portland cement mortar. Length 6400 ft., 1800 ft. solid, remainder has 180 sluices each 6.56 ft. wide. Top width 17.8 ft. Masonry 704 000 cu. yd. Cost $11 907 000. Height 95 ft. Width 80.3 ft.

(25) Coolgardie, Australia. 1900–02. Rubble concrete. Length 755 ft. Top width 10 ft. Height 119.9 ft. Width 88 ft.

(26) Blackbrook, England. 1900–05. Length 525 ft. Top width 14 ft. Height 108 ft. Width 65 ft.

(27) Boonton, New Jersey. 1900–06. Cyclopean syenite masonry. Top width 17 ft. Length 2150 ft. Masonry 166 lb. per cu. ft. 255 000 cu. yd. Maximum progress 21 000 cu. yd. per month. Height 103 ft. Width 77 ft.

(28) Spier Falls, New York. 1900–05. Rubble. Length 552 ft. Top width 17 ft. 180 000 cu. yd. masonry. Height 150 ft. Width 107 ft.

(29) Wachusett, Massachusetts. 1900–06. Granite, rubble, cut-stone faces. Top width 22.5 ft. Length 971 ft. Three-quarters of heart is laid in natural cement. Volume 266 663 cu. yd. Cost $2 270 117. Height 205 ft. Width 187 ft.

(30) La Jalpa, Mexico. 1902. Body of dam rough limestone rubble laid in mortar of native hydraulic lime and sand. Clay embankment, slope 2 : 1 on upstream face. Length 1800 ft. Top width 9.1 ft. Contents 92 000 cu. yd. Cost $500 000 gold. Height 87.2 ft. Width 65.6 ft.

(31) Cataract, Australia. 1902–08. Cyclopean masonry. Sandstone blocks in cement mortar packed with concrete; blocks about 65% of mass. Faces, concrete downstream, concrete blocks upstream. Length 811 ft. Top width 16.5 ft. Rectangular conduits filled with broken stone and earthen pipes for drains. 146 242 cu. yd. Height 154 ft. Width 120 ft.

(32) Pedlar River, Virginia. 1904. Concrete with large stones embedded. Length 415 ft. Width at crest 10 ft. Concrete laid as large blocks about 10 × 10 × 15 ft. and dovetailed. Portland cement on face, natural in heart. Contract price $103 708. Height 73.5 ft. Width 39.2 ft.

(33) Swansea, Wales. 1905. Cyclopean masonry, brick facing. In heart concrete 1 : 2 : 5. Lower base and upper 6 ft. of water face 1 cement : 2 sand : 3.4 parts of

fine crushed rock. Length 1250 ft. Maximum height 144 ft. Thickness at base 107 ft. Maximum depth water 100 ft.

(34) Cross River, New York. 190–507. Cyclopean masonry, concrete block facing. Length 772 ft. Top width 23 ft. 158 000 cu. yd. Maximum progress 18 400 cu. yd. per month. Contract price $1 246 212. Height 155 ft. Width 125.3 ft.

(35) Connellsville, Pennsylvania. 1906. Concrete, boulders used as plums. Ashlar facing. Length 650 ft Top width 6 ft. Boulders about 25% of masonry. Height 39 ft. Width 26 ft.

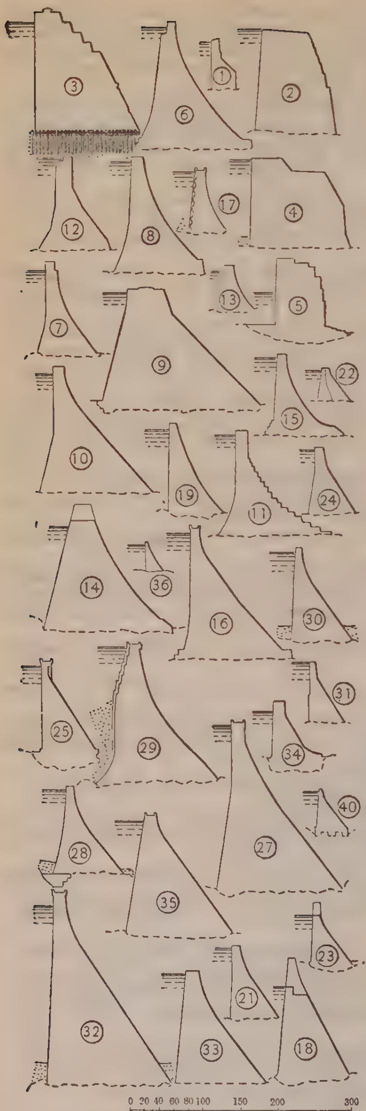
(36) Sand River, South Africa. 1906. Concrete 1 : 1.3 : 5.5 with large quartzite rocks, iron rods and rails embedded. Length 398 ft. Height 55 ft. Base width 38 ft. Foundation hard shale. Contents 9000 cu. yd. Cost about $140 000. Masonry 150 lb. per cu. ft.

(37) Ashokan. Olive Bridge dam, New York. 1908–13. Cyclopean masonry. Length 1000 ft. Top width 26.3 ft. Facing concrete blocks. Height 220 ft. Width 190.2 ft. Contraction joints, wells and galleries for inspection and drainage, and vertical drains provided. (See Fig. 2, p. 1522.)

(38) Blackwater, Scotland. Cyclopean concrete. Top width 10 ft. Height 84 ft. Width 58 ft.

(39) Esperanza, Mexico. Rubble masonry. Length 580 ft. Top width 19.7 ft. Base width 75.7 ft. Maximum height 137.5 ft. 55 000 cu. yd. Mortar of lime somewhat hydraulic. Leakage estimated 0.4 cu. ft. per sec.

(40) Barker, Colorado. 1909. Masonry 1 : 3 : 5 concrete with plums. Expansion joints in upper 145 ft.,



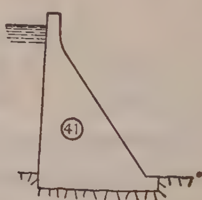


Fig. 4. Curved Masonry Dams with Gravity Sections without Overflow

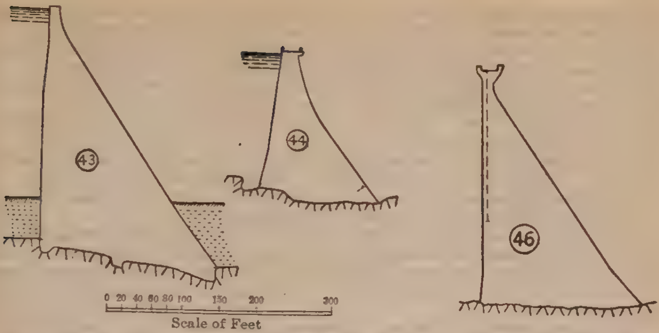

Fig. 4 (continued). Curved Masonry Dams with Gravity Sections without Overflow

48 ft. apart. Length 625 ft. Top width 16 ft. Height 175 ft. Maximum base width 124 ft.

(41) Kensico, New York. 1910–16. Cyclopean masonry; concrete blocks on upstream face, cut stone on downstream face. Length 1830 ft. Top width about 27.75 ft. Base width 227.7 maximum. Expansion joints, vertical drains and inspection galleries. Height 250 ft.

(42) Austin, Pennsylvania. 1909. Maximum height 50.5 ft. Width at base 30 ft. Top width 2.5 ft. Length 554 ft. Foundation, sandstone in layers 8 in. to 3 ft. thick with beds of shale and disintegrated sandstone between the layers. When filled in January, 1910, a section 90 ft. long slid 18 in. at bottom and 31 in. at top. Dam then repaired but not strengthened. In September, 1911, it failed suddenly with loss of 80 lives and $3 000 000 of property.

(43) Medina, Texas. 1911–12. 1 : 3-1/2 : 6-1/2 concrete with 9.9% plums. Length 1580 ft. Top width 25 ft. Maximum height 164 ft. Base width 128 ft. Total volume 300 000 cu. yd.

(44) Elephant, Butte, New Mexico. 1910–16. Cyclopean concrete. Length 1200 ft. Top width 18 ft. Maximum height 304.5 ft. Base width 212.58 ft. Volume 611 400 cu. yd. Drainage gallery, vertical drains and expansion joints.

(45) Brisbane, Australia. Completed 1916. Heart 1 : 2.5 : 6.5 concrete with 25% plums. Upper 30 ft. and faces to toe and heel 1 : 2 : 4 concrete. Length 580 ft. Top width 10 ft. Maximum height 125 ft. Volume 58 400 cu. yd.

Curved Masonry Dams with Gravity Sections without Overflow (Fig. 4)

(1) Almanza, Spain. Built before 1586. Radius 86 ft. Rubble cut-stone face. Oldest existing masonry dam. Top 9.84 ft. thick. Height 67.8 ft. Width 33 7 ft.

(2) Alicante, Spain. 1579–84. Rubble, cut-stone facing. Radius at top 351 ft. Height 134.5 ft. Width 110.6 ft.

(3) Puentes, Spain. 1785–91. Polygonal in plan, arched upstream. 925 ft. long. Rubble, cut-stone facing. Mostly founded on rock; on piles over deep pocket. Held 82 ft. depth for 10 years. 1802 water rose to 154 ft. depth and pile foundations washed out, leaving dam bridging deep pocket. 608 lives lost. Height 164.2 ft. Width 145.2 ft.

(4) Val de Infierno, Spain. 1785–91. Polygonal arch. Reservoir silted to top of dam. Built on rock. Height 110.3 ft. Width 136.4 ft.

(5) Nijar, Spain. 1843–50. Rubble, cut-stone facing. Height, 90.5 ft. Width 67.6 ft.

(6) Furens, France. 1862–66. Rubble of mica schist with cut-stone front face. Length about 330 ft. Top width 9.91 ft. Radius 828.4 ft. Built in narrow gorge. No leakage. Few damp spots. 52 300 cu. yd. Cost $318 000. Height 170.6 ft. Width 161 ft.

(7) Ternay, France. 1865–68. Granite rubble. Top width 13.12 ft. Radius 1312 ft. Height 124.6 ft. Width 81.7 ft.

(8) Ban, France. 1867–70. Rubble. Length 512 ft. Top width 16.4 ft. Radius 1325 ft. Built on rock. Cost $190 000. Height 156.8 ft. Width at base 126.9 ft.

(9) Gillepe, Belgium. 1870–75. Sandstone rubble. Top width 49.2 ft. Radius 1640 ft. Length top 771 ft. Height 156.5 ft. Width 215.89 ft. 325 000 cu. yd.

(10) Villar, Spain. 1870–78. Rubble. Top width 14.75 ft. Length 349 ft. Radius 440 ft. Height 170.3 ft. Width 154.6 ft. Cost about $390 000.

(11) Hijar, Spain. 1880. Top width 16.4 ft. Length 236 ft. Radius 210 ft. Height 141.1 ft. Width 146.9 ft.

(12) Gorzente, Italy. Genoa water supply. 1880–83. Serpentine rubble with casale lime mortar. 492 ft. long. Top width 22.96 ft. Height 126.3 ft. Width 99.4 ft.

(13) Thirlmere, England. 1886–93. Top width 18.5 ft. Plan is reverse curve to follow bedrock. Radius 100 ft. Height 63 ft. Width 51.7 ft.

(14) San Mateo, California. 1887–88. Concrete molded into dovetailed blocks on dam. Planned for maximum height 170 ft. Stopped at 146 ft. Top width 25 ft. and top length 680 ft. at 170 ft. height. Radius 637 ft. Volume 139 000 cu. yd. A few damp spots on face only sign of leakage. No cracks visible. Concrete 1 : 2 : 6.5. Width at base 176 ft.

(15) Beetaloo, Australia. 1888–90. Concrete. Top width 14 ft. Length 580 ft. Radius 1414 ft. 60 000 cu. yd. masonry. Founded on rock. Cost $573 300. Height 110 ft. Width 110 ft.

(16) Chartrain or Tache, France. 1888–92. Rubble or porphyritic rock and hydraulic mortar. Weight per cu. ft. 150 lb. Top width 13.12 ft. Radius 1312 ft. Upstream face coated to 33 ft. below coping with artificial cement of slaked lime, 1-1/4 in. thick, made of equal parts of cement and sand. Some leakage. Height 174.7 ft. Width 159.9 ft.

(17) Remscheid, Germany. 1889–92. Rubble linneite slate in trass mortar. Water face plastered with cement and asphalt, covered by brick wall. Top width 13.1 ft. Radius 410 ft. 22 886 cu. yd. Height 82 ft. Width 49.2 ft.

(18) Hemet, California. 1890–95. Granite rubble and concrete. Designed with maximum height 160 ft.; only carried to 122.5 ft. Top width 10 ft. Length 260 ft., including 50-ft. spillway in center. Radius 225.4 ft. 31 105 cu. yd. at present height. In time of flood spillway too small. Base width 100 ft.

(19) Bhatgur, India. About 1891. Uncoursed rubble. Upper portion concrete and rubble blocks. Faces coursed rubble. Top width 12 ft. Length 3257 ft. Irregular curve to follow outcrop of bedrock. Height 127 ft. Width 73.7 ft.

(20 Butte City, Montana. 1892. Concrete, granite facing. Top width 10 ft. Maximum height 120 ft. Bottom width 83 ft. Length of top 350 ft. Radius 350 ft.

(21) Lauchensee, Germany. 1892–95. Cyclopean masonry. Trass mortar, 1 lime, 1 trass, 2-1/2 sand made by crushing sandstone. Earth bank to protect from sun. Top width 13 ft. Length top 840 ft. Radius 2950 ft. Cu. yd. 37 400, of which 65% stone and 35% mortar. On sandstone. Total cost $243 750. Height 98 ft. Width 65.3 ft.

(22) Lennep, Germany. Old dam, 1893. Length 416 ft. Radius 460 ft. Dam was increased in height from 37.7 ft. to 48.4 ft. and buttresses built to take added thrust. Width at base 50.8 ft.

(23) Wigwam, Connecticut. 1893–96. Designed for 90-ft. height, built only 75 ft. high. Width 12 ft. at designed height, and length 600 ft. 14 887 cu. yd. in completed portion. Radius 600 ft. Width at base 62 ft. Completed to designed height in 1903.

(24) Einsiedel, Germany. 1894. Rubble. Top width 13.12 ft. Length 590 ft. Radius 1310 ft. 31 600 cu. yd. Height 93.6 ft. Width 65.5 ft.

(25) Echapre, France. 1894–98. Top width 17 ft. Length 541 ft. Radius 1148.2 ft. Hydraulic mortar coat on upstream face, on which coat of hydraulic cement was later placed. Maximum depth of water 121.4 ft. Width at base 88.6 ft.

(26) Ondenon, France. 1900–04. Top width 15.4 ft. Length 420 ft. Radius 984 ft. Maximum height 123 ft. Base width 94 ft.

(27) Lake Cheesman, Colorado. 1900–04. Top width 18 ft. Length 710 ft. on crest, 30 ft. at base. Granite rubble, coursed rough-pointed facing. Radius 400 ft. 103 000 cu. yd. Total cost about $1 000 000. Height 227 ft. Width 176 ft.

(28) Komotau, Austria. 1901–04. Cyclopean masonry. Gneiss in portland cement concrete. Top width 13 ft. Length 508.5 ft. at top, 170.6 ft. at bottom. Radius 820 ft. 53 600 cu. yd. Asphaltum and tar coat held in place by concrete dovetailed into upstream face. Height 118.9 ft. Width 98.4 ft.

(29) Urfa, Germany. 1901–04. Slate and trap masonry, earth embankment to 77 ft. below crest, slope 2 : 1, rock paving. Length 741 ft. Top width 18 ft. Radius 656 ft. Height 190 ft. Width 165.5 ft.

(30) Mercedes, Mexico. 1901–05. Rubble, cut-stone facing. Top width 11.48 ft. Length at crest 535 ft., also 98-ft. spillway; 13 ft. at base. Straight for half the length, rest 196.8 ft. radius. 28 000 cu. yd. Cost $200 000 Mexican currency. Height 135.6 ft. Width 84.5 ft.

(31) Granite Springs, Wyoming. 1903–04. Uncoursed rubble. Weight per cu. ft. 165 lb. Top width 10 ft. Length 410 ft. on top, 10 ft. at base. Radius 300 ft. 14 422 cu. yd. Cost $109 194. Height 96 ft. Width 56 ft.

(32) Roosevelt, Arizona. 1905–11. Cyclopean masonry, range rubble facing. Sandstone. Top width 16 ft. Length 680 ft. Radius 400 ft. About 340 000 cu. yd. Height 260 ft. Width 158 ft.

(33) Marklissa, Germany. 1905. Gneiss rubble. Upstream face has 2-in. mortar layer coated with siderosthen. Has interior drainage system. Length 427 ft. Radius 410 ft. 83 700 cu. yd. Height 147.7 ft. Width 124.8 ft.

(34) Marquina, Manila, Philippine Islands. 1906. Rubble, hard cyrstalline limestone marble. Length 400 ft. Radius 500 ft. Height 75 ft. Width 68.7 ft.

(35) Cher, France. Top width 15.4 ft. Radius 656 ft. Height 154 ft. Width 141 ft.

(36) Burraga, Australia. Cyclopean concrete in heart. T-rails bedded near top. Top width 2 ft. Length 285.6 ft. Radius 539.8 ft. Cost $44 500. Height 41 ft. Width 25.3 ft.

(37) San Jose, Mexico. Rubble. Top width 15 ft. Maximum height 151 ft. Base width 128 ft. Length 592 ft., including two spillways 95 ft. and 86 ft. Radius 6560 ft.

(38) Murrumbidgee River, Australia. Concrete, large stones embedded. Maximum height 232 ft. Length 910 ft. Radius 940.5 ft. Maximum base width 160.33 ft. Crest width 18 ft.

(39) Mochne, Germany. Length 1312 ft. Maximum height 98.4 ft. 353 160 cu. yd.

(40) Griffin, Pennsylvania. Concrete laid in 12-in. courses usually from end to end during one working day. Length 284 ft. Radius 400 ft. Top width 4 ft. Spillway near center 80 ft. long. Concrete 8000 cu. yd. At first leaks appeared near ends. Height 62 ft. Width at base 44 ft.

(41) Barren Jack, New South Wales. 1909–13. Cyclopean concrete. Length 784 ft. Top width 18 ft. Base width 163 ft. Height 240 ft. Radius 1200 ft.

(42) La Boquila, Chihuahua, Mexico. Cyclopean masonry with 10-ton blocks of limestone. Length 840 ft. Top width 19 ft. Base width 200 ft. Radius 866 ft.

(43) Arrowrock, Boise, Idaho. 1912–13. 1 : 2.5 : 5 concrete with large rock and cobblestone. Length 1050 ft. Top width 15.5 ft. Height 351 ft. Base width 238 ft. Radius 662 ft. Inspection gallery. Contraction joints every 150 ft.

(44) Mauer, Silesia, Germany. Completed in 1912. Stone masonry. Length 918 ft. Top width 23.6 ft. Height 203 ft. Base width 165 ft. 332 000 cu. yd. Radius 820 ft. Drainage and inspection tunnels.

(45) Camarasa. 80 miles from Barcelona, Spain. 1917–20. Length 460 ft. Base 250 ft. at height of 333 ft. Radius 1000 ft. Cyclopean concrete, 285 000 cu. yd. Top width 13 ft.

(46) Exchequer, California. 1923–26. Length 950 ft. Height 333 ft. Radius of upstream face 675 ft. Batter of downstream face .63.

Curved Masonry Dams Depending on Arch Action without Overflow (Fig. 5)

(1) Meer-Allum, India. About 1800. Large arch made up of 21 small arches with buttresses between. Spans between buttresses 70 to 147 ft. in clear. Spillway provided, but at times water flows few inches deep over entire dam. Length about 2640 ft.

(2) Zola Dam, France. 1843. Rubble masonry. Length 205 ft. Top width 19 ft. Radius at top 158 ft.

(3) Bear Valley dam, California. 1884. Radius 335 ft. Rough granite ashlar facing and rubble hearting. 300 ft. long. Thickness 2.5 ft. to 3 ft. at top and 8.5 ft. at 48 ft. below crest. Inaccessible location. Haulage of cement to site cost $10 per bbl. 3400 cu. yd. In 1911, in order to store more water, a new reinforced-concrete dam 30 ft. higher than the old was built just below this dam, submerging it.

(4) Sweetwater, California. 1887–88. Rubble. Weight per cu. ft. 164 lb. Length

about 380 ft. Radius 222 ft. 19 269 cu. yd. Top width 12 ft. Mortar used mostly 1 portland to 3 sand, but near upstream face mortar was 1 : 2. Cost about $234 000. 1895 dam was overtopped by 22 in. of water for 40 hours without damage. In 1911

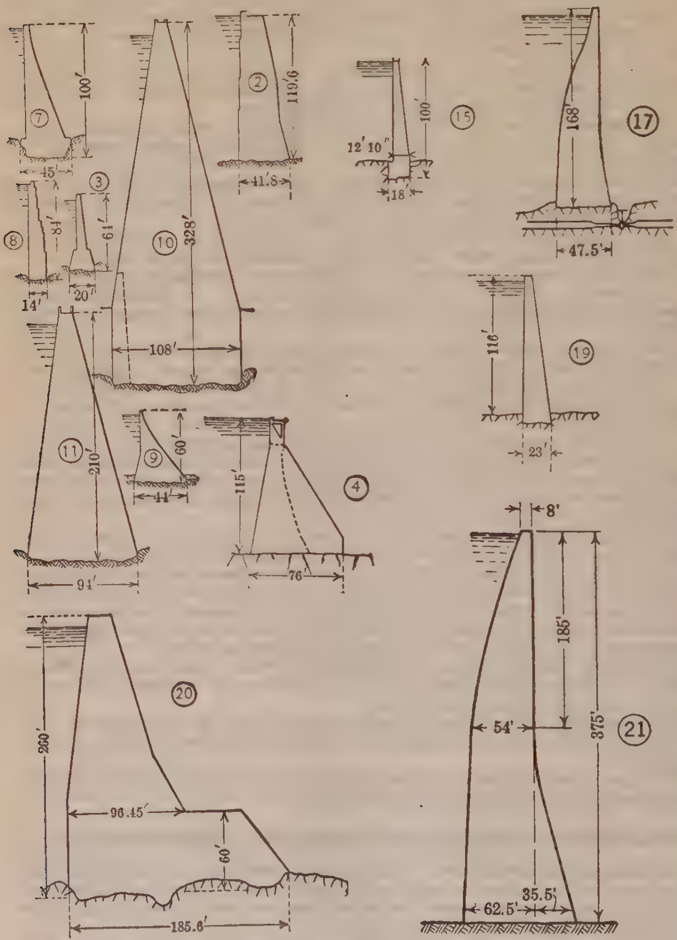

Fig. 5. Arched Masonry Dams

the dam was increased 20 ft. in height and a new section, reinforced with old rails, was built on the downstream side, 76 ft. wide at the base and reducing to nothing at the elevation of the top of the old dam. Care was taken to bond the old and the new concrete.

(5) Belubula, Australia. 1898. Concrete and brick. Lower part up to 23 ft. height

s concrete, above this brick arches and buttresses built 36.7 ft. higher. Series of buttresses 28 ft. c. to c., elliptical arches between, axes inclined 30 deg. to vertical. Arches 4 ft. thick at bottom, 1 ft. 7 in. at top. Buttresses 40 ft. long, 12 ft. wide at wall and 5 ft. at outer end. Each buttress forms a segment of circle 36 ft. 2 in. radius and diminishes in thickness from 8-1/2 ft. at center to 4 ft. at outer circumference.

(6) Johannesburg, South Africa. 1898. Rubble masonry, hard blue quartzite, concrete foundations reinforced with rails. Top width 7 ft. Length 585 ft. 30 000 cu. yd. Arch and tangent; part on tangent, gravity section. Radius of arch section 275 ft. at crest, decreasing to 206 ft. 75 ft. below to meet lines of gravity section.

(7) Barossa, South Australia. 1899–1903. Concrete with plums, reinforced at top with steel rails. Length 472 ft. Radius 200 ft. Cu. yd. 17 975, of which 12.3% large stones. Top width 4.6 ft. Range of temperature during construction was from 30° to 168° F. Total cost $827 000.

(8) Upper Otay, California. 1900. Masonry reinforced with steel plates and cables. Top width 4 ft. Length 350 ft. at crest, 20 ft. at base. Radius 359 ft. In a rock gorge.

(9) Geelong, Australia. Sandstone concrete. Top width 2.5 ft. Radius 300 ft.

(10) Shoshone, Wyoming. 1903–10. Concrete. Top width 10 ft. Length 200 ft. Radius 150 ft. 75 000 cu. yd. In narrow solid granite gorge. Contract price $515 730.

(11) Pathfinder, Wyoming. 1905–09. Cyclopean masonry. Radius 150 ft. 54 000 cu. yd. Length on top approximately 425 ft., at base 80 ft. In narrow granite gorge. Contract price $482 000.

(12) Sand River, Port Elizabeth waterworks, South Africa. 76 ft. high. Radius 300 ft. Length 360 ft. Cyclopean masonry faced with concrete blocks. Soap and alum washes on faces for waterproofing. Dam reinforced with steel rails.

(13) Dam at Hume, California. Concrete reinforced by railroad iron and cable. Concrete approximately 1 : 2 : 4, crusher run of granite being mixed with sand. Series of buttresses parallel to stream with arches between; 12 arches each of 50-ft. span. Water face and parts of downstream face plastered. Water face two coats cement mortar 1 to 1-1/2 and wash coat of neat cement on bases of middle arches. 2207 cu. yd.

(14) Salmon River dam, Idaho. Cyclopean masonry. 220 ft. high. 463 ft. long. Top width 15 ft. Base width 119 ft. Radius upstream face 225 ft.

(15) Huacal, Mexico. 1911–12. Crest length 140 ft. Radius 76 ft. Maximum height 100 ft. Base width 12 ft. 10 in., 80 ft. below top.

(16) Goodwin, California. 1911–12. Concrete two spans of 135-ft. radius abutting on central pier. Length 466 ft. Width at top 8 ft. and bottom 16 ft. Maximum height 78 ft.

(17) Salmon Creek, Juneau, Alaska. 1913–14. Concrete. Constant-angle arch type. 52 000 cu. yd. Height 168 ft. Width at top 6 ft. Base 47.5 ft. Radius at top 331 ft., at bottom 147.5 ft.

(18) Eagles Nest, New Mexico. 1916–18. Concrete. Length 300 ft. Top width 8 ft. Bottom width 46 ft. Maximum height 140 ft. Radius 155 ft.

(19) Corfina, Italy. 1915. Concrete. Top width 5 ft. Bottom width 23 ft. Maximum height 116 ft. Radius 75 ft. Built in 65 days.

(20) Spaulding, California Built to height of 225 ft. in 1913 and raised to 260 ft. in 1916. Estimated yardage 169 000. Width at 260-ft. level 14 ft. Planned ultimately to be 305 ft. high. 304 000 cu. yd. Vertical drains and inspection gallery. Lower 60 ft. of gravity section.

(21) Pacoima, Los Angeles, California. 1927. Variable-radius constant-angle arch type. Span across canyon at crest 550 ft. Height 375 ft. Thickness at crest 8 ft., and 98 ft. at 375 ft. below crest. Upstream radius 340 ft. at crest and 170 ft. at base. Downstream radius 332 ft. at top and 54 ft. at base. 150 000 cu. yd. concrete. Cost $1 750 000

Straight Masonry Overflow Dams (Fig. 6)

(1) Vir Weir, India. Uncoursed rubble. 2340 ft. long. 43.5 ft. high. Top width 9 ft.

(2) Henares Weir, Spain. Concrete with ashlar facing. 390 ft. long. Maximum height 23 ft. Base width 45.8 ft.

(3) Vyrnwy, England. 1882–89. Cyclopean masonry. Length 1164 ft.

(4) Lynx Creek, Arizona. Intended for ultimate height of 50 ft. Height was about 31 ft. In 1891 flood overtopped and destroyed dam.

(5) Folsom, California. 1886–91. Rough granite ashlar blocks. 48 590 cu. yd. Top width 24 ft.

(6) Betwa, India. 1888. Length 3296 ft., made in three tangents between islands. Top width 15 ft. Rubble masonry laid in native hydraulic lime. Ashlar coping 18 in. thick in portland cement mortar. Cost $160 000. Has had 16.4-ft. head on crest.

(7) Austin, Texas. 1891–92. Hard limestone rubble, granite facing and coping.

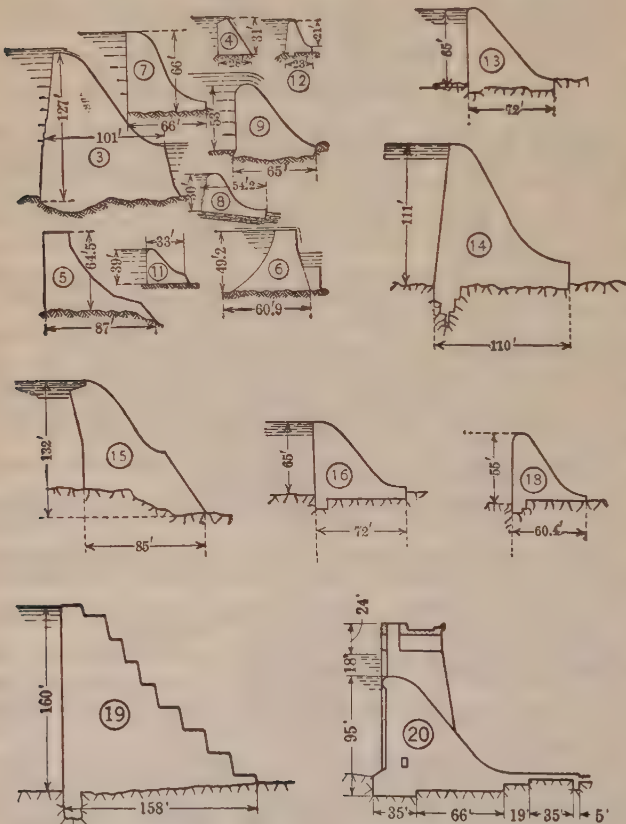

Fig. 6. Straight Overflow Dams

Length about 1100 ft. 88 000 cu. yd. Cost $608 000. Failed under head of 11.07 ft. on crest. Previously stood 9.8 ft. head. About 300 ft. slid forward. No overturning.

(8) New Holyoke, Massachusetts. 1897. Rubble with dressed stone cap and facings and concrete toe. Length 1020 ft. Upper part of downstream face is parabolic, lower part is cycloidal.

(9) Holtwood, McCall's Ferry, Pennsylvania. 1904. Concrete with plums. 2350 ft. long.

(10) Great Northern Power Co., Minnesota. 1907. Concrete. 365 ft. long, 38 ft. high. 42 ft. wide at base, curved crest.

(11) Connecticut River dam. Concrete with plums (1 : 2.5 : 5 except in deep foundations where 1 : 3 : 6 was used). Length 600 ft.

(12) Escanaba, Michigan. Concrete with earth banks at end. Length 810 ft. Concrete in heart 1 : 3 : 6 on sides and bottom 1 : 2 : 4. Facing 1 ft. thick upstream and 1.5 ft. downstream. Founded on stratified limestone. 8-in. drain pipes at 10-ft. intervals from cutoff to toe of dam.

(13) Hales Bar, Tennessee. 1905–13. Cyclopean concrete. Foundation limestone badly fissured. Fissures closed in part by grouting, and, in addition, 26 reinforced-concrete caissons 30 × 32 to 54 × 72 were sunk by pneumatic process through fissured rock to solid foundation. Height 65 ft. Length 1200 ft. Width 72 ft. Curved crest.

(14) Holter, Wolfcreek, Montana. 1910. Concrete with plums. Length 1362 ft., including 504 ft. overflow section. Height 111 ft. Width 110 ft. plus 70 ft. of apron. Cutoff trench 44 ft. deep.

(15) Hauserlake, Montana. Completed 1911. Replacing steel dam which failed by undermining. Length 490 ft. 85 000 cu. yd. Maximum height 132 ft. Width 85 ft. Ogee type. Part of foundations placed by pneumatic caissons.

(16) Coosa River, Lock 12, Alabama. 1912–14. Cyclopean masonry. Length of spillway 930 ft. Height 65 ft. Width 72 ft. Parabolic crest.

(17) Keokuk, Iowa. 1 : 3 : 5 concrete. Length 4278 ft. Height 32 ft. Width 42 ft. Ogee type.

(18) Youngstown, Ohio. 1916–18. Concrete. Length 638 ft. Height 55 ft. Width 60 ft. 5 in. Earth embankment at ends.

(19) Gilboa, New York. 1919–27. Stepped spillway section 1300 ft. long. 160 ft. high.

(20) Wilson, at Muscle Shoals, Alabama. 1918–26. Length comprises 200 ft. north abutment, 2668 ft. spillway section and 230 ft. sluiceway section. 1250 ft. power house section. Dam proper has height 98 ft. above river bed and 140 ft. from lowest point of foundation to operating bridge. 101 ft. thick at base. Inspection gallery 6 ft. wide and 9 ft. high. Dam divided into sections 46 ft. long by expansion joints.

Curved Masonry Overflow Dams (Fig. 7)

(1) Elche, Spain. 16th century. Rubble, cut-stone facing. Length 230 ft. Radius 205.38 ft. 1836 breach made during flood.

(2) Verdun, France. 1866–70. Rubble, cut-stone facing downstream. Concrete foundation. Riprap in front of wall. Length 131.23 ft. Radius 108.83 ft. Width of top 14.17 ft. Designed for depth 16.4 ft. water on crest.

(3) La Grange or Turlock, California. 1891–94. Rubble. Length 320 ft. on crest and 80 ft. at base. 39 500 cu. yd. Radius 300 ft. Has had about 15 ft. depth of water on crest.

(4) Cornell University dam, New York. 1897. Concrete of 4 parts argillaceous shale. 2 parts of sand, 1 part of cement. Length 153 ft. Radius 166.5 ft. Maximum height 30 ft.

(5) Walnut Canyon, Arizona. Rubble faced with ashlar. Length about 268 ft. Radius 400 ft. 6986 cu. yd.

(6) Seligman, Arizona. 1897–98. Concrete foundation. Rough rubble above with dressed ashlar facings. Top width 1.75 ft. Total length on crest 643 ft. The center section, 340 ft. long, is built as an overflow dam. Length at base 145 ft. Radius 800 ft.

(7) Espanola, Ontario. Concrete with plums. Built for 10-ft. overflow. Radius in plan 187 ft.

(8) Tallulah, Georgia. 1914. Crest length 444 ft. Radius 900 ft. Automatic flashboards of the Stauwerke type installed between piers on the 280-ft. spillway. Height 135 ft.

(9) Yadkin Narrows, North Carolina. 1917–19. Cyclopean concrete. 525 000 cu. yd. with 25% plums. Length 1400 ft. Radius 1678 ft. Height 200 ft. Designed for 10-ft. overflow. Taintor gates on crest. Drainage and inspection galleries.

(10) Martin Dam, Tallapoosa River, Alabama. 1923–26. Length straight abutment 300 ft. Headworks 224 ft. Curved spillway 720 ft. on arc of 530-ft. radius. Dam proper has height 138 ft. above river bed and 168 ft. from lowest foundation to operat-

ing bridge. Thickness at base including bucket, 160 ft. Dam designed for 21-ft. over crest.

(11) Baker River, Seattle, Washington. 1924–26. Upstream radius 250 ft. Spillway crest 493 ft. long provided with gates 12 ft. high and operating bridge 22 ft. above gate-sill. Gates at crest 10 ft. wide and 12 ft. high. Dam 24.5 ft. thick 13 ft. below

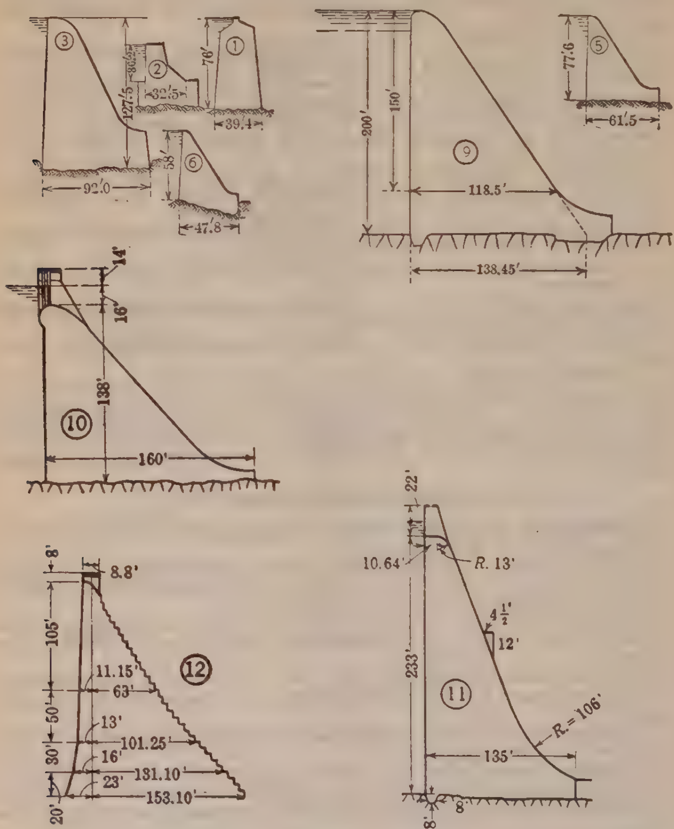

Fig. 7. Arched Overflow Dams

gate-sill. Below this point downstream face has batter of 3 on 8. Maximum height 263 ft., bedrock to bridge deck.

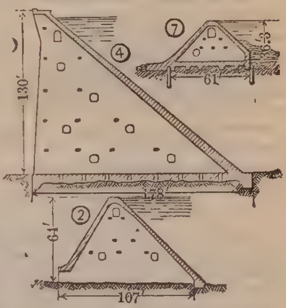
(12) St. Francis Dam, California. Maximum height 205 ft. 148 ft. thick at 193 ft. below top. Radius of upstream face 505 ft. Failed March 12, 1928, when the reservoir was first filled to within a few feet of the crest, suddenly releasing about two billion cu. ft. of water, causing a loss of between four and five hundred lives. Cause of failure: poor foundation.

2. Reinforced-Concrete Dams

Reinforced-concrete dams are usually of cellular construction, in some cases containing power houses. If properly designed they are admirably adapted to many situations. The general practice is to build a series of piers or buttresses 12 to 18 ft. apart and cover with a flat deck of concrete reinforced between the different bays as a beam. In the multiple-arch type, the buttresses are spaced 30 to 40 ft. apart and support a deck of concrete arches springing between the buttresses.

Unit stresses in such dams should be much lower than would be safe for ordinary building construction for an incipient failure in the latter case usually means only an unsightly crack, whereas for a dam it might mean a catastrophe. The following data refer to Fig. 8.

(1) Schuylerville, New York. 1904. Rollway 250 ft. long. Designed for 5-ft. head on crest. Founded on Hudson River shale. 5 × 3 cutoff wall. Passageway through dam from shore to shore. Average height 25 ft. with base width 52 ft.



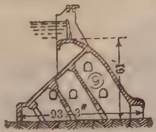


Fig. 8. Reinforced-Concrete Dams

(2) Ellsworth, Maine. 1907–08. Buttresses 15-ft. centers, 1 ft. thick at top, 2 ft. at bottom and braced by 12-in. × 18-in. reinforced concrete beams. Deck 1 ft. 2 in. thick at top, 3 ft. 1 in. at base. Total length 500 ft. Concrete, 8000 cu. yd. Flash-boards provided. Designed for flood 6.5 ft. on crest. Vents to prevent vacuum on apron.

(3) Pittsfield, Massachusetts. 1907–08. 42 ft. high. 465 ft. long. 3950 cu. yd. concrete. Founded on gravel underlain at depth of 12 ft. by dense yellow clay. Cutoffs extend 3 ft. into clay. Work carried on continuously when temperature was 12° below zero by heating materials and using salamanders. Concrete laid in winter and in moderate weather said to be uniform in quality.

(4) La Prele, Wyoming. 1908. Buttresses 18-ft. centers, 1 ft. thick at top, 4 ft. 2 in. at bottom, braced by 18 in. × 24-in. reinforced-concrete beams. Deck 1 ft. thick at top, 4 ft. 6 in. at base. About 15 000 cu. yd. concrete. Cutoffs 15 ft. to 18 ft. deep. Concrete in buttresses 1 : 3 : 6, deck 1 : 2 : 4.

(5) Dansville, New York. 368 ft. long including earth embankment. Gravel concrete used. Footing course on water bearing gravel and boulders. Bed of seamy blue stone under gravel. Cutoff around footing course. At height of 10-ft. base width 14 ft. Failed by undermining when water stood about 14 in. against flashboards. Deck slab snapped where reinforcing bars came together. Bars were not bent after failure.

(6) D. L. & W. R. R., Scranton, Pennsylvania. 262 ft. long. 16.5 ft. high. Base width 11.5 ft. Uniform slab thickness 10 in. Buttresses 7-1/2 ft. apart in center, increasing to 10-1/2 ft. at end. Soil under dam partly sand and partly yellow clay. 1/2-in. cup bars 12 in. c. to c. 1-1/2 in. from face, to prevent temperature cracks. Clay bank 8 ft. high at center to prevent percolation under dam.

(7) Uncas Power Co., Connecticut. Spillway 80 ft. long. Foundation very compact gravel. Buttresses 10 ft. centers, 1 ft. 6 in. thick at bottom, 1 ft. at top, stiffened by 12-in. × 15-in. beams. Upstream deck 1 ft. 6 in. to 1 ft. 8 in. thick, downstream 1 ft. 8 in.

(8) Bear Valley, California. 1910–11. Multiple-arch of Eastwood type. Ten arches between buttresses. 33 ft. 6 in. centers. Radius of extrados 16-ft. axis of arches vertical for 14. ft height at top, below which they are on batter of 4 on 3. Buttresses 1 ft. 6 in. thick at top increasing by .36 in. per ft. to bottom. Arch rings 12 in. thick at top increasing by .17 in. per ft. in radial thickness. Downstream edge of buttress 2 : 1

slope. Buttresses stiffened by reinforced-concrete struts. Maximum height 92 ft. Length 363 ft. 4684 cu. yd. concrete.

(9) Austin, Texas. 1911–15. 560 ft. long. Replaces portion of straight masonry overflow section which failed in 1900. Buttress 20-ft. centers. Height 61 ft. to crest, which is provided with automatic gates 14 ft. high.

(10) Stony River, West Virginia. 1912–13. Buttresses 15-ft. centers. 12 in. thick at top and 18 in. at bottom. Braced with reinforced-concrete struts and a curtain wall. Six months after erection, foundation for length of 7 spans was washed out and buttresses and deck dropped into the hole. Reconstructed 1914–15 by deepening cutoff wall, increasing the safety against sliding and adding 3-ft. flashboards. Maximum height 51.17 ft.

(11) Lake Pleasant, Arizona. 1926. Multiple-arch. 1850 ft. long. Maximum height 176 ft. above river bed and 256 ft. above deepest foundation. Has double-wall type of buttress. Buttresses 60-ft. centers. Clear span of arches 44 ft. Minimum thickness of arches and buttresses at crest 18 in. At 200-ft. depth arches 7 ft. thick and buttress walls 5.4 ft. thick. Concrete of arches 1 : 2 : 4. Buttresses 1 : 2-1/2 : 5, all heavily reinforced. Contains 75 000 cu. yd. concrete and 1200 tons steel.

(12) Anyox, British Columbia. 1923–24. Length including spillway 680 ft. Maximum height 156 ft. Buttresses 24-ft. centers with thickness varying from 1.2 ft. at crest to 10.08 ft. at 150 ft. below crest. Upstream slope variable. Thickness of arch concrete 12 in at crest and 3.17 ft. near base. Radius of extrados constant 15.66 ft. Central angle 100 deg. Arch concrete 1 : 2 : 4 reinforced with 3/4-in. square bars 24-in. centers at extrados and intrados with 1/2-in. square tie bars 6 ft. apart. Buttress concrete 1 : 2-1/2 : 5 not reinforced.

3. Steel Dams

Steel dams are not very numerous. In many cases they may be built much more cheaply than other types, but to keep them safe requires frequent and careful inspection, and the question of their maintenance and length of life should always be taken into account when considering their relative economy. The following data refer to Fig. 9.

Fig. 9. Three Types of Steel Dams

(1) Ash Fork, Arizona. 1898. Steel portion 184 ft. long and 46 ft. maximum height. 24 triangular bents, vertical downstream side and 1 : 1 upstream, 8 ft. c. to c., braced laterally in pairs. Batter posts 20-in. I-beams, 65 lb. per ft. and reinforced on under side with plate 1/2 in. thick and 18 in. wide. Series of 3/8-in. curved plates on upstream face concave upstream with radius 7-1/2 ft. No leakage. Total weight of steel 478 704 lb. Framed and erected at $55.78 per 2000 lb.

(2) Redbridge, Michigan. 1900–01. Steel portion 464 ft. long. Maximum height of dam 74 ft. Concrete base throughout. "A" frame bents 8 ft. apart, 3/8-in. face plates concave upstream radius 7 ft. 6 in., riveted to I-beams 15 to 24 in. deep. Batter upstream face 2 : 3. To cut off percolation under dam, line of drill holes 2 in. in diameter and 10 ft. long, 7 in. apart drilled and filled with grout under heavy air pressure. Rock floor covered with concrete and then by bank of puddle clay.

(3) Hauser Lake, Montana. 1907 630 ft. long. Maximum height 81 ft. Inclination upstream face 3 : 2. Portion of dam founded on solid rock. About 300 ft. founded on steel sheet piles in gravel. Bents 10 ft. apart connected in groups of four. Actual head to top of flashboards 69 ft. Working head about 66 ft. About 1700 tons of steel.

Blanket of volcanic ash above dam to prevent seepage. Downstream face had flat plates on slope 7 : 11, connecting with plank apron carried on stone-filled cribs. Dam undermined where founded on gravel. Concrete placed over top of steel piling, said to have been placed in depth of 10 ft. or more water, so quality may have been very poor. Part of dam on rock remained standing. Replaced by concrete dam in 1911.

4. Timber Dams

The Rafter and Strut-Framed Dam (Fig. 10) is a structure which may be proportioned with reference to its stresses, but requires careful design, sawed timber and skilled workmen and is proportionally more expensive.

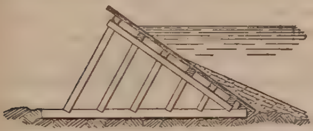

Fig. 10. Framed Timber Dam

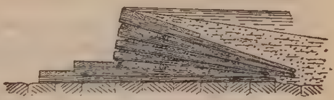

Fig. 12. Beaver Type Dam

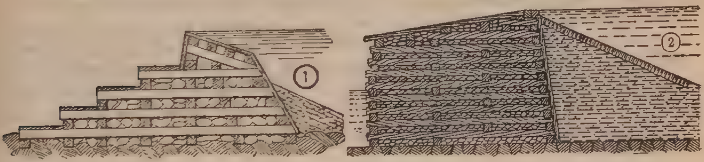

Fig. 11. Crib Dams

Crib Dams (Fig. 11) have been extensively used where timber was cheap and masonry dear. They must be designed largely by judgment and by following precedent. They are not subject to a very rigid analysis of stresses. The whole crib filled with loose rock may be considered as a unit adapted to resisting ordinary stresses of compression, tension and shear. The compressive stresses are resisted largely by the bearing of the timbers, one on the other; the tensile stresses are resisted by the bolting and sometimes dovetailing of the timbers and the shear largely by the friction in the rock fill. Considered from this angle the crib dam can be designed with some reference to stresses. Another way of looking at it is to give about the width required for a rock fill dam and consider the crib acting somewhat as a binder and mainly as an attachment for a watertight timber sheeting to cut off leakage on the upstream side and to take wear and impact of the overflow on the top and downstream sides. The width of the crib-work is seldom less than one and one-third times the height and may be two or three times where long aprons are provided for overflow as in (1) Fig. 11. The highest dam of this type which has not failed was the Butte dam, about 70 ft. high. No. (2) Fig. 11 is a cross-section of a crib dam in the Schuylkill River subject to floods 11 ft. high over crest. If crib dams are subject to heavy floods provision should be made for admitting air to the downstream side underneath the sheet of overflowing water.

The Beaver Type of timber dam is adapted to comparatively small heights. It is built as indicated in Fig. 12. The longitudinals are all laid with butts downstream. The crevices are filled with gravel, and the whole is covered with brush tightly packed and a bank of the most impervious earth obtainable.

A plank flooring is carried from the crest well under the earth fill. Most failures of timber dams have been due to leakage underneath or to undermining by the overfall.

5. Earth Dams

Foundations. One of the reasons for building a dam of earth is usually that a rock foundation cannot be had, though several earth dams have been built on the best of bedrock. The foundation, whether earth or rock, should be thoroughly examined to learn if it is impervious. If not impervious, cutoffs should be constructed, if possible down to an impervious stratum. Imperviousness is a relative condition. No earthy material is absolutely impervious, and if the width of the dam is so extended that the loss of head of water flowing through the shortest course to an exit is so great that the velocity is so slight that water will not move the earth or reduce its cohesion at the exit, then the cutoffs under the dam may be unnecessary. In any case the site is usually stripped and shallow trenches are dug across it. If the foundation is rock the creeping of water along its surface is guarded against usually by building a masonry wall entirely across the valley. This may be extended upward to the top of the dam as a core-wall, as in the Titicus dam, or, if the embankment is impervious, it is sometimes only 3 or 4 ft. high, as in the Borden Brook dam, Mass. Where the foundation is open sand or gravel, deep cutoff trenches have usually been excavated and filled with concrete or puddle clay. Sheet piling is sometimes used. The character of the ground and other local conditions must determine the kind of cutoff wall best to use. Springs which may be found within the area of the foundation may sometimes be dug out to their source outside the area of the dam, or intercepted outside that area and diverted.

Core-Walls. The dam itself usually consists of three parts: an interior impervious part with an embankment on each side to support it. The impervious part is a masonry, puddle or steel core-wall or a heart of selected impervious material. Occasionally the builders are fortunate enough to have at hand a natural mixture of gravel and clay of which the whole dam may be built, thus combining the three parts in one, but usually the impervious material available is either too expensive or is unstable at a practicable slope. What is the best type of core-wall is a mooted quested. Rubble, concrete, puddle clay, sheet steel and wood have been used. It is argued that masonry, whether rubble or concrete, must have a solid rock foundation, and that even then it is in danger of being cracked by settlement of the embankment or by temperature changes. On the other hand, it is argued that slight cracks will not be made larger by water but will be silted tight; that, if embankments are well built and the masonry core wall is 4 to 6 ft. thick at top with sides battered at about 1 to 10, it will not crack from settlement of the embankment; and also that, when outlets pass through or under the dam, they are much safer when masonry core-walls are used.

In regard to clay puddle it is argued that its integrity depends entirely upon great care and much intelligence and skill in mixing and placing, and that if once punctured its entire integrity is destroyed. On the other hand, it is argued that settlement does not rupture it, and that it makes a better union with the rest of the embankment.

At the Boston Water Works the endeavor was made to overcome all objectionable features and preserve the merits of both by building a masonry core-wall and placing a selected clayey material next the upstream side of the masonry.

Riveted steel plate cores coated with asphalt have been used. Timber sheeting should not be used, as it is likely to decay. Whether the core-wall should be placed in the middle or near the upstream side of the embankment will depend upon the material used and local conditions. If the core-wall is to be of masonry it should be vertical, and this usually requires it to be under the crest of the dam. If the core-wall is of clay it is usually placed vertically under the crest, but sometimes on the upstream face, in which case it should be protected by additional filling. The slope must be very flat or else there must be considerable filling outside it to prevent slipping; also provision must be made against burrowing animals, if the clay is near the surface. Small stones or furnace slag mixed with the puddle are frequently used for that purpose.

The Placing of Embankment when not done by the hydraulic process is usually done by carts or cars. It is usually specified that the earth shall be spread in from 4- to 8-in. layers, rolled with a heavy roller, and that, before placing the next layer, the last one shall be sprinkled and harrowed to insure bonding. Variations in details of construction on different dams have been

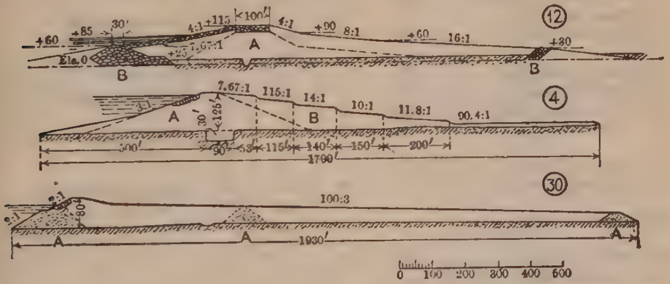

Fig. 13 Earth Dams

the use of a drove of horses and sometimes goats to trample the earth, also heavy four-horse teams for hauling, runways being avoided. Rollers having grooves or projections on their faces are used on many dams. The embankment is usually kept 4 or 5 ft. higher on the outer edge than in the middle.

Slopes must be determined by the engineer for each individual case. Precedents may be studied in the following table. If it were simply a question of the stability of the face the slope for the same material should be flatter on the upstream side than on the downstream side, for the angle of repose, especially of very fine material, is less in water than when not saturated but slightly damp, which is usually its condition on the downstream side. If the dam is without a core-wall or other impervious hearting and subject to seepage either under or through the embankment, it may be necessary to make the downstream slope very flat. The upstream face is pitched or otherwise protected against wash of waves. The downstream slope is sodded to protect it from wash of rains. Berms with paved drains are used frequently in addition to sodding.

Top Width and Height above Water. The formula $W = \frac{h}{5} + 5$ in which h = height of dam in feet, has been suggested as giving safe widths in feet, for tops of earth dams. The top should be so high and wide that no burrowing animals can reach the heart of the dam at water level. It should also be high enough above the highest water level to be beyond the reach of all waves. Stephenson's formula for height of waves is commonly used.

$$X = 1.5\sqrt{F} + (2.5 - \sqrt[4]{F})$$

in which X is the height in feet, F the fetch in miles or sweep of the wind in

Data on Compacted Earth Dams

Numbers in parentheses refer to Figs. 13 and 14 and to the following notes.

Number and name	Maximum height, ft.	Top width, ft.	Slope up-stream	Slope down-stream	Material	Core-wall

P = Puddle. C = Concrete. R = Rubble. O = No core-wall.

the longest straight line which may be drawn from the dam on the water surface of the reservoir.

(1) Goose Creek, Idaho. 1910–13. Upstream face covered with 3 ft. of loose rock, and loose rock dumped at toes. Core-wall 3 ft. thick to 10 ft. above natural surface and 1 ft. thick from this point to top. Length 1050 ft.

(3) Patillas, Porto Rico. 1914. Length 1020 ft. Contains 970 000 cu. yd. First 50 ft. in height made by dumping from two trestles near either toe. Successive lifts then made by shifting track. Outer slopes of gravel and boulders. Middle of dam about 25% clay washed into position and allowed to settle in pool maintained by the side banks. Total settlement 0.56 ft. in three years.

(4) San Leandro, Calif. 1874–76. Portion "A" in cut built in 1874 of earth in layers 1 ft. thick. No rollers used, but material dumped and sprinkled and band of horses used to compact. In 1898 portion "B" was placed by the hydraulic process. Shaken by San Francisco earthquake 1906. No damage. Puddle trench 30 ft. below ground.

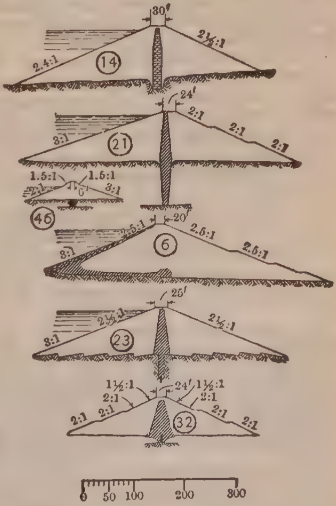

Fig. 14. Earth Dams

(5) Lahontan, Nev. 1913. Length 1359 ft. Volume 710 000 cu. yd. Upstream portion of gravel and silt, mechanically mixed and rolled in 4-in. layers and faced with riprap and gravel. Downstream portion of pit-run gravel. Foundations a red sandstone. Puddled cutoff wall. Grouted rock foundation.

(6) Tabeaud, Calif. 1900–02. Built in 6-in. layers first 60 ft. Not over 8-in. layers above. Top kept basin-shaped. Clay puddle on bottom and part of upstream face. 1 berm upstream, 3 downstream. Foundation hardpan and rock.

(7) New Croton, N. Y. 1901. Dam partly constructed, then replaced by masonry structure. 2 berms downstream.

(8) Costilla, Colorado. 1917. Length 600 ft. Upstream slope riprapped. Cutoff wall 30 ft. into clay and gravel foundation and 5 ft. above natural ground surface. Built by dumping earth in ridges about 5 ft. high and partly filling trench between with water, then filling the trenches by dumping from wagons, then building new ridge over former trench and repeating process.

(9) Druid Lake, Maryland. 1864–70. Upstream face covered with puddle. Stone wall in bottom of clay core. Embankment each side of puddle core well rolled. Part of the material in dam placed in basins filled with water. Surface soil stripped, and where foundation is sand, core carried to impervious stratum.

(10) Belle Fourche, South Dakota. 1910. 6-in. layers. Some sheet piling near upstream toe. $879 164 contract price.

(12) Gatun, Panama. 1913. Portion "A" in cut is hydraulic fill, "B" is rock fill and the remainder is dry fill. There is a layer of 3 ft. of rock paving 170 ft. wide on the upstream slope to resist wave action.

(13) Standley Lake, Colorado. 1908–12. Length 6630 ft. Material lumpy, blue clay which slaked very readily and became a slimy ooze on being saturated. Upstream face protected by loosely dumped riprap. In 1912 a small slide of the downstream face occurred and in 1914 there was a much larger slide of the same face. In 1916, following a rapid draining of the reservoir for irrigation purposes, about 88 000 cu. yd. slid from the extreme face.

(17) Somerset, Vermont. 1911–13. Length 2100 ft. Contains 1 000 000 cu. yd. Material was coarse gravel and sand with some clay. Excavated by steam shovel hauled to site and dumped from trestles on the upstream and downstream slopes. From there the material was sluiced down about a 2 : 1 slope toward the middle of the dam, the object being to leave coarse material on the faces and gradually grade to a fine impervious heart.

(18) Temescal, California. 1866–68. Originally built in layers with carts and scrapers, with top width 18 ft. at maximum height of 105 ft. and slopes 3 : 1 upstream and 5 : 2 downstream. In 1869 downstream slope flattened by sluicing. In 1886 height increased to 115 ft. by sluicing. As finished downstream slope 5 : 1.

(19) Carite, Porto Rico. 1914. Length 520 ft. Upstream face paved. Downstream slope, lower half paved. 200 000 cu. yd. Fill dumped from trestle and spread by scrapers and wheelbarrows. Very little sprinkling done. Settled 0.96 ft. in three years.

(21) Yarrow, England. Maximum depth excavation 97 ft. Puddle core-wall on concrete foundation in rock. 2 berms on downstream slope.

(22) Morris, Connecticut. 1910. Upstream slope 3 : 1 for a height of 30 ft. from toe, 2.5 : 1 above, faced with 1 ft. 6 in. of paving stones. Four berms 8 ft. wide on downstream slope, and slope sodded. Core-wall carried to rock 12 ft. wide at base and 2 ft. 5 in. at top. Length 1100 ft.

(23) Pilarcitos, California. 1864–66. Puddle core-wall 24 ft. thick, keyed to rock with concrete wall 3 ft. by 6 ft. Length of dam 640 ft. 1-3/4 miles from fault line of San Francisco earthquake of 1906. Dam uninjured by earthquake.

(24) Dale Dyke, England. Failed 1864. 95 ft. high, 1254 ft. long, 12 ft. wide on top. Upstream and downstream slopes 2.5:1. Puddle core. Failed; opinions as to cause varied. Said to be because outlet pipes laid naked or because dam above core-wall was a sort of rock fill, bringing full static pressure against core-wall.

(25) San Andreas, California. 1868–70. Dam raised in 1875. Puddle core-wall keyed to rock with concrete wall 3 ft. by 5 ft. Length 800 ft. Fault line of San Francisco earthquake of 1906 passes across east end. Crack 2 to 3 in. wide along axis of dam but it did not fail.

(26) South Haiwee, California. 1912. Length 1523 ft. 559 750 cu. yd. Upstream slope paved with 3 in. of concrete. Cutoff trench carried down to rock, in some cases to a depth of 120 ft.

(27) Forest Park, Maryland. Clay puddle on upstream face and carried to bed-rock in a trench near upstream toe.

(28) Dry River, Watervliet, N. Y. 1913–14. 1 berm 8 ft. wide, 40 ft. below top on both faces. Material rolled in 6-in. layers. Upstream face partly paved.

(29) Sherburne Lakes, Montana. 1918. Length 900 ft. 250 000 cu. yd. Upstream slope has 18-in. paving of field stone on a 12-in. layer of gravel, and concrete parapet wall 3 ft. high at top. Downstream slope covered with 12 in. of gravel. Unique feature was permeable core-wall of screened gravel 5 ft. thick at crest, increasing with 3.5 in 100 batter, with system of pipe drains running from base of core to downstream toe. Two cutoff trenches on upstream side, 1 on downstream. Material hauled in dump wagons spread in 6-in. layers rolled with 20-ton roller.

(30) Wachusett, N. Dike, Massachusetts. 1900–05. This dam is about 10 000 ft. long. 5 500 000 cu. yd. There are three embankments of sand and gravel shown at "A" in the cut. The remainder was built largely of fine loamy soil stripped from the reservoir site. Material spread in 1-ft. layers and rolled by steam road roller and harrowed before adding new layer. Foundation pervious sand and gravel. For a portion of the length a trench was dug 60 ft. deep in this gravel, and triple-lap tongued-and-grooved sheet piling built up of 2-in. plank was jetted down from 20 to 60 ft. On April 11, 1907, a portion of the upstream face 675 ft. long, of a thickness of 35 ft. normal to the slope, slid down the bank, causing little damage but indicating that 1 vertical to 2 horizontal was too steep for such fine material under water.

(31) Cold Springs, Oregon. No core-wall. Cutoff trench.

(33) Talla, Scotland. 1897–04. The clayey or adhesive material in middle third placed in 9-in. layers. Outside this is stony or open material in 18-in. layers.

(34) Throttle, New Mexico. 1914. Length 1060 ft. Concrete core wall 600 ft. long with galvanized corrugated iron extending from cutoff wall to crest. Upstream slope paved. Center portion of dam well puddled. Downstream slope faced with selected rock, hand laid.

(35) Seros, Spain. 1913–14. Dam No. 3 is the highest of 7 earth dams in hydro-electric development near Barcelona. Length 1312 ft. 497 250 cu. yd. Upstream face riprapped. Puddled cutoff trench. 1 berm downstream slope.

(36) Las Vegas, New Mexico. 1917. Upstream slope riprapped 9 in. thick. 1 berm on downstream face. Length 1400 ft. Material hauled by dump cars and sluiced into place with water jet.

(37) Mammoth, Utah. 1908–14. Proposed height 125 ft. Concrete core-wall with buttresses. Earth placed by wagons and scrapers and rolled. In June, 1917, dam was at a height of 70 ft. with water stored to nearly the same height. Washout occurred at flume carrying water across the top. One-half billion cu. ft. water released cutting dam to foundation causing great damage to structures below.

(38) Johnstown, Pennsylvania. Lower face entirely stone, 4 ft. thick at top, 20 ft. at bottom, and backed by slate rock 3 ft. thick at top and 30 ft. at bottom. Heart of selected earth. Upstream face of dry rubble 15 in. thick. Failed: flood over-topped dam.

(39) Keechelus Lake, Washington. 1914. Length 6500 ft. 522 000 cu. yd. Upstream slope faced with riprap. Concrete cutoff wall.

(40) Phelps Brook, Connecticut. 1917. Length 1200 ft. Upstream slope 3 : 1 below water surface, 2 : 1 above, faced with 12 in. of riprap. 1 berm on downstream slope. Concrete core-wall to rock.

(41) Youngstown, Ohio. 1913–16. Length 2202 ft. Concrete cutoff. Upstream slope faced with 9 in. to 18 in. of concrete.

(43) Glenwild, New York. 1902. Core-wall is broken boulders grouted with 1 : 3 cement mortar. Dam curved upstream with radius of 708.6 ft. Contract cost $47 360.

(44) Hatchtown, Utah. 1908. Failed in May, 1914, probably due to leakage along the outer surface of the outlet culvert and leakage through foundations of black clay sand and gravel. Length 780 ft. 126 000 cu. yd.

(45) Bog Brook, New York. Masonry core-wall 10 ft. thick at base and 6 ft. at top. Upstream face has 12-in. paving on 6-in. broken stone. Berm on downstream side.

(47) Hebron, New Mexico. 1914. Length 3700 ft. Puddled cutoff trench. In May, 1914, a section 200 ft. long washed out.

(48) Horse Creek, Colorado. 1911–12. Length 5150. ft. Volume 714 000 cu. yd. Downstream slope 1.5 : 1 for distance of 16 ft. from crest, and 2.5 : 1 for balance. Upstream slope 1.5 : 1 face paved with 5 in. of concrete. Earth placed by dump wagons and spread with scrapers. No sprinkling and no packing of material done. In January, 1914, 200 ft. of the dam above the concrete culvert outlet washed out. Immediately after reservoir emptied, 3600 ft. concrete paving slid down slope.

Failures of Earth Dams. In a record of 30 failures of earth dams, which may be assumed to be representative, 11 were due to overflowing, 10 to leaks in outlet pipes, 3 to undermining, and 1 was attributed to burrowing animals. The causes of the other five were somewhat doubtful, but several causes were assigned, such as poor foundations, slopes too steep, lax construction methods and carelessness in preparing the site.

6. Hydraulic Fill Dams

Sluicing is a method of building earth dams by which, especially in mountainous regions, the material often may be excavated, conveyed to the site and placed much more cheaply than by any other means. The ideal material is a mixture of sand, clay and gravel with plenty of small rock. The develop-

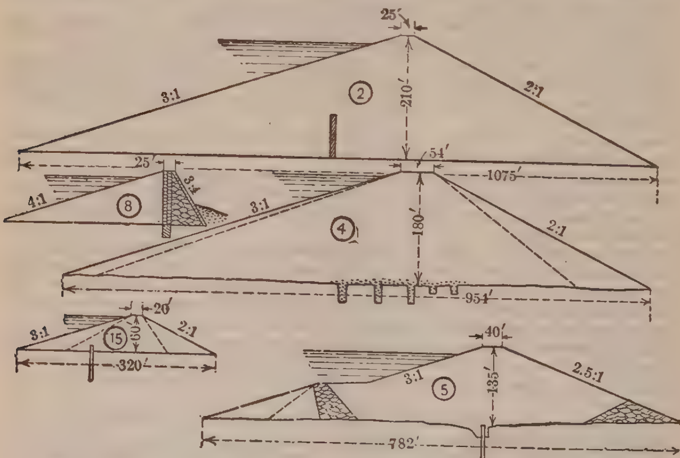

Fig. 15. Hydraulic Fill Dams

ment of the art has evolved a number of excellent properties of such dams, so many, in fact, that a number have been built by hauling dirt with cars to the site and sluicing it into place. The practice is for the sluices to discharge near the outside edges of the embankment. The coarse material drops there, and the fine flows with the water toward the middle of the dam, depositing, as it goes, the coarser first, the medium next, most of the clay going to the pond of still water in the center, where it is precipitated, forming a wide clayey core-wall. The coarse material remaining on the outer edge is most useful in maintaining the slopes due to its greater angle of repose. In practice, however, the danger is that the material will not be properly graded, either too fine, making the faces unstable, as in the case of the Calaveras Dam, or too coarse, making the core permeable. For that reason, continuous physical analysis should be made. Even if the material is properly graded the sluices may not deliver a uniform mixture, resulting in permeable layers across the dam. This danger is believed to be avoided by keeping men continuously spading and kneading the bottom of the pond in the middle of the dam. As the work progresses, a few men keep the edges built up just enough to keep the discharge from the sluices always flowing toward the center. The pond is sometimes allowed to drain by filtering through the coarser outside material, and sometimes by a vertical waste pipe built up in short lengths of from 6 to 15 in., changing its direction at the foot to a horizontal leading to the downstream face, or by pumping the surplus water out of the pond by a pump mounted on a raft and discharging over the top of the fill and never through it. There has been developed a modified hydraulic fill process in which the material is dumped on the outer edges of the dam and a stream of water is then played upon it which washes the finer parts into the central pond. This method was used on the Somerset, Davis Bridge, and Wanaque dams where the material was well graded from cobbles down to very fine.

Data of Hydraulic Fill Dams

Numbers in parentheses refer to following notes and to Fig. 15.

(1) Calaveras, California. Material is clay sand and gravel with dry rock fill at toes. Material sluiced from borrow pits down open channel 5 to 7% grade into concrete sumps and raised to dam with 12-in. centrifugal pumps. Designed to contain

3 000 000 cu. yd. After 2 800 000 cu. yd. placed, upstream face for length of 700 ft. slid. Aggregate 20 to 50% clay.

(2) Terrace, Colorado. Material sluiced from a clayey bank to form heart of dam, and from a separate bank clean rock and gravel were sluiced to the two slopes in flume on 7% grade using 26 sec.-ft. of water. Concrete core-wall about 65 ft. high in bottom of canyon.

(3) Little Bear Valley, California. Disintegrated granite and clay deposited from spoil trains on toes of dam and finer materials were washed to the center. Concrete core-wall.

(4) Necaxa, Mexico. Broken limestone and yellow clay. Concrete core-wall, about 6.5 ft. above stripped surface. Sluicing flumes 20 in. in diameter, 4 ft. wide, rectangular section with V-shaped bottom, grades 5% and 8%. During construction a slide of the upstream face occurred which was attributed to the use of unsuitable material. Dam since completed and now in use.

(5) Magic Reservoir, Idaho. Cutoff walls in sides of canyon. Cutoff trench and sheet piling under dam. Constructed by combination of methods. Excavated by steam shovels; spoil trains delivered material close to site, thence it was sluiced to place.

(6) San Leandro, California. 160 000 cu. yd. sluiced. Sluicing flume grades 4–6%. See earth dams.

(7) Crane Valley, California. Sluicing flume 12 in. by 10 in. Flumes on 6% grade. Ground sluicing was used; that is, material was dumped into flume after loosening.

(8) Waialua, Hawaii. Rock fill portion: base width 80 ft., crest 11.5 ft.; downstream batter 3/4 to 1, upstream face vertical; volume 26 000 cu. yd. Wooden diaphragm embedded at bottom in concrete wall. Earth fill 141 000 cu. yd. Soil dumped into flowing stream of 8 sec.-ft. in ditch 1300 ft. long with bottom grade 4%. The soil was a decomposed lava of a cohesive and unctuous character, very free from grit. Earth fill 11 cents per cu. yd. Leaked during first year. 1905 material obtained by enlarging spillway sluiced against lower toe.

(9) Santa Maria, Colorado. Two cutoff trenches to hardpan sheeted and puddled. Dirt and boulders conveyed by rectangular sluices 3 × 3 ft.

(10) Quemahoning, Johnstown, Pennsylvania. Slopes 4 : 1 for lower half and 3 : 1 for the upper half. Concrete cutoff wall extends 10 to 27 ft. into the shale rock; also puddled cutoff. Rectangular flumes 24 in. wide and 18 in. deep, grade 6%. Material a mixture of clay and shale rock.

(11) Lake Frances, California. Old earth dam failed, about 20% being washed away. Repaired and enlarged by hydraulic process. 182 937 cu. yd. of new dam sluiced in. 1.76 sec.-ft. of water used at first; later 4.5 to 7 sec.-ft. Sluicing flume 22 in. in diameter, minimum grade 2.2%. Most of material sluiced was clay. Brush used to maintain slopes.

(12) Snake Ravine, California. Built of fine silt and clay; slid as a body 1000 ft. down ravine at rate 6 to 10 ft. per sec. Failure attributed to lack of coarse material on slopes and fact that fine material did not drain when building.

(13) Santo Amaro, Brazil. Clay and disintegrated granite. Slip of blanket over core-wall of section east of hydraulic fill occurred during construction. Excess of clay in blanket did not allow good drainage outward. Sluicing flume 2000 ft. long, grade 3%.

(14) Croton Michigan. Fine yellow sand. Sluicing flume 30 in. in diameter semicircular; grade 8–9%; length 800 ft. Cost 6.8 cents per cu. yd., including plant, materials, labor, power, etc.

(15) Conconully, Washington. Loose rock, gravel, sand and silt. Sluicing flume, sloping side 2-3/4 ft. apart at top. No. 10 steel curved bottom bent to 12-in. radius, clear depth being 2-1/4 ft. Lateral flumes trapezoidal 12 in. wide at bottom. Sheet piling across valley 70 ft. upstream from center line driven 33 ft. and projecting 3 ft. above valley bottom. Flume grade 4%.

(16) Silver Lake, California. Heavy sandy loam containing considerable clay which was carefully separated and placed in center. Drains to prevent slipping during construction. Concrete core-wall under dam and 3 to 6 ft. above original surface. Sluicing flume 8 in. in diameter. 2.5 sec.-ft. water used in later stages. Flume length 4000 ft.

(17) Yorba, California. About 80% by hydraulic ground sluicing process. Adobe clay soil, sand and gravel. No core-wall; puddle trench through top soil. Material supplied to parts too high for gravity flume by pumping through an 8-in. pipe a maxi-

mum distance of 800 ft. Cost 8 cents per cu. yd. for ground sluicing. Flume grade 4–7%.

(18) Tyler, Texas. Sluicing flume 13 in. in diameter. Material 65% sand and 35% clay. Cost 4-3/4 cents per yard, including everything.

(19) Miami Conservancy, Ohio. A group of five dams located at Taylorsville, Englewood, Huffman, Lockington and Germantown were built near Dayton in 1919–20 to control floods on Miami River. They range from 75 to 125 ft. high and in volume from 800 000 cu. yd. to 3 500 000 cu. yd., totalling 9 000 000 cu. yd. for the five dams. The material was a well graded mixture running from coarse gravel down to fine sand and clay. Most of this material was pumped to the dam by 14-in. centrifugal pumps which had their suctions in hog boxes that were supplied partly by trains hauling material excavated by dragline excavators from borrow pits and partly by material excavated by hydraulic monitors and sluiced into the hog boxes. By continuous mechanical analysis and control at the hog boxes it was possible to obtain a very uniform grading of material going to the dam.

7. Rock Fill Dams

Dams of Loose Rock were designed to meet the requirements of miners in western America, where the great cost of hauling cement made the use of that material prohibitive. Since most of these structures are located in deep rock canyons, it was a simple matter to quarry the material at a higher elevation than the dam and transport it by gravity to the site or even to throw the material directly to place by blasting. Dams of this type are made watertight by a variety of methods. In some cases the upstream face is covered with planking spiked to studding buried in the rock fill, or with steel plates fastened to I beams set in the face, or with rubble masonry walls or reinforced-concrete facing. Steel core-walls are also used. A later development is the combination earth and rock-fill dam in which the earth is either dumped or sluiced into place on the upstream face.

Most of the failures of rock-fill dams have been due to insufficient spillway, causing overtopping. Some have been caused by poor design in making the slopes steeper than the natural angle of repose of the loose fill and trusting to dry rubble facing walls to hold the mass in position.

The following numbers correspond to those on the cross-sections of Fig. 16:

(1) Escondido, California. 1895. Faced with redwood plank. Timber face backed with concrete. Contains 6000 cu. yd. dry rubble and 31 157 cu. yd. rock fill. Leakage when full 450 000 gal. per day. Cost $110 000. Stones laid by hand on inner face to form dry wall 15 ft. thick at bottom and 5 ft. at top. Bedrock trench at upper toe filled with rubble masonry, in which plank facing is embedded. 76 ft. high. 380 ft. long on top and 100 ft. on bottom. 140 ft. wide at base and 10 ft. on top. Slopes are 1 : 2 on water face; 1 : 1 on back for half the height and 5 : 4 from mid-height to base.

(2) Castlewood, Colorado. 1890. Lower slope covered in steps of 2 ft. with large blocks of stone in cement mortar. General slope 1 : 1. Upper face wall rough rubble masonry 4 ft. thick, on batter 1 : 10. Walls joined at top with coping. Crest width 8 ft. Dam founded on clay. Front face wall carried 6 ft. to 22 ft. into clay. Lower slope wall also founded on clay at depth 10 ft. below surface. Length 600 ft. Height above reservoir floor 70 ft.; above foundation of face wall 92 ft. Rock pavement 25 ft. wide, 200 ft. long, 3 to 6 ft. deep, heavily grouted at top with cement mortar to prevent scouring. Dam leaked. Earth embankment added to upstream face, 8 ft. wide at crest with 3 : 1 slope faced with 12 in. of riprap.

(3) Lake Avalon, New Mexico. Length 1050 ft. Earth slope covered with revetment of loose stone 2 to 3 ft. thick for wave protection. Failed 1893, water passing over top, washing out 300-ft. length to bedrock. Immediately repaired and built 5 ft. higher. Second failure 1904. Stated that water did not pass over top but forced way through the dam. Failure attributed to burrowing animals, or faulty construction where dam connected with bank. Reconstructed with top width 43 ft. Substantial

addition made to earth fill and core-wall built of concrete heavily reinforced. Part of core-wall on concrete base and part on sheet piling driven to rock.

(4) Walnut Grove, Arizona. 1887–88. Destroyed by flood 1890 with loss of 129 lives. Length 400 ft. Slopes much steeper than natural angle of repose of loose rock. Faces laid up as dry walls. With 70 ft. of water above bedrock, dam leaked 3.75 cu. ft. per sec.

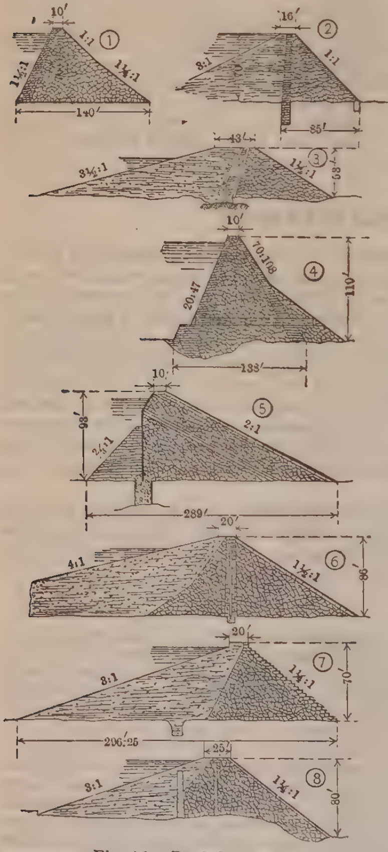

Fig. 16. Rock Fill Dams

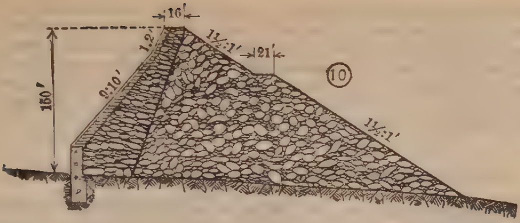
(5) East Canyon Creek, Utah. 1899. Originally built 68 ft. high. Length 100 ft. Concrete wall 15 ft. thick, carried down through gravel to bedrock and steel plates for core anchored in center. Rock thrown on wall by blasting sides of canyon. Open cut made in pile of rocks thrown down and steel core-wall built from anchor plates. Asphalt concrete 4 in. each side of plate. Settlement of wall caused asphalt to draw away from steel an extreme distance of 5 ft. at top. Dam cost $60 200 and required 23 000 cu. yd. rock, 810 cu. yd. cement concrete, 183 cu. yd. asphalt concrete, 69 800 lb. of steel and 50 500 ft. b.m. of lumber. Enlarged 1900–01 by addition to downstream side. Maximum height 93 ft. Additional work required 16 000 cu. yd. rock, 410 cu. yd. of masonry and 370 cu. yd. concrete, 62 000 lb. steel and 20 000 ft. b.m. lumber. Length 173 ft. Crest width 10 ft. Steel core-wall continued to top, protected by concrete.

(6) Milner, Idaho. 1903–05. Three dams form one main structure. Rock fill with core of wood. Earth embankment sluiced into voids of rock above core. Main channel dam: Length 340 ft. Maximum height 86 ft. Crest width rock fill 10 ft. Downstream slope rock fill 3 : 2; upstream 3 : 4. Crest width earth fill 10 ft.; slope 4 : 1. Rock fill 39 650 cu. yd. Earth fill 58 000 cu. yd. Middle dam: 335 ft. long. 81 ft. maximum height. 42 800 cu. yd. rock, 62 850 cu. yd. earth. South dam: 560 ft. long. Maximum height 66 ft. 34 700 cu. yd. rock; 48 000 cu. yd. earth. Total length of 3 dams, spillway and regulating gates, considered as one structure, 2100 ft.

(7) Zuni, New Mexico. Combination rock and hydraulic fill. Rock fill built as dry wall. Rock fill 720 ft. long. Total volume dry wall 40 160 cu. yd. Indian labor. Cost rock work $2.50 per cu. yd. For sluicing, steam pumping plant with capacity 2.5 sec.-ft. at 90 to 95 lb. per sq. in. pressure. Total volume earth in dam 60 120 cu. yd., about 40 000 yd. sluiced in. Total cost for sluicing 12 cents per cu. yd. All earth, either very fine sand or clay, no attempt being made to separate them. Undermined 1909 by passage of water under cap of lava rock which flanked dam and extended



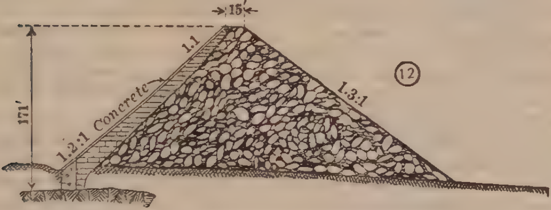


Fig. 16 (continued). Rock Fill Dams

beneath spillway. Spillway, south abutment and extreme south end of dam undermined. Considerable portion of spillway dropped 7 ft. and settlement of 9 ft. at junction of spillway and abutment. Small amount of fill at south end washed out and there was 5 ft. settlement about 30 ft. long in earth fill at north end. Main part of dam appears uninjured.

(8) Minidoka, Idaho. Rock fill, earth facing and concrete core-wall. Length 625 ft. Maximum height 80 ft. above bedrock and about 60 ft. above original bed of stream. Crest width 25 ft. Base averages about 300 ft. Total volume 191 000 cu. yd. Concrete core on solid rock. Top of wall 44 ft. below crest in central portions and about 11 ft. near end. Earth and rock-fill banks built up and core-wall built in trough between them. Fill then carried up on both sides over core-wall to required height. Cost $425 923.

(9) Lower Otay, California. 1897. Originally planned for masonry dam and masonry carried up 8 ft. above river bottom. Core of steel plates anchored to masonry and carried up to crest, protected with asphaltum and burlap and 1-ft. thickness of concrete either side. Failed January 27, 1916, by flood overtopping the dam. About 30 lives lost.

(10) Morena, California. 1896–1909. Length 520 ft. 306 000 cu. yd. Built in canyon about 130 ft. wide at stream bed with narrow fissure 4 to 16 ft. wide, extending 112 ft. below. In 1896 a rubble concrete wall 36 ft. thick at bottom and 12 ft. thick at top was built to seal fissure, and carried up 30 ft. above stream bed, when work was suspended in 1898. Construction resumed 1908. Upstream face for width of 7 ft. built of 6- to 10-ton granite blocks, set in cement mortar. Behind this for width of 50 ft. at bottom, reducing to 16 ft. at top, rock was placed by hand and derricks. Remainder of rock fill dumped by 2 cableways. Reinforced concrete slab 1 ft. thick on upstream face.

(11) Swift, Montana. 1914. Upstream face covered with a layer of hand-placed rock, 4 to 6 ft. thick, with face plastered with cement mortar. On top of this was placed a concrete slab, heavily reinforced, 6 in. thick at top of dam and 2 ft. at toe. Dam built on curve of 1276-ft. radius. Foundation of sand, gravel and boulders.

(12) Strawberry, California. 1914–16. Upstream slope faced with 9 in. to 18 in. of concrete carried down to concrete cutoff wall and backed by hand-laid rock. Main portion of rock dropped from cableways. River bed a cemented gravel. Dam arched in upstream direction. Radius 1880 ft. Contents 400 000 cu. yd. Length 612 ft.

(13) Dix River, Kentucky. 1923–25. Length 1000 ft. Height 275 ft. Contains 2 000 000 cu. yd. blasted rock. Upstream slope merges from 1 : 1.2 at river bed to 1 : 1 at crest. Downstream slope 1 : 1.4. Dam curved upstream on compound curve of 1250-ft. and 1700-ft. radii. Upstream slope of loose rock supports section of dry rubble masonry upon which is laid reinforced-concrete slab carried into sides and bed of canyon 20 to 30 ft. Spillway 2300 ft. long, 250 ft. wide and a maximum depth of excavation 107 ft., which supplied most of rock-fill.

8. Overflow Dams on Earth Foundation

Three Conditions influence the design of overflow dams on earth foundations. First, the character of the earth, ranging from loose fine sand to firm, well cemented hardpan; second, the height of the fall; and third, the volume of water to be passed. Designs for dams to meet various combinations of degrees of severity of these conditions may best be studied from precedents. The engineers of India have developed a type for their rivers in alluvial beds subject to great floods. The type has been adopted by the U. S. Bureau of Reclamation for similar conditions, the Laguna dam being a case in point. One form of the India dam is essentially a rock fill with very flat slopes downstream protected by heavy pitching or concrete-slab construction and containing one or more masonry core or cutoff walls. This type has never been used except for very moderate heights of from 6 to 15 or 20 ft. They have, however, been built on sand foundations and have passed great floods. The greatest trouble is usually experienced at the toe where the structure is likely to be undermined. The Avignonet dam is a precedent for a high dam on an earth foundation, but there the earth foundation is compact gravel, fine sand, and boulders. Following numbers in parentheses refer to Fig. 17.

(1) Narora Weir, India. Brick. Base 8 ft. thick. Founded on blocks or wells 10 ft. square and 18 in. thick sunk 7 ft. below river bed. Downstream from weir floor is 40 ft. wide, 5 ft. thick, consisting of 3 ft. 3 in. concrete, 9 in. brick and 12 in. ashlar. Beyond floor, talus is 100 ft. wide. Crest covered with ashlar. First crest covering destroyed and replaced with masonry set with wider joints. Head on crest 8 ft. End of talus 14 ft. below crest.

(2) Dauleshwiram, India. 1840. 16.8 ft. head on crest. Length 12 000 ft. Crest 11 ft. above normal bed level. Width 230 ft. Crest cover with ashlar masonry.

(3) Srivakantham, India. Length 1380 ft. Discharge over weir 123 000 sec.-ft. Weir wall and curtain walls on clay which lies under 3-ft. bed of sand.

(4) Pelandorai, India. Length 860 ft. Head on crest 13.3 ft. Crest 9 ft. above the river bed above weir.

(5) Burma Crib Weir, India. Boards were placed on top at first pending grouting of weir body with silt, and final settlement, with idea of replacing by rubble.

(6) Mahanuddee Weir. 6400 ft. long. Folding shutter 3 ft. high on crest. Calculated to discharge about 900 000 sec.-ft. Crest 13 ft. above average summer water level of river. Face of weir protected by rubble-stone packing with base varying from 20 to 40 ft. Breach 1886 at site of center sluices; about half sluices and portion of weir carried out and deep hole scoured on line of weir and below it. Cause never explained.

(7) Upper Colerum, India. 1836. Length 2929 ft. Head on crest 8.6 ft. Crest 7.4 ft. above river bed. River bed, fine sand. Founded on double row of wells sunk 6 ft. into river bed on upstream side and single row on downstream side. Masonry floor 27 ft. broad, 3 ft. thick, 2 ft. being brick masonry. Season after completion about 240 ft. of weir swept away. Caused by leakage undermining foundation. Weir repaired.

(8) Old Croton, New York. 1837–42. 180 ft. long. Mud and boulders cleaned from river bottom and crib cofferdams built enclosing space where masonry was to be laid. These cribs were left in the foundation. Space between cofferdams excavated to hardpan and filled with concrete and masonry. Earth bank 5 : 1 slope paved near top and with bottom width 275 ft. against upstream face. Dam has passed 8-ft. depth on crest.

(9) Kistna Weir, India. 1854–55. Length 3000 ft. for weir proper; nearly 4000 ft. including under sluices and piers. Crest 20 to 25 ft. above original river bed. Flood velocity over weir said to be 16 ft. per sec. and depth on crest 20 ft. Deep holes that had been scoured in river bed by floods were filled with sand. Wells sunk for foundation of weir.

(10) Avignonet, France. 1902. Concrete. Length 197 ft. Curved radius 656 ft. Height 75.5 ft. Built in narrow canyon on boulders, sand and gravel. Two cutoffs, 13 ft. deep and 8 ft. thick. Passes over 35 000 sec.-ft. during flood.

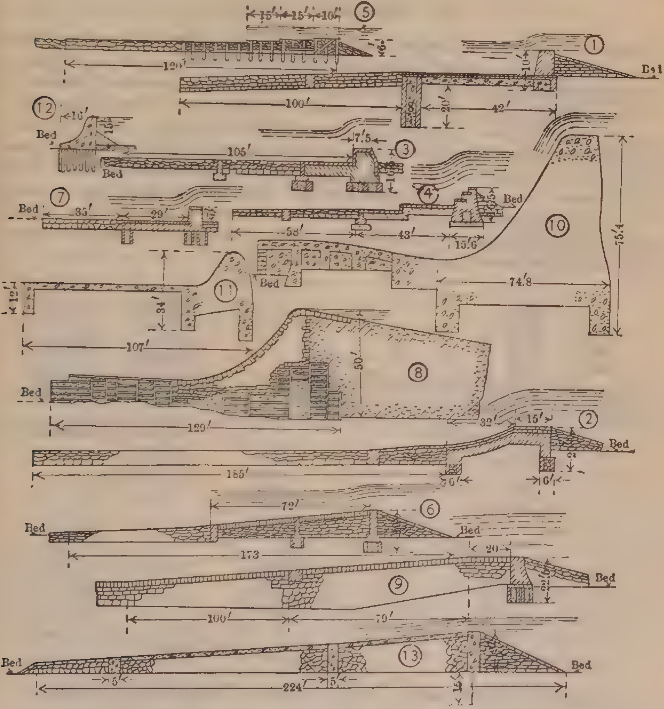

Fig. 17. Overflow Dams on Earth Foundations

(11) Granite Reef, Arizona. 1906–08. Partly founded on gravel and boulders. 1000 ft. long. Three curtain walls. Openings in the wall under lower toe 6 in. sq. 5 in. apart and about 6 ft. above bottom of wall to allow drainage of seepage. About 3-in. joints in apron to allow escape of water.

(12) Spooner, Wisconsin. Concrete structure 72 ft. long. Foundation sandy soil covered with thin layer of gravel. Pile foundation.

(13) Laguna, Arizona. Begun 1905. Crest 19 ft. above natural river bed. Three concrete walls 4800 ft. long and 57 and 93 ft. apart. Upper wall on row of sheet piling 12 to 20 ft. long. Between walls is rock fill. Apron of derrick stone extends 40 ft beyond lower wall. Rock fill between walls covered by 18 in. of concrete. Approximate quantities: rock fill 350 000 cu. yd.; concrete paving 37 000 cu. yd.; concrete core-walls 28 000 cu. yd.; sheet piling 90 000 lin. ft. Discharge from 4000 to 100 000 sec. ft.

(14) Sherman Island, Hudson River, New York. 1921–23. Length 590 ft. Height 80 ft. Founded on sand and boulders with interlocking steel piles to form cutoff. Lower half of upstream face slope 5 : 12. Upper portion 45 deg. There are 31 arches on buttresses 19 ft. on centers. Buttresses 3 ft. 6 in. thick stand on concrete base 108 ft. wide by 3 ft. thick. Arches are 24 in. thick in lower part and 18 in. in upper. To add to stability of dam interior of bays between buttresses partly filled with sand. Also 30 000 cu. yd. fine sand dumped upstream along dam to improve seal of cutoff piling.

9. Movable Dams

Needle, Wicket and Curtain Dams form a group of movable dams having many common and numerous interchangeable features. Common to all are upright pieces, the lower ends of which bear against a sill on the river bottom, the upper ends of which bear against some form of bridge. The bridge may be a stationary structure or a collapsible structure. In case needles are used (Fig. 18) they form the closure. In case wickets are used (Fig. 19) the closure is formed by sliding stop gates down grooves in the upright pieces. With curtain dams (Fig. 20) an overhead bridge is generally used, and a screen rolling on the upright pieces is let down from above. When a draw or fixed bridge is used, the upright pieces are hinged at the upper end and are swung up out of the water with suitable machinery.

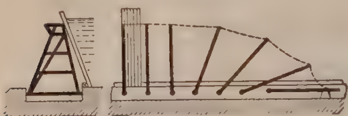

Fig. 18. Needle Dam

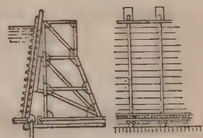

Fig. 19. Wicket Dam

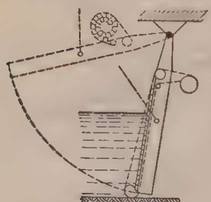

Fig. 20. Curtain Dam

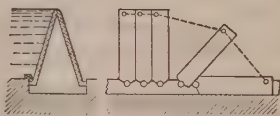

Fig. 21. Thomas A-Frame Dam

The Thomas A-Frame Dam (Fig. 21) consists of a series of A-frames set side by side and pivoted at the bottom to a sill. The plates which fasten the two legs of each section together at the top form a footpath. One of these dams 120 ft. long and 13 ft. high was built as part of Dam No. 6 in the Ohio River.

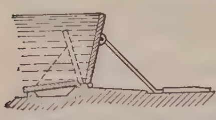

Fig. 22. Thénard Shutter Dam

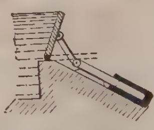

Fig. 23. Girard Shutter

The Thénard Shutter Dam (Fig. 22) consists of leaves hinged to a sill which extends across the channel. The leaves are raised and supported by struts hinged to the leaf and at the lower end fitting into a socket from which they may be tripped and the leaf lowered. Above is a counter shutter which is raised by the current as a temporary dam until the main dam can be raised by hand. A dam of this type, built in France and finished in 1843, had shutters 5.6 ft. high and 3.9 ft. wide. Others have been built in India to close flushing sluices, and some of them support heads of nearly 10 ft. The counter shutter is held in position by chains, which on account of the severe shocks occurring when the gate swings up, often break and are objectionable.

The Girard Shutter (Fig. 23), invented as a substitute for the Thénard, does away with the counter shutter, and the main dam is raised directly by hydraulic pressure. Seven of these were erected at Auxerre, the shutters of which were 11-1/2 ft. wide and 6-1/2 ft. high.

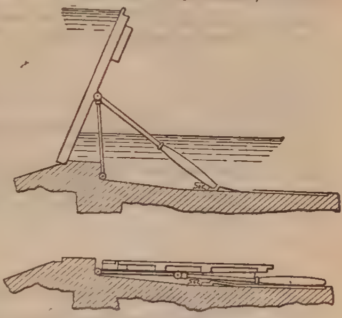

Fig. 24. Chanoine Wicket

The Chanoine Wicket (Fig. 24) was invented in 1852. The shutter is pivoted a little below its center point to a collapsible horse held in place by a long prop. It is adapted to large rivers where the flood rises are very sudden.

The Rolling Dam (Fig. 25) consists of a large steel cylinder placed across the current between piers or abutments and arranged to be rolled up entirely clear of the current on an inclined rack track. The rolling cylinder is operated by cables wrapped around one or both ends of the cylinder and passing to a winch. They have been built for openings up to 115 by 6-1/2 ft. and 60 by 14 ft., and are said to operate very quickly and pass ice readily.

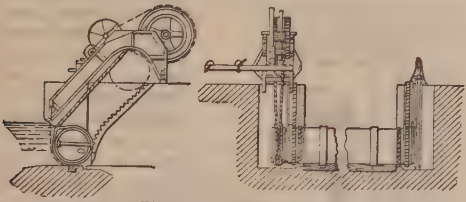

Fig. 25. Rolling Dam

Stoney Sluice Gates (Fig. 26) consist of a gate bearing at its end against a train of rollers. The gate is usually hung to chains at either end, which pass over sheaves to a counterweight. The roller train is also hung by a cable and counterweighted. They are usually operated by gearing on the supporting sheaves turned by hand cranks or traveling electric motors. These gates have given excellent satisfaction and are widely used. Power for operating has usually been underestimated. Fig. 26 is an example of Stoney sluice gate at the lake regulating works, Sault Ste. Marie, Canada. Fig. 27*a* shows the detail of the end bearing. Fig. 27*b* shows the end bearing of the Stoney gates on the Manchester Canal, England.

On the New York Barge Canal several movable dams of the bridge type have been used (Fig. 65*a*). Those dams have abutments, piers and superstructures like ordinary bridges; from the downstream sides hang steel frames resting against shoes in concrete sills that stretch across the stream between the abutment and pier. Against the upright frames are placed " Boule " gates forming the dam proper. Electric winches raise the gates and uprights by chains. The spans vary from 150 to 240 ft.

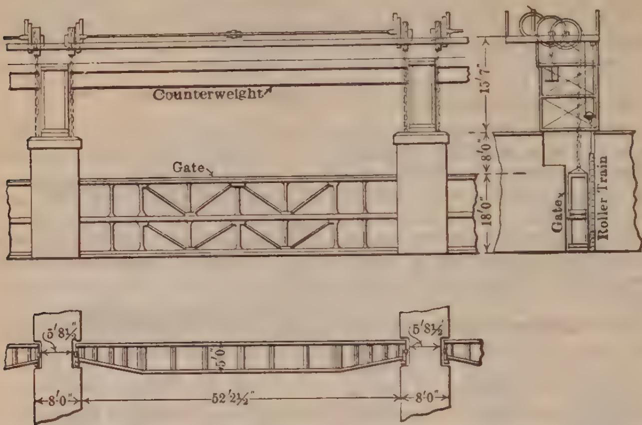

Fig. 26. Stoney Sluice Gate, Lake Superior Power Co.

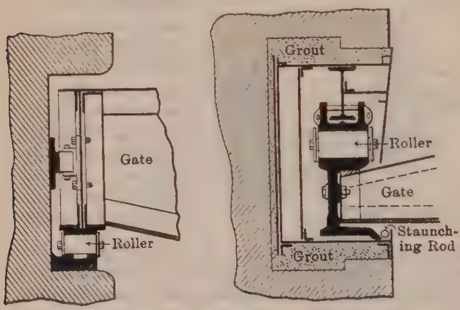
The Bear Trap Dam (Fig. 28), of which there have been many modifications, consists of two rectangular leaves extending over the full width of the opening; and when in their lower position the downstream leaf overlaps the upstream leaf. The gate is raised by admitting water from the upper pool to a chamber under the leaves. A dam built at Davis Island on the Ohio River in 1889 was of this type. The gates were of wood and 52 ft. long. In 1905 this was replaced by a new bear trap with wooden leaves heavily bound with steel. The new leaves were much stronger than the old ones and were proportioned so that they would just float without the need of air forced to the under side. At the bear trap on the Marne in France a counter shutter was provided, as in the Thénard shutter dam, as an assistance to raising the main dam.



a *b*

Fig. 27. Ends of Stoney Gates

The Bear Trap on the Chicago Drainage Canal (Fig. 29) is of somewhat different design. The two leaves do not overlap, but are hinged together at the apex. The downstream edge of the dam is hinged to the foundation, while the upstream edge carries a roller and moves up and down on the masonry face. The gate is counterweighted and its movements up and down are controlled by hydraulic cylinders. The dam is 160 ft. long, the downstream leaf 35 ft. wide, and the upstream leaf 21 ft. wide.

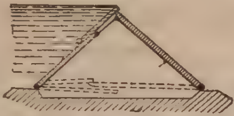


Fig. 28. Bear Trap Dam

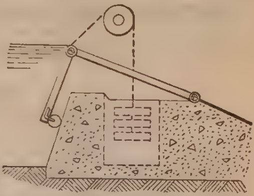

Fig. 29. With Hinged Leaves

The Parker Gate (Fig. 30) modifies the original bear trap by hinging the two leaves at the apex and introducing a hinge at a little above the midpoint of the upstream leaf; this does away with the sliding friction between the leaves. An auxiliary leaf, called the idler, is introduced above the upstream leaf to protect the moving parts from drift and ice. A dam for the Muscle Shoals Canal in Tennessee was built in 1892, 40 ft. wide and 8.5 ft. high.

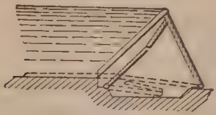

Fig. 30. Parker Gate

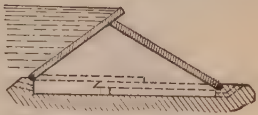

Fig. 31. Lang Gate

The Lang Gate (Fig. 31) is a modification of the Parker gate, in which the section of the upstream leaf above the hinge is removed and rods or chains take its place. The auxiliary leaf, or idler, is hinged to the downstream leaf, and its lower edge either slides or rolls on the upstream leaf. Several Lang gates, reaching the size of 80 ft. long and 14 ft. high, have been built in America.

The Chittenden-Drum Dam (Fig. 32) consists of a gate in the form of a sector of a circle, with a central angle of 67-1/2°, hinged at its center, and a watertight chamber into which it fits snugly when down. Water admitted to this chamber from the upper pool raises the dam. A dam of this type was constructed on the Osage River, Missouri, in 1901, with a difference in head of 16 ft. between the upper and lower pools.

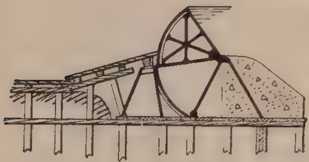

Fig. 32. Chittenden-Drum Dam

The Drum Dam of the Chicago Drainage Canal, Fig. 33, consists of a 45° sector of a cylinder 52 ft. in diameter, having its face covered with steel plates carried by radial frames pivoted at the center on the downstream side and a watertight chamber into which it fits when down. Dam raised or lowered by varying the head of water in the chamber, for which special valves are provided. This dam differs from earlier forms of sector dams in being pivoted on the downstream side. The vertical range of movement is 18 ft. A drum dam similar

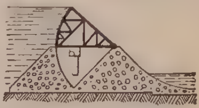

Fig. 33. Drum Dam, Chicago Drainage Canal

to that noted in Fig. 33 has been built across the Genesee River at Rochester with a vertical range of 9.4 ft., and each section 53 ft. 11 in. wide.

The Taintor Gate is similar to the drum dam (Fig. 32) except that the axis is higher and on the downstream side, and, to open it, it is usually lifted clear of the water by cables and winches. It is often used on power dams. The

U. S. Government built at Sterling, Ill., gates 21 ft. wide and 13-1/2 ft. high. On the New York Barge Canal there are several Taintor gates, the largest having a lift of 14.3 ft. and a width of 48 ft.

AQUEDUCTS

10. Reservoir Outlets

Outlets for reservoirs are preferably put in the natural formation outside the dam whether earth or masonry. Fig. 37 shows an outlet through a natural hill. They may be carried through tunnels in the adjacent hillsides where practicable, otherwise through the dam. When in an earth dam, with masonry core-wall, the gatehouse may be economically built as an integral part of this core-wall. Instead of intake pipes, an intake channel may be provided by extending wing walls back into the reservoir, from the gatehouse. The outlet may be similarly constructed, or the pipe or conduit type of outlet may prove more advantageous in a given case. Fig. 34 shows an adaptation

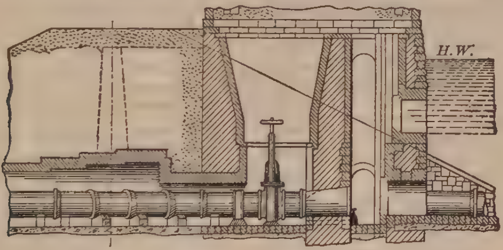

Fig. 34. Gatehouse, Jerome Park Reservoir

of this type. Outlet pipes in earth dams may be broken by the settlement of the embankment. If the dam is high, the outlets may be placed in the natural earth below, in a trench, where if properly built they are reasonably safe from dangers due to settlement. In low earth dams outlets are usually carried directly through the embankment. Leaky outlet pipes have caused many failures of earth dams. Water from the reservoir also is likely to force a passage along the outside surface of the pipe or conduit. A precaution is to place the outlet pipe within a masonry conduit where it may be inspected for leakage and repairs may be made. Transverse projections or cutoff collars are placed along such pipe or conduit at intervals, say of 20 ft. or less, to

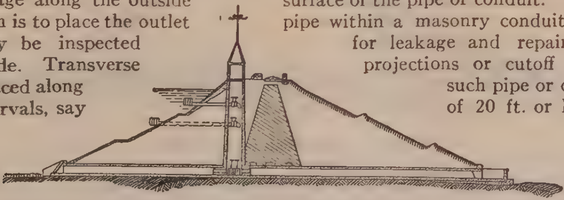

Fig. 35. Outlet Borden Brook Reservoir

prevent leakage along its outside. Fig. 36 shows metal collars for pipes embedded in masonry. Fig. 35 shows an outlet design where the conduit is placed wholly in the earth embankment. This is possible as the gatehouse is upstream of the core-wall, the head is small and the outlet below is without pressure. In masonry dams outlets weaken the section somewhat if built through them. The distribution of stresses in the mass of the masonry is changed and, if the opening is large, temperature and shrinkage cracks are concentrated. To compensate, the dam is strengthened locally, either by buttressing, or, as shown in Fig. 36, by extending the upper chamber back of the upstream face of the dam.

Gatehouses. The gatehouse is an essential feature for the control of water drawn from a reservoir through its outlet. Fig. 36 shows the gatehouse of the Boonton dam and is typical. Openings at *A* and stop-planks in grooves at *B* are the means by which water may be drawn from the top, mid-depth or bottom of the reservoir. Gratings in these openings prevent large objects from floating into the upper chamber. Fish screens could be placed in the line of stop-planks, although in the lower chamber, at *F*, there is provision for screening the water just prior to its admission into the service conduit. The sluice gates and upper stop-planks in the wall *C* provide the direct control of admission of water at the different elevations into the second well. By placing stop-planks in grooves *B* the inflow can be entirely interrupted in case it is necessary at any time to examine or repair any of these gates, access to which is obtained by means of the well above them, which in such emergency would be drained. Each half of the gate chamber is independent of the other, so that an inspection or repair would affect only half the flow at a time, the other half of the outlet continuing in operation. Water is thus admitted to each pair of steel pipes through these large openings with a small loss of head and to the control valves in the lower gate chamber at *D*. The upper sluice gates afford protection to these gate valves in an emergency. The overflow trough at *E* prevents dangerous heads from coming upon the grade conduit, should a

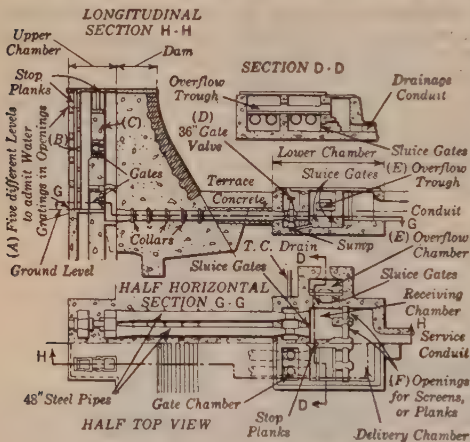

Fig. 36. Gatehouse, Boonton Dam

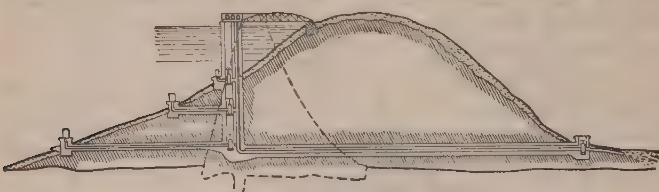

Fig. 37. Outlet San Mateo Dam

gate down the service line be closed without warning. In some systems a weir built along the side of the aqueduct serves this purpose. Screens are provided in the lower chamber at *F*, where they may be conveniently cleaned. Fish and trash screens are usually copper netting having about six meshes to the inch, with wire about 1/16 in. in diameter made up in frames which are slid into grooves, such as those for the stop-planks. Stop-planks of moderate size are constructed of wood but the larger sizes are preferably built of steel plates and shapes. The screen frames and those for the stop-planks are usually made to be used in the same grooves. The grooves are of cast iron, set into the concrete masonry. Smaller plants may have their chambers provided only with sluice gates, and stop-planks and screens upstream of them. A single chamber rather than an upper and lower chamber would be involved, although one chamber may be designed to accommodate racks, screens and stop-planks, sluice-gates and gate valves, in the order named, in the direction of flow.

The gatehouse for an earth dam may be put in the dam as in the case of the Jerome Park Reservoir (Fig. 34) and the Borden Brook Reservoir (Fig. 35). In the latter example, the gatehouse is of the tower type. This type is common for smaller reservoirs and the intake tower with bridge shown in Fig. 37 for the San Mateo dam is illustrated, except that the tower may be located at the toe of the slope and have screened inlets at different heights. The tower type, especially at toe of slope, is subject to ice thrusts which in colder latitudes may become serious. This objection was met in the case of the Borden Brook Reservoir by thickening the upper portion of the dam at that point.

At high water stages, ice formation in the reservoir may result in a thrust toward the dam, the ice between it and the embankment giving way by sliding up the embankment slope. This may be met by building a solid pier or stiff bridge between the gatehouse and the dam. Or the tower may be lifted vertically from its base by an ice sheet which rises with the water in the reservoir. Pressures due to ice are assumed at 30 000 lb. per square foot of ice one foot thick. (See Index for references on ice data.)

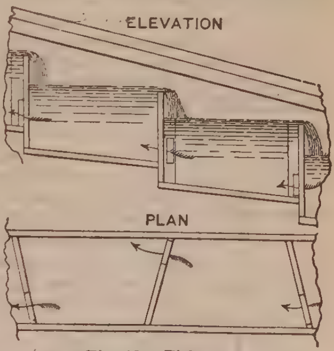

Fig. 38. Fishway

A 152-ft. concrete gate tower at the Magic reservoir on the Big Wood River near Shoshone, Idaho, was so ruptured at the base. The tower is octagonal, about 20 ft. in diameter, with a dividing wall in the center. It is situated at the toe of the embankment of an earth dam. In March, 1928, an unusual leakage of water into the normally dry operation chamber of the tower led to investigation. The tower appeared to have been lifted and then tilted several feet out of vertical; but afterwards settled back to plumb almost exactly in place. It had broken through the holding ice sheet on the side facing the dam, indicating a list towards the dam. (*Eng.-News-Rec.*, Aug. 30, 1928, p. 327.)

Fishways. The laws of many states require a fish ladder or fishway to be built at dams. Fig. 38 shows fish ladder recommended by the U. S. Commission of Fish and Fisheries. The cut shows two pools of the ladder which may be multiplied to surmount any desired height. Each pool is

1-1/2 ft. higher than the one below, 4 ft. wide, 6-1/2 ft. long on one side, and 4-1/2 ft. on the other. The opening in the bulkheads between pools should be about one foot square at the lower pool, increasing in size toward the upper level to insure a waterfall over the bulkhead; the amount of increase will depend upon the leakage.

11. Flow-line Masonry Aqueducts

Most of the flow-line aqueducts constructed since 1900 have been of concrete of horseshoe shape built in open cut and backfilled. Where the detour would be too great to carry the flow line around valleys, inverted siphons of steel pipe or pressure tunnels are introduced. In some cases for short distances the flow line with the horseshoe cross-section has been carried across depressions on filled ground. Masonry aqueducts constructed on embankments require great care in securing an unyielding foundation, since even a slight settlement may cause cracks and leaks. A crack below the water-line may erode the embankment materials and possibly give rise to destruction of a portion of the masonry with serious consequences. A small quantity of steel reinforcement in the invert of concrete sections on embankment will increase the ability of the structure to resist the ill-effects of slight settlement where the construction of the embankment type cannot reasonably be avoided. Elevated crossings of valleys and streams are seldom resorted to. The Assabet Bridge, 359 ft. long, on the Wachusett Aqueduct, completed in 1898, is the most notable case of a bridge crossing. The horseshoe shape is best adapted to resisting the pressure from the backfill and to ease of construction, cleaning and maintenance and at the same time has fairly good hydraulic properties.

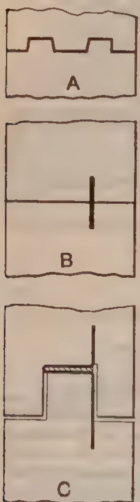

Fig. 39

Design. The intrados and extrados are made up of compound curves of circular arcs. The thickness at crown depends upon the earth and water loads to be expected; in the larger aqueducts the internal water pressure, varying with the depth, must be considered. Also where tests are prescribed before backfilling, the structure must be designed to meet this requirement of filling and emptying, as there is a critical depth of water in an aqueduct which may induce serious stresses at the crown, if unsupported by fill. The thickness of invert depends upon depth of ground water expected.

The dishing of invert need not be beyond that required for cleaning or draining, except to take excessive external upward pressure or side thrust from the walls, in which case the inverted-arch shape will serve. The methods of arch analysis for tunnels may be adapted to study of aqueduct cross-sections. The lines of pressure must be carried around from arch crown to invert, in this respect differing from arch bridge analysis.

The late F. F. Moore devised a graphic adaptation of the method of least work to these problems (Journal Association of Engineering Societies, Vol. 47, July, 1911). Fig. 14, p. 1562, shows the largest section of the Catskill Aqueduct in different kinds of material.

Contraction Joints. The practice in flow-line conduit construction is to place the concrete continuously in sections with a contraction joint, designed to prevent leakage between sections. The Catskill Aqueduct developed transverse cracks in some cases in those sections where the contraction joints were 75 ft. apart, but none in sections which were 60 ft. or less in length. Two types of contraction joints were tried, indicated by *A* and *B* in Fig. 39. Type *C* has been tried elsewhere with indifferent success, because of the construction difficulties of properly placing in the masonry of the curved sidewalls the thin bent strips of non-corrosive metal. In the Catskill Aqueduct, type *A* was found unsatisfactory because of the practical difficulty of making the tongues and grooves sufficiently exact for sliding, and the tongues broke off in some cases. Type *B*, a steel plate coated with asphaltum, gave in general good results, although the concrete was cracked by the plate in pulling in a relatively small number of joints, due to improper placing of the plate or to other defects of construction. However, all of the joints, of whatever type of construction and condition, were calked in the cold season, when open the maximum amount at the lower masonry temperatures. Several kinds of calking materials were used with more or less satisfactory results, but the most successful treatment was the complete filling of the joint with portland cement grout. Tests made subsequent to the grouting indicated that the outward leakage from the whole length of aqueduct, when carrying the maximum quantity, would not exceed one-quarter of one per cent of the capacity. For lesser quantities and aqueduct depths the leakage will, of course, be less, and moreover it has been the experience with this aqueduct, as well as with similar structures elsewhere, that the masonry tightens in service with consequent reduction in leakage.

Data Regarding Flow-line Masonry Aqueducts. Numbers in parentheses in the table on page 1561 refer to Fig. 40 and to the accompanying notes.

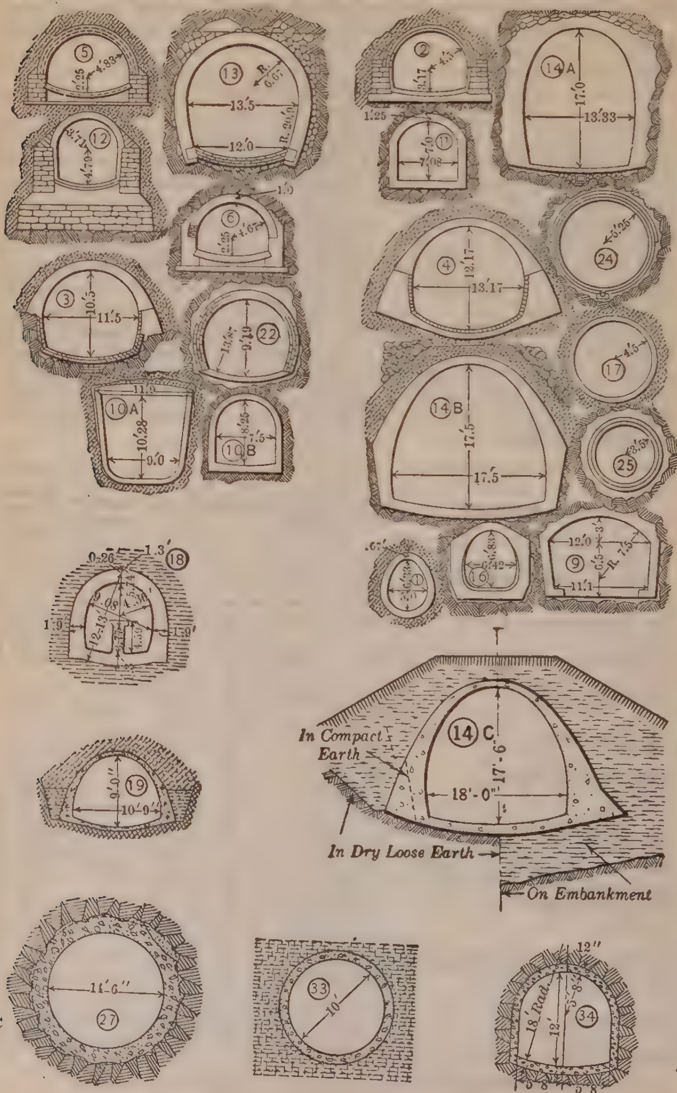

Fig. 40. Flow-Line Aqueducts

(1) Lining is brick throughout.

(2) Lining is brick and rubble. Cost per lin. ft., $23.90.

(3) Lining is concrete with brick-lined invert. 2 miles in tunnels, 6.9 miles in cut and cover or embankment, and last 3 miles in open channel. Cost per lin. ft. $22.90.

(4) Lining is concrete with brick-lined invert. 9.14 miles are in cut and cover or embankment, 1.02 miles are in open channel, 2.30 miles are in tunnel and 0.98 mile is in cast-iron pipe siphons. Cost per lin. ft. $32.60.

(5) Arch and invert are brick; walls and backing rubble. Invert on concrete cradle.

(6) Arch and invert are brick; walls and backing are rubble. Invert placed on concrete cradle. Average depth of cutting 16 ft. Maximum depth of cutting 23.9 ft.

(7) Lining is blue brick. About 11-1/2 miles are in tunnel, 25 miles in cut and cover and the remainder is in cast-iron pipe siphons.

(8) Pa.t of aqueduct was lined with masonry. About 10 miles are in open channel, 12 miles in tunnel and 4 miles in siphons.

(9) Lining is of concrete. 1.42 miles are in cut and cover or on embankment, 18.97 miles in tunnel and 3.10 miles in siphons.

(10) 164 tunnels with combined length of 42.7 miles, not including 9.2 miles of power tunnel. Open unlined canals 21.1 miles. Open lined canals 39.56 miles. Concrete covered conduit 97.72 miles. Siphons, steel and concrete 12.06 miles.

(11) The lining in tunnel and in cut and cover is of concrete. 36.75 miles are in cut and cover, 14.12 miles in tunnel and 45.01 miles are in 40-in. cast-iron siphons. Cost of whole work per lin. ft. $42.00.

(12) 37.1 miles are in cut and cover or on embankment, the lining being brick backed with rubble, 0.8 mile is in 4 36-in. cast-iron pipes, and 0.3 mile is in pipes carried on high bridge over the Harlem River. Average cost was about $59.00 per lin. ft.

(13) Lining is brick backed with rubble. 29.75 miles are in tunnel of which 7.17 miles are siphons, 1.12 miles are in cut and cover and the last 2.38 miles are in cast-iron pipe. Cost about $112.00 per lin. ft.

(14) Lining is concrete even in siphons. 54 miles of flow-line sections, 14*A* and 14*B* in cut and cover at grade of 21 ft. per thousand ; of which 14*C* type extends 17 miles. 0.5 mile is in embankment, 13.9 miles are in grade tunnel, 35 miles in pressure tunnel and 6.3 miles in siphons.

(15) Concrete. 1.42 miles are in tunnel and 0.8 mile is in cut and cover.

(16) Concrete is used quite generally. 44 miles are in tunnels, the longest being 17 630 ft.; there are also several iron pipe siphons, the longest of which is 6 miles, and a masonry arch bridge carrying a concrete aqueduct.

(17) Lining is brick and rubble masonry. 9.51 miles are in cut and cover or on embankment and 1.49 miles are in tunnel.

(18) Concrete. 99 tunnels of an aggregate length of 60 miles, the longest being 12 miles. 85 bridges.

(19) Concrete conduit in cut and cover or on embankment. Part on pile foundation. River crossing made by reinforced-concrete siphons. Supply line from reservoir to city, a reinforced-concrete pipe 5 ft. 6 in. in diameter and 10 miles in length.

(20) Water Supply, N. Y. City. Rock tunnel lined with brick, backed by rubble masonry. The face of the brick lining was washed with three coats of neat cement mortar.

(21) Milwaukee Water Works, Wisconsin. Hard clay and water-bearing sand and gravel. Compressed air used. No timbering used in hard clay. Progress averaged 6-2/3 ft. per day in clay. Drills and explosives used in hard clay. Circular section lined with 4 rings of brick.

(22) Water Supply, Washington, D. C. Rock tunnel lined with brick backed by rubble. Length of 500 ft. is iron-lined. Average cover is 150 ft.

(23) Water Supply, Jersey City, New Jersey. Steel plate pipe 5/16 in. to 7/16 in. thick except at crossing of Hackensack and Passaic Rivers where the thickness is 11/16 in.

(24) Water Supply, Torresdale, Philadelphia, Pennsylvania. Rock tunnel lined with 13-1/2 in. of brick in the rock and 9 in. in the invert, backed with a minimum of 6 in. of concrete. The maximum cover is 115 ft.

(25) Water Supply, Cincinnati, Ohio. Rock tunnel lined with two rings of brick backed by a minimum of 6 in. of concrete. Average cover over tunnel is 130 ft.

12. Siphons and Pressure Tunnels

Data regarding siphons and pressure tunnels are given below, the numbers in parentheses referring to the notes and to Fig. 40. The first pressure

* Section shown for Rondout typical for all pressure tunnels on the Catskill system.

tunnel of note was the Harlem River crossing on the New Croton Aqueduct, and this was lined with brick.

(26) Water Supply, Buffalo, New York. Rock tunnel, concrete-lined 1 to 2 ft. thick. Extends 6000 ft. under Lake Erie; inside dimensions 12 ft. by 11 ft. 3 in. Land tunnel 4300 ft. long; inside dimensions 9 ft. by 8 ft.

(27) Rondout, Catskill, New York Water Supply. Rock tunnel driven from 8 shafts by top heading and bench method, known as American method. Maximum progress (full section) 488-1/2 ft. per month. Four 3-1/4-in. Ingersoll-Rand drills on 2 vertical columns and 2 on bench. 22 holes, 8 to 12 ft. deep per round in heading. 175 to 200 lb. of 60% dynamite per round. Concrete lining 1 : 2 : 4, 15 to 17 in. thick. Steel forms. Approximate cost to city per linear foot based on contract prices: Tunnel $180, shaft $285 in rock and $350 in earth. Minimum rock cover 180. Maximum depth 710 ft.

(28) Wallkill, Catskill, New York Water Supply. Rock tunnel driven from 6 shafts in Hudson River shale, by American method. Four air drills in heading and 2 on bench. 22 to 24 holes per round. Muck hauled by mules and electric locomotives. Maximum monthly advance one face 523 ft. Ventilation by blowers. Concrete lining 15 to 17 in. thick.

(29) Moodna, Catskill, New York Water Supply. Tunnel in shale and granite. 7 shafts. Concrete lining 13 to 15 in. thick.

(30) Hudson, Catskill, New York water supply. Tunnel in sound granite, 1100 ft. below surface of river. Hydraulic gradient 400 ft. above river. Shaft at either end. Concrete lining 13 to 15 in. thick. Water-bearing fissure sealed by building concrete

bulkhead 8 ft. thick heavily reinforced with drains and grout under pressures up to 1000 lb. per sq. in. forced through pipes set in bulkhead and leading to fissures.

(31) Yonkers, Catskill, New York. Tunnel in gneiss, driven from 4 shafts. Concrete lining 15 to 17 in. thick.

(32) City Tunnel, Catskill, New York. Tunnel under New York City in gneiss, schist and limestone from 200 to 750 ft. below surface. Driven from 25 shafts by American method. Electrically operated machinery generally used. Ventilation by blowers. Cost of excavation per linear foot of tunnel based on contract prices varied from $86 for 11-ft. diameter tunnel to $90 per 15-ft. diameter tunnel. Lining 11 to 19 in. thick of 1 : 1-1/2 : 3 concrete. Cost of lining based on bid prices varied from $51 for 11-ft. diameter tunnel to $52 for 15-ft. diameter.

(33) Cleveland, Ohio. Waterworks tunnel in stiff clay under Lake Erie, driven by hydraulic shield. Excavation for about half the length of tunnel done by rotary cutting machine which was abandoned and rest of work done by hand. Maximum monthly advance 886 ft. Considerable trouble with inflammable gas. Tunnel lined with concrete blocks 11 in. thick radially by 18 in. wide, six segment blocks and key to the ring, blocks weighing 1200 lb. each.

(34) Chicago, Illinois. Water works tunnel in rock, 3 miles under Lake Michigan and 5 miles under Wilson Avenue, Chicago 4 shafts. The top heading and bench method and bottom heading method were tried and the former proved more economical. Maximum monthly progress one heading 630 ft. Excavated rock crushed and screened and made into concrete, mixed in the tunnel and placed by pneumatic process back of steel forms. Tunnel of horseshoe section; 5883 lin. ft. of lake tunnel, 12 ft. 3 in. wide and 13 ft. high. Rest 11 ft. 4 in. wide and 12 ft. high. Lining 12 in. thick. Cost per linear foot, $61.48, done by city force account.

There are several cast-iron siphons not included in the above. The aqueduct for the Liverpool and Manchester Water Supply has siphons consisting of from three to five 39-in. and 42-in. cast-iron pipes laid side by side under heads of 300 to 480 ft. The new Croton aqueduct passes under the 125th Street valley in 8 cast-iron pipes 48 in. in diameter laid side by side. The Catskill aqueduct crossing under the Narrows is a 36-in. diameter cast-iron pipe with specially designed flexible joints, to facilitate sinking the connected pipes from the surface.

Siphons of steel plate, cement-mortar-lined, enveloped with concrete and covered with earth embankment were used on the Catskill Aqueduct to join the flow-line aqueduct across valleys where the rock was not sound or where for other reasons pressure tunnels were not feasible. There are 14 of these siphons aggregating 6 miles. Each consists of three separate pipes built of plates from 7/16 in. to 3/4 in. thick, riveted together. The diameters are from 9 ft. to 11 ft. and the lining is 2 in.

13. Reinforced-Concrete Conduits

Data regarding reinforced concrete conduits are given below, the numbers in parentheses referring to the following notes and to Fig. 41. In the Salt Lake City conduit the joints at the end of the sections were thoroughly grouted in the coldest weather and the concrete was thus thrown into compression, effectually cutting off leakage. In the Jersey City aqueduct fine cracks appeared at the joints, but the leakage was not serious, and eventually they silted up. The Cottonwood and Pinto pressure pipes were built without any provision being made for expansion joints, the ends of section being left rough for the purpose of affording a good bond with the next day's work. Numerous cracks developed which were from time to time repaired, with the result that, one year after their completion, tests showed no leakage in the two Cottonwood pipes; in the north Pinto pipes a leakage of 0.002 sec.-ft. and in the south Pinto pipe 0.03 sec.-ft., all tests being made under maximum head.

(1) Hydro-electric plant. Hoops and longitudinal rods forming a 4-in. mesh used for reinforcement. Maximum head sustained 65.6 ft.

(2) Power pipe lines. This is a double-line siphon with a maximum internal head of 75 ft. and an external head not exceeding 10 ft. Reinforced with 5/8-in. steel hoops spaced 3 in. c. to c. and 10 longitudinal rods.

(3) Pressure Pipe. In a trench 4 ft. wide and backfilled with a minimum cover of 30 in. Used for siphons up to a head of 105 ft. Reinforced with hoops of No. 5 steel wire spaced 12 in. c. to c. 7 tunnels on the line aggregate in length 1500 ft. Pipes were cast in lengths of 2 ft. before being placed in trench.

(4) Flow-line water supply aqueduct. Reinforced with transverse 3/8-in. twisted steel rods 12 in. c. to c. and longitudinal 1/4-in. twisted steel rods 24 in. c. to c. Portion of the 22.99 miles of aqueduct from Boonton to Jersey City.

(5) By-pass on Catskill Aqueduct at Kensico reservoir. Maximum depth of invert below flow-line of reservoir in which by-pass is located is about 53 ft.

(6) Flow-line water supply aqueduct. The reinforcement is expanded metal. Conduit entirely built in cut and cover.

(7) In Cedar Grove Reservoir. Maximum head inside 50 ft. and outside 50 ft., depending on whether pipe or reservoir is empty. Reinforcement is No. 10 gage expanded metal with 3-in. mesh and joints lapped. 4000 ft. are single conduit and 1500 ft. are double conduit.

(8) Power pipe lines. Double-line siphon with maximum internal head of 31 ft. and external head not exceeding 10 ft. Reinforcement is 5/8-in. steel hoops placed 6 in. c. to c. and 6 longitudinal rods.

(9) Big Cottonwood Water Supply, flow-line aqueduct. Part of conduit was built in cut and cover, part in fill and part in tunnel. The reinforcement is twisted steel bars 3/8 in. to 1/2 in. in diameter, spaced 6 in. to 9 in. c. to c. Cost was about $9.80 per linear foot.

(10) Consist of a steel tube 0.118 in. thick, embedded between an inner mortar coat 0.9 in. thick, plastered on wire mesh, and an outer concrete shell 5.9 in. thick reinforced by hoops of T iron, all in shallow trench, maximum head 85 ft.

(11) A siphon on the Umatilla irrigation system. The maximum head is 55 ft. The reinforcement is a coil of 5/16-in. wire.

(12) Same irrigation system as Sosa and Ribabona. Maximum pressure head 97 ft. Shell of pipe 7.28 in. of concrete faced with 0.59 in. of cement mortar. Reinforcement 124 longitudinal round bars 4 in. apart and circumferential T bars. Concrete: 1 portland cement : 1.28 sand : 2.56 gravel under 1-1/4 in. and 0.58 to 1.00 part of water, all by volume. Lining 1 cement : 1 sand. Seepage loss under full head 0.14 sec.-ft.

14. Wood-Stave Pipe

Stave Pipe is much used in Western United States on account of the cheapness of lumber and the high cost of steel and cement. It is built in place by assembling the staves for the lower half in a cradle, after which a pipe ring is set inside and the staves for the upper half assembled on it. The staves all break joints with those adjoining and are " driven home " on the end. Bands are placed but not finally tightened until the wood is thoroughly saturated. Junctions are made by cutting the last staves a little long and springing them into place.

The Staves vary between 1-1/4 in. and 2-1/2 in. in thickness and 6 to 8 in. in width and are uniform throughout the length of the pipe, the variation of head being met by variation in spacing of bands. The staves are shaped to true cylindrical surfaces on the inside and to true radial lines on edges. The outside is usually curved, but sometimes flat. A very shallow bead left on the edges crushes and results in greater watertightness. Thin steel tongues let into the ends of the staves make tight joints and insure a smooth interior surface. The timbers most used are California redwood, Oregon and Washington fir, yellow pine and several kinds of spruces. The timber should be clear, somewhat seasoned and protected from warping.

Bands are from 3/8 in. to 3/4 in. in diameter. They are proportioned for the initial tension on erection, plus the stress from water pressure plus the stress from swelling wood. It is generally agreed that a pressure sufficient to keep the wood saturated, or nearly so, prolongs the life of the staves, and that contact with earth charged with decaying vegetable matter and crushing of the exterior surface of the wood in adjusting bands shortens it. Examinations of pipes which have been in use for a number of years show that the interior surfaces wear smoother and do not become fouled.

15. Flumes

Flumes are used where excavation for a canal is difficult, as on steep hill-sides, where the soil is so loose that an unlined canal is impossible, or where the canals cross rivers or deep depressions and the use of siphons is undesirable. Since much higher velocities can be used than in canals, and the frictional resistance is less, it is possible to use a much smaller area of cross-section. Concrete, iron and wood are the principal materials employed.

Reinforced-Concrete Flumes of varied design are used by the U. S. Bureau of Reclamation on its irrigation projects. No. 1, Fig. 42, shows the type con-

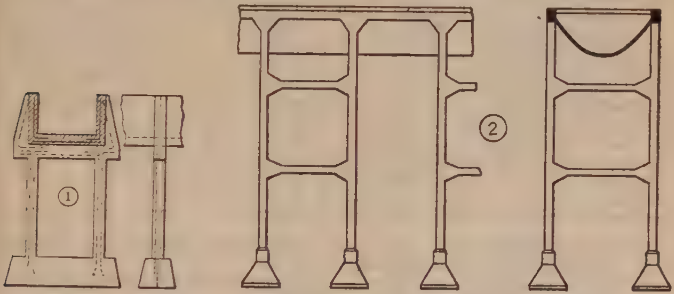

Fig. 42. Reinforced-Concrete Flumes

structed in 1908. This design is more or less standard for flumes up to 72-sq. ft. section, the spans between bents varying from 14 to 30 ft. No. 2, Fig. 42, shows the Brooks Aqueduct, Alberta, consisting of a curved shell of reinforced concrete suspended between two girders on a reinforced-concrete trestle, bents 20 ft. c. to c.

Wooden Flumes are most numerous on account of smaller first cost, although they have short life. Fig. 43 shows a 2 by 3-ft. wooden flume on trestle. The bents are 15 ft. between centers, 4 in. by 4 in. up to 7 ft. high and 6 in. by 6 in. up to 12 ft. high. The stringers are 4 in. by 10 in. by 16 ft. long. The sides and bottom are 2 in. by 12 in. with 5/8-in. by 1-in. splines set in edges and quarter-round molding nailed in corners; the sides are spiked to the bottom by

20d nails 1 ft. on centers; the yoke frames are spaced 4 ft. on centers. Fig. 44 is a cross-section of the San Diego flume, California. Fig. 45 shows the wood-stave flume. Flumes across valleys are frequently used as links in earth canals; in such cases it is most important that the junction between the flume and the natural earth bed of the canal be absolutely watertight.

(1) Bear River Canal, Utah. Plate girder bridge of three spans: 60 ft., 45 ft., and 25 ft. Flooring between lower flanges carries canal.

(2) Washington. Temporary flume for water supply used in hydraulic fill dam in 1909. Material used was timber.

(3) Sides and bottoms are redwood. Carried on trestle. Frames spaced 4 ft. c. to c.

(4) Canal in Spain. Steel bridge aqueduct formed by two box girders with iron floor between, attached to lower flanges. 62-ft. clear span.

(5) Canal. Reinforced-concrete bridge on concrete piers. Framework of floor reinforcement is 19 longitudinal I-beams 20 in. deep and 34 ft. 11 in. long laid abreast. Side wall reinforcement is two I-beams 20 -n. deep, 6 ft. apart vertically and trussed.

(6) Kern River Power Plant, Los Angeles. Redwood, seams beveled and calked on sides and flushed with asphalt on the bottom. 1-in. by 6-in. battens used. Carried on concrete foundations.

(7) Aqueduct of the Lower Ganges Canal. Masonry bridge of 15 spans, 60 ft. clear.

(8) Canal crossing Spring Canyon. Bridge carried on three arches of reinforced concrete. Walls are reinforced with 3/4-in. to 1-in. steel rods 6 in. c. to c. in two rows. Floor reinforcement is 1-in. steel rods 6 in. c. to c.

(9) Platte or Highline Canal. Timber.

(10) Platte or Highline Canal crossing Plum Creek.

(11) Colorado. Timber with joints calked with oakum. Constructed on rock bench.

(12) Colorado. Timber with joints calked with oakum. Constructed on trestle.

(13) New Mexico. Irrigation canal built in 1903. Concrete reinforced with T-irons spaced 4 ft. c. to c. Supported on four concrete arches of 100-ft. clear span and 25-ft. rise.

(14) Power canal in Washington built in 1903. Timber, carried on trestle from 6 to 80 ft. high. The maximum curve is 70 deg. and the total curvature is 10 280 deg.

(15) Redwood. Carried on timber stringers and mudsills.

(16) Wooden Stave. Redwood. Held by T-irons 2-1/4 in. by 2-1/4 in., 4 lb. per lin. ft., spaced 8 ft. c. to c. and two intermediate 5/8-in. steel binders. Supported on timber cradle and concrete piers.

(17) Washington. Semicircular reinforced concrete. Transverse reinforcement 3-8-in., steel rods 4 in.c. to c., longitudinal 18 steel rods 1/4 in. in diameter, 12 in. c. to c. Carried on reinforced-concrete trestle.

CANALS

16. Navigation Canals

Canal Prisms (Fig. 46). The cross-section varies with the material passed through, the value of adjacent property, and the facilities to be given to traffic. In earth the side slopes are usually from 2 : 1 to 3 : 1 but there are many examples of steeper and of flatter slopes. The Erie and Manchester canals have in places side slopes of 1 : 1, but these are protected by paving for the full height, and have failed in some cases. In cities it has often been found economical, as in the case of the Erie canal, to provide vertical side walls. In rock the sides are usually made vertical, or nearly so. The recent use of channeling machines has facilitated the formation of smooth vertical sides, with great benefit to vessels. Clearance between the keel of the vessel and the bottom of the canal varies with the form and area of cross-section of the vessel, the width of the channel and the speed desired, as the table shows.

Canal	Depth	Haul-age	Speed, miles per hour	Clear-ance	Authority
	ft. in.			ft. in.	
Erie (enlarged)	7 0	Horse	1.67	1 0	N. Y. S. Eng., 1877
Upper Escaut, St. Quentin, Lateral Oise	7 2-1/2	Horse	1.67	1 3-1/2	Lindley

Merwede, Holland	10 0	Tug	4.66	1 6	Int. Engr. Congress
Brussels to Rupel, Belgium	10 6	Tug	3.73	0 4	
Ghent-Terneuzen, Holland	20 8	Steam	5.40	1 5	Int. Engr. Congress
Amsterdam (before last enlargement)	28 3	Steam	5.59	2 0	Int. Engr. Congress
Suez (before last enlargement)	31 1	Steam	6.20	4 1	Panama Report, 1906

The width of the canal should be at least sufficient to permit two boats meeting to pass each other, but on account of the rapidly increasing resistance to the movement of a boat as the cross-section of the canal diminishes, the width of boat canals is generally greater, so that the area of the wet cross-section may be three to five times the area of the cross-section of the boat. On the New York State Barge Canal, the ratio is designed to vary from 4.76 in earth sections to 4.51 in rock sections.

Level Sections are required for a navigation canal, since strong currents are inadmissible. Difference of level between adjacent sections is overcome by locks, inclines or mechanical lifts. **Inclines** or high mechanical lifts are suitable only in the exceptional cases where the slope of the valley is very steep or where they can be so located as to concentrate a large descent within a short distance. They effect a saving of water as compared with locks. **Locks** are usually best adapted to meet topographical conditions; in general, lifts of locks vary from 5 or 6 ft. to 15 or 20 ft., but some locks have less than 5 ft. and a few have been built with lifts of from 25 to 30 ft. and upward. Larger lifts require more water for lockage and reduce the time required by a boat to overcome a given elevation, but tend to reduce the ultimate traffic capacity of the canal. Locks are used in most places where an incline or high

mechanical lift would be practicable. If the slope of the ground is not too steep, sections of canal are placed between adjacent locks which enables some saving of water to be effected; where the topography does not permit these intermediate canal sections the locks are connected into a succession of steps forming a "flight."

Widening Prism on Curves. It has not been usual in the United States to increase the width of canals on curves. In the plans of the New York Barge Canal no increase in width was proposed for curves of 5 deg. or less; for 6 deg. the widening proposed was 5 ft. On the Canal du Centre in Belgium the widening was $400/R$ in meters, R being the radius of the curve. At the International Congress for Inland Navigation held at Vienna in 1886, a rule was adopted that the amount of widening should be twice the versed sine of the arc whose chord is equal to the length of the largest boat traversing the canal. This was adopted for the Dortmund and Ems Canal, the length of the boat being taken at 220 ft.

On the Ship Canal from Ghent to Terneuzen, the widening on curves was deter-

mined by the formula $4\ (R - \sqrt{R^2 - 200^2})$ in feet, R being the radius of the curve. On the Kiel Canal, the widening was determined by the formula $26 - 0.01\ R$ in meters, or $85.3 - 0.01\ R$ in feet. On the Kiel Canal it has been found by experience that "it is not so much a large radius that is required as a proper widening of the cross-section." This view is abundantly confirmed in the United States regarding vessels moving under steam power.

Protection of Side Slopes (Fig. 47). In earth some form of protection is usually advisable, particularly in sandy soils, to protect the slopes against wave action caused by passing boats. The extent required depends upon the character of the traffic. At the Dortmund and Ems Canal, traversed by boats drawing 6 ft. 7 in. at a speed of 3.1 miles per hour, it has been found sufficient to extend the protection 2 ft. under water: one of the several forms used is shown in Fig. 47. On the New York Barge Canal, the protection is extended 2 ft. 6 in. or more under water. In larger canals, traversed by large ships and at higher speed, the protection is usually extended 5 to 8 ft. under water, and terminated at its lower edge on a berm. Of the three figures relating to the Kiel Canal, the last one is designed for use when the canal is filled with water, and the stones cannot be laid with regularity below water level without unwarranted expense. In some cases the protection has been designed to serve the further purpose of maintaining the bank at a steeper slope than it would otherwise sustain, as in the standard section of the Erie Canal and at places in the Manchester Canal. This is decidedly objectionable for propellers, as the slope walls are liable to break the wheels and it is better practice in nearly all cases to give the earth below the belt requiring protection from wave action a slope at which it will stand.

When the protection is of stone it usually consists of a paving of rubble masonry or selected stone laid dry with as close joints as practicable in order to prevent washing through the joints of the paving, the earth is first covered with a layer of gravel or of small broken stone. A cheaper form of revetment has been used successfully at the Soulanges Canal, and has been adopted for the New York Barge Canal, where specifications describe it as consisting of three grades of stone; first one-quarter of the whole volume to be quarry waste, stones ranging in size from 9 in. to 15 in. in longest dimension; second, one-quarter of stones from 4 in. to 9 in. in longest dimension; and, third, one-half of stones from 1 in. to 2 in. in diameter. The larger stones are bedded on smaller ones and rammed firmly in place; the remainder of the small stones are used to fill voids and form a smooth surface. No flat stones are permitted. On the eastern section of the Illinois and Mississippi (Hennepin) Canal a trench was cut in the face of the embankment, extending from 2 ft. above normal water level to 1 ft. below it, and filled with rubble laid roughly by hand. On other sections no protection was provided until after the canal was put in use and a berm had been formed by wave-wash; stone was then brought in on barges and deposited in the trench thus formed. Bricks have been used in various forms; also concrete blocks and reinforced concrete. Where water seeps into the canal, revetments of masonry or of concrete require to be back-drained by being laid on sand or gravel or by other means.

Control of Leakage from Canal (Fig. 48). Where canals are formed in sandy soil or other permeable material, the loss of water by percolation or seepage may be so great as to endanger the adequacy of the water supply. If the water supplied to the canal carries silt the seepage will become less as the voids in the sand gradually become filled with fine particles of silt carried by the water, or with silt, sawdust or similar material thrown into the water near the points where leakage is greatest; but in such material it is usually advisable to take means to prevent or reduce seepage during the construction of the canal by interposing less permeable material, and where the canal is carried on an embankment this is usually essential to insure the safety of the work. In such a case the canal should have an impermeable lining, which is usually of clay with sand or gravel well puddled or rammed. In order to prevent shrinkage cracks above the water line and in the sides and bottom when the water is drawn out, and also to protect the puddled material from abrasion by boats, the puddle is usually covered by a layer of ordinary soil.

In the canal from the Marne to the Rhine the watertight layer contained three parts of sand to two parts of clay, the mixture, after spreading, being sprinkled and rammed to two-thirds of its original volume. In the navigable feeder of the Arroux, Canal du Centre, France, the mixture contained 65 to 70% of clay; the material in the bottom was compacted by grooved rollers drawn by horses, and in the slopes was rammed; the material was spread in 4-in. layers and reduced in volume 40% by rolling or ram-

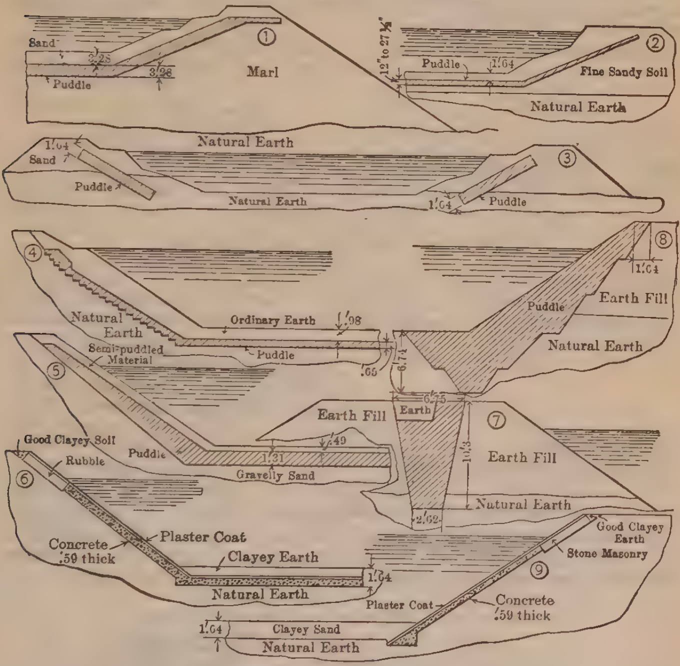

Fig. 48. Methods of Tightening Canal Prisms.

(1) (2) (3) Dortmund and Ems. (4) Marne to Rhine. (5) Arroux. (6) (7) (8) (9) Canals du Centre, Belgium

ming. In the Dortmund and Ems Canal, where the canal was in embankment, the material of the embankment was principally marl, and the watertight lining was of the form shown in the figure, the thickness of the puddled material increasing with the height of the embankment. In the Canal du Centre, Belgium, a lining of concrete has been used successfully, protected on the bottom of the canal by a fill of clayey earth. This is suitable only where the bank is of firm material not liable to irregular settlement, and is liable to injury by boats. In the canal from the Marne to the Rhine concrete in banks was also covered with earth.

Where the bottom of the canal is subjected to uplift pressure when the canal is laid dry, the watertight layer is likely to be breached; underdraining is sometimes practicable. The case may arise where the head of the inflowing water is above the bottom of the canal but below the water surface desired; each case of this kind must be studied as it arises. A watertight lining of the sides and a silt lining of the bottom may be suitable in such a case. Where the bottom of the canal is in excavation and the material sufficiently watertight, where the sides are embankments, seepage may be prevented by a puddle lining on the slope or by a puddle wall in the middle of the embankment. When placed on the slope the thickness should be great enough to permit considerable abrasion by boats without cutting through it. This is avoided by forming a puddle wall in the middle of the embankment, but the fill on the water side is likely to become saturated and then may contribute little to the stability of the embankment, or may even reduce it. Care must be taken to remove all loose or yielding material and to avoid forming a permeable joint between the original ground and the fill.

Drainage of Adjacent Territory. A canal in a river valley is so located that its banks may be above the highest flood level. Small streams, artificial

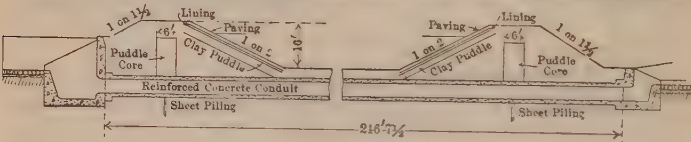

Fig. 49. Dive Culvert, New York Barge Canal

drains, or storm water may be received directly into the canal or passed under it through culverts (Fig. 49). When circumstances permit, the latter is preferable; the principal objections to draining into the canal are the resulting silting, which will involve continual expense, and the variations produced in the water level. Where practicable, water, if silt-bearing, should be made to pass through a settling basin before entering the canal. If the amount of water flowing into the canal is considerable, the resulting current is objectionable. The surplus water received into the canal is discharged over **waste-weirs** (Fig. 50*a*) or through **waste-gates.** Where the requisite control can be

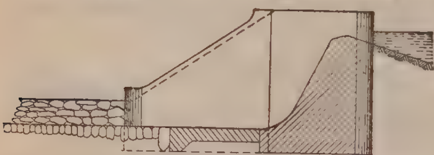

Fig. 50*a*. Waste-Weir, New York Barge Caaal

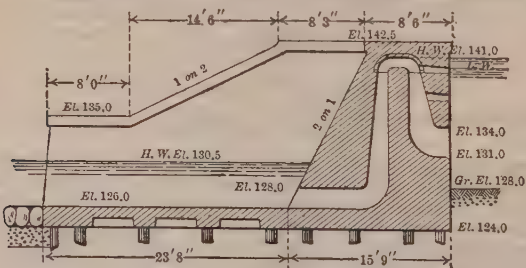

Fig. 50*b*. Siphon Spillway, New York Barge Canal

given by a weir it has the advantage of being automatic; but this may at times cause waste, since a high wind blowing in the direction of the canal, or a succession of boats moving in one direction, may cause a rise at one end of a canal level. Waste may also result from the difficulty of adjusting the supply to the summit level to the varying demand for lockages; to overflow from short levels; to unequal lift at locks, etc.

In the New York Barge Canal the crests of the waste weirs are at low water elevation. Channels are provided for placing flashboards to raise the crest of the waste weir if required. On this canal a siphon spillway shown by Fig. 50) 'has been used.

Waste-gates are usually placed with their sills at canal bottom and are useful for draining the level when desired for repairs.

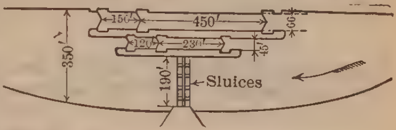

Fig. 51. Irlam Locks, Manchester Ship Canal

At the Manchester Canal where large amounts are received into the canal at times of floods, each level is controlled by Stoney sluice gates placed in a sluiceway adjacent to and parallel with the locks. The sills are at the same elevation as the sill at the upper end of the locks; the sluice gates are each of 30-ft. opening, and can be raised about 20 ft. The Irlam sluices (Fig. 51) can discharge 26 000 cu. ft. per second.

Large streams are usually crossed by aqueducts forming part of the canal, but usually reduced in width to the requirement for a single boat. The superstructure, or " trunk," may be of wood, masonry or iron. The crossing of the Erie Canal over the Mohawk River at Rexford Flats is a good example of a trunk of wood; of the same canal over the Genesee River at Rochester is a good example of a trunk of masonry; both of these structures were in use for many years. The Bridgewater Canal is carried over the Manchester Canal on a swing bridge, the trunk is of wrought iron, has a clear width of 19 ft., and a depth below ordinary water surface of 6 ft. and a free-board of 1 ft.

17. Water Required for Operation

Filling the Prism of the Canal. The prism of the canal may be emptied either for repairs or as a result of accident. In dealing with the question of water supply for the proposed New York Barge Canal, E. Kuichling assumed that the prism of the summit level would be laid dry once per year; also that, in addition to the volume of the prism, an equal amount would be required to saturate the adjacent soil to its normal condition, but this additional amount depends on the watertightness of the wetted contour of the canal prism, and, if this is not well provided for, by the porosity of the adjacent ground. In the case considered by Kuichling it was contemplated to line the canal with clay where formed in permeable ground.

Evaporation and Seepage. For the New York Barge Canal, Kuichling estimated that the evaporation from the water surface would be 0.30 in. per day, to which he added 10% as a liberal provision for consumption by aquatic plants, or a total of 0.33 in. evaporation per day from the surface of the canal.

In the summer of 1900 observations were made to determine the loss by percolation from various sections of the Erie and Champlain canals. In some cases where the canal had been deepened within a short time before the gagings were made the loss was large, running up to 773 cu. ft. per mile per minute; in other cases, even where percolation through the banks could be seen, the gagings indicated little loss, and, on the whole, the results were not of great value, but, rejecting the abnormal results, a loss from percolation of 100 to 150 cu. ft. per mile per minute was indicated.

Kuichling finally estimated that the loss from evaporation and seepage from the Barge Canal would appregate 4-1/2 in. in depth per day, equivalent to 169 cu. ft. per mile per minute, but this was based on the assumption that clay linings would be provided in permeable soil. The thickness of the puddled material was intended to be

3 to 4 ft. on the slopes on embankments and 1-1/2 ft. in excavation where the materials were of a nature to permit seepage. The thickness on the bed of the canal was to be 1-1/2 ft. in all cases where puddle was deemed necessary. The canal was to be 123 ft. wide at the water line, 75 ft. at the bottom and 12 ft. deep.

G. W. Rafter estimated the probable percolation from the summit level of the proposed deep waterway from the Great Lakes to tidewater at 330 to 440 cu. ft. per mile per minute. At the divide near Rome, N. Y., the water in the canal would be slightly below the level in the adjacent streams, and about 15 ft. above at the ends of the summit level. No puddle lining was intended for the canal.

Measurements of Loss of Water from American Canals by Evaporation and Seepage, Including, in Some Cases, Waste at Structures

* For these cases evaporation, seepage, and waste were measured. For the other cases only evaporation and seepage were measured.

The excessive loss of 4144 cu. ft. per mile per minute from the Marne-Saone Canal is said to be due to fissures in the rock in which a section of the canal is excavated. A similar loss, and for the same reason, has been met in the Glen Falls feeder for the Champlain Canal. Such leaks are difficult to close after the water is once admitted to the canal. On the other hand, earth sections of canals become tighter with use. Some of the large losses shown in the table occurred when the canal was new or had been deepened within a short time.

Percolation, infiltration or seepage is usually much greater in amount than evaporation. The combined loss from evaporation, seepage and waste is usually measured together by current observations at two or more cross-sections of the canal, and simultaneous measurements made of waste. The loss by evaporation plus seepage is then given by subtraction and usually reported together. Evaporation can be estimated with reasonable correctness and seepage determined within a small range of uncertainty. The table on p. 1578 is condensed from Kuichling's report on Water Supply Canal for New York Barge Canal.

The loss by evaporation, seepage and leakage from the Illinois and Mississippi Canal is stated to be less than 60 cu. ft. per mile per minute.

In some of the European canals where the water supply is limited, and particularly where the summit level is maintained by pumping from the lower levels, greater expense is incurred to reduce seepage than is usual in the United States. In the Dortmund-Ems Canal the loss by percolation and evaporation amounted to 32 cu. ft. per mile per minute of which 9 cu. ft. was estimated to be due to evaporation and 23 cu. ft. to percolation. This was rather more than had been anticipated but it is expected that it will be reduced by silting. The watertightness of the prism was of much importance because the water on the upper levels was supplied in large part by pumping. Lindley states that the mean value of the loss by evaporation and percolation is estimated for the whole of France at about 40 cu. ft. per mile per minute. In a given permeable soil the amount of seepage varies with the width and depth of the canal, but no satisfactory expression of the relation has been advanced.

Leakage at Aqueducts, Culverts and Waste-Gates. The amount of leakage at these structures depends principally upon the care taken in design, construction, maintenance and operation, and can be limited to a small amount. In a report made in 1837 by W. H. Talcott the leakage of waste-weirs and aqueducts on 22 miles of the Chenango Canal (depth 4 ft.) was given at 220 cu. ft. per minute, or 10 cu. ft per mile per minute. Kuichling gives an estimate of 1.6 cu. ft. per mile per minute on certain old canals in France. The losses will obviously depend on the depth of water and may be assumed to vary with the square root of the depth as an approximation. Kuichling estimates for the New York Barge Canal (depth 12 ft.) 12 000 cu. ft. per day for each culvert and waste-gate, and 96 000 cu. ft. per day for each aqueduct, which appears to correspond approximately with the observations of Talcott, without allowance for increased depth. With modern methods the older class of masonry should be improved upon.

Leakage at Locks. This occurs at the valves for filling and emptying the lock and at the lock-gates. Seepage around the locks should be prevented by suitable construction or reduced to a negligible amount. From observations at the Chenango Canal (in 1839) W. H. Talcott estimated leakage at a canal lock of 11-ft. lift at 447 cu. ft. per minute or 643 680 cu. ft. per day. Kuichling gives an estimate as low as 14 100 cu. ft. per day on certain small French canals. Measurements of leakage around the filling valves of the Weitzel lock, St. Marys Falls Canal, made by J. Ripley in 1899, gave a coefficient of 0.49 for use in the formula $v = C\sqrt{2gh}$ or $v = 4\sqrt{h}$ nearly. The valves were of the butterfly type, 8 ft. by 10 ft., turning about the 10-ft. axis. The mean width of opening around the closed valves was about 3/8 in. The valves had been in use about 18 years, and saving of water was not important. This type of valve is wasteful and should not be used where saving of water is important, although there should be no difficulty in reducing the leakage to one-half the amount observed by Ripley; its advantages are in simplicity, low cost of maintenance, and facility of operating. Leakage at the gates results from imperfect fitting; in the case of the ordinary mitering gates, the gates may be too long, in which case one or both (usually one) will not be in contact with the sill when closed, resulting in an opening, approximately triangular, extending from the miter to or toward the quoin; or the gates may be too short (usually from wear), in which case an opening of similar form will exist between the ends of the gates, extending from the sill upward.

For the gates of boat canals, maintained in good condition, it will be sufficient to assume an opening between the sill and one gate 1/2 in. wide at the miter and gradually tapering to nothing at the quoin. For ship canals the maximum width of opening may be doubled. While locks are being operated the head on the opening through which water is being wasted may vary from nothing, when the filling or emptying of the locks begins, to the full lift of the lock when the operation is completed; but as a safe provision, which covers small leaks between the quions and the gates and elsewhere, the full head is usually taken.

Using the coefficient for leakage at valves found by J. Ripley, and computing the leakage at gates as just indicated, the leakage at the Weitzel lock (60 ft. wide at gates, 20-ft. lift) is estimated at 72 cu. ft. per second, but the valves are not close-fitting. The various commissions of the old and new French Panama Canal Company allowed 35 to 53 cu. ft. per second for each lock, the lifts being about 30 ft. Kuichling estimated the leakage at locks from the summit level of the Barge Canal at about 23 cu. ft. per second, the lock at one end having a lift of 20-1/2 ft. and the lock at the other end 16 ft. He followed the method above outlined, assuming 1/4-in. opening around each valve and an opening of 1 in. at the miter between the sill and one gate of a pair.

Loss over Waste-Weirs. It is impracticable to adjust the supply of feed-water to the varying requirements of traffic; therefore the crest of the waste-way must be fixed at such a height that the canal will always have the required depth of water, or the crest may be provided with flashboards, permitting a temporary surplus of water to be held until wanted, or the water must be wasted. Waste may also result from the action of the wind blowing toward the weir, from a succession of boats moving toward it, etc. It is customary to provide a limited amount of storage by fixing the elevation of the crest of the wasteway somewhat above the level required for traffic, but it is restricted by the cost of the corresponding increase in height of the canal banks, lock walls, etc. In general, the best form of wasteway for ordinary conditions is a simple overflow weir, because its action is automatic; its length must be fixed with reference to the allowable rise of water in the canal.

Data regarding existing or projected canals vary greatly. For the eight waste-weirs on a 22-mile level of the Chenango Canal W. H. Talcott observed (in 1839) a waste of 96 cu. ft. per minute; for the proposed deep waterway from the Great Lakes to tidewater, G. W. Rafter estimated the waste for the summit level at 150 to 200 cu. ft. per second = 9 000 to 12 000 cu. ft. per minute, but his large esimate resulted from the provision of a waste-weir long enough to pass the floods of the Mohawk which was to be taken into the summit level. For the summit level of the New York Barge Canal Kuichling assumed a waste-weir long enough to control the water level within about 5 in. with a water supply sufficient for normal amount of lockages flowing in but with no lockages, and estimated the discharge over the waste-weir from this and other minor causes of waste to average 46 cu. ft. per second (400 000 cu. ft. per day) from each end of the summit level.

Power for Operating Locks. This is usally developed by water from the higher level. Power may be required for (1) opening and closing valves; and (2) hauling boats into or out of the lock. (1) For opening and closing of gates and valves, occupying only a small part of the time, accumulators may be employed. At the Dortmund and Ems Canal, where the locks are

28-1/4 ft. wide with 9.84 ft. on the sills and maximum lifts of 20-1/3 ft., the lock-gates and sluice valves are moved by power; the greatest amount required for any single operation is 7.2 hp. At the Weitzel lock, St. Marys Falls Canal, there are two turbines of 25 hp. each; one is sufficient to accumulate power as quickly as necessary, the other is a duplication for safety. The largest gates are 39 ft. high, the lock 60 ft. wide at the gates; two valves for filling the lock and two for discharging, each valve 8 ft. by 10 ft. The power required being given or estimated, the corresponding water consumption can be approximated in any given case. (2) The power required for haulage at the locks of the Erie Canal was given at about 8 hp., the immersed cross-section of the boats being 17.5 ft. × 6 ft. = 105 sq. ft. For the Barge Canal and boats of 25 ft. × 10 ft. = 250 sq. ft. immersed cross-section, Kuichling proposed 20 hp. as sufficient, the power to move a boat at a given speed being assumed to vary with the immersed cross-section.

Power Required for Lighting. For the New York State Barge Canal from 10 to 14 arc lights each of 750 cp. have been used. The United States canal at Sault Ste. Marie has 13 lights, each of 1200 nominal cp. (300 actual) for the duplicate locks, and one similar light each 400 ft., approximately, on each side of the canal. The Canadian canal on the opposite side of the St. Marys River has 8 lights, each 1200 cp. nominal, at the locks, and one similar light on each side of the canal every 300 ft. The length of each of these canals is approximately 1-1/2 miles. The Kiel Canal is lighted by incandescent lights placed opposite each other on the canal banks, spaced on curves at distances $R/15$ between pairs up to a maximum of 820 ft., on tangents.

Practice is not well defined as to the extent of lighting desirable, and the only practicable course is to prepare a plan for lighting believed to be the best suited to the case in hand, from which the amount of water required can be computed. The fall at the locks is usually the most convenient source of power, in which case the amount of water consumed is an element of the quantity to be supplied to the upper level, but in many cases the electric current may be supplied from a distance, between the reservoir and the canal, requiring no additional water; in other cases it may be found economical to buy current.

Under present conditions arc lighting is estimated to require 0.4 hp. per 1000 cp. with efficient plant management, and incandescent lighting with carbon filament 4.2 hp. per 1000 cp. These are approximations, and for canal illuminations the power should probably be doubled. For the New York State Barge Canal, Kuichling estimated a consumption from the summit level of 21 cu. ft. of water per second or 6 hp. for four arc-lights, each of 1000 cp.

Water Consumed for Lockages. Let Q = area of lock multiplied by lift of lock, D = displacement of vessel, N = number of locks in flight. There are four possible conditions of lockage affecting the consumption of water. Case 1: A boat ascending after another has descended will draw from the upper level, past the upper gate, $V = NQ + D$. Case 2: A boat descending after another has ascended will force into the upper level, past the upper gate, $V = D$, the draft from the upper level being $- D$. Case 3: A boat ascending following another that has ascended, will draw from the upper level, past the upper gate, $V = Q + D$. Case 4: A boat descending following another which has descended will draw from the upper level, past the upper gate, $V = Q - D$. The ascending boats draw from the summit level their displacements, and the descending boats force their displacement back into the summit level. Ordinarily no material error will be introduced if the displacements be assumed equal, therefore D may be eliminated from the formulas, which become:

Case 1, $\mathbf{V} = \mathbf{NQ}$ (boat ascending); Case 2, $\mathbf{V} = \mathbf{Q}$ (boat descending);
Case 3, $\mathbf{V} = \mathbf{Q}$ (boat ascending); Case 4, $\mathbf{V} = \mathbf{Q}$ (boat descending).

If the summit level is reached by a single lock and the number of boats passing in one direction is equal to the number passing in the opposite direction the minimum consumption of water would be given by alternating ascending and descending boats, cases 1 and 2; in case 1, N becomes 1, and the two boats of a pair would consume $Q + O = Q$, or an average per boat of $1/2\ Q$. If the boats follow each other the average consumption per boat is Q. The actual consumption will be between these extremes $1/2\ Q$ and Q since it will frequently be impracticable to delay a boat which is awaiting another from the opposite direction.

If the summit level is reached by a flight of two locks, ascending and descending boats alternating require $2\ Q$ for the ascending boat and O for the descending boat, or an average of Q, and the same average amount if the boats follow in the same direction.

For a flight of three locks two boats alternating will require $3\ Q$ or an average for the two of $3/2\ Q$, and the average for all lockages will equal or exceed Q. When the number of locks in a flight exceeds two, economy in use of water for lockages results from duplicating the flights of locks, using one flight for up-bound and the other for down-bound boats, the consumption for each boat being Q.

Water for lockages may be economized by the use of side ponds receiving the water discharged from the lock chamber during the earlier part of the process of emptying and returning it to the lock chamber during the earlier part of the operation of filling At the Dortmund and Ems Canal two pairs of side ponds are used, at different elevations, two ponds at each side of the lock and about 50% of the lockage water is saved.

18. Speed of Canal Boats

Where steam power is used the speed is usually limited by regulations. The power required to move a boat increases rapidly as the ratio (wet cross-section of canal) ÷ (wet cross-section of boat) decreases. On boat canals the boats are usually of the largest dimensions permitted by the locks. On ship canals the tendency to uniformity is not well marked, and is affected or controlled by numerous conditions other than lock dimensions. The table gives data for various canals.

Canal	Cross-section of of canal			Cross-section of boat		Ratio of cross-section	Power	Speed, miles per hour
	Surface width, ft.	Bottom width, ft.	Depth, ft.	Beam, ft. in.	Draft, ft. in.

* Actual average is somewhat less. † By trial. ‡ Permitted by rules.

§ By regulations; actual speeds allowed on tangents 7.4 miles per hour. Average speed on sharp curves 3.7 miles per hour.

‖ Permitted by rules for small vessels. Large ships cannot attain 6.2 miles per hour.

¶ By regulation; enforced for large ships. Small vessels specially licensed to run 9.2 miles, but attain 11.5 to 15 miles per hour.

The New York Barge Canal with a wet cross-section of 1188 sq. ft. is intended for steam barges having a wet cross-section of 250 sq. ft. when loaded, giving a ratio of 4.75. In concluding a report on the probable speed in such a traffic, E. Sweet expressed the opinion that a higher speed than 3 miles per hour would be "economically inadmissible."

In France the speed limit on canals is considered to be 1.67 miles per hour; traction by horses. On the Northeastern canals where on account of congested traffic a concession for horse traction was instituted in 1875, the contractor is bound to maintain the speed of 1.24 miles per hour for ordinary service and 1.8 miles per hour for accelerated service. Interesting experiments have been made on the French waterways on the tractive force required by various types of boats at various speeds and in various channels. The types of boats were: " Peniche flammande,"—box bow and stern, only slightly rounded where the ends join the sides and bottom; " Flute," cut-away bow, rising in a curve from the keel; "Toue," pointed peaked bow and square box stern; " Prussian barge," pointed bow and stern; " Margotat," punt-shaped. The boats were towed in a river of large section (practically an unlimited cross-section) at a uniform speed of 3.35 miles per hour to determine the influence of the form of boat on tractive force required.

Type of boat	Length, ft.	Beam, ft.	Draft, ft.	Coefficient of displacement	Gross tonnage	Traction force, lb., at 3.35 miles per hour	
						On boat	Per gross ton
Peniche flamande....	126	16.4	5.25	0.99	305	1530	5.03
Flute..............	126	16.4	5.25	0.95	283	785	2.77
Flute..............	126	16.4	4.27	0.95	250	695	2.78
Toue...............	126	16.4	5.25	0.97	299	590	1.97
Prussian barge......	113	16.4	4.27	0.94	210	410	1.95
Margotat...........	72	16.4	4.27	0.82	116	310	2.67

Another set of experiments was made in various canals with the " flute " at 4.27 ft. draft at various speeds. The coefficient of resistance is the factor to be applied to the tractive force required in an unlimited cross-section in order to obtain the tractive force required in the canal named. The ratio of cross-section of channel to cross-section of boat is represented by r.

	Depth ft.	Area, sq. ft.	r	Coefficient of resistance for speed in miles per hour				
				0.56	1.12	1.67	2.23	2.79
Diversion of the Yonne at Joigny..................	8.20	450	6.39	.....	.....	1.38	.....	.....
Canal de Bourgogne........	7.95	320	4.54	.....	.....	1.98	.....	.....
Canal de la Curé (Yonne)...	6.85	250	3.57	1.92	2.13	2.38	2.75	3.17
Canal de St. Dizier at Vassy.	6.80	207	2.94	.....	.....	3.32	.....	.....
Canal du Nivernais.........	5.60	207	2.94	.....	.....	3.82	.....	.....

The resistance at 1.67 miles per hour in the unlimited section was 172 lb. and in the Diversion of the Yonne at Joigny with r = 6.39 it was 238 lb., or 38% greater; but with r reduced to 2.94 it increased 232% in one case and 282% in another, the greater resistance being in the shallower canal, a diminution of 1.2 ft. in depth or 48% in clearance under the boat, increasing the resistance 15%.

Experiments to determine influence of form of boat and cross-section of canal on cost of transportation were made in 1898 on the Dortmund and Ems Canal, and in 1906 on models in the government experimental tank in Berlin comparing cross-sections of equal area, one with a greater central depth, also cross-sections of different areas, and two forms of boats moving at different speeds with a view of determining the most economical conditions of transport for assumed amounts of traffic. The effects of draft and speed were found to be similar to those indicated by the French experiments and for the conditions assumed r = 4.2 to 5.3, and boats carrying 667 tons one way and 1/5 as much the other way, with mechanical haulage, a speed of 3.1 miles gave economical transport.

19. Locks and Lock Gates

Locks are usually employed to overcome differences of level. In the earlier canals in the United States they were frequently built of wood, but these were soon replaced with stone masonry, the face being cut accurately to true lines and surfaces, and until within the last 25 years practically all canal locks in the United States were of stone masonry. Now concrete made with portland cement has come into use. Brick masonry laid in cement or hydraulic lime has been used largely in European canals, either for the entire mass of masonry or for facing, except at quoins and other exposed places, where heavy stone blocks have been built into the brickwork. Bricks for facing are of specially good quality.

In the locks of the Kiel Canal the floors and lower portion of the side walls up to the floor level are of concrete; above the floor the side walls are of brick masonry built with large openings filled with concrete of 1 cement to 8 sand. Fender courses, lock-sills, angles of gate recesses, and guide grooves for the pontoon gates are of granite. The

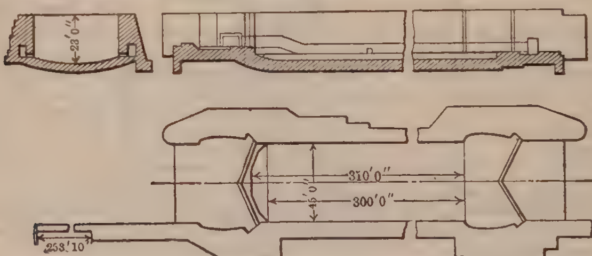

Fig. 52. Barge Canal Lock

locks of the Manchester Canal are of concrete, with brick facing above low-water and stone copings; miter sill masonry facing of sandstone, the coping of specially hard quality, but stones in contact with gates (no timber sill) are of granite; brick and stone are used at other exposed places.

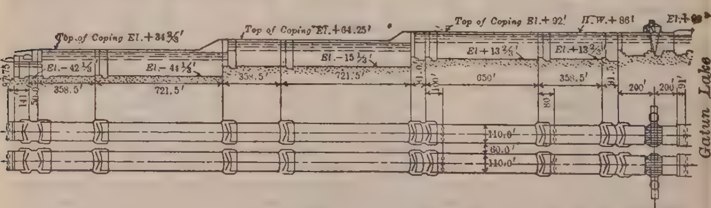

Fig. 53

The Poe and Weitzel locks at Sault Ste. Marie are of limestone masonry. The new locks are of concrete. Fig. 52 illustrates a lock of the New York Barge Canal. Fig. 53

shows the principal dimensions and Fig. 54 the cross-sections of the Gatun locks of the Panama Canal.

Foundations and Floors of Locks. Where rock foundation is not available, the lock is usually founded on piles, and the entire foundation enclosed within

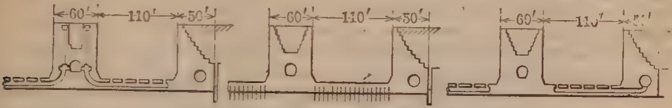

Fig. 54. Gatun Locks, Panama Canal

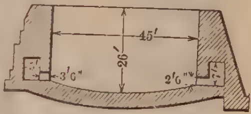
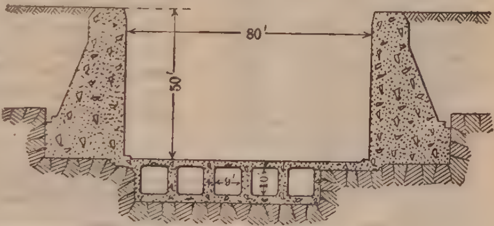
sheet piling and with lines of sheet piling under the sills. In American practice the floors of small locks have usually been built of wood, but with increased width the use of timber is not advantageous. In foreign canals, lock floors are usually of concrete in the form of an inverted arch. The thickness of the floor is usually sufficient to resist the full upward pressure of water when the lock is pumped out, but in some cases weep holes have been formed in the floor to relieve this pressure.



(a) Barge Canal

Where founded on rock, the thickness of the floor is more frequently reduced and may be, in great part, omitted if the rock is especially sound and free from fissures, but usually a covering is required, either to protect the rock or to give a smooth surface. In the St. Marys Falls Canal this protection is of timber and concrete; the floors are firmly bolted to the underlying rock. With the increasing price of timber, the reduced cost of portland cement, and the introduction of reinforced concrete, the economy formerly effected by the use of timber is reduced



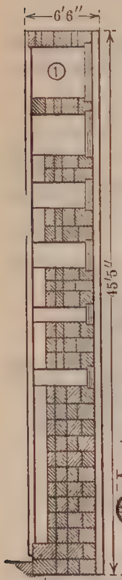
(b) St. Marys Falls Canal

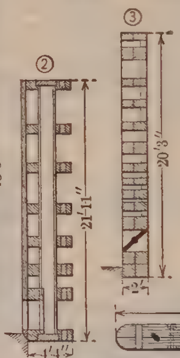
Fig. 55. Locks of Large Canal

Facilities for Filling and Emptying Lock. Small locks are usually filled and discharged through valves in the gates or through short culverts around the quoins. This causes the boat to surge, and in large locks this action prevents rapid operation. The large boat canals, and nearly all ship canals, have sluiceways or culverts formed in the side walls of the locks, provided with a valve at each end to open or close connection with either level and with openings leading into the lock chamber near the bottom of the side walls. At the St. Marys Falls Canal, the timber floors have facilitated forming culverts underneath, discharging upward through many small openings, affording a more uniform distribution of water supply and giving the least possible disturbance to ships.

Valves in gates are usually of the butterfly type turning on a central axis. In culverts or sluices they may be plain slide valves, either of wood or metal, but with large sluices friction makes the operation of such valves difficult or slow. Stoney sluices have been used, for example, at the Manchester Canal. At the St. Marys Falls Canal butterfly valves are used for the 8-ft. by 10-ft. openings, but are not economical of water. Valves moving on four large wheels have been adopted for the New York Barge Canal (Fig. 62). On this canal one lock at Oswego has no valves for filling and emptying the lock chamber, and it is filled and emptied by means of siphons in the lock wall.

Lock Gates. Mitering gates are in pairs, each of the two "leaves" turning about a vertical axis in a recess in the lock wall. When closed, the two leaves, usually of equal length, meet and support each other about 1/4 to 1/5 the width of the lock from a straight line connecting the two axes of rotation. In earlier practice, and particularly in small locks, the gates were made of timber, but steel is coming into more general use; at the Manchester Canal, and at the Liverpool docks, greenheart timber is still used for openings up to 80 ft. or more in width, and the engineers claim for it much longer life than for metal gates.





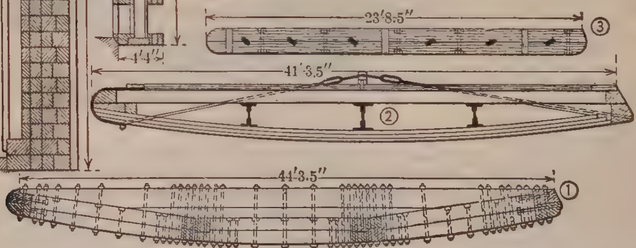


Fig. 56. Wooden Lock Gates
(1) Manchester (2) Kampsville (3) Kanawha

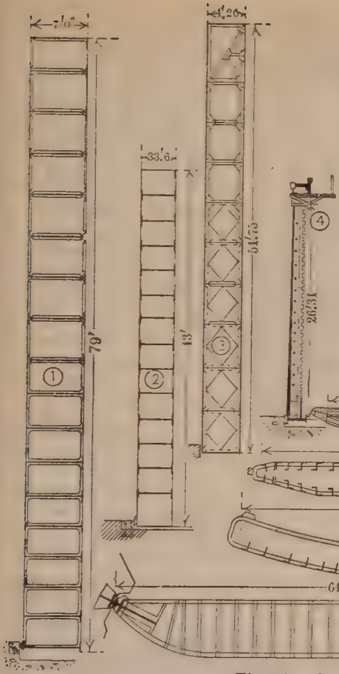
Timber gates (Fig. 56) consist of horizontal girders usually framed into strong end verticals called, respectively, "quoin post" or "heel post" and "miter post" or "toe post"; the gates are planked on the upstream face, where necessary for watertightness. On the Canadian canals the miter and quoin post and planking are omitted and the gates built solid.

Steel gates (Fig. 57) have a strong vertical girder at each end which is usually furnished with a timber-bearing face. The intermediate framing may consist of horizontal girders carrying stresses directly from the miter to the quoin, or of a heavy girder top and bottom to which the vertical girders carry the water-pressure loads. The upstream or both faces are covered with continuous plating, and in cases of heavy gates an airtight chamber is formed to facilitate moving the gate.

Fig. 58 shows one leaf of a gate for the New York Barge Canal. The gate is supported by a pivot under the quoin post and a steel strap or other device at the top strongly anchored to the side wall of the lock. In the United States and Canada, and in some foreign canals, these arrangements suffice to support the gates in position. In English practice, a heavy gate is usually supported on a roller at the miter end, which moves along a path laid in the lock floor.

Many forms of single-leaf gates are in use. On the Erie Canal the gate at the head of the lock is frequently of the form called "tumble" gate, which turns about the lower edge, falling upstream when opening and lying flat on the bottom of the lock, boats passing over it (Fig. 59). The span (width of lock) is 18 ft. and the depth of water 7 ft. Similar gates are in use at the head of locks on the Oder and Spree Canal, where the span is 29.52 ft. and depth of water 8.2 ft. These gates are of wood.

On boat canals, where a limited overhead clearance is admissible, gates lifting vertically have been used, as in the recently built Teltow Canal. A lifting gate on the Coevorder Canal, Holland, has a length of 21.3 ft. and a height of 5.6 ft., is of metal, and lifts vertically high enough for boats to pass under. On this canal one



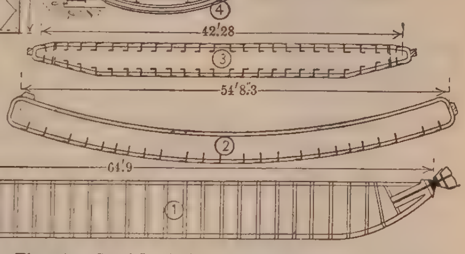


Fig. 57. Steel Lock Gates
(1) Panama (2) Poe (3) Kiel (4) Spree

lock with a lift of 40.5 ft. has a vertical lift gate at the lower end of the lock. Gates turning about a vertical axis at one end and closing the entire width of the lock are in use in some European canals. Following are examples: In the diversion of the Scarpe around Douai the single-leaf gates at the foot of the locks are 21.8 ft. long and 25.2 ft. high; those at the head of the locks are 21.6 ft. long and 11.7 ft. high; the depth of water over the sills is 8.2 ft. and the lift of the lock 13.4 ft.; gates are of iron with wood sheathing and contact

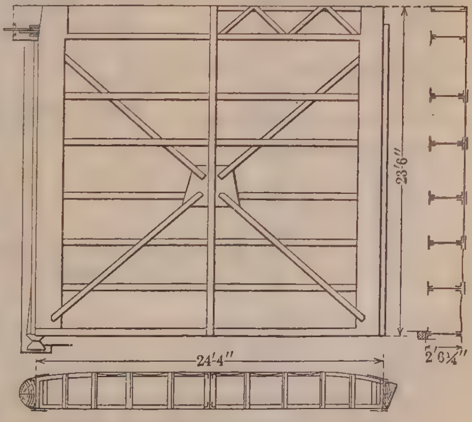

Fig. 58. Barge Canal, Steel Lock Gate

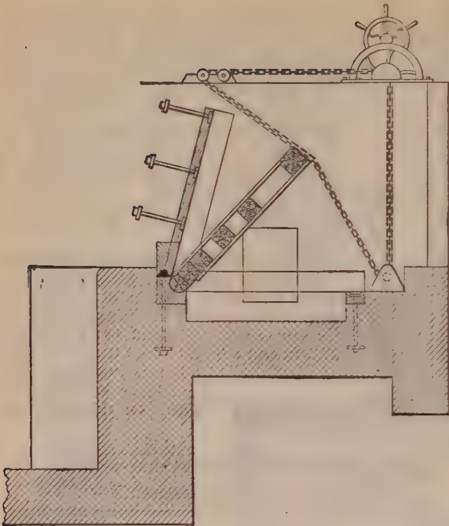

Fig. 59. Tumble Gate, Junction Lock, Erie Canal and New York Barge Canal

pieces. At Lichmis on the Dedemsvaart Canal, Holland, single-leaf gates at the head of the lock span 19.7 ft.; depth of water on sill 6.6 ft.; height of gate 7.3 ft.; built of iron. At the canal St. Denis a single-leaf gate is used at the foot of a lock where the lift is 32.5 ft. As a clear headroom of only 17.2 ft. is required, a masonry arch is extended across the lock, and the gate when closed is supported on all four sides; the gate is 28.7 ft. long and 33.6 ft. high; depth of water over sills about 10 ft. It has a frame of iron with wood sheathing and contact pieces.

Rolling gates moving transversely to the canal are in use in many places. In the locks for the Ohio River navigation at Davis Island and elsewhere (Fig. 60), which are 110 ft. wide, the gates at the head

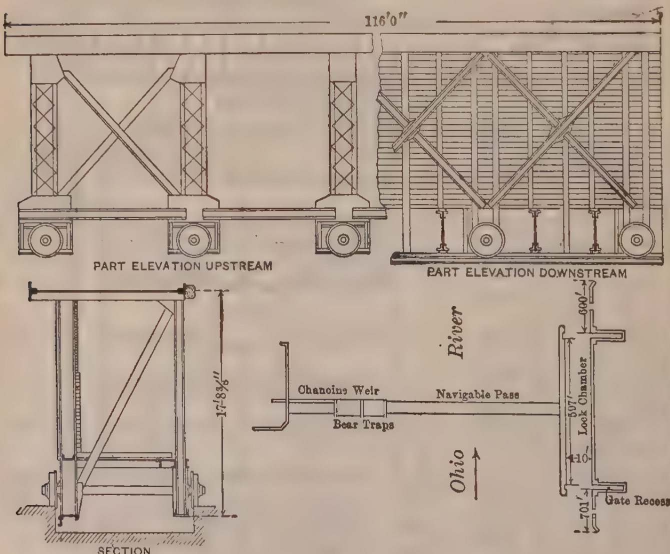

Fig. 60. Ohio River, Rolling Lock Gate

and foot of the lock are alike; the lift is limited to about 8 ft. and the maximum height of gate built up to this time is 18.5 ft. The gates have steel frames with wood sheathing, and are carried on wheels which run on tracks laid in the lock floor. The gates are opened and closed in 1-1/2 to 2 minutes with steam power. In the Canal François, Hungary, the locks (two in flight) near the R. Sisza have a width of 52.5 ft. and a depth of 8.2 ft. on sills; the upper and middle gates are of iron and of the roller type, suspended from trucks running on an overhead bridge. The middle gate is 55.6 ft. long, 30.1 ft. high, and weighs 150 tons mounted. It has air chambers which lift 44 tons, leaving the net weight to be moved 106 tons; operating machinery is electric. Time to open and close the gate 3 minutes.

Operating Machinery. In the smaller boat canals the gates and valve are operated by hand. The lock gates of the Erie Canal have " balance beams " attached to the top of the gate and extending back over the side walls, and the gate is moved by men pushing against the beam. In some foreign canals a segment of a toothed wheel is attached to the quoin post and extends back over the wall and is operated by means of a windlass with vertical axis carrying a pinion which acts upon the toothed segment. At the Dortmund and Ems Canal the piston rod of a hydraulic cylinder acts upon an arm extending back from the gate, replacing the toothed gear just mentioned. At the larger locks, hydraulic machinery is in most general use. As the machinery is operated for only a small part of the time, accumulators are employed, usually in the form of a vertical cylinder, into which water is pumped, lifting a heavily loaded plunger, and from which the water is drawn when wanted. At many places, as the Manchester Canal and the Liverpool docks, the gate is opened by means of a chain attached to one end of the gate and then led around guides and rove through two sets of pulleys, one attached to the lock wall and the other to the plunger of a hydraulic cylinder. The effect of this is to multiply the movement of the end attached to the gate when the plunger is operated. A similar arrangement effects the closing of the gate. At the Weitzel lock of the St. Marys Falls Canal a single cylinder is used to open and close each gate, a piston being substituted for the plunger, a long piston rod passing through both cylinder heads with a set of pulleys at each end (Fig. 61). At other places winding drums are operated by three-cylinder hydraulic engines, at the as Kiel Canal. A simple and efficient machine, consisting of a hydraulic cylinder with its piston rod guided and a connecting rod attached directly to the gate and opening or closing the gate by a single movement of the piston was introduced at the Barry dock at Bristol, England, and is used at several places.

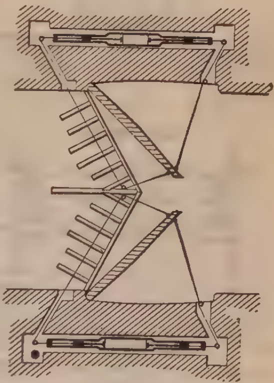

Fig. 61. Method of Operating Gates, St. Marys Falls Canal

In the smaller canals the valves for filling or emptying the locks are operated by hand power. The 8-ft. by 10-ft. butterfly valves at the locks of the United States canals at St. Marys Falls are opened or closed by a single stroke of a hydraulic engine, the connecting rod being attached directly to the valve—all below the lock floor. At the Canadian Canal, St. Marys Falls, the valves are operated by a long connecting rod attached to a crank arm of the valve stem. On the New York Barge Canal the valves which are counterweighted are operated by electricity (Fig. 62).

In foreign canals the water pressure used in hydraulic machinery at locks is usually 40 to 50 atmospheres. In recent years the use of electric current for operating lock machinery is increasing; two notable examples are the Canadian lock at the St. Marys Falls and the sea lock of the Amsterdam Canal.

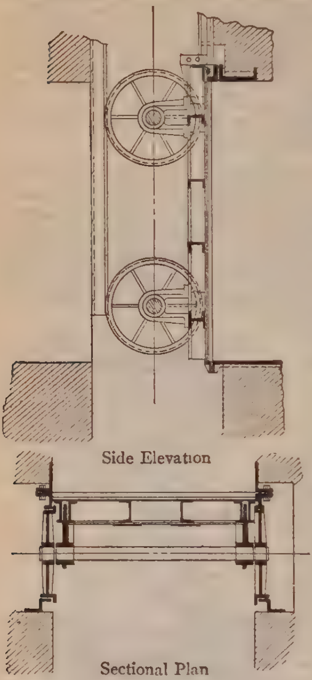

Fig. 62. Lock Valve, New York Barge Canal

Approaches to Locks. In canals where boats are moved by men or horses at low speed the change from canal section is effected abruptly at the ends of the lock walls but where vessels are moved by steam the danger of accidents to lock gates is greatly increased, and a long guide wall should be built at each end of every lock or flight of locks with posts strongly anchored placed at short intervals for use in checking speed by means of lines. Such arrangements exist at the St. Marys Falls canals, at the New York Barge Canal, and at the Panama Canal.

20. Lifts and Inclines

High Lifts. There are several examples in European and Canadian canals of so-called " hydraulic lifts." This type consists of two tanks, each large enough to receive a boat, and supported by a plunger working in a cylinder of sufficient length to give the desired lift by one stroke of the plunger. The cylinders of the two tanks are interconnected, so that the tanks balance each other. The boat to be lifted or lowered is placed in one of the tanks, displacing its own weight of water, and thus not affecting the balance. Movement is effected by admitting a small amount of excess water to the tank which it is desired to lower. The tank has a gate at each end; a gate is also placed at the end of each canal level. The table at top of next page gives some of the details of existing hydraulic lifts.

The Anderton lift, the first to be built, was operated with little trouble for several years, but finally the plunger became scored to such an extent that it was decided to remove the hydraulic appliances; each tank is now counterweighted separately, the counterweights being connected to the tank by wire cables carried over pulleys supported by an elevated frame; the operation is by electric machinery. This change was carried out in 1908.

The high lift at Henrichenburg, built in 1899 on the Dortmund and Ems Canal, consists of a single tank supported on five watertight air-filled cylinders immersed in wells which are interconnected and kept full of water. Principal data are:

	Ft.	In.		Ft.	In.
Depth of wells	98	6	Carrying capacity of boat, tons	950	
Diameter of wells	30	2	Length of largest boat	220	0
Diameter of cylinder floats	27	6	Width of largest boat	27	0

Cost in dollars	230 000	380 000	320 000	500 000	....

* The record time of complete operation was 6-1/2 minutes.

The movement of the lift is controlled by guides, and uniformity is secured by four massive vertical screws, interconnected, and working through nuts fixed to the lift. It is stated that "a lift constructed on the open trough principle should be adopted only where conditions for it are favorable and a good foundation can either be found or can be prepared without any great trouble and expenditure. It should also be mentioned that when the further extension of the Dortmund and Ems Canal is taken in hand, it is contemplated to construct a flight of locks by the side of the canal lift."

Inclined planes have been used to surmount high lifts, both in the United States and Europe. The table gives details of several examples.

Canal	Number of inclines	Total lift, ft.	Largest boat: Length	Width	Draft	Load, tons	Built	In use or abandoned
			ft.	ft. in.	ft. in.			
Morris, U. S.	23	1449.0	89.0	10 6	4 0	70	1831	In use

Oberland, Germany	5	66.0 to 80.3	....	......	......	70	1860	In use
Bude	1	....	20.0	5 6	1 8	.....	.....	In use

The small boats using the Bude incline have wheels built in, and are drawn up the incline in trains, counterbalanced to some extent by descending trains or boats. On the inclines of the Morris, Pennsylvania, Shropshire, Shrewsbury, Ourcq and Overland canals, boats are (or were) carried on trucks; on the inclines of the Chard and Monkland and Chesapeake and Ohio canals, the boats are hauled while water-borne, or nearly so, in tanks. In some cases the incline is double, the boats or tanks counterblancing each other. Boats are usually carried endwise, but on the Foxton incline on the Grand Junction Canal, the boat is carried sidewise and is water-borne; two tanks are used counterbalancing each other.

The incline of the Chesapeake and Ohio Canal (at Georgetown, D. C.) provided for larger boats than any other yet built. In connection with the projected Austrian system of canals to connect the Danube with the Ober, the Elbe and the Moldau, inclines have been proposed for boats of 600 to 800 tons capacity. It was announced in 1902 that the Government of Austria had decided to build an experimental incline for boats of 600 tons, investigations having indicated a saving in cost of transport by the use of inclines instead of locks, provided no unforeseen difficulties develop in actual use of inclines constructed on a scale so much exceeding any previously built.

21. Guard Gates, Safety Gates, Stop Gates

Guard Gates are arranged at the St. Marys Falls canals by extending the lock walls at each end sufficiently to receive an additional pair of gates, each opening outwardly. They could be used to protect the ordinary lock gates from approaching vessels, but are not so used, their purpose being to enable the lock to be closed quickly by unworn and perfectly fitting gates, for repairing the lock and its gates and valves. The summit level of the Charleroi Canal (supplied by pumping) is divided into short sections by **safety gates,** so that in case of a break in the canal bank the gates may be closed and the loss of water limited to about 20 000 000 cu. ft. **Stop gates** (Fig. 63) were introduced in the Dortmund and Ems Canal which in places is carried on heavy embankments. These act on the same principle as Taintor gates, and when opened permit the passage of boats underneath. In the New York Barge Canal guard gates (Fig. 64) are placed at least every 10 miles in canal sections; these are lifting gates and in duplicate, each affording a clear opening of 55 ft. and a clear head room of 15.5 ft. above the water surface at high navigable stage when opened. These gates are steel and carry wheels moving on vertical tracks fixed in the masonry. They are operated by hand power. The last three devices are designed to be operated in moving water.

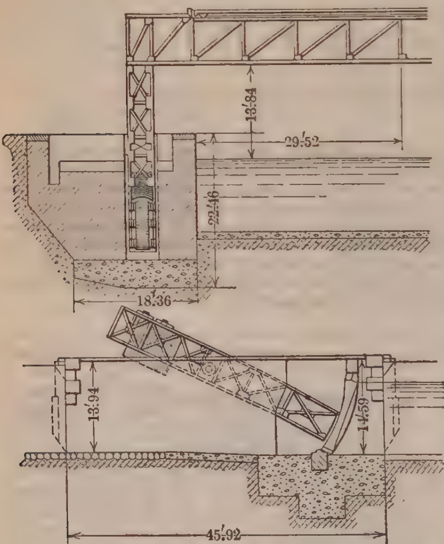

Fig. 63. Guard Gate, Dortmund and Ems Canal

These devices are impracticable for closing a ship canal where unlimited height is required, and for such canals the safety gates are some form of movable dam. As these are to be manipulated in powerful currents, a subdivision of the structure is considered necessary, and as the emergency requiring their use will seldom arise, and if not in sight they would be more liable to be neglected and unserviceable when needed, they should be above water and readily inspected when not in use. These conditions

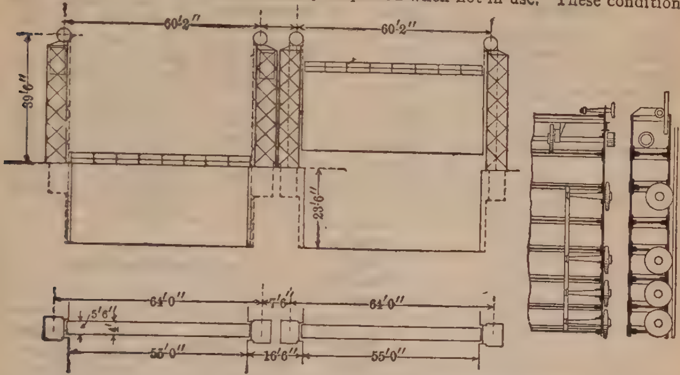

Fig. 64. New York Barge Canal Guard Gates

have been met at the St. Marys Falls canals by swing bridges carrying the sectional dams. Fig. 65 shows the structure in the canal on the Michigan side of the rapids. The canal, which is in rock excavation, is separated by an island into two channels, each 108 ft. wide and 25 ft. deep. Each channel is closed by 16 wickets which can be lowered separately. Each wicket will consist of two parts, a frame and a shutter mov-

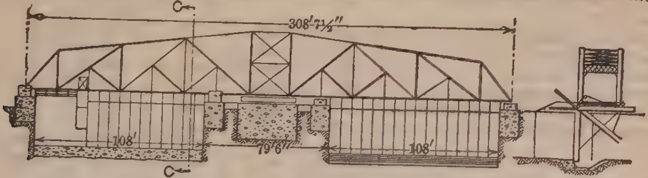

Fig. 65. Movable Dam. United States Ship Canal, Sault Ste. Marie

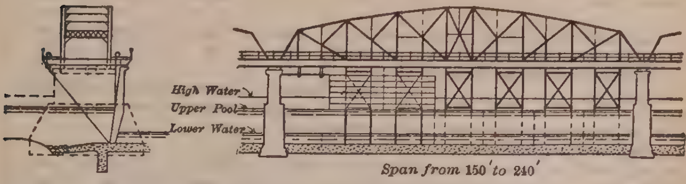

Fig. 65a. Movable Dam. New York Barge Canal

able in the frame. It is expected that the frames will be lowered first, offering only a partial obstruction to the current, and when all are properly placed, the shutters, guided in the frames, will be lowered one at a time. This structure is similar to the one at the Canadian Canal which was successfully operated when lock gates were carried away in June, 1909. On the Panama Canal a safety device is used similar to that shown in Fig. 65. It is described in more detail on p. 1600.

Nearly all the canals built by the United States Government are lateral canals, avoiding rapids in the natural waterways and providing for steamboats as well as barges. The most important one is the St. Marys Falls Canal, which will be described as one of the great ship canals (see p. 1598).

The Colbert Shoals Canal is typical of lateral canals along navigable rivers. It avoids Big Tree and Colbert Shoals in the Tennessee River; length 8 miles, depth at low water 7 ft. Width for lower 5-1/2 miles in earth excavation 112 ft. at bottom, 140 ft. at low-water surface, side slopes 2 : 1. Width for upper 2-1/2 miles, mainly in rock excavation, 175 ft. at bottom, about 190 ft. at water surface. Lock at lower end of canal: available length 350 ft., width 80 ft. Lift, maximum at extreme low water, 26 ft. Mitering gates steel, circular in plan. Culverts in side walls for filling and discharging, 8.6 ft. by 9 ft., with 11 openings into the chamber from each wall. Valves of the Stoney type. Banks 20 ft. wide at top extend 9.5 ft. above low-water line and are protected Bermuda by grass above that line. Side drainage received into the canal usually through culverts. Five waste-weirs, each 100 ft. long, are built into the bank on the river side, exclusive of a guide wall 7000 ft. long at head of canal serving also as a weir. Crests of weirs 0.5 ft. above low-water surface.

Only two canals with summit levels and intended for boat or barge navigation have been undertaken within recent years in the United States. One of these is the Illinois and Mississippi Canal (also called " Hennepin " Canal), and the other is the New York Barge Canal with its branches, the Oswego, Champlain, Cayuga and Seneca canals.

Traffic in the boat canals of the United States has been steadily decreasing with increasing competition of the railroads and motor vehicles, and this has not been checked materially by the removal of tolls and the assumption of fixed charges and operating expenses by the state. On the continent of Europe, where the canals are generally owned by the state and free from tolls, the assumption of construction, operation and maintenance by the state enables water transportation to compete with rail, and traffic on the waterways is increasing.

New York Barge Canal. The Barge Canal is the improvement of four existing canals, and consists of (1) the Erie, stretching across the state from east to west and joining the Hudson River and Lake Erie; (2) the Champlain, running north from the eastern Erie terminus to Lake Champlain; (3) the Oswego, starting north midway on the Erie and reaching Lake Ontario; (4) the Cayuga and Seneca, leaving the Erie a little west of the Oswego junction and extending south, first to Cayuga lake and then to Seneca lake.

The Barge Canal is largely a river canalization project, natural water-courses being available for much of its length. With intervening lakes and adjoining rivers there is a total length of a little more than 800 miles in the state's internal waterway system that is of Barge Canal dimensions.

The main water supply is taken from Lake Erie, from reservoirs in the Adirondack region and from the upper Hudson River. The supply is adequate not only for the 10 000 000 tons seasonal traffic for which the canal was designed, but also for the maximum traffic which the canal is capable of handling, namely, from 18 500 000 to 20 000 000 tons per season.

The locks on all branches of the canal are of standard dimensions. The lifts range from 6 ft. to 40-1/2 ft. They are built of concrete throughout and except on rock or hardpan have pile foundations. Within each side wall runs a culvert for filling and emptying the lock. The culverts are connected with ports that open into the chamber at the bottoms of the walls. With a few exceptions the lock gates are of the mitering, girder type, carrying the principal load as beams. They are built of steel, with single skin-plates, have white-oak quoin and toe posts, swing on cast-steel pivots set in the concrete, are held at the top by adjustable anchorage and bear against cast-iron quoin plates bolted into the side walls. In general a power station at each lock supplies the energy for operating and lighting the lock. A majority of these installations are hydroelectric, but at locks beside movable dams gasoline-electric stations are employed.

At about fifty cities and villages along the waterways the state has built terminals, which provide suitable dockage, mechanical devices for handling goods quickly and cheaply, a building for temporary storage and, where possible, railway connections—all available to any shipper or boatman.

France. Practically the whole of the canal system is owned and controlled by the state. In 1905 the total length of canals in use was 3010 miles. The more important canals have a bottom width of 33 ft. or more; depth 6.6 ft. to 7.25 ft.

Belgium. The total mileage of the waterways (canals and rivers) is 1345 miles. The total length of the more important canals is 334 miles. The total lift at 141 locks (excluding lifts) is 1445 ft. The total lift at 4 lifts (1 completed, 4 building) is 217 ft. When new work or enlargement is taken up the locks are given greater lifts, up to 14.8 ft., and water saving effected by side ponds.

Germany. The total length of the waterways on which the traffic is of importance is 6200 miles and the total lift at 359 locks (excluding lifts) is 3129 ft. In the canal connecting most directly with the French waterways the width at the water surface is about 52 ft., at the bottom 33 ft., depth 6.6 ft.; useful length of locks 126 ft., width 17 ft., adapted for use of boats on the French and Belgian canals.

Great Britain. The canals were built by independent companies, without assistance from the state. Nearly one-third of the total mileage has been acquired by railway companies. The total length is 3811 miles (Eng. News, Apr. 16, 1890). The annual traffic on the independent canals is about 33 000 000 tons; on the railway-owned canals, about 6 000 000. The greater part of the traffic is short distance, there being no uniformity of canal dimensions, making frequent transshipment necessary on through business. Excluding the ship canals, only 10% of the total mileage has a depth of 6 ft. or more, while 46% has a depth of less than 4 ft. On account of the diverse ownership a material extension or improvement of the boat canal system is not expected.

Holland. There are 265 canals, with a total length of 2100 miles, of which about 5% belongs to the state; the remaining canals are under control of provincial or municipal authorities, administrative corporations, or private companies. Many of these canals are designed primarily for drainage, and some of the branch canals can be navigated only by small boats poled or towed by manual labor. Power boats and tugs are used on the larger canals. On the Merwede Canal recently built, length 43-3/4 miles, 106 ft. wide at water surface, 66 ft. at bottom, 10.2 ft. minimum depth, the tugs tow trains of 12 boats. This canal cost $8 480 000 for construction; annual maintenance $103 000. All the canals owned by the state, and nearly all the others, are free from tolls.

23. Ship Canals

Suez Canal. Connects the Mediterranean Sea and the Red Sea. Shortens the sailing distance from northern Europe to India about 5000 miles; to Australia about 1000 miles. Total length of canal including harbor at Port Said and roadsteads at both ends 104.08 miles. Minimum depth 31.1 ft. Width at this depth (excluding harbor and roadsteads) 108.26 to 118.11 ft., widened on curves to 131 to 262 ft. There are 23 passing places where the bottom width is increased to 147.63 ft. for a length of 2460 ft., reducing at each end to standard width in a distance of 984 ft. Side slopes vary from 2 : 1 to 3 : 1 or flatter. The width and depth are being increased gradually. Cost of the work up to the end of 1908 was $122 275 000. Expenses during 1908 were about $8 668 000 and net profits about $12 850 000.

On account of the tides and effect of the wind in the Mediterranean and Red seas currents are produced in the canal reaching 1-1/3 miles per hour between the Bitter Lakes and Port Said, and 3 miles per hour between the Lakes and Suez. The speed of vessels is limited to 7-3/4 miles per hour on the 28-mile tangent beginning at Port Said, and to 6.2 miles per hour elsewhere in canal sections. A high speed is permitted in the lakes. The average time actually consumed in passing the canal is from 18 to 19 hours.

Corinth Canal. Connects Gulf of Corinth with Gulf of Ægina. Is at sea level. Shortens sailing distance from Adriatic ports about 175 miles, and from Mediterranean ports about 100 miles. The canal is 3.91 miles long. The great central cut is 2-1/2 miles long with a maximum depth of 286 ft. from surface of ground to bottom of canal. The canal is 26.64 ft. deep and has a bottom width of 68.9 ft. The sides have a batter or slope of 1 horizontal to 4 vertical (1 : 4). Unless vessels move very slowly they strike the sides of the cut frequently. The traffic is small.

Manchester Canal. Connects Manchester with the River Mersey at Eastham near Liverpool. It is 35-1/2 miles long; when opened for navigation (1894) its depth was 26 ft.; ruling bottom width 120 ft. Side slopes in earth from 1 : 1 to 3 : 1, in rock 1 : 5. For a distance of four miles from Manchester the bottom width was 170 ft. The depth of water on the lock sills was made 28 ft., and the canal was deepened to that depth.

The Manchester level is 70 ft. above mean tide at Eastham, and is reached in five lifts, varying from 9 ft. 6 in. to 16 ft. 6 in.; the smallest lift is at Eastham and overcomes the difference of level between mean tide and mean high water.

At the Eastham terminus there are three parallel locks having the length and width respectively, of 600 ft. by 80 ft., 350 ft. by 50 ft., and 150 ft. by 30 ft.; the lengths given are from quoin to quoin. At the other lock sites there are only two parallel locks, respectively, 600 ft. by 80 ft. and 350 ft. by 50 ft.

Each set of locks is paralleled by a sluiceway, with sluice gates of the Stoney type 20 to 30 ft. wide (30 ft. except at Eastham), and with sills at the same level as the upper sill of the adjacent lock. Each 30-ft. gate has a discharging capacity of about 6500 cu. ft. per second. There are three to five (excluding Eastham) such outlets in each sluiceway, so that in times of flood strong currents may be set up for short periods. The smaller sluiceway at Eastham is supplemented by extensive sluices in the bank of the canal in the level immediately above. The speed permitted is 6 miles per hour for the largest vessels, rising to 12 miles or more for smaller vessels and tugs. The time required for passing through the canal varies from 5 to 8 hours.

Kiel Canal. Connects Baltic and North seas. It is 61.31 miles long, 36.08 ft. deep, 144.32 ft. wide at bottom, 333.74 ft. and upward at water surface. The width is increased on curves at bottom. The canal has 11 passing places, four of which are 984 ft. wide at bottom to serve as turning places; the others are 439.52 ft. wide at bottom, length 1968 to 3608 ft. There is a lock at each end of the canal with ebb and flood gates at each end of the lock. Normal water level in the canal is mean tide in the Baltic. There is also in each an intermediate pair of ebb gates and one pair of flood gates, permitting use of a shorter lock chamber. The locks have a useful length of 984 ft., width 147 ft. 8 in., depth on sills 45 ft.

The speed allowed by regulations is 9.3 miles per hour, but the largest vessels cannot attain this. The time required to pass through varies with the draft, from about 8 hours for the smaller vessels to 13 or 14 hours for the larger.

Amsterdam Canal. Connects the North Sea at Ymuiden with Amsterdam and also with Zuyder Zee. Its principal purpose is to make Amsterdam a seaport. Its length from the North Sea locks at Ymuiden to the Zuyder Zee locks is 17.4 miles, and from the North Sea locks to the entrance to Ymuiden Harbor about 2 miles, making a total of 19.4 miles. Depth 32.14 ft. below "ordinary water-level"; width at bottom, 164 ft. on tangents increased to 196.8 ft. on curves. Side slopes generally 3 : 1 with a berm of varying width and depth.

The new great lock at Ymuiden is intended to accommodate vessels of the maximum length of 721.6 ft., width 82 ft., draft 30.18 ft. It has intermediate gates to permit the use of a shorter lock for small vessels, and ebb and flood gates, making 6 pairs in all. The operating machinery is electric throughout, and it is the second ship-canal lock to be so equipped.

The speed permitted varies with the draft of vessel; it is 6.52 miles per hour for vessels drawing 19.68 ft. or more, 7.45 miles per hour for vessels drawing 13.12 to 19.68 ft. and 9.32 miles per hour for vessels drawing less than 13.12 ft.

Leningrad and Cronstadt Canal. Connects deep water in the roadstead in the Gulf of Finland with one of the delta mouths of the River Neva at Leningrad, and it is intended to make Leningrad a seaport. It consists of a channel about 17-3/4 miles long dredged in the open water of the bay and across the Neva bar and protected by dikes for a distance of about 6 miles at the upper end. Its depth was made 28 ft. Bottom width from 213 to 275-1/2 ft. in the diked portion and 355-1/2 ft. in the portion not diked.

Cape Cod Canal. Sea level canal connecting Cape Cod Bay and Buzzards Bay; shortens the sailing distance from Boston to New York by 66 miles and avoids the dangerous Cape Cod coast. Highest part of ridge cut through was 29 ft. above mean sea level. Material chiefly sand. Length of canal proper 8 miles, 25 ft. deep at low water, 100 ft. wide at bottom, side slopes 1 on 2. There are 5 miles of approach channels having bottom widths of 250 ft. and 300 ft. and side slopes of 1 on 3. Mean range of tide at one end 8.9 at the other end 3.6 ft. This tidal difference produced velocities as great as 5 ft. per sec. Completed in 1915.

St. Marys Falls Canals. These are lateral canals avoiding St. Marys Rapids in St. Marys River between Lakes Superior and Huron. There are two canals, one on the American side of the river and the other on the Canadian side. The fall in the rapids varies from about 17 to 21 ft. with the varying stages of the lakes and is overcome by one lift in each of the canals.

The American Canal is about 1.6 miles along with four parallel and adjacent locks at the downstream end. The canal consists of two channels, the Poe and Weitzel locks serving the old south channel, and the new third and fourth locks serving the new channel to the north. The Weitzel lock is 515 ft. long from quoin to quoin, 60 ft. wide at gates, 80 ft. wide in chamber and has from 15 to 17 ft. of water on the sills. The Poe lock is 800 ft. long, 100 ft. wide, and has 20 to 22 ft. of water on the sills. The two new locks are each 1350 ft. long, 80 ft. wide, and have 24-1/2 to 26 ft. of water on the sills.

Upstream from the Poe and Weitzel locks is a narrow island on which is located the pivot pier of a swing bridge carrying the wickets and machinery of a movable dam, the purpose of which is to close this portion of the canal in case of a break at the locks permitting a free flow. (See Fig. 65, p. 1593.)

The Canadian canal is 1.4 miles long, 141 ft. 8 in. wide at bottom, 150 ft. at water surface, and about 22 ft. deep. The single lock is 900 ft. long from quoin to quoin, 60 ft. wide and has 20 to 22 ft. of water on the sills, depending on the varying stages of the lake.

Canadian Canals from Lake Erie to Tidewater at Montreal

Canal	Length, miles	Width, feet		Locks				Total lift, ft.
		Bottom	Water surface	Length, ft.	Width, ft.	Depth, sills, ft.	Number	
Welland	26.75	100.0	164.0	270.0	45.0	14.0	26*	326.75

* One is a guard lock. † Minimum. ‡ Variable.

The two canals actually constitute one system. No charges are made to vessels passing, which usually take the canal having the smaller number of waiting vessels. Hydraulic power is used at the American canal; the Canadian canal is operated electrically, and was the first ship canal to be provided with such operating machinery. A boat can be passed through the lock in either canal in 8 to 11 minutes, but on account mainly of fleet lockages, the average time for a lockage is about 33 minutes in the American canal. In the Canadian canal, where fleet lockages form a smaller proportion of the total time, the average is about 20 minutes.

The time necessary to pass through the canal depends largely on the amount of traffic and the congestion resulting, and has varied in the American canal from 4 hr. 58 min. in 1895, when only one lock was in operation, to 1 hr. 10 min. in 1900, when two locks were in use. With increased traffic since that date the time has increased to 2 hr. 40 min.

Panama Canal. Connects the Atlantic Ocean (Caribbean Sea) with the Pacific, crossing the Central American Isthmus in Lat. 9° N. and Long. 85° W. at approximately its narrowest and lowest point. It reduces the sailing distance from New York to San Francisco by 7873 miles (5262 miles as compared with 13 135 miles via Magellan Straits) with a similar saving in distance to many ports in South America and the Orient. The canal is 50 miles long between deep water in the two oceans. The average time of passage is 12 hours, the shortest recorded time is 6 hours 30 minutes.

Its construction was begun in 1882, by the French, whose rights were acquired by the United States for $40 000 000 in 1904, when a Canal Zone 10 miles wide was secured from the Republic of Panama, for $10 000 000 and a perpetual rental of $250 000 per annum. The canal was completed by the U. S. Government in 1914.

The canal is a lock canal with a summit level normally 85 ft. above mean tide in the two oceans, the maximum tidal range being 22 ft. at the Pacific and 2 ft. at the Atlantic end. Its most distinctive feature is Gatun lake, an artificial body of water, 164 square miles in area, which forms the summit level. The lake provides wide and deep channels which permit vessels to travel at high speed for over half the distance between the two oceans. Its formation involved the building of a huge earth dam for closing the valley of the Chagres at Gatun and of three expensive groups of locks, but on the other hand, the depth of the summit cut at Culebra was reduced decidedly, and a large amouunt of excavation eliminated so that there was a decided saving in the total time and cost of construction in comparison with a sea level canal. As practically no excavation was required in the deeper portion of Gatun lake the work of building the canal resolved itself essentially into the excavation of the sea level sections, and of the cut through the Continental Divide, the building of the Gatun and some smaller dams and the construction of the locks and spillways. Some details of the several parts of the work are given below:

Beginning at the Atlantic end, the successive sections of the canal are the following: (1) A sea-level channel 7 miles long and of 500 ft. bottom width, extending to the locks and dam at Gatun. (2) Gatun lock flight with 3 lifts of about 28 ft. each. (3) Gatun lake at Elev. + 85 forming the summit level which extends across the Continental Divide through the Culebra (Gaillard) Cut to the lock at Pedro Miguel. The total length of channel in the summit level is 32 miles, of which 16 miles is 1000 ft. wide, this section having a depth of 45 to 75 ft., 4-1/2 miles is 800 ft. wide, 4 miles is 500 ft. wide, and 8 miles (in Culebra Cut) is 300 ft. wide. (4) Pedro Miguel lock with a 30-ft. single lift. (5) Miraflores Lake (area 1.6 sq. miles) at Elev. + 55 with a channel 500 ft. wide, 1-1/2 miles long, and 45 ft. deep. (6) Miraflores Locks, a flight having two lifts of 22 to 33 ft. each, according to the tidal stage, and finally (7) A sea-level section 500 ft. wide and 7 miles long to deep water in the Pacific.

It will be noted that, except in the locks, the channel has a minimum width of

300 ft. and a minimum depth of 45 ft. Where there is a change in the direction of the canal axis, instead of connecting the tangents by curves, the channel was widened so as to allow vessels to turn readily.

Locks. The principal dimensions of the locks are shown in Figs. 53 and 54. They have a clear width of 110 ft., a usable length of 1000 ft., and a minimum depth on the sills of 41 ft. 4 in. There are twin chambers, with a central wall 60 ft. thick between them, which is extended 1000 to 1200 ft. beyond each end of the lock—to act as a guide wall for vessels.

For filling and emptying there is one longitudinal culvert 255 sq. ft. in cross-section (equal to a circle 18 ft. in diameter) in the middle wall and in each sidewall connecting with transverse culverts of elliptical section built in the lock floor, which are each 41 sq. ft. in area and discharge upward into the lock chamber through 5 circular outlets of 12 sq. ft. each. These laterals extend across the lock at intervals of about 35 ft., connecting alternately with the culverts in the side and middle walls. The main culverts are controlled by rising stem gate valves of the Stoney type, located close to the upper, intermediate and lower lock gates. They are 8 ft. wide and 18 ft. high and are placed in pairs separated by a dividing wall. As a safeguard, a duplicate set is provided close to each pair of valves. The valves are each opened and closed by a single valve stem, which extends through a horizontal cast-iron bulkhead, placed just above the valve, and fitted with a stuffing box. The stem connects with a guided cross head, which is raised and lowered by 2 non-rising screws driven through reducing gears by a 50-hp. electric motor. The time of operation is one minute. Each lateral culvert leading from the middle wall is fitted with a cylindrical valve 78 in. in diameter, placed vertically, which is opened or closed in 10 seconds by a 7-hp. motor.

Lock Gates. The lock gates are double-skin steel gates of the mitering type with air chambers. The sill angle is 26° 33′ 54″. There are duplicate operating gates at both ends of Pedro Miguel lock and at the upper chambers in the lock flights and an intermediate set in all the chambers except the lower ones at Miraflores. These subdivide the locks into usable lengths of 550 and 278 ft. A reverse guard gate is provided in the lower approach to each lock. There are in all 46 gates of 2 leaves each, weighing nearly 60 000 tons. The leaves are uniformly 65 ft. long and 7 ft. thick and vary in height from 47 to 82 ft. and in weight from 395 to 745 tons. The horizontal girders which are spaced from 3 ft. 8 in. to 5 ft. apart have straight parallel sides and curved ends. See Fig. 57. The bearings along the quoin and miter posts and in the hollow quoins are polished steel plates. Their joints have proved to be absolutely watertight. There is a wooden clapping sill with a rubber seal.

The gate-moving machinery is of a novel type developed and first used on the Panama Canal. A horizontal strut is used, hinged at one end to the top of gate, and at the other to a crank pin fixed in a horizontal wheel 19 ft. in diameter (the so-called "bull wheel"), which is supported on the lockwall. This is turned by a 25-hp. motor through a series of reducing gears, the time for opening or closing a leaf being 2 minutes. The special merit of the design is the fact, due to the kinematics of the mechanism, that it gives the leaf a relatively slow motion at both ends of its travel, where the hydraulic resistances are greatest.

Safeguards. The following safeguards are provided in the locks: (1) The duplicate lockgates mentioned above. (2) A novel system of chain fenders placed in the upper and lower approaches to all the locks and also just above the intermediate and lower gates in Pedro Miguel lock and in the upper chambers of the other two locks. They consist of 3-in. anchor chains stretched across the locks at the top, which are raised and lowered by vertical hydraulic cylinders in the walls. These chains serve to check vessels that may strike them, by paying out under strain, the amount of pull being regulated by relief valves on the cylinders. It has been shown by actual tests that a vessel of 18 000 tons displacement, moving at a speed of 2-1/2 miles per hour, can be readily brought to rest in a distance of 55 ft. without injury to the vessel or chain. (3) Electric towing locomotives, traveling on rack railways on the walls on both sides of the lock chambers, which are used in the case of all vessels for moving them during their passage through the entire length of the lock flight. They exert a pull of about 25 000 lb. and move at a speed of 1 or 2 miles per hour. (4) Emergency dams at the upper end of each lock for shutting off the flow of water in case of a serious accident to the lockgates, which has resulted in establishing a connection between the upper and lower levels. The dams are of the swing bridge type, similar in design to the movable dam at the St. Marys Falls Canal, shown in Fig. 65. At Panama, there is an independent dam (supported on the side wall) for each twin lock flight. The arm spanning the lock is 164 ft. 3 in. long, while the other arm, which is 98 ft. long, carries a heavy concrete counterweight and the operating machinery. The wicket girders are 60 ft. long, and spaced 9 ft. 2 in. apart. There are 5 wickets in each vertical bay, which roll down along the upstream flanges of the girders. In operation, the flow of water is to be gradually shut off by building up the wickets in horizontal tiers from the bottom. In still water, the dam has been swung, and all the girders and wickets put in place, in 26 minutes.

All the machinery in the locks is operated electrically. The current, which is 3-phase at 25 cycles, is generated at 2200 and 6600 volts in a hydroelectric station at the spillway in the Gatun dam operating under a head of 77 ft. Its present capacity is 13 140 kw., to be ultimately increased to 22 140 kw. There is also a reserve steam turbine plant of 7500 kw. capacity near Miraflores. The current is distributed at 6600 volts to transformer rooms in the lockwalls at Gatun, all motors operating at 220 volts. It is carried across the isthmus at 44 000 volts on an overhead transmission line supported on structural steel frames along the line of the Panama Railroad.

The machines for moving the lock gates, valves and chain fenders are located in small rooms in the lock walls just below the coping level, which are all connected by continuous longitudinal tunnels.

The principal machines in each of the three groups of locks are normally operated from a central control house on the middle wall. This contains a horizontal control board or table, which resembles a miniature ground plan of the lock, with models of the different gates, valves, etc., which open and close when the actual gates are being operated. Local control is also provided in the several machine rooms. The principal gates, lock gates and chain fenders are interlocked so as to guard against errors in operation.

In the operation of the locks, several novel and important hydraulic features have been observed:

(1) A very unequal discharge from the several orifices in a given lateral culvert, the flow being greatest from the outlet farthest from the main culvert. This results in forcing a vessel in the lock strongly towards the wall from which filling is taking place and has made it necessary to use both culverts throughout the process of filling, thus obtaining a very uniform distribution and permitting a maximum rate of changing levels of 7.5 ft. per minute with safety.

(2) An "over travel" of the water levels, due to the acceleration of the water in motion through the culverts. Owing to the great length and cross-section of the locks, this action, not taken into account in the ordinary formulas, is important, as it shortens the time of filling by about two minutes.

The coefficients of flow are approximately:

For filling—	using side and middle wall culverts,	$C = .65$
	using side wall only,	$C = .82$
For emptying—	using side and middle wall culverts,	$C = .67$
	using side wall only,	$C = .73$

The time for filling (for a length of lock of 900 ft.) is 7 to 8 minutes, using both culverts, and 12.5 to 13.5 minutes using the side-wall culvert only.

Dams. The Gatun dam is shown in cross-section in Fig. 13, No. 12. It is about 1-1/2 miles long and polygonal in ground plan. The maximum bottom width is 2300 ft. The central portion of the cross-section, except near the top, was hydraulically filled, by pumping a mixture of sand and clay from the bed of the Chagres by 20-in. suction pumps, working in two lifts. The hydraulic fill was confined on each side by rock-fill dams, built for the purpose, which form a part of the main dam. The remainder of the cross-section is dry fill, earth and rock, brought partly from the Culebra Cut, partly from borrow pits close to the dam. There is no core-wall. The total volume of Gatun Dam is 22 958 000 cu. yd., of which 12 229 000 cu. yd. was dry fill. Its cost, exclusive of the spillway, was $9 871 635. The much smaller dams, at the Pedro Miguel and Miraflores locks, are of a similar character.

Spillways. Lake Gatun is regulated entirely by a concrete spillway, built on a rocky ledge, which divides Gatun dam into two approximately equal parts. The total watershed drained is 1320 sq. miles, the annual rainfall 120 in., with a runoff of 62%. The yearly evaporation of the lake area is 60 in., while there is no appreciable seepage.

The maximum observed momentary discharge of the river was 175 000 cu. ft. per sec., the maximum for 33 hours, 137 500 cu. ft. per sec., and for 48 hours 120 000 cu. ft. per sec. The spillway has a capacity of 180 000 cu. ft. per sec., with the lake at + 87. It is circular in plan with 14 clear openings of 45 ft. controlled by electrically operated Stoney gates 19 ft. high. The crest is at +69.

A similar spillway but straight in plan, with 8 openings of 45 ft., is provided adjacent to Miraflores lock, as a safeguard in case of a serious accident to the Pedro Miguel lock. Its capacity is about 92 000 cu. ft. per sec.

Capacity of the Canal. The maximum number of complete lockages at both ends of the canal possible with an unlimited water supply is about 48 in 24 hours, corresponding to the passage through the canal of 60 commercial vessels of average size. With the present provisions for water storage, the practicable number of lockages is much lower, varying with the power demands and the rainfall in different years. In average years 21 lockages will be possible even when operating the power plant at its full projected capacity of 22 140 kw. In very dry years, the number would be still smaller, but the capacity of the canal can be largely increased by using the auxiliary steam plant for part of the year, or by providing additional storage by reservoirs on the upper Chagres.

Excavation. The earth and rock excavation formed the largest single item in the canal construction, its cost amounting to nearly half the total cost of the canal. To June 30, 1918, the total excavation was 267 834 201 cu. yd., of which 130 465 874 cu. yd. was dry excavation, the rest being removed by dredging and hydraulic methods. Apart from a portion of the lock excavation and a few short channel sections elsewhere, the dry excavation was confined almost wholly to the 8-3/4 miles of the Culebra Cut, which included all the most difficult work. The prism section is shown in Fig. 46. The excavation below the berm was wholly in rock as was fully 70% of all the excavation in the cut. The established slope above Elev. + 95 was 2 on 3, which was generally maintained except in the deepest portion close to the Continental Divide. This section, not over 7/8 mile long, was the scene of the serious slides which delayed the opening of the canal and subsequently stopped navigation for many months. These slides have been practically overcome by flattening the slopes to approximately 1 on 7 by dredging after the channel was filled with water in October, 1913. The material removed from the slides to June 30, 1918, was about 56 000 000 cu. yd.

The wet excavation, mainly in the sea-level sections, the lock pits and the slides, was carried on by an elaborate plant, comprising suction, ladder and dipper dredges of varied types and great capacity. Hydraulic sluicing was also resorted to on some parts of the work.

Aids to Navigation. In addition to the lighthouses at the entrances to the canal a complete system of range lights, beacons, and buoys marks the channel clearly both by day and at night. The tangents in the lake and sea-level channels are defined by range lights, vessels going in opposite directions using different ranges giving courses 200 to 250 ft. apart, a somewhat novel arrangement. In the Culebra Cut, beacons placed at frequent intervals on the banks take the place of range lights. There are also numerous gas buoys at the sides of the channel.

Terminals. Both terminals are protected by rock-fill breakwaters, giving ample anchorage space, and are equipped with concrete and steel piers for the transfer of freight. At the Pacific end, there is a concrete drydock with a clear width of 110 ft. and a usable length of 1000 ft., close to which large repair shops have been built. There are very complete coaling plants at each end of the canal, the one at the Atlantic end having a maximum storage capacity of 100 000 tons of submerged and 350 000 tons of dry coal. The corresponding figures for the Pacific Plant are 44 500 and 167 000 tons.

Total Cost of Canal. The total amount charged to Canal construction to June 30, 1918, is given on p. 1603; but a considerable additional sum since expended for dredging out the slides and for many other purposes should properly be charged to capital account. In the figures given, an overhead charge is included, covering general and administrative costs, expenses for hospital and sanitation, etc. An additional sum of $30 000 000 was appropriated for fortifications.

Cost of Construction of Panama Canal to June 30, 1918

Prism excavation	\$137 674 924.79
Locks and Dams	92 768 591.66

24. Power, Drainage, and Irrigation Canals

Cross-Sections. Unlined canals in earth have usually a large trapezoidal section, at least when first built. The side slope must be fixed with reference to the character of the soil in which the canal lies. It is usually assumed that the slope should be a little flatter than the angle of repose of the earth in water. In very light fine soil the slope may be as great as 3 or 4 horizontal to 1 vertical; in clayey loam or coarse soil or ordinary firm soil 1-1/2 or 2 horizontal to 1 vertical; in firm clayey gravel or hardpan or firm clay 1-1/4 or 1 horizontal to 1 vertical. Experiment with the earth of the locality may be necessary, to fix the best side slope.

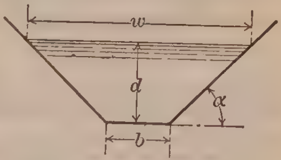

Fig. 66

Trapezoidal Sections. Having the side slope fixed, the relation of depth to breadth may be chosen. The efficiency of canals used as aqueducts, other things being equal, is directly proportional to the square root of the hydraulic radius. Let b, d and w be as in Fig. 66, A the area of cross-section, p the wetted perimeter and r the hydraulic radius. The values of b and d which will furnish a section of the maximum hydraulic radius for a given value of A, are given by the formulas:

$$b = \frac{A}{d} - d \cot\alpha \qquad d^2 = \frac{A \sin\alpha}{2 - \cos\alpha} \qquad p = b + \frac{2\,d}{\sin\alpha} \qquad r = \frac{A}{p}.$$

The table, p. 1604, computed by these formulas, gives the values of d, b, p and r in terms of A, which will furnish sections of maximum hydraulic radius, and consequently maximum efficiency, for various slopes in common use.

The Semicircular Section has the greatest hydraulic radius for a given area of cross-section, but it is only practicable when lined with concrete or steel. For a given A, the formulas are

$$d = 0.798\sqrt{A} \qquad p = 1.773\sqrt{A} \qquad r = 0.564\sqrt{A}.$$

Slope	α	d	b	p	r
1 on 3	18° 26′	$0.548\sqrt{A}$	$0.178\sqrt{A}$	$3.647\sqrt{A}$	$0.274\sqrt{A}$
1 on 2	26° 34′	$0.636\sqrt{A}$	$0.300\sqrt{A}$	$3.145\sqrt{A}$	$0.318\sqrt{A}$
4 on 7	29° 45′	$0.662\sqrt{A}$	$0.352\sqrt{A}$	$3.021\sqrt{A}$	$0.331\sqrt{A}$
2 on 3	33° 41′	$0.689\sqrt{A}$	$0.417\sqrt{A}$	$2.902\sqrt{A}$	$0.345\sqrt{A}$
4 on 5	38° 40′	$0.716\sqrt{A}$	$0.502\sqrt{A}$	$2.794\sqrt{A}$	$0.358\sqrt{A}$
1 on 1	45° 0′	$0.740\sqrt{A}$	$0.613\sqrt{A}$	$2.704\sqrt{A}$	$0.370\sqrt{A}$
3 on 2	56° 19′	$0.759\sqrt{A}$	$0.812\sqrt{A}$	$2.636\sqrt{A}$	$0.379\sqrt{A}$
7 on 4	60° 15′	$0.760\sqrt{A}$	$0.882\sqrt{A}$	$2.632\sqrt{A}$	$0.380\sqrt{A}$
2 on 1	63° 26′	$0.759\sqrt{A}$	$0.938\sqrt{A}$	$2.635\sqrt{A}$	$0.379\sqrt{A}$
Vertical	90° 0′	$0.707\sqrt{A}$	$1.414\sqrt{A}$	$2.828\sqrt{A}$	$0.354\sqrt{A}$

For small canals the equations above will often fix the best dimensions, but there are numerous considerations which may modify the section. If the canal is very large the excavation may be enough cheaper for a shallower canal, so that the necessary greater sectional area may be removed more economically than the smaller section of equal capacity. This will depend much upon the methods of excavation and the type of machinery used. Again, losses from seepage increase with depth, so that where such losses are liable to become important, or where the bottom of a deep canal would reach an open impervious stratum, it may be wise to adopt a shallower section than would otherwise be economical. On the other hand, for canals on side hills, a still deeper section of greater area may be more economical.

Small canals are subject to a reduction of cross-section by encroachment of vegetation on the banks, and by silting. Jeffreys, in Professional Papers on Indian Engineering, says: "Whatever slope is adopted in construction it is found that this cannot be maintained after the channel has been in use some time. A distributary at the close of an irrigating season invariably assumes the shape seen in Fig. 67. When the time for clearance comes around the engineer in charge, if he is wise, will not attempt to restore the original section. . . . . The custom in the Ganges Canal distributaries is to trim off the slope at 1/2 to 1, as shown by dotted lines *a–b* and *c–d*."

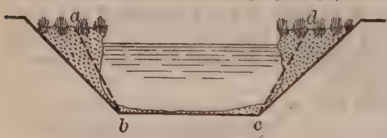

Fig. 67

The canal may be all in cutting, or all in embankment, or part in each. Each type has its advantages and disadvantages, depending on the local condition. In some localities canals in cutting may be cheaper in maintenance and suffer less loss from seepage; the drainage from the surrounding territory may be more easily handled. In other localities there may be danger of reaching an open pervious stratum in cutting which may require lining to prevent excessive loss.

Irrigation Canals all in embankment are sometimes necessary to command the surrounding land or for short lengths to avoid long detours. It is easier with this type, if for any reason it becomes necessary to avoid absorbing the drainage of the country, to pass that drainage across the line of the canal in culverts. The disadvantages are the danger that the banks may break, the higher cost of construction, inspection, and maintenance, and, usually, the greater loss by seepage, which in some cases is further objectionable by forming stagnant pools on the neighboring land. This type of canal generally costs more than either of the other two types.

The advantages of the type in which the section is part cutting and part embankment are that it is usually the cheapest and quickest constructed, that for irrigation it is high enough to command the neighboring land, and that the head of water against the embankments is usually small enough to reduce to little or nothing seepage through the banks.

Limiting Velocities. Loss of head is to be avoided as much as possible in power canals, whereas in irrigation and drainage canals the velocity will often be limited only by the ability of the earth of the banks and bed to resist erosion. The velocity should be great enough to prevent the growth of weeds and the deposit of silt, and not so great as to cause erosion. The experiments of Du Buat give velocities in feet per second next to the bed of the canal which will begin to erode various materials as follows: 0.25 for soft clay, 0.50 for fine sand, 0.70 for gravel as large as peas, 2.2 for gravel 1 in. in diameter, 3.3 for pebbles 1-1/2 in. in diameter, 4.0 for heavy shingle.

Seepage. Sometimes power canals, and usually irrigation canals, are located on hillsides well above ground-water level, so that seepage from unlined canals often amounts to 25%, and sometimes 50%, of the total water entering their headworks. For example, from 20 irrigation canals in operation, taken at random, including canals in France, Belgium, Italy and the United States, the average loss from seepage expressed in depth times area of the water surface of the canal was 3.8 ft. depth per day. Omitting two which were between 6 and 7 ft. per day, the average was 1.5 ft. depth per day. In gravel the loss was from 3 to 7 ft. depth per day; in sandy soils 1 to 2 ft.; in sandy loam and firm compact alluvial soil 0.2 ft. to 1 ft. depth per day. These canals varied in depth from 2 to 8 ft.

The common remedies for loss by seepage are silting, puddling, and lining with concrete. Excessive losses are likely to be in some short length. Good results are reported to have been obtained by producing stagnant water, which is then made turbid by dumping pulverized clay or other fine material. If the canal water is normally turbid, slack water may be formed by a temporary weir and silting encouraged at the leaky length. A more effective method, but more expensive, is to puddle the bottom and sides with clay when the canal is drained. It may be necessary to protect the puddle from erosion by a layer of coarser material. Where the saving will warrant the expense, the canal may be lined with concrete, as has been done in the case of numerous canals in California.

Canal Linings. Power canals in earth are frequently lined with either timber or concrete to reduce the friction and assure permanency of the cross-section. The timber lining consists of mud sills laid at right angles to the

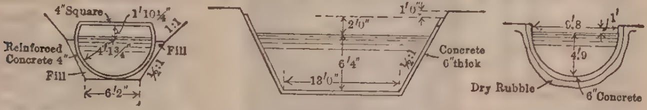

Fig. 68. Three Types of Concrete Lining

direction of flow and planed plank flooring spiked to the mud sills. The mud sills may rest upon and be held down by bearing piles or be held down by rods to masonry anchors. Fig. 68 shows linings used in the West.

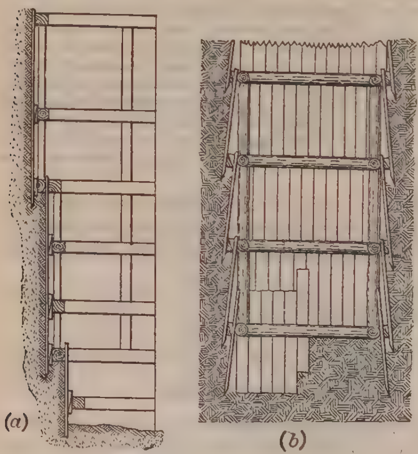
If the ground is very firm, concrete may be laid upon it without other support; in very soft ground bearing piles may be necessary, care being taken, however, that the concrete is in contact with the ground. The concrete should be deposited back of very smooth forms in order to get a smooth surface. For irrigation canals the concrete-lined canal not only costs less to maintain, and prevents loss of water by seepage, but the first cost is often less than for an unlined canal, for the allowable velocities may be from two to four times as great and the section correspondingly smaller.

For the Tieton Canal (left-hand cut of Fig. 68) the reinforced-concrete lining was molded in steel forms in sections 2 ft. long which were later transported on cars to the canal and set in position by derricks; each section weighing about 1800 lb. was 4 in. thick, of gravel concrete reinforced by 3/8-in. corrugated rods 4 in. apart. Each section was stiffened by a 4-in. by 6-in. crossbar reinforced by two 3/8-in. rods. The molds were removed after about 3 days and the section allowed to harden for at least 30 days, during which time it was frequently sprinkled. The sections were set in place about 1-1/2 in. apart and immediately backfilled with earth which on the lower quarter was selected and tamped in from the ends with the greatest care; above this the backfilling was placed from above. The 1-1 2-in. space between sections was later filled with rich concrete of fine aggregate which would pass a 1/2-in. ring. The joint was rubbed smooth on the inside before the joining concrete was completely set. The canal has a fall of 8.71 ft. per mile and was designed to have a capacity of 300 sec.-ft. A test in the completed canal gave a value of .012 for the coefficient *n* in Kutter's formula. The gross cost, exclusive of excavation, of 13 000 ft. of the concrete lining was found to be $5.80 per foot.

SHAFTS AND BORINGS

25. Timbered Shafts

Timbered shafts are sunk vertically by mining much the same as a heading is driven horizontally. A frame of four waling timbers joined at their ends, forming a rectangle, is laid out on the ground. Outside are driven vertical polings or sheeting; inside, as the sheeting is being driven, the earth is excavated to a little above or a little below its lower end, depending upon whether the ground is soft or hard. As soon as the excavation is from 2 to 5 ft. below one frame a new frame is placed, and so on to the depth of the length of the sheeting; a new frame is then set with clearance for a new set of sheeting. If the shaft is to be shallow it may be started large enough at the top so that the sheeting may be vertical, and the shaft reduced in size by the thickness of the timbering at the bottom of each set of sheeting, which may be from 10 to 20 ft. long, as in Fig. 69*a*. If the shaft is to be deep, the sheeting will ordinarily be 5 or 6 ft. polings, as in Fig. 69*b*.



(*a*) (*b*)

Fig. 69. Timbered Shafts

The main thing to be avoided in shaft sinking is the starting of a general movement of the earth. The great danger is that cavities will be left or formed back of the timbering or that the timbering though not slack will have to deflect to develop resistance and a small progressive movement of the earth will be started which may extend to the surface. The precautions are, if possible, to allow no cavity to form, securely pack any accidental one, and to wedge all timbering tight against the sheeting so that it will develop resistance before the sheeting begins to move. Perhaps the greatest danger is in water-bearing earth, where leakage is liable to bring into the shaft earth in such small amounts that they are not noticeable but may form cavities back of the sheeting in time.

In rock shafts the principal use of timbering is to prevent the falling of loose pieces from the sides of the shaft, endangering the workmen below. If the rock is fairly good, the timbering is usually kept from 10 to 30 or 40 ft. behind the excavation. It is not an uncommon practice to place the permanent lining, usually of concrete, in short lengths 40 or 50 ft. above the bottom of the shaft as the work of excavation progresses.

The method of open excavation and timbering or otherwise lining the shaft as sinking progresses is no doubt cheaper, where practicable, than any other method that has been devised, but when quicksand or other soft material is encountered or where rock yielding too much water is encountered, the method may be either impossible or impracticable. For such cases various devices have been used, notably caissons sunk by the aid of compressed air, drop shaft, freezing process, and under-water boring.

Shafts by caissons are frequently used in tunnel construction for railroads. The depth of compressed air work is limited by the pressure at which work becomes either too expensive or too dangerous. After a depth of 70 ft. below water is reached the cost of labor in compressed air increases very rapidly on account of both greater wages and shorter hours. Very little caisson work has been done under heads of over 100 ft.

26. Drop Shafts

Drop shafts are sunk by building a heavy lining, usually circular, upon the surface, and then excavating the earth inside, allowing the structure to settle slowly into the ground. Drop shafts have been used in a great variety of places, from small wells a few feet deep to mine shafts 20 ft. in diameter and over 500 ft. deep. The shell or lining may be of timber, masonry, brick, reinforced concrete, cast iron or steel.

Several very large drop shafts of moderate depth in water-bearing soil have been built circular of brick masonry provided with a cast-iron shoe or cutting edge at the bottom. A large number of small drop shafts, having steel plate shells, have been sunk for foundation work. Most drop shafts for deep mines have had shells of cast-iron rings with, in some cases, steel shoes for cutting edges. The excavation in some cases has been by hand, but usually drop shafts are in water-bearing strata, often in quicksand, and the water is allowed to fill the interior while the earth is removed by under-water excavators, such as chain-bucket dredges, grab buckets, and sand pumps.

In moderate-depth shafts the weight of the lining is usually sufficient to overcome friction on the sides. In the case of deep shafts this is not the case, and the lining must be weighted with pig iron or sand or be forced down by jacks. Water or air jets which may be forced up along the exterior surface have been used to reduce friction on the exterior, but it has frequently been necessary to abandon the sinking of the first shell and proceed with a lining of a smaller diameter sunk inside the outer lining, which will be subject to friction only below the depth of the bottom of the exterior lining.

The cost of drop shafts is often less than sinking by compressed air, the freezing process, or the boring method. The method is, however, less sure than any of these. In the drop-shaft method the lining is very liable to be distorted, and in some cases ruptured, due to drawing in material from outside the lining, forming cavities, which results in unequal pressures.

27. Freezing Process for Shafts

About 60 shafts, mostly in northern Europe (France, Germany, and Belgium), were sunk up to 1910 by the aid of the freezing process. The general features of all cases are indicated by Fig. 70. Vertical pipes are sunk, usually forming a circle in plan, completely surrounding the site of the proposed shaft; inside each pipe is placed a smaller pipe, called a circulating tube, opening into the outer pipe at the lower end. These circulating tubes are all joined together at the top by a pipe known as the circulating ring. The freezing pipes are joined together at the top by a similar ring called the collector ring. Cold brine at a temperature of from − 10° to − 30° F. is then

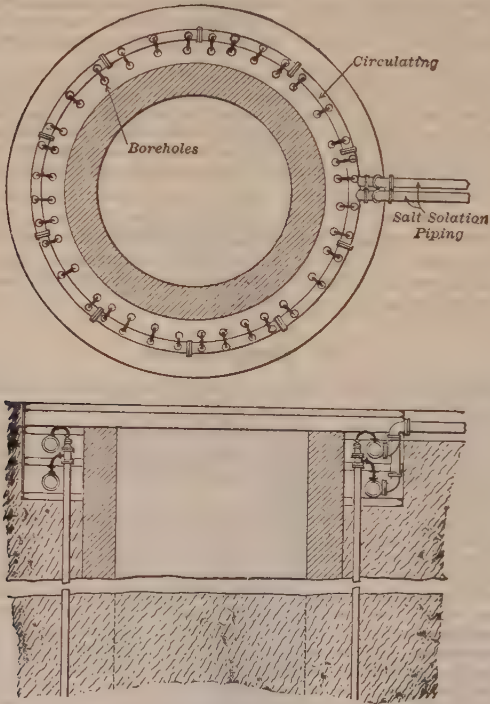


Fig. 70. Freezing Process for Shafts

pumped into the circulating ring and down the circulating tubes, back up the freezing tubes to the freezing machine.

The freezing pipes are put down by one of the well-known boring methods. Originally the casing of the bore hole was used for the freezing pipe. On account of the difficulty of closing the lower end of the pipe and making all joints of the casing watertight, in all later work the freezing pipes are put together and tested on the surface and then lowered into the bore hole, after which the casing is withdrawn. The freezing pipes are 4 to 6 in. in diameter, the circulating pipes 1 to 1-1/2 in.

In the center of the shaft an equilibrium pipe is usually sunk. This pipe is kept open, as a vent, for the escape of water forced out of the interior mass by the expansion of the freezing material; it is sometimes necessary to keep this open with a steam pipe, because rock or clay strata will freeze much faster than quicksand and possibly congeal to the equilibrium pipe and freeze it before the lower sand strata are frozen.

It is very difficult to keep deep bore holes for the freezing pipes from departing from the vertical. Long freezing pipes are very likely to spring a leak from contraction at low temperatures. Both these considerations have led to the attempt to do the shaft in shorter lengths, say 150 ft. in height. The time required for freezing a solid wall about the shaft site will vary with the character of the strata, size and distance apart of the freezing pipes, and the temperature at which the brine is maintained. The freezing usually continues from 4 to 10 months or longer. After an ice wall has been formed around the site of the shaft, the shaft may be sunk by hand methods and lined as the excavation progresses or it may be sunk as a drop shaft.

28. Shaft Sinking by Borings

The Kind-Chaudron System for sinking shafts in water-bearing rock strata is almost identically the same method as ordinary well drilling except that it is on a very large scale. In Fig. 71 a very large chopping bit or trepan is seen at *a*, which may be from 10 to 15 ft. in diameter, weighs from 30 000 to 50 000 lb., and cuts a hole the full diameter of the shaft; *b* are rods, usually of wood, each about 65 ft. long, connected by iron links; *c* is a bar in a swivel joint and screw connection by which the tool is rotated and lowered slightly between the blows; *d* is a walking beam which alternately lifts and drops the trepan; and *e* is a steam cylinder which operates the walking beam. The shaft is completely filled with water during sinking. A small trepan is used alternately with the large one, and bores a pilot hole, usually about 1/3 the diameter of the shaft, into which the choppings from the large trepan fall and are removed by a grab bucket.

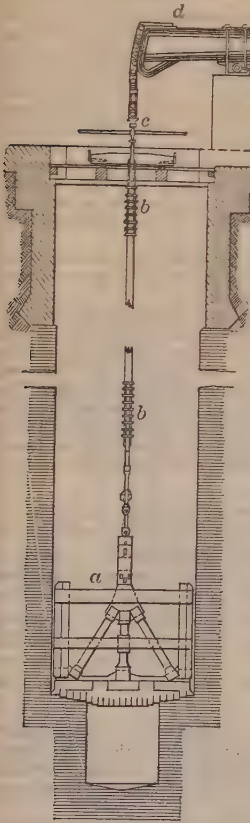

Fig. 71. Kind-Chaudron System

After the shaft is drilled, sometimes to a depth of 1300 ft., a watertight cast-iron casing or tubbing is then sunk inside the bore and sealed at the bottom. The sealing of the bottom is accomplished by building what amounts to a great stuffing-box. The packing used is moss.

In sinking the tubbing, which sometimes weighs several million pounds, the first rings are suspended in the top of the shaft from beams. Rings are added on top until the tubbing, which is provided with a bottom, reaches the water surface; the whole thing is then partially and later completely water-borne, after which it is sunk as the rings are added by admitting water to the interior. On reaching the bottom the great weight bearing upon the moss in the packing rings presses it against the sides of the rock and makes a watertight joint. There is then an annular space above the moss box between the tubbing and the rock, which must be filled with either grout or concrete. After this is placed and set, the shaft is pumped out, the false bottom removed, and sinking continued in the impervious strata below.

About 80 shafts from 300 to 1300 ft. in depth have been sunk by this method, nearly all in northern Europe (France, Belgium, and Germany), where, to reach the coal measures, water-bearing strata of marl, shale, rock salt, and limestone must be passed. The rate of sinking varies greatly. 25 ft. per month is a fair average. The cost varies for 15-ft. shafts from $500 to $1000 per foot of depth for boring and lining with cast iron.

29. Wash Borings

Apparatus for making wash borings can be obtained from companies which make rock-drilling machinery. However, a very efficient outfit, for holes 150 ft. deep or less, may be made by any mechanic, and is not only adapted to work in isolated localities but has often been used in cities. The following is an inventory of the outfit:

1 derrick. 1 hand force pump with suction hose and fittings. 200 ft. 1 7/8-in drill rods with couplings. 200 ft. 2-1/2-in. flush-joint casing. 1 bushing to 2-1/2-in. casing. 1 hoisting water swivel 1-7/8 in. 1 hoisting plug with coupling. 2 cross chopping bits 6 in. long to fit rods. 3 pairs Brown's pipe tongs; 2 No. 3, 1 No. 4, 1 pair No. 3 Brock's chain tongs. 2 Coe's monkey wrenches, 15 and 10-in. 3 Stillson wrenches, 10, 14, and 24-in. 1 15-lb. crowbar. 1 pair sister hooks for 1-1/4-in. rope. 1 16-in. iron hoisting sheave for 1-1/4-in. rope, with strap and hook. 50 ft. 1-1/4-in. manila rope. 40 ft. 3/4-in. three-ply water hose. 150 ft. 1-in. pipe with couplings. 1 blasting battery with 500 ft. No. 20 wire, and supply of exploders and 40% dynamite. 1 tool box. 1-1/2-gal. oil can. 1 squirt can. 1 pail and cup. 1 pick. 1 spade. 1 ax. 1 hatchet. 3 1-3/4-in. sand pumps. 2 1-3/4-in. earth augers to screw into rods. 4 sets reducers 1-1/2-in. to 1/2-in. 1 portable forge, small anvil, and small set blacksmith's tools.

The derrick is illustrated by Fig. 72. When set up, the drum amd attached wheel are used as a hoisting winch. When folded and brought horizontal, the wheels become a truck on which the whole apparatus is moved to the next hole.

The drill rods are usually 1-7/8 in. in exterior diameter, extra heavy pipe, in 5 to 10-ft. lengths, with square female threads on each end, and coupling of about 6 in. long of the same pipe with square male threads at each end. The casing (for shallow holes usually 2-1/2 in. external diameter pipe) may be either "flush joint" or "drive casing." The drive casing consists of heavy pipe with ordinary sleeve couplings. The flush-joint casing is of heavy pipe, each length of which screws into the next, making the joint flush, outside and in. The chopping bit may be screwed into the drill rods, and is sharpened like a rock drill, but is provided with holes to allow the water, forced down the drill rods, to pass out under the bit. A chopping bit should never be used unless a full force of water is passing through it.

The process of sinking holes with flush-joint casing is usually about as follows: The derrick is set up and a hole is made, usually with a crowbar, to admit a 5-ft. length of casing set a few inches into the ground; into this is inserted a 10-ft. length of rod with chopping bit on the lower end and a hoisting water swivel on the upper end, which is connected to the derrick rope and by hose to the force pump. Large pipe tongs are then clamped to both the casing and rod. Water is turned on, and as the material is washed from inside the casing the latter is turned by the pipe tongs and gradually settles into the ground. A new length is added to both casing and rods, and then the washing and turning are repeated.

In most localities a small portable gasoline engine equipped with a "nigger head" or other winding gear is substituted for the hand power portion of the above equipment. In this case the derrick may be a simple tripod made of saplings. If heavy beds of gravel are to be penetrated the common portable blast hole or well drill using 4-in. casing or larger can be used to advantage.

Careful measurement should always be kept so that the relative position of the bottom of the casing and drill rods is always accurately known. In soft clayey silts and sands, holes may be sunk to a hundred feet of more in depth in this way with very little trouble, but conditions are seldom so favorable. If hard sand and gravel are encountered, the drill rods are churned as well as turned, by which the material may be broken up, pulverized, and washed out with water and the casing allowed to descend. In general the drill rods work below the bottom of the casing. If loose sand or gravel is encountered, there is likely to be trouble by the bind- ing of the casing. If the sand is a thin stratum it may be possible to wash or even blast out a cavity in it which will allow the casing to pass through into the next possibly more favorable stratum. Another expedient is to withdraw the rods, cap the top of the casing and at- tach the water supply to the casing, then to twist or drive, if drive casing is being used, while the water, which is being forced down inside the casing and up the outside, reduces the friction between the sand and outside of the casing. If a casing becomes badly bound so that no fur- ther progress down- ward can be made, it may be necessary to abandon the hole, or having started with a large casing to put a smaller casing inside the first when the latter becomes fast, in which case the friction will only begin at the bottom of the first casing. If the required depth cannot be

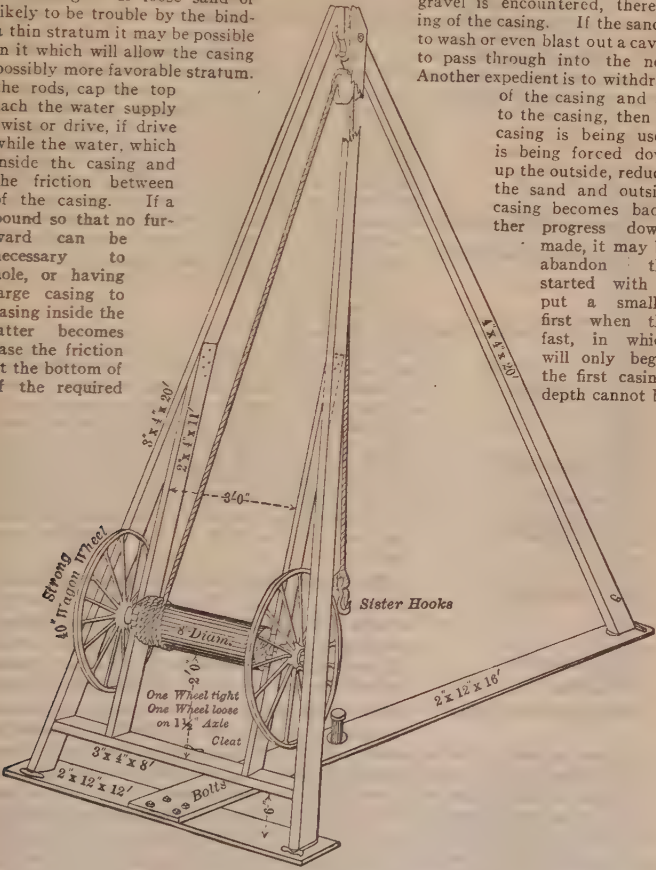

Fig. 72. Derrick for Wash Borings

reached with the second casing, a third and sometimes a fourth will be required. When a boulder or other obstacle is encountered a charge of dynamite is lowered to the bottom of the hole, the casing raised 5 ft. or more, depending somewhat on the size of the charge, a good rule being 5 ft. for one pound and 2 ft. for each additional pound of dynamite used, one-half to two cubic feet of sand is then poured down the hole, the charge exploded, the casing worked down again as quickly as possible, and if the boulder is a small one it may be found to be shattered so that the casing may be advanced through it. A single shot often makes no gain whereas a third or fourth will begin to break the boulder and show progress, but on bed-rock

7 or 8 shots will make practically no progress. If after blasting several times in this way no progress can be made, the conclusion is generally drawn that either bedrock or a very large boulder has been encountered, and if the purpose of the boring requires it, the hole is continued with a core-boring apparatus. A core boring is the only sure test to determine whether or not bedrock is reached.

For Drive Casing the bottom is provided with a heavy steel shoe or cutting edge, and instead of being simply twisted down as in the cash of the flush joint casing, it is driven by using the jar weight (Fig. 73); at the same time the chopping and washing are being done with the drill rods. Working with the drive casing is somewhat slower than with flush-joint casing, but in some cases such as where considerable depth of loose sand and gravel is encountered, it is preferable. In hard ground the process is to bore or chop with the drill rods a hole some distance ahead of the bottom casing, then withdraw the rods 10 or 12 ft. above the bottom and drive the casing down as far as it will go.

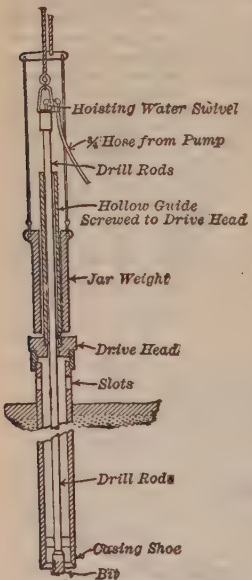

Fig. 73. Drive Casing

Fig. 73 shows one form of apparatus in place, where drive casing is used. There are many possible variations of this; the jar weights are of various sizes and shapes, a second drive head or collar is often screwed to the top of the hollow guides for use in pulling the casing. The jar weight hammers upward against this collar; at the same time the casing is turned with pipe tongs if possible. It is sometimes necessary, however, to clamp a yoke on to the casing itself and hoist on this yoke with jacks. When flush-joint casing is used, the drive head is seldom necessary, and the joints of the casing will not stand much driving.

To Obtain Samples of the material passed through by the drill the wash water is caught in a bucket after it rises to the surface through the casing, and the sediment is allowed to settle. Water should not be allowed to continue running into the bucket after it is once full, for it will wash out the clay and leave an unrepresentative sample. Such samples are often misleading as to the true nature of the material in place. A drive sample may be obtained by attaching to the bottom of the drill rods a sample barrel consisting of a pipe open at the bottom and provided with a small vent hole in the side near the upper end but plugged at the top to prevent the weight of water in the rods from forcing out the sample. This may be lowered and driven into the material which is removed from the sample barrel after being raised to the surface. Samples obtained in this way are much better than wash samples, but have the disadvantage that they have been considerably compacted in the taking, and unless the sample barrel is driven only a short distance into the material it may be doubtful from just what elevation the samples come. When the material is sand, samples may be taken or the casing cleaned out by using an ordinary sand pump, which is simply a length of pipe provided with a foot valve. This is churned up and down in the hole until filled with sand and water.

An auger may be screwed to the bottom of the drill rod and lowered into the hole and bored into the material at the bottom. If the material is not clean, open sand it will remain in the helix of the auger and come to the surface with it. In soft clayey materials it is often possible to use drive casing in connection with an auger instead of using water and the wash method. A hole is bored ahead of the bottom of the casing, which may then be driven down after the auger has been lifted well above the bottom.

The cost of wash borings is variable, depending on the character of the material penetrated. For holes up to 200 ft. deep in soft ground, such as silt and clayey sands the cost of well-managed work is $0.25 per foot and less under very favorable conditions. Where the ground is running sand or hard earth without boulders, the price runs from $0.50 to $1.00 per foot of depth. Where boulders or other obstructions are encountered the cost is from $1.00 in ordinary cases to $4.00 or $5.00 per foot. The above prices are for favorable conditions on the surface and enough work to perfect an organization. If the location is unfavorable, say in a swamp where staging will have to be built, or if water is not available, or if the conditions are otherwise difficult, the cost of overcoming the difficulties must be added. For jobs involving only a few holes, the cost of moving the apparatus to the ground and organizing the work may more than double the above prices. For deep holes, say between 800 and 1500 ft. deep, the cost is much increased. A larger plant with steam or other power must then be used.

Sub-aqueous borings are made upon the ice, or from a platform built on piles, or by use of a floating pile driver or from a catamaran.

30. Core Borings

The Diamond Drill consists of a short length of soft iron tube called a "bit," into the lower edge of which black diamonds are set. This bit is screwed into the bottom end of another tube called a "core barrel," which in turn is screwed to the hollow drill rod. A casing is sunk through the overlying earth to the rock surface by wash boring; inside this the drill rods with bit attached are placed and then rotated and pressed down by the drilling machine; at the same time water is forced down through the drill rods and bit, and comes to the surface outside the drill rods, carrying with it the rock, ground to a powder by the diamonds and bit. At intervals the drill rods are pulled out of the hole, the core removed from the barrel, the bit inspected, and the operation repeated. Diamond drilling, and especially the art of setting the diamonds in the bit, can be learned only by experience. All that can be done here is to call attention to some of the difficulties and methods of overcoming them. The first care should always be that an ample supply of water is being forced down the drill rods to the bit at all times; the second is to use every precaution to see that the space outside the drill rods does not become clogged by either borings or sand washing in around the top or bottom of the casing.

The difficulty most often encountered arises when seamy rock is met. Sometimes it happens that the water forced down the drill rods flows away through seams, carrying drillings with it. If drillings are carried into a seam sloping upward, they are likely to run back into the hole and pack around and bind the drill rods when the flow of water is shut off. Small pieces from the wall of the hole of seamy rock are likely to fall in and wedge the drill rods. A single bad seam may often be stopped by pouring sawdust or horse manure into the hole; the escaping water carries this into the seam and clogs it. The second method is to drop balls of soft neat cement mortar down the hole and after it has hardened proceed with the drilling. It is usually wise to treat all seamy rock in this way and drill carefully and remove drill rods relatively often. It is sometimes possible to blast or chop with a chopping bit and sink the casing through a loose seamy layer of rock. Frequently the hole is reamed out with a special tool and the casing driven down through the seamy rock.

It is a good rule to let the water run a little time after stopping the drill to clean out the hole and take careful measurement of the position of the bit. In lowering the rods again, if the bit does not reach the original position, the water should be turned on, and if then it will not sink to position without drilling, the bit should be raised and the hole cleaned out with a chopping bit to a smooth clean bottom.

Shot Drilling is done in much the same way as with diamond drills, and about the same rules apply; the difference is that instead of diamonds being set in the bottom of the bit, hardened steel balls are fed down with the water inside of the drill rods, and are rolled around under the edge of the rotating bit and wear out an annular ring the same as cut by diamonds. It has an advantage over diamond drilling because the apparatus is less expensive both to buy and to operate. It takes a much larger core, which is a great advantage in well drilling, and for prospecting usually gives a better sample because the large core is not so liable to break and crumble. On the other hand, shot drilling is usually slower than diamond drilling and it has been mostly used for vertical holes.

The cost of diamond drilling varies greatly with circumstances. In the softer rocks like limestone, for holes 200 ft. deep or less, taking 1-1/4-in. cores from 1-3/4-in. holes, the rate of actual drilling will vary from 1 to 3 ft. per hour. Delays will average from 50 to 200 per cent of time of actual drilling, and moving from hole to hole will usually take one or two days. Costs will vary from $2 to $5 per foot.

31. Test Pits

Test pits are sunk to determine the character of the earth as a preliminary to more expensive operations. If deep, the method of work is the same as already described for timbered shafts. One test pit is usually considerably more expensive than several wash borings, but it is worth much more in the reliability of the information which it gives. A combination of test pits and wash borings often yields the greatest amount of reliable information for a given outlay; the borings may locate the strata with sufficient exactness, and one test pit to every ten or twenty borings will show the character of the strata.

As the earth is excavated from the test pit, the different kinds of material should be placed in separate piles, and the boulders and smaller stones in each kind separated. It often happens that workmen in digging a test pit will pile the dirt in a single pile and cover up all the boulders. While the walls of a test pit generally show the character of the material, they do not give a correct idea of the amount of boulders likely to be encountered.

TUNNELS

32. Tunneling in Earth by Mining

The Elementary Operation of Mining is illustrated in Fig. 74. Starting with the face of earth which is to be mined, sharpened boards P, called polings, supported by the cross timber C, are driven into the earth. Under the protection of the polings the earth is excavated. The excavation is advanced beyond the end of the first polings by erecting another cross roof timber, C_2, and starting new polings and repeating the operation indefinitely. The mining of soft ground is largely a multiplication of this elementary operation. The sides of the excavation may be treated in the same way; small headings may be enlarged to full-sizes tunnels by opening the sides by the same process. In principle this elementary operation covers all conceivable requirements of protecting the sides and roof of a working where pressures are within the strength of the timbering. But there is always exposed a face F which must remain unprotected, at least for a short time, and here is where mining troubles begin.

The angle at which an exposed earth face will stand depends (1) upon the nature of the earth, in general, clay standing steeper than sand, and coarser and steeper than fine sand, and a mixture of clay with coarse sand or gravel being better than either alone. (2) Upon the amount of water present. Dampness will increase cohesion, but as complete saturation is approached the angle becomes flatter. If sand besides being completely saturated has an unbalanced head of water, that is, if the head or pressure of water in fine sand exposed to the air is greater than the air pressure, then it is quicksand and will take nearly a horizontal slope. Whatever the material, its thorough draining is of the greatest importance for successful mining. (3) The length of time exposed. Time is an important element in tunneling. Some of the most unstable materials will stand even vertical for a little while, so that a small vertical face may be exposed and a breast-board quickly placed. Clayey earth sometimes may move so slowly that the excavation may be made without the protection of the poling, which may later be simply put up against the roof and supported by timbering which will be thoroughly loaded later. (4) The area of the face exposed. A small area exposed will often stand vertical for a long time when a larger one would cave quickly. (5) The distance below the earth surface. By the ordinary accepted theory of earth pressures the horizontal thrust of earth is a function of the vertical pressure or distance below the surface. But where small areas are exposed, dry or only damp earth will arch across the area, so that depth does not usually appreciably affect the angle at which the exposed earth face will stand until some time has elapsed. The arching cannot be depended upon in wet running material. (6) The amount of agitation the earth has received. Earth which may be stable in its natural state may be very treacherous after it has been moved. The fear of starting a general movement of the earth makes miners thoroughly pack all voids back of supporting timbering and use the greatest care to prevent the starting of a run.

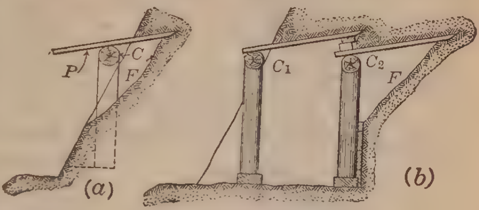

Fig. 74. Mining in Earth

Timbered Headings. In all methods of soft-ground mining the face is opened with a heading varying in cross-section according to the material penetrated, from a one-man burrow to full width and 7 or 8 ft. high, and any length (Fig. 75). The heading timbering consists of posts P, caps C, poling boards p, and breast-boards b. If the ground is stiff, the face of the heading is cut down straight at nearly the forward end of the polings and new posts and a cap are set. If the ground is soft a small excavation, say 2 ft. high, under one or two polings is made and a short board is quickly set vertical under the end of the polings and acts as a combined breast-board and prop for the poling. This is repeated under all polings. As soon as all short vertical breast-boards are placed a new cap is set supported by short posts. The remainder of the face is then worked down, usually with horizontal breast-boards, to the bottom of the heading.

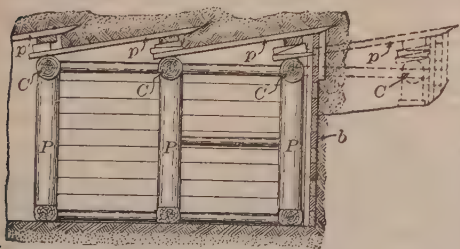

Fig. 75. Timbering Headings

33. Methods of Soft Ground Tunneling

Small bores are driven by simple headings. Large bores are worked in a variety of ways which have been classified in general according to the country in which the method originated, as English, Belgian, German, Austrian, and Italian. Obviously the classification though widely accepted is far from strict, because each method has many variations, nor has the use of any of the methods been confined to the country for which it is named.

English Method. The entire section is removed in short lengths, usually from 12 to 20 ft., in advance of the permanent lining already built, as shown in Fig. 76. The masons and miners alternate in the possession of the face, and the work of excavation and building the masonry is uninterrupted until

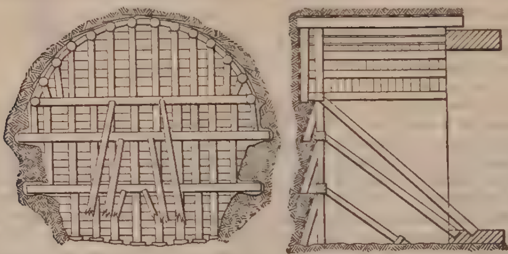

Fig. 76. English Method.

each is complete for the length. A small drift in wet material is commonly driven at the bottom of the tunnel prism from end to end of the tunnel, both for the purpose of furnishing good drainage facilities and for the establishment of the alignment below ground; also it allows the tunnel to be attacked at several points. The main attack on the face, however, always begins at the top of the section with a heading which in stiff material is often taken out without timbering but in softer material is timbered. Two roof bars are then placed in this heading with their forward ends resting on posts and their rear ends supported on the completed masonry lining. Transverse polings are then driven over these bars. The heading is then widened out under the transverse polings for the length of the roof bars, vertical breasting boards placed under the transverse polings and new side bars are placed; when the ground is stiff enough the polings are not driven over the side bars but placed against the earth roof after excavation as in Fig. 77. This operation is continued down the sides as far as required by the nature and pressure of the ground, sometimes to the bottom, while at the same time the face is securely breasted and back-strutted to the completed lining. The miners now give way to the masons, who construct the length of lining within the completed timbering, and the operation is repeated. If the roof bars are not too firmly gripped by the overlying material, the lagging is blocked up on the masonry and the roof bars are barred or pulled forward by jacks and used over again.

This method as a whole is best adapted to very firm material, but has been used with success where the ground was heavy and wet. The Saltwood tunnel on the Southeastern Railway between London and Dover was built through greensand, which when disturbed was a quicksand and not workable by the English method without being drained. A small bottom drift driven through from end to end drained off the water, care being taken to confine the sand, and the main construction proceeded by the usual English method. The advantages of the system are the large open area in which the masonry lining can be built up in one operation and the facility with which the spoil cars can be handled. The disadvantages are that the excavators miss alternate shifts while the masons are at work, thus delaying the work, and that the timbering is partly carried on fresh masonry. The fact that the full section is excavated at once limits the use of the method to fairly firm material.

Belgian Method. The upper half of the tunnel is excavated much the same as in the English method except that the excavation is frequently carried a considerable distance ahead of the masonry, and, as the method is most often used in firm ground, the transverse polings are frequently not driven over the roof bars, but instead are placed as in Fig. 77, against the earth roof after the excavation has been made for a side roof bar.

A cut is then excavated through the center half of the tunnel to the invert, leaving a berm on either side to support the arch of the tunnel lining. From this center trench narrow cuts are made at intervals to the side and the masonry arch is underpinned; the cuts are widened and the underpinning extended until a complete side wall is built, and finally the invert arch is turned. The main advantage of this method lies in the fact that it is possible in firm material to push the work from many points of attack, the successive developments of the tunnel, the heading, its enlargement, the masonry arch, the underpinning operations, etc., all being carried on simultaneously at different points along the tunnel. When the work is carried on with this system of successive development the timbering is arranged as in Fig. 77, to permit the ready access of the spoil cars to the furthest workings. This method is adapted to firm material, but may be used, with considerable risk, however, in the heavier soils by shortening the timbered section, in which case it loses its chief economy mentioned above. The disadvantage of this method is that the arch is first carried on earth and then on timbering, both liable to unequal settlement with the consequent risk of fracture in the key. If it becomes necessary in very stiff material to do blasting, danger to the temporarily supported arch is increased.

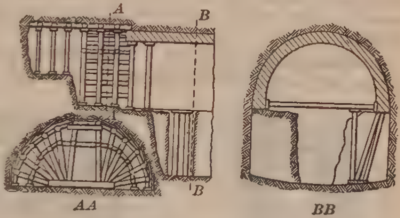

Fig. 77. Belgian Method

German Method (Fig. 78). The invert is put in last, but the rest of the lining is built from the bottom up, but without removing the center core of earth. In its most characteristic form the method consists in driving two bottom headings, one at the foot of each side wall. In these the side walls are built as high as the roof of the heading will allow. On top of these headings two others are driven and the side walls brought up to their roofs, and so on until the two side walls are joined in a center heading at the top. Practically the number of headings one on top of the other is limited to three, with

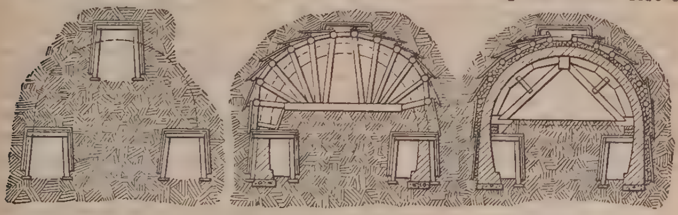

Fig. 78. German Method

a top center heading which is widened out to the upper side headings. Usually only two headings on each side have been used, which brings the sides up to the springing of the arch; above this the entire section is taken out by widening out a center top heading down to the side heading by the same plan as in the Belgian method.

The most notable example in America of a tunnel done by this method is the Baltimore Belt Line tunnel. There only one heading on each side was driven; the center top heading was widened out down to the spring line and pits sunk down from this large upper working to the side walls which had been built in the side bottom headings. The sequence of operations is shown in Fig. 78. The chief advantages of the German method are the saving in timber due to large cores of earth being used to brace against; the cheapness with which the central core, a relatively large mass of earth, can be removed; the fact that only small areas are opened, thus increasing safety in soft materials, and the fact that the masonry is built continuously from the bottom upward. The disadvantages are that the restricted area available for removing spoil from the small headings causes a great amount of inconvenience and interference with the masons and timbermen; ventilation in these small passageways is very difficult; and there may be danger in some cases of movement of the center core when used as an abutment for strutting.

Austrian System (Fig. 79). The essential feature is a center cut from top to bottom of the tunnel with timbering as in *G-G*. The cut is widened out from

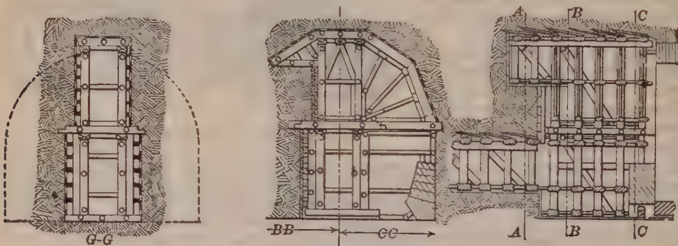

Fig. 79. Austrian System

the top as indicated in section *BB* and timbered with segmental arch timbering up to the time the sills are placed above the horizontal diameter and is supported by the central frame. The poling boards over the segmental arch timbers are all driven parallel to the axis of the tunnel, and the widening out is done in short lengths, working practically the full face. The variations in the method, depending largely on the character of the material, are practically all in the method of making the central cut. A top heading may be driven, which then may be cut down in short lengths to the invert of the tunnel, or a bottom heading may be driven, then the top heading, then the core between the two removed in short lengths, the short posts of the top heading being replaced by long ones resting on the cap timbers of the bottom heading.

Mr. Rziha, the eminent Austrian engineer, who did much to develop the system and who is its principal advocate, recommends the bottom heading to be first driven from end to end of the tunnel, then enlarging this to about half the height of the tunnel and placing in it all of the lower half of the timbering required in the center cut, section *CC*, Fig. 79. The upper half of the center cut is then taken out in a top heading and the timbers placed as in Fig. 79. The excavation of the remainder of the full section is then done, being kept 10 to 20 ft. ahead of the masonry. The masonry lining is begun at the bottom and carried up continuously, the reaction of the timbers being transferred to the masonry as they are reached. The advantages of the method are that the timbering is strong, that the timbers are in short lengths and easily handled, and that the work may be attacked at a number of points and each operation carried on continuously. A disadvantage is its expense.

The Italian Method (Fig. 80) was especially developed for very soft and treacherous ground and is strictly an emergency method. The success of the

Fig. 80. Italian Method

system depends on the fact that only small areas are opened and the material can thus be well controlled. A bottom center drift about one-eighth the height of the tunnel is started and driven a very short distance, 6 to 10 ft., after which it is enlarged to full width of the tunnel, very heavy and tight timbering being used. The invert and as much as possible of the side walls are constructed in the drift, and the open area is backfilled with earth. A center top heading is then driven and enlarged to full width and about one-half the height of the tunnel, leaving a bench the full width of the tunnel and something less than one-third the height. This upper section of the tunnel is very heavily timbered and braced; connection between the upper section and the masonry walls already built is made by trenching through the bench, after which the side walls are completed and the arch turned as one operation. The central bench and the backfilled earth are excavated inside the completed tunnel.

The chief advantage of this method is that the workings are so small as to be readily braced and maintained in very treacherous ground. The disadvantage is the excessive cost. Modern shield methods would now be used for all tunnels for which this method was designed, except possibly where only a short length of very treacherous ground is encountered.

American Method (Fig. 81). Here the segmental arch timbering and side posts only are used and no interior struts. It has been much used in all rock; it is especially adapted to fairly firm material. In rock a top heading is driven and timbered with posts and caps. A short length is widened out down to the springing line of the arch, the sills are placed and the segmental timber arches erected between the posts and caps, which may then be removed. In earth the face is opened by a top heading, which is poled and timbered in the usual way. In the space between two bents of the heading timber the crown segments of the timber arches are set in position and held in place temporarily by secondary posts or by strips of scantlings spiked to the

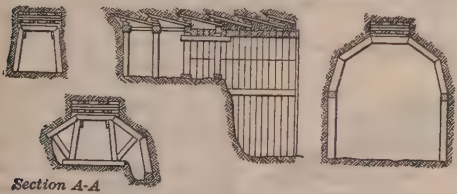

Fig. 81. American Method

main posts as shown in Fig. 81. A short length of from 2 to 6 ft., depending on the nature of the ground, section *A-A*, is then widened out without polings or other roof support and the segments adjacent to the crown segments are put in position and held by iron dowels and a short prop. If the segmental timbers are not set close together, lagging is inserted above the timbering and cavities between the lagging and the earth are packed. The widening out for the next timber is done in the same way down to the sill. After the two sills are placed the roof timber is completed and the bench is then removed.

During each operation the sill timbers are underpinned by any one of the several different methods. If the material is very firm a longitudinal cut is made in the bench, leaving a berm on which the sill rests, and the counterforts are excavated at intervals under the sill and posts placed. If the material is too soft for this, pits are sunk at intervals, and first short posts and later, if excavation has proceeded, long posts are placed to support the sills. If the material is firm enough, as for example rock, the sills or wall plates are set in niches at about the springing line and no posts are used. The number of segments in the arch varies from 3 to 7 or even more. It can be used successfully in firm material which will stand for a short time without support. This type of timbering has been used in American tunnel practice as a semi-permanent lining, but is usually replaced within 10 to 15 years by masonry. The chief advantages of this method are in the large open area within which the masonry lining can be built continuously from invert to crown and the saving of timber.

34. Tunneling in Rock

The methods employed to drive a rock tunnel should depend upon the character of the rock, the size and length of bore, the kind of plant available, the price of labor and the time required to complete.

Usually a small heading is driven within the area of a large cross-section of a rock tunnel and is then enlarged to full size. This heading may be long or as short as 10 ft. but generally it is kept to a size about 6 ft. high by 8 ft. wide, which is about the minimum size for economical driving. This minimum size is maintained because at best the cost of heading work is from two to four times the cost per cubic yard of the enlargement, which requires less drilling and explosives, the blasting being toward a free face.

Whether the heading is at the top, center, or bottom of the full-size cross-section, or is even to be of the full size, will depend on conditions of the particular job.

During the thirty to forty years previous to 1915 when labor was cheap and nearly all mucking was done by hand shoveling, the top heading, and bench method shown by Fig. 82 was the prevailing practice especially in America. The advantage of the method is that the roof is made safer by convenient scaling and timbering if necessary. Its disadvantages are that everything going into or out of the heading must go over the bench work at considerable expense for handling, and interference, which is one reason for keeping the heading very short so that the heading blast will throw most of its muck over the bench.

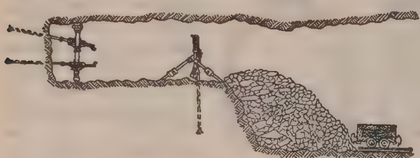

Fig. 82. Top Heading and Bench Method

For greater speed the bottom heading was sometimes used and the enlargement started at frequent intervals along the bottom heading permitting the full size work to be completed nearly as soon as the heading. The disadvantage is that the bottom heading had to be completely timbered to protect traffic through the intermediate working faces.

In the last fifteen years much faster cutting drills and especially faster mucking machines have been developed. Now (1928) there are available all sizes of mucking machines from the smallest adapted to working in a 6-ft. by 8-ft. heading up to power shovels of any desired capacity for large tunnels. These new drillings and mucking tools have made possible new methods and a greater flexibility in adjusting methods to the characteristics of a particular job and have resulted in a general cheapening of tunnel work.

In rock requiring timbering or other support for the roof during enlargement to full size, some form of top heading method is likely to continue to be used. Its disadvantage was partly overcome in the Moffat tunnel, recently completed, by the use of a belt conveyor carried between two plate girders 65 ft. long supported on a track on the bench and projecting into the heading and back over the bench. This conveyor passed muck from the heading to cars behind the power shovel working in the full-size enlargement. It also passed timber and tools into the heading, and the girders were used as temporary support for roof timbers just at the bench.

Another effect of the improved drilling and mucking plant is an increase in the advantages of the outside pioneer heading method for long tunnels which can be attacked from the ends only.

This method consists in driving a heading about 8 ft. by 8 ft., parallel to but 50 ft. or more from the main tunnel. At intervals of from 1500 to 2000 ft. cross drifts are driven to the main tunnel, which is there attacked by whatever method is best suited to existing conditions. Where the rock is sound and requires no timbering the favorite method is to drive a center heading which can proceed as fast as the pioneer heading for which records exceeding 1000 ft. per month have been made. From this center heading radial holes at right angles to the axis of the tunnel are then drilled to the limits of the full-size tunnel and blasted. The center heading between cross drifts is open at both ends therefore

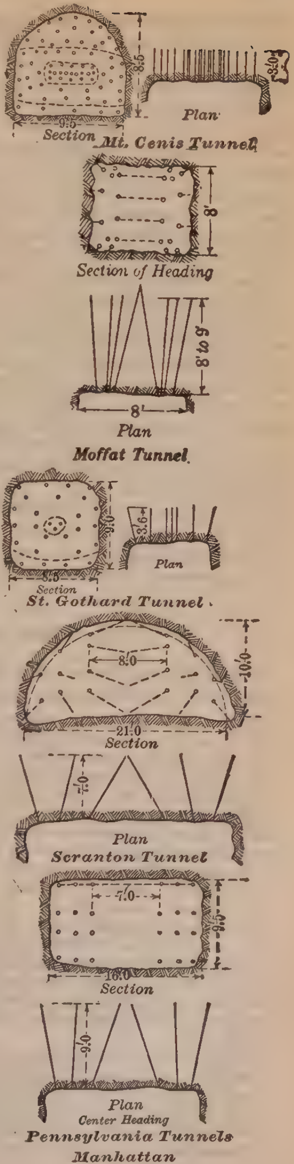

Fig. 83. Drilling Diagrams

the drilling operations can be carried on from one end while the mucking goes on at the other end without interference.

The pioneer tunnel was used for the Roger Pass, Moffat and New Cascade tunnels, 5, 6, and 7-3/4 miles along, respectively.

After the blast in a heading the face is usually nearly buried by muck which interferes with the next drilling. Speed is usually desired in heading work and much thought and ingenuity have been employed to lessen the loss of time caused by interference of the muck pile with drilling. A number of drill carriages have been developed differing in detail but all equipped with a long arm or boom to carry drills, drill columns and hose at its outer end. As soon after the blast as practicable the carriage is moved forward and passes the drilling equipment over the muck pile, and drilling is started on the portion of face exposed. The gain is the difference between the time carriage takes and the longer time required for men to handle the heavy columns and drills over the muck pile. The shorter the drill holes the smaller the muck pile and the shorter the time of setting up drills but the less advance per blast.

Prior to the inception of the plan of center cut holes on the Hoosac tunnel drill holes were placed normal to the face. This is still done frequently in European practice. The cut holes concentrate the explosive back of the center. These holes are fired before the side holes. This breaks a relieving cut so that fewer side holes and less explosive are required. Formerly, considerable delay was occasioned by the necessity of two blasts for first the cut holes and second the side holes. Now delay exploders are used and all holes are loaded and fired at once with faster exploders in the cut holes.

Fig. 83 shows the method of spacing drill holes in several notable tunnels. The drilling plan should be worked out to suit the characteristics of rock and the requirements of each individual heading.

35. Data Regarding Tunnels

In the following notes the numbers in parentheses refer to the tables on pages 1624 and 1625 and to the numbers within the circles in Fig. 84.

(1) Box, Great Britain. Oölite rock, forest-marble, and Lias marl. Lined with brick 27 in. thick at springing line.

(2) Blechingly, Great Britain. Blue Clay of Weald. 11 shafts. Maximum progress 792 ft. per month, 187 ft. per month average for completed work. Hand drills and gunpowder. Lined with brick varying from 22-1/2 to 27 in. thick.

(3) Saltwood, Great Britain. Greensand (quicksand before being drained). 12 shafts. Average progress completed work 238 ft. per month. Lined with brick in horseshoe section; thickness varies between 22-1/2 and 27 in.

(4) Moncreiffe, Great Britain. Poor rock. Widened and relined in 1902, 88% lined with brick arches 18 in. thick on 9-in. brick walls.

(5) Lydgate, Great Britain. One-fourth of length on curve. Clay, strong shale, rock with veins of shale, limestone, fire clay, and coal. Thickness of arch in shale 2 ft., in rock 1 ft. 6 in. 5 shafts. Progress for completed work 52 ft. per month. Hand drills used in rock and strong shale; clay and loose shale axed out.

(6) Netherton. Great Britain. Carries a canal. Marl, coarse sand, rock, hard shaly clay, coal, Lias ironstone and fireclay. 17 shafts. Average progress for completed work 294 ft. per month. Hand drills used. Lining 22-1/2 in. thick, in horseshoe section.

(7) Bergen No. 1, Erie Railroad, New Jersey. Dolerite (very hard trap). Hand drills used. 20% lined with brick arch and stone masonry side walls.

(8) Buckhorn Weston, Great Britain. Kimmeridge clay and veins of loose wet rubble, 5 shafts. Average progress 168 ft. per month. Lining 27 to 32 in. thick.

(9) No. 6 Union Pacific Railroad, California. Granite. Average progress 1.6 ft. of finished tunnel per working day, using 4 working faces.

* Above rails. For waterworks tunnels see Aqueducts.

S = Straight, C = Curve, Q = Straight and curved, B & M = Brick and stone masonry, B & C = Brick and concrete, B & S = Brick and artificial stone bricks, T C & M = Timber, concrete, and stone masonry, C & M = Concrete and stone masonry, B C & M = Brick, concrete, and stone masonry.

A = American method. B = Belgian method. E = English method. G = German method. H = Top heading and one bench. K = Top heading and two benches. L = Bottom headings, from which small shafts at intervals are driven to top of tunnel and full width top headings are excavated in both direction; the bench is removed between the top and bottom headings and the lower section of the tunnel is enlarged to full width. M = The full tunnel prism is removed as one operation. O = Cut and cover method. P = Top heading and enlargement, no other particulars are available. R = Bottom headings followed successively by their enlargement laterally and upward. V = Cut and cover and English method. W = Top heading and one bench and English method. X = Belgian and English method. Y = Top heading and one bench and cut and cover method. Z = See description of methods in the notes.

Costs are taken from published accounts in which the elements composing the figures are seldom recorded.

(10) Sand Patch, Pennsylvania. Red sandstone and shale varying from hard to soft. About 50% lined with sandstone masonry.

(11) Mont Cenis. From France to Italy. About 3/4 mile is on curve. Limestone, calcareous schist, quartz, carbonaceous schist, gneiss and schistose sandstone. Maximum depth below surface 5277 ft. Maximum rock temperature was 80° F. No shafts. Maximum progress one heading 297 ft. per month; average for both headings completed 231 ft. per month. Cost $272 per lin. ft. Hand drilling used

for first four years with holes 1.5 ft. deep, subsequently 3-in. cylinder compressed-air drills with holes 3.5 ft. deep were used. After first four years 70 to 80 drill holes 1.2 in. in diameter in heading averaged 67 lb. gunpowder per round, or about 3.8 per cu. yd. Mucking done by hand; horses for hauling. Gas for lighting. Ventilation at first by exhaust from drills, then blowers and bratticing were installed, and finally exhaust bells. 2 rounds were fired in 24 hours. Time of drilling 6 to 8 hr., loading 1.5 to 2 hr., mucking 3 to 5 hr. Lined with side walls of stone and arch which is stone for one-half length and brick for the rest; the thickness is 31-1/2 in.

(12) Baltimore, B. & P. R. R., Maryland, 20% on curve. Soft rock, clay, sand, and earth. 16% tunnel, 84% cut and cover. Hand drills and black powder used. Brick arch 22 in. thick; limestone side walls 54 in. thick.

(13) Clifton, Great Britain. Mountain limestone, conglomerate, and red sandstone. 2 shafts. Average progress of completed headings 196 ft. per month, using 6 faces. 92% by hand drilling, 8% diamond boring machine. Partly lined with 5-ring brick arch on stone masonry walls.

(14) Church Hill, Virginia. Miocene clay with infusorial shells. 22-in. brick arch on masonry side walls.

(15) Musconectong, New Jersey. Soft ground, limestone and syenitic gneiss. English method in soft ground; top heading and bench method used in rock. 3 shafts. Maximum progress in one heading 144 ft. per month, average for whole work 181 ft. per month, using 8 faces. 5-in. cylinder Ingersoll compressed air drills and dynamite used. 36 drill holes in heading, 10 in bench. Depth of holes 11 ft. 270 lb. explosive per round in heading, 107 in bench. 6 drills in heading, 2 on bench. Spoil loaded into barrows, wheeled to traveling platform at bench, and dumped into chutes over cars. A derrick on the platform handled large bench excavation. Average time of drilling and loading for one round 32 hr. 20% lined with 7 or 8-ring brick arch on masonry walls.

(16) Hoosac, Massachusetts. Hard granitic gneiss, conglomerate, and mica schist. Maximum cover 1800 ft. English method in soft ground. Top heading and bench method in other material. 1 shaft. Maximum progress for 1 heading 184 ft. per month, average per month for all faces 194 ft. Holes 2.1 ft. deep were drilled by hand during the first 12 years, using 16 lb. of explosive per linear foot of tunnel. During the last 10 years holes 11.5 ft. deep were drilled by 12 compressed-air drills at each face, and 33 lb. of powder per linear foot of tunnel were used. Spoil loaded into cars, wheeled to traveling platform at bench. Derrick on platform handled large bench excavation. Lined with brick in sections in poor rock.

(17) Bergen No. 1, D. L. & W. R. R., New Jersey. Dolerite (very hard trap). Rendrock powder used. Brick arch on masonry side walls.

(18) Osakayama, Japan. Soft rock with clay veins. Lining is 2, 4, or 6-ring brick arch on brick side walls. Hand drills. Fans for ventilation.

(19) St. Gothard, Switzerland. Straight except about 500 ft. Gneiss, mica schist, serpentine, and hornblende schist. Maximum depth below surface 5576 ft. Maximum rock temperature 88° F. No shafts. Average progress of single heading 225 ft. per month. Sommelier drills used for a few years, then Ferroux 2-1/4-in. cylinder and McKean 4-in.-cylinder drills with compressed-air. Enlargement by hand drills. 6 drills, mounted on a carriage, bored 24 to 26 holes in each heading 2.6 ft. to 4.2 ft. deep. 29 lb. 75% dynamite, explosive per round, or about 5 lb. per cu. yd., were used in each heading. Horses used in headings, compressed-air locomotives in full-size sections. Oil lamps for lighting. Exhaust bells for ventilation. Time of drilling 3 to 5 hr., mucking 3 to 4 hr. Brick arch on rubble masonry walls varying between 17.7 and 29.6 in. thick. Although in rock, was built by the Belgian method.

(20) Mullan, Montana. Treacherous rock. Relined with masonry in 1892. Costs, including engineering superintendence and interest: concrete $8 per cu. yd.; brick $17 per cu. yd. Total relining $50 per lin. ft., brick arch 20 in., and concrete side walls 30 in. thick.

(21) Arlberg, Austria. Mica schist and gneiss more or less rich in quartz. Maximum rock cover 2300 ft. Maximum rock temperature 64° F. No shafts. Maximum progress for 1 heading 641 ft. per month, average for single headings 408 ft. per month. Ferroux compressed-air and Brandt's rotary hydraulic drills used. With Ferroux drills 4.8 lb. of powder per cu. yd. and with Brandt 4.0 lb. Lining is mostly between 19.7 and 37.4 in. thick, 6% of length not lined.

(22) Severn, Great Britain. Conglomerate, limestone, carboniferous beds, marl, gravel, and sand. Lining of vitrified brick 27 to 36 in. thick.

(23) Vosburg, Pennsylvania. 138.5 ft. on curve, the rest is on tangent. Red, green, and black shales and red and blue sandstone. Short length earth roof. American system of timbering used. No shafts. Average progress single heading 137 ft. per month. In the heading 4 Rand or Ingersoll 3-1/8-in. cylinder drills bored 12 to 18 holes 9 to 10 ft. deep. 3.13 lb. rack-a-rock were used per cu. yd. excavated. 2 drills and Altas powder were used on the bench. 10% of all the drilling was done by hand. The average amount of explosive used was 1.71 lb. per cu. yd. of all excavation. No special provision was made for ventilation. Mostly arched with 3 rings of brick. About one-sixth arched with stone 18 to 24 in. thick. Side walls of stone 30 to 36 in. thick. Stone used is black limestone.

(24) Stampede, Washington. Soft basaltic rock. No shafts. Maximum progress of single beading 274 ft. per month, average for two headings 413 ft. per month. About 9% with hand drills, the rest with compressed-air drills. 31 lb. of Giant and Hercules 45% and 60% dynamite were used per linear foot of tunnel. 20 to 23 drill holes 12 ft. deep in heading, 18 ft. in bench. Spoil from heading hauled by mules to chutes at traveling platform at bench. Removed in cars from chutes by small locomotives. Electric lighting. Ventilation by exhaust fans. Concrete side walls and brick arch.

(25) Ronco, Italy. Argillaceous schist with considerable water. 6 shafts. Average progress one heading 231 ft. per month, average of completed tunnel 123 ft. per month. Brandt rotary hydraulic drills and Ferroux compressed-air drills. 0.48 to 0.68 lb. 75% to 78% dynamite used per cu. yd. Sheeles system of ventilation. 2 exhausts coupled.

(26) Belt Line, Baltimore. Howard Street Tunnel. Sand with seams of loam, clay, and gravel. 5-ring brick arch.

(27) Little Tom, Norfolk & Western R. R. Seamy gray sandstone disintegrating on contact with air. 1410 ft. originally lined with timber. Later relined with brick. Arch made of four rings of brick. Cost of relining complete was $33.50 per lin. ft.

(28) Cowburn, Great Britain. Material about one-third shale, two-thirds rock intermixed with thin beds of shale. Quite dry. Average progress for single heading, dry shale by hand drilling 299 ft. per month, rock by hand drilling 111 ft. per month, rock and shale by machine drilling 270 ft. per month, rock by machine drilling 199 ft. per month. One-third excavated with hand drills, rest with Larmuth compressed-air drills. 17 lb. gelignite used per lin. ft. 2 drills in heading. Horses used in headings and locomotives in finished sections. Ventilation by fan. Arch entirely brick. Side walls two-thirds length stone masonry and one-third length brick.

(29) Totley, Great Britain. Hard and soft black shale, coal, fire clay, sandstone, and grit rock. 4 shafts. Average progress machine-drilled heading 242.4 ft. per month. 3-1/4 and 3-1/2-in. Schram percussion drills and 3-in. Larmuth. Average number drill holes in heading 13.4. Holes 6.2 ft. deep. 38 lb. gelignite per round 2 drills in heading. For clearing heading of fumes and dust, a jet of compressed air and spray of water were used. The arch is entirely brick and the walls are brick for 70% of length and coursed masonry for 30% of length.

(30) Niagara Falls Power Co., New York. Limestone and shale with slaty seams extremely wet. Progress 304 ft. per month with 5 headings. Rand compressed-air drills, 4 to 6 per heading. Dynamite. Electric lighting. Ventilation by exhaust from drills. Lined with from 4 to 6 rings of brick.

(31) Busk, Colorado. Gray granite, disintegrated in places. Maximum progress of single heading 202 ft. per month, average completed tunnel 190 ft. per month. 3-1/2-in. cylinder Ingersoll compressed-air drill. Holes 12 ft. deep. Electric lighting. Blower for ventilation. 78% lined with timber.

(32) Panir, India. Limestone, clay, and soft sandstone. Average progress single heading 145 ft. per month, average whole work 95 ft. per month. 4-in. cylinder Climax compressed-air drill bored 25 holes in heading 3.8 ft. deep and 1-7/8 in. in diameter. Dynamite and gelignite were used. The time for drilling one round was 5 hr. 520 ft. is one-half lined and 2690 ft. is three-quarters lined.

(33) East River Gas, New York. Gneiss, mica schist, veins of decomposed feldspar, and black mud. Maximum progress 101 ft. per week on New York side in rock, average 69 ft. per week in good rock in each heading. Compressed air 15 to 48 lb. per sq.

in. used while in soft material. Good rock not lined; soft material lined with cast iron —see table of cast-iron lining in tunnels, p. 1641.

(34) Tequixquiac, Mexico. Sandstone with lime, soapstone, and conglomerate. Very wet. Progress 18 ft. per day in heading. Timbered Lined with 20-in. arch of brick and 18-in. walls of artificial stone blocks. Hand drills and dynamite. 6 drill holes in heading 6.5 ft. deep. 6 lb. of explosives per round in heading.

(35) Ampthill 2nd, Great Britain. Kimmeridge clay. Progress averaged 6 days to complete 1 length of 12 ft. 1-1/2 lb. tonite per lin. ft. Horseshoe section, walls, and arch lined with 33 in. of brick; invert 27 in. brick.

(36) Cwm Cerwym, Port Talbot R. R. Slight curves at end. Shale, hard clift, fire clay, thin veins of coal, and about 500 ft. of pennant rock. Originally lined with brick without invert, afterward relined without interrupting heavy traffic. Concrete blocks in invert and cast-iron segments above.

(37) Catesby, Great Britain. Clay. 9 shafts. Average progress for finished work 330 ft. per month. Lined with brick 22-1/2 to 31-1/2 in. thick.

(38) Boulder, Montana. 150 ft. curved at one end. Material penetrated 80% seamy-blue trap rock and 20% syenitic boulders and débris. Originally lined with timber. Later relined with 20-in. coarse granite rubble in walls and 4 rings of brick in arch.

(39) Palisades, New Jersey. Hard trap rock with many seams in places. 1 shaft. Average progress 186 ft. completed tunnel per month. 24 holes in heading drilled by four Ingersoll-Sergeant 2-1/2-in. compressed-air drills. 6 drills on bench. A derrick car was used to handle large stones from the bench. Horses were used at first, dummy locomotives later.

(40) Cascade, Washington. Medium hard gray granite, seamed and wet. Temporary 5-segment timbering used. Maximum progress using two headings 527 ft. per month. Maximum progress in single heading 301 ft. per month. Average two headings 350 ft. per month. Six 3-1/4-in. Rand compressed-air drills bored 24 to 28 holes 12 ft. deep in heading. 8 drills on bench. Spoil run out in wheelbarrows to a traveling platform at the bench and dumped through chutes into cars. A six-ton derrick mounted on platform handled large bench excavation. Ventilation by exhaust fan. Electric lighting and electric motor haulage.

(41) Sherman, Wyoming. Solid granite. Top heading and two benches. Heading progress 4.92 ft. per day. Drill holes 9 ft. deep. 6 drills on 3 columns in heading.

(42) Graveholtz, Norway. Quartzy granite or gneiss. Average progress of finished headings was 263 ft. per month. Hand drills used at one end for 2-1/2 years, after which Brandt boring machines and compressed-air drills used. Only 3% lined.

(43) Barrientos, Mexico. Hard granitic porphyry with clay seams. No shafts. Heading progress 367 ft. per month, completed excavation 245 ft. per month. 3 Ingersoll-Sergeant compressed-air drills bored 14 holes in heading 10 to 12 ft. deep. 29.3 lb. of 60% dynamite used per lin. ft. 3 drills on bench. Small cars were loaded and run to platform at bench, where they were dumped into larger cars. Lined with concrete blocks 28 to 31 in. by 60 in. deep by 7 ft. 8 in. long.

(44) Scranton, Pennsylvania. Sandstone and shale. 2 shafts. Maximum progress in single heading 261 ft. per month, average all headings 387 ft. per month. 3-1/4-in. cylinder compressed-air drills and 50% dynamite. 1305 ft. not lined, 2717 ft. 5-segment timber lining and 725 ft. concrete and stone masonry.

(45) Chicago Telephone and Express Subway. Stiff blue clay. Small-section tunnel. Full-size excavation. Excavated with spades and draw knives. Compressed air used, 9 lb. per sq. in. Floor 30 ft. below street. Lined with 10 in. of 1 : 3 : 5 concrete.

(46) Gallitzin, Pennsylvania. Sandstone and shale, also some limestone, fire clay, and slate. No shafts. Average progress of completed tunnel 164 ft. per month. 16 holes in the heading and 11 on the bench 10 ft. deep were drilled respectively by 4 and 2 Ingersoll-Sergeant compressed-air drills. 2.5 lb. 40% forcite were used per cu. yd. An air-operated steam shovel following up at the bench handled the excavated material. Horses were used in the headings and dinky locomotives in the full-size tunnel. Electric lighting. Time of drilling was 8 hr., two rounds being fired per day. Concrete arch 22 in. thick and concrete and rubble side walls increasing from 38 in. at spring line to 54 in. at bottom.

(47) Alfreton 2, Great Britain. Gray sandstone, rock, shales, and fire clay with

seams of coal. Worked from 5 shafts with no portal headings. Average time of mining a 15-ft. length was 19.7 days. Lined with 28 in. of brick.

(48) Simplon, Italy to France. Short curves at ends. Mostly very hard gneiss and calcareous rock, also short lengths in green cipolin, disintegrated slate, clay, and mica schist. Maximum depth below surface 9118 ft. No shafts. Maximum progress single heading 685 ft. per month, average both headings 440 ft. per month. In bottom headings Brandt rotary hydraulic drills, enlargement by hand drills. 83% dynamite and 64% blasting gelatine used in opposite ends of tunnel. 10 to 12 drills holes 4.5 ft. deep. 3-1/2 in. in diameter, in heading. 2.8 lb. explosive per cu. yd. 3 drills in the heading. Time of drilling one round 2.75 hr. and time of loading, firing, and mucking 6 hr. Steam and compressed-air locomotives for hauling. Blowers and water sprays used to keep tunnel air clean. Both gas and oil for lighting. Lined with coursed masonry of various thicknesses.

(49) Capitol Hill, Washington, D. C. About one-third on curve. Gravel and fine sand overlying hard blue clay. Very wet. 1600 ft. in open cut and 2400 ft. in tunnel. Separated by lining into twin tunnels. Each tube excavated separately. 2 side drifts at bottom and crown drift excavated in one tunnel. Crown bars 24 ft. long placed in top drift and supported by radial struts. As top heading was widened segmental timbering was placed under crown bars and carried down to posts on concrete footings in side drifts. The radial struts were removed and the core of earth between side and crown drifts was excavated with a steam shovel. The lining was placed in this portion of the tunnel and the excavation of the other tube was proceeded with, the timbering for it abutting against the crown bars of the first tube. The arch is brick backed by concrete of a total thickness of 36 in. The side walls are concrete 72 in. thick and the core-wall is stone 58 in. thick.

(50) Haversting, Norway. The cross-section is about 270 sq. ft. Gneiss with varying amounts of feldspar and quartz. Total progress both ends 114 ft. finished tunnel per month. Hand drills. Horses for hauling.

(51) Bergen No. 2, D. L. & W. R. R., New Jersey. Very hard trap rock. Ingersoll-Sergeant compressed-air drills. 29 holes in heading 7 to 8 ft. deep. 8 holes in bench. Electric lighting. Air-operated steam shovel for mucking. Lined with concrete 24 in. thick.

(52) St. Paul Pass, Idaho to Montana. Laminated quartzite with some talc layers. Average progress two headings for four months 576 ft. per month. 3-1/2-in. cylinder Ingersoll-Rand compressed-air drills, 8-in. heading and 5 on bench. An air-operated steam shovel used at bench. Excavated material hauled by electric locomotives. Fans for ventilation. Electric lighting. Lined with five-segment timber arch.

(53a) Pennsylvania R. R., twin tunnels under Manhattan from Sixth Avenue to East River. Hudson schist. Two sets of twin tunnels averaging about 4730 ft. long. At east end 350 ft. excavated as 4 single tunnels and the remainder was excavated as two tunnels from 42 to 52 ft. wide and separated by lining into four single tubes in sets of two. 2 shafts for each set of tunnels but no portals. Three methods of excavation used in wide tunnels: double heading, center heading, and full-width heading. Bench was usually 10 to 15 ft. behind the face. The maximum progress of a single heading was 206 ft. per month, the average for all six headings was 451 ft. The average length of tunnel completed per month was 257 ft. The number of holes drilled varied greatly with width and location of headings and averaged between 8 and 9 ft. in length. In single headings 4 Ingersoll-Rand 3-1/4-in. drills mounted on 2 columns and in full-width headings 10 drills mounted on 5 columns were used. 1.9 lb. 60% forcite were used per cu. yd. of all excavation. Air-operated steam shovel followed at the bench. Electric motors for haulage. Blowers for ventilation. Electric lighting. Lined mostly with concrete. Small sections in wet rock have brick arch and concrete side walls. Minimum thickness of lining 22 in.

(53b) Pennsylvania R. R., three-track tunnels under Manhattan. 218 ft. long on west end of one set of twin tunnels and 683 ft. long on the other. Hudson schist. Sand in the crown at places. Part done in open cut. Lining in open-cut sections concrete throughout with a minimum thickness of 59 in. and in tunnel brick arch 56-1/2 in. thick on concrete side walls.

(54) Pennsylvania R. R., Bergen Hill Tunnels. Mostly hard trap rock, also 940 ft. in decomposed sandstone, shale, feldspar, calcite, and sandstone. Maximum progress of a single heading was 145 ft. per month, average progress 3.13 ft. per day at each

face. 8 Rand 3-5/8-in drills on 4 columns drilled 32 holes 12 ft. deep in the headings. The holes tapered from 2-3/4 or 3 in. at the top to 1-3/4 or 2-1/4 in. at the bottom. 1 ft. of steel was used up for every 10 cu. yd. of excavation. An average of 5 lin. ft., of hole was drilled per cu. yd. at the average rate of 2.66 ft. drilled per hour of the machine at the face. An average of 2.9 lb. of 60% forcite was used per cu. yd. of all excavation. The average time of each attack was 36 hr. Air-operated steam shovels handled the muck. Fan for ventilation. Electric lighting. Lined with concrete with a minimum thickness of 22 in.

(55) Gunnison, Colorado. Irrigation Canal. Mostly black shale and metamorphic granite; other materials penetrated, clay, water-bearing gravel and sand, sandstone, limestone, coal, and marble. 1 working shaft. Maximum progress of single heading 824 ft. per month, average length of tunnel completed 566 ft. per month. Sullivan 3-in. and 2-1/2-in. and Leyner 2-1/2-in. cylinder compressed-air drills were used. Jeffrey coal augers were used in shale. 40% gelatine dynamite used. 18 to 22 drill holes 6 ft. to 7 ft. deep in the heading. 4 drills in the heading and one on the bench. Blowers for ventilation. It was necessary to drive an inclined shaft for ventilation. Electric lighting. Lined with concrete 16 to 26 in. thick.

(56) Arthurs Pass, New Zealand. Badly fissured sandstone and shale, 3% grade, not much timbering. 2 to 3 Ingersoll-Sergeant 3-1/4-in drills on a 4-1/2-in. cross-bar without arms in heading. 10 to 16 holes 4-1/2 ft. to 6-1/2 ft. deep per round and 4 to 6 lb. of Noble's gelignite per cu. yd. in heading. Electric haulage. Side walls of concrete poured in place, arch roof of concrete blocks 12 in. radial by 9 in. by 18 in. along tunnel, mortar joints. Over break of hand-packed stone.

(57) Fu-Chin-ling, Manchuria. Hard limestone. No timbering. Lined with cut lomestone on sides with a 3-ring brick semicircular arch of 8-ft. radius in roof. Cost $75.00 per ft. lined and ready for track.

(58) Loetschberg, Switzerland. Limestone, slate, gneiss and granite. Greatest thickness of overlying rock 4692 ft. No shafts. Temperatures 75° to 110° F. Maximum progress of single heading 1013 ft. per month. 4 to 5 Ingersoll-Rand 3-5/8-in drills on carriages in bottom heading and on columns in top heading. In the headings there were 12 to 14 holes 4 ft. to 5 ft. deep and 85% dynamite was used. Lighting by individual acetylene lamps. Due to an inrush of water, sand and gravel which filled 5900 ft. of the excavation and buried 25 men 0.85 mile of the old working was abandoned and the alignment changed.

(60) Pirahy, Brazil. To divert water from Pirahy River to power company's reservoir in adjacent valley. Mostly solid gneiss. Bottom heading 13 ft. wide by 8 ft. high. Best month 512 ft. Very little timbering. About 1000 ft. of concrete lining, the rest unlined. Five 3-1/4-in. Ingersoll-Rand drills at each face on an 8-in. horizontal bar operated by a Carter tunnel carriage. Total construction period less than 23 months working from portals and 4 shafts.

(61) Laramie-Poudre, Colorado. Irrigation tunnel. Granite syenite and quartzite. Leyner pneumatic hammer drills. 20 holes 7 ft. to 9 ft. deep per round. 100% blasting gelatine in the bottom of the cut holes and 50% and 60% dynamite for the rest of the blasting. Holes fired and fuse cut to proper length to discharge them in prearranged order. Muck hauled out by hoist and by mules. Average monthly advance 473.7 ft. for 19 months.

(62) Mount D'Or, France and Switzerland. Limestone and marl. Swiss heading averaged 566 ft. advance per month for 25 months. 4 Meyer type air drills mounted on a bar and 12 to 15 5-ft. holes per round in heading. Water up to 20 000 cu. ft. per min. encountered. Lining placed immediately behind the excavation. Compressed-air locomotives.

(63) Astoria-Bronx, New York. For gas mains under East River. Gneiss and dolomite. About 250 ft. below mean sea level. Much trouble with water. Rock seams grouted through pilot drill holes driven in advance of excavation, grouting under pressures up to 500 lb. per sq. in. and using a total of 118 000 bags of cement. Working once flooded by leak of 12 000 gal. per min. Tunnel then bulkheaded and whole heading grouted back of bulkhead. Work then advanced by small heading through grout with pilot drill holes for grouting as before.

(64) Rogers Pass, British Columbia. Quartzite and schists. Not much water. No shafts. Thickness of overlying rock 5690 ft. A pioneer tunnel 7 ft. by 8 ft. was driven from each end parallel to the main tunnel and about 50 ft. away. The central mile of this pioneer tunnel was not excavated. 3 and 4 light hammer drills on a hori-

gontal bar per heading and 21 to 28 holes per round. Maximum monthly advance for a single heading 932 ft. From the pioneer bore cross cuts to the main tunnel were made at intervals of 1500 ft. to 2000 ft. and headings 11 ft. wide by 9 ft. high carried each way along the tunnel center line. This central heading was then enlarged to full section at one operation, working in from each portal. Steam shovels and air locomotives used in mucking. The best monthly advance for one shovel was 1030 ft. Only partly lined with concrete.

(65) Twin Peaks, San Francisco. For 2-track street railway. Clay, sand and sandstone. Heading 8 ft. by 8 ft. 65 000 cu. yd. of reinforced-concrete lining placed by pneumatic process through a maximum length of 4,000 ft. of pipe. 8 lb. hydrated lime was used per 100 lb. cement.

(66) Roosevelt, Colorado. For underdraining Cripple Creek mining district. The tunnel at its inner end is over 1800 ft. below the surface and takes the ground water from the surrounding mines. Maximum discharge 17 000 gal. per min. Part in granite and remainder in hard volcanic rock. In granite it cost $27.27 per lin. ft. Section about 75 sq. ft. In volcanic rock cost $20 to $25 per ft. Section about 80 q. ft. Two Ingersoll-Leyner drills on a horizontal bar, about 30 holes per round. Muck hauled to shafts by mules.

(67) Rove, France. Rhone-Marseilles canal tunnel. Dolomite and limestone. 2 side drifts 9.8 ft. by 10.7 ft. are driven at bottom, enlarged to give room for track and drainage and small heading at the crown. Side headings enlarged upward and connect with crown heading. After this the lining is placed and the core removed.

(69) Moffat Tunnel. Single track, 25 ft. high, 16 ft. wide, six miles long, 2800 ft. below surface at divide, 8 ft. by 8 ft. pioneer tunnel, 75 ft. south of main tunnel with 20 cross cuts to it. Heading encountered 1500 gal. per min. flow of water. Much of roof of main tunnel required timbering.

Top heading and bench in timbered section center heading in good rock. Cost $15,000,000, which was over twice the amount estimated.

(70) New Cascade Tunnel, Washington. Single track 7-3/4 miles long nearly parallel to old tunnel but 500 ft. lower elevation, 16 ft. wide, 22 ft. high, 8 ft. by 9 ft. pioneer tunnel. Main tunnel enlargement from center heading.

36. Shield Tunneling

A Shield (Fig. 85) consists of a circular steel box or ring generally provided with a transverse diaphragm. The forward end of the ring, or cutting edge,

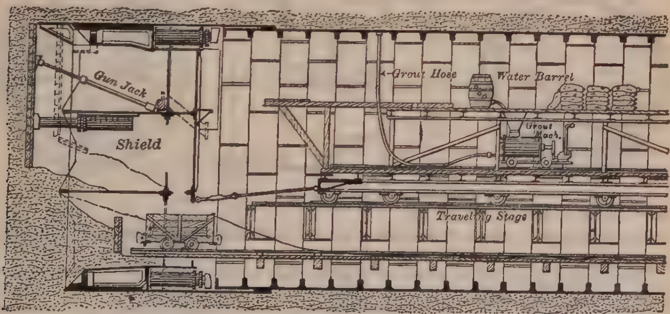

Fig. 85. Shield Tunneling

projects into the earth to be excavated, and the rear end or tail projects backward a little distance over the completed lining, which usually consists of rings of cast iron. To the shield are attached powerful hydraulic jacks which react against the completed lining and shove the shield forward as the earth is excavated. As soon as the shield is advanced a short distance the jack plungers are withdrawn, a ring of lining built, and the operation repeated.

Methods of Work. In clay or other firm material which will stand alone for a short time the full face is simply excavated to about the length of one shove in front of the cutting edge without poling or breasting, and the shield quickly shoved forward. If the earth is not hard enough to injure the cutting edge, only the center of the face is excavated for a depth equal to length of shove and the cutting edge is allowed to break in the rest. In softer clay the cutting edge and working floors may be always buried; only the back of the working chamber in front of the diaphragm is kept clear of earth. In still softer material the shield is sometimes shoved against the earth face, part of which is allowed to flow through the openings in the diaphragm of the shield and the rest is pushed aside. In sand or gravel the face is usually breasted with timber, which is held by struts against the shield. These struts must be collapsible so that the shield may be shoved up to the face. A favorite form is simply two pieces of pipe which telescope as the shield is shoved, the resistance being regulated by set screws in the larger pipe. Hydraulic rams attached to the shield have been used for this purpose.

Numerous London shields have been provided with sliding platforms operated by hydraulic rams. When driving the shield for the Waterloo and City tunnel, London, through sand and gravel, pot holes were raked out in front of the cutting edge and filled

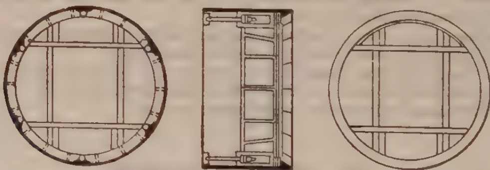

Fig. 86. Shield, Central London Tunnel

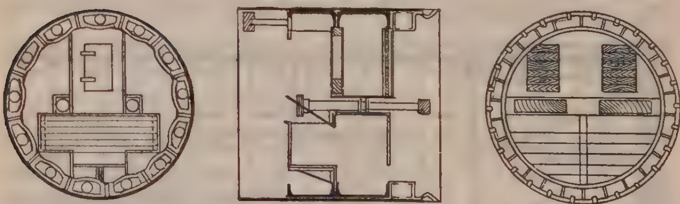

Fig. 87. Shield, Greenwich Tunnel

with soft tempered clay. This formed a continuous ring of soft clay into which the cutting edge was shoved. The full face was then excavated under cover of the shield.

Where the material to be tunneled is part earth and part rock the full-sized tunnel above the rock is usually poled and excavated and the face breasted as in ordinary mining for a length of one or two shoves in front of the cutting edge, the rock in the same length is then drilled, blasted and removed, and the rock bottom smoothed off to the form of the bottom of the shield with concrete in which steel rails are embedded; the shield is then advanced for that short length and the operation repeated.

The General Design of the different types of shields used for tube tunnels up to the year 1928 is shown in Figs. 86-89. The working chamber in front of the diaphragm has been small as in Fig. 86 or large as in Figs. 87, 88, 89, depending upon the character of the material and the methods of excavation. The diaphragm has openings for the passage of men and materials, and may be designed to be closed by locks or doors or be always open. Under either condition the diaphragm should be designed to lend stiffness to the skin, and since, when closed, it may take a part or even all of the water or earth pressure at the face, a system of transverse girders is introduced as reinforcement. Some of the later shields working in London clay had practically no diaphragm because the material was well known as being uniform, and not water-bearing. The shields for the Blackwall tunnel, Greenwich (Fig. 87), and Pennsylvania R. R. East River tunnels (Fig. 89) were built with a double diaphragm, the doors of which when closed formed air locks between the working chamber and the tail for the passage of men and materials. These locks were never used, and the lower plates in all cases were removed during the course of the work to give easy access from the tunnel to the face.

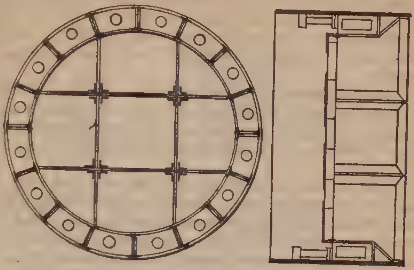

Fig. 88. Shield, Hudson Tunnel

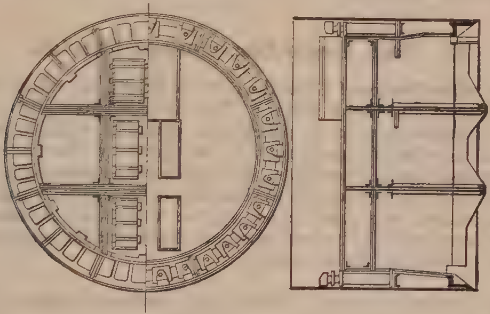

Fig. 89. Shield, East River Tunnel, P. R. R.

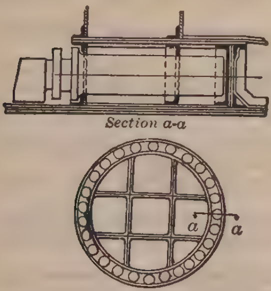

Fig. 90. Circular Box Girder

Fig. 91

The cutting edge at the extreme forward end of the shield in the earlier shields was the edge of the skin plates stiffened by brackets, but in later practice with few exceptions was a heavy ring made up of cast-steel segments beveled on the forward edge. Costly delays have resulted from damage to cutting edges caused by unexpected boulders and rock ledges. The reaction of the hydraulic jacks must be transmitted to skin, cutting edge, and partly to diaphragm. These requirements have developed the circular box girder, a form of which is shown in Fig. 90, attached to the skin, bearing on the cutting-edge brackets and carrying the connections of the transverse diaphragm girders. The box girder is provided with cells into which the jacks are placed, the location being convenient for substitution and repairs.

Shield jacks are all connected with a battery of valves under the hand of the operator so that he may advance or withdraw any one or any combination of jacks at his will. A number of spare jacks should be provided and they should be designed so that they may be easily and quickly removed as they are sure to need repairs and delays are very expensive.

Most shields for work in sand are provided with a hood or extension of the upper part of the cutting edge. The tail of the shield should be long enough to extend about 6 in. beyond the joint between the second and third rings before the shove, to facilitate repairs to jacks and shield, and, more particularly, so that, should a segment of the tunnel lining be broken during the movement of the shield, it may be replaced at the conclusion of the shove without exposing the earth. The inside of the tail at the extreme end is provided with a bead or narrow steel plate, Fig. 91, which more nearly closes the annular space between the tunnel lining and the skin of the shield and yet allows the shield to be pointed at an angle large enough to pass around curves or regain direction when off line or grade.

37. Data Regarding Tunnel Shields

Elements in the Design of a shield which are known are merely the depth below the ground and water surface. The meager information as to the character of the material to be penetrated, generally obtained from wash borings, and the absolute uncertainty of the nature of the forces involved make its rational design impossible; the only guide is precedent. The following tables give the principal dimensions and important facts about several shields which have been used under a great variety of conditions. The numbers in parentheses in the first column of the first table refer to the notes below where additional data are given.

(1) Thames, England. 1825-42. London clay. Maximum progress 2 ft., average 0.5 ft. per day.

(2) Tower, England. 1869. London clay. Maximum progress 9 ft. per day.

(4) City and South London, England. 1886. Mostly clay, also several lengths of water-bearing sand and gravel. The average progress of each shield was 333 ft. per month during 1/3 of work.

(5) Mersey, England. 1888. Clay, coarse ballast and running sand. Maximum progress was 57 ft. per week.

(6) St. Clair River, Michigan. 1889. Almost entirely in soft damp clay. Maximum progress per month was 382 ft., average 231 ft. per month.

(7) Hudson River, New York. 1879-1905. Mostly in silt; at New York side some sand and short length in rock. From May, 1890, to August, 1891, the average progress per month was 126 ft. in the first tunnel; in the second tunnel the average progress per day was 15.3 ft.

(8) Glasgow Harbor, Scotland. 1890. One-third in clay with boulders, the rest in sand and gravel. The average progress in sand was 2 ft. per day.

(9) Glasgow District Subway. 1891-95. Clay, sand, gravel, and quarry waste. The average progress was 100 ft. per month.

(11) Blackwall, London. 1892. London clay, sand, and one-third in open gravel. The maximum progress was 12-1/2 ft. per day. The average progress under the river was 98 ft. per month.

(12) Siphon de Clichy, France. 1892. Open water-bearing sand. The maximum progress was 10 ft. per day and the average 6.5 ft. per day.

(13) East River Gas, New York. 1892. Short lengths in decomposed schist and black mud.

a Height 22 ft. 3 in ; width 37 ft. 6 in. *b* Hand operated screw jacks. *c* Tons of 2000 lb. *d* Driven a very short distance. *e* Includes 2 foot hood. *f* Includes 2 foot 2 in. hood. *g* Includes hydraulic equipment which weighs about 40 tons on 60th St. shield and 28 tons on other shields. *h* Per jack.

(15) Waterloo and City, England. 1893. Clay and ballast. 10 ft. per day was the average progress while the work was in full swing.

(16) Siphon de la Concorde, France. 1895. Clay and sand.

(17) Central London. 1896. London clay and silty sand.

(19) Siphon de l'Oise, France. 1896. Sand.

(20) Baker St. and Waterloo, England. 1898. About 350 ft. was in gravel under the Thames River, the rest was in London clay. The average progress per month was 117 ft. in gravel and 137 ft. in clay.

(21) Greenwich, England. 1898. Mostly in clay with the crown in close gray sand; about one-third length is in close gray sand and a small part in ballast. The maximum progress was 260 ft. per month and the average 148 ft.

(22) Lea, England. 1901. Mostly peaty clay and open ballast.

(23) Battery, East River, New York. 1901. 500 ft. almost entirely in rock; 1500 ft. in fine sand with some clay, the rest was coarse sand. Rates of progress follow: In normal air above water line in sand and gravel average 140 ft. per month; under river in rock, fine sand and clay, and sand and gravel, 91 ft. per month.

(24) East River, Pennsylvania R. R. 1903-09. Land portion in rock, soft top in places. Under river 18% in fine sand stretched with clay, stiff clay, sand and boulders; 35% sand and boulders, sand and clay and fine sand; 22% all in rock and 25% in rock with sand, gravel, and boulders in the crown. Rates of progress were: Best day's work 17.5 ft. Average for month in earth 176 ft., in rock and earth 56 ft., and in rock 61 ft.

(25) North River, Pennsylvania R. R. 1903-09. Mostly in silt, also short lengths in sand and in rock. The maximum month's progress was 545.2 ft. The average progress in rock was 58 ft. per month and in silt 2.39 ft.

(26) Brackenagh, Ireland. 1903. Water-bearing glacial deposit and running sand.

(27) Rotherhithe, England. 1904. Clay, conglomerate sand and gravel.

(28) Kingsway, England. 1904. Clay. Average progress 5.0 ft. per day.

(29) River Dee, Scotland. 1904. Alluvial clay and boulders. Average progress per day 4.5 ft.

(30) Charing Cross and Hampstead. 1904. London clay. Maximum progress 180 ft. per week.

(31) Great Northern and Strand. London clay.

(32) New York Subway. 1916. B. R. T. system from North 7th St., Brooklyn, to 14th St., Manhattan. Shaft at each side of river. 2 land shields, 2 river shields from each shaft (8 shields in all). Tunnel part in rock and part in sand and part in clay. Average progress per month river section, in earth 147 ft., in heart and rock 44 ft.; land section, in earth 168 ft.

(33) New York Subway. 1914-1919. B. R. T. system from Montague St. Brooklyn, to Whitehall St., Manhattan. Shaft on each side of river. From Brooklyn shaft two shields driven each way. River shields met rock tunnel driven without shields under river from Manhattan shaft. Material on Brooklyn side sand with some clay. Average progress per month river section, in earth 192 ft., in rock and earth 80 ft.; land section in earth 209 ft. Maximum progress per month, river section 345 ft.; land section 454 ft.

(34) New York Subway. 1914-1919. B. R. T. 2 shields driven under streets of Brooklyn at a depth of from 43 ft. to 75 ft. All above tide water. Extension of the Whitehall-Montague street tunnel. Material sand. Compressed air not used.

(35) New York Subway. 1914-1919. I. R. T. Shafts on each side of river. 2 shields in each direction from Brooklyn shaft; 2 shields toward river from Manhattan shaft. Material sand on Brooklyn side. Tunnels part in rock, part in sand on Manhattan side. Average progress for month, river section, in earth 184 ft., in earth and rock 74 ft. Land section in earth 167 ft.

(36) New York Subway. 1916-1919. B. R. T. from North Jane St., Queens to East 60th St., Manhattan. One shaft on each side of river and shaft in rock on Blackwell's Island. From Queen's Borough shaft, 2 shields were driven under east channel of East River, pushed through rock tunnels, previously excavated under Blackwell's Island and continued through earth under west channel to rock on Manhattan side. Average progress for month, river section in earth 188 ft., in rock 119 ft.

(37) Holland vehicular tunnel 1921-27 New York to Jersey City. One tunnel east-bound one west-bound each with 20-ft. roadway to accommodate automobile traffic only. There are four ventilating shafts equipped with powerful blowers, each shaft serving both tunnels. The blowers having a total capacity of 3,700,000 cu. ft.

per min., force fresh air into the ducts under the roadways from which it passes through small openings distributed along the curbs. Air is exhausted from the tunnel through the large duct above the roadway. There are 84 blowers and exhaust fans driven by electric motors totaling 6000 hp.

There were 13 795 lin. ft. of shield-driven subaqueous tubes. Of this, 2412 ft. was through mixed river mud, 1900 ft. mica schist rock, 7650 ft. Hudson river silt, and 1833 ft. through sand-clay and cinder fill. In addition, 2012 ft. of cut and cover and 649 ft. of open approach were built in New York and 1082 ft. cut and cover and 970 ft. of open approach in New Jersey. The New York power house from which two shields were operated furnished 28 000 cu. ft. free air per min. at a pressure of 50 lb. per sq. in. and 3550 at 125 lb. The shields were operated by three 25-gal. per min. pumps at 5000 lb. per sq. in. pressure. The New Jersey power house from which four shields were operated furnished 40 000 cu. ft. free air per min. at a pressure of 50 lb. and 2600 at 125 lb. The shields were operated by four 25-gal. per min. pumps at 5000 lb. pressure. All erectors operated at same pressure as jacks. The average progress was 295 ft. per month in silt, 142 ft. per month in mixed ground, and 57.6 ft. per month in rock. This progress included all delays due to starting shields, placing bulkheads and locks, and passing through shafts. In the Hudson River silt the shield could be pushed without taking any material into the tunnel but that procedure distorted grade and alignment of tunnel lining for a considerable distance back of the shield and therefore approximately one-half of the cross-section was taken through shield. This material was left in the tunnel until after driving was completed and then mucked out with a large power shovel.

The air pressure was seldom above 30 lb. per sq. in. All lining was cast iron calked with lead, except that for a short distance east and west of the New Jersey shaft the lining is of steel castings. Bolts in the lining are 1-3/4-in.-diameter high tensile steel of 110 000 lb. per sq. in. ultimate strength and 85 000 lb. per sq. in. yield point. This was a successful innovation as it reduced handling costs and waste due to stripped threads. All shafts were sunk as pneumatic caissons. Each river shaft on the New Jersey side rests on 42 24-in.-diameter steel pipe piles filled with reinforced concrete.

The cost of the 13 795 ft. of shield-driven tunnel was $17 050 000. The four shafts cost $3 100 000. The ventilating machinery cost $572 000. The cost of approaches, street changes, paving and housing for ventilating machinery and purchase of real estate, which included a number of city blocks, brought the cost of the whole project up to about $50 000 000.

38. Roof Shields

Roof shields for masonry-lined tunnels have been used with success principally in France and to some small extent in America. In use they are peculiarly adapted to the drier soils, usually under streets where open-cut methods are not permissible, although they have been used, as in the East Boston tunnel, in connection with compressed air for subaqueous tunnels. They are usually semielliptical or semicircular in form and consist of a skin of steel plates riveted to girders which at their lower extremities are tied together with a transverse girder and mounted on rollers. Hydraulic jacks supported by the ribs and bearing against the completed masonry or the arch centers move the shield forward. The two general methods of using roof shields are: first, to excavate the area of cross-section of the shield, build the masonry arch, and subsequently underpin with the side-wall construction; second, to drive timbered headings in advance and construct in them the side walls on which the shield is later supported or rolled.

(1) Commenced 1895. Contract price $55.45 per lin. ft. Semielliptical shield. Average progress 14 ft. 9 in. per day of 24 hr., maximum 29 ft. Material penetrated of loose sandy nature.

(2) Commenced 1897. Average progress 9 ft. per day of 24 hr. Material penetrated: 450 ft. compacted clay and sand, 100 ft. loose sand and gravel. Height = over all.

* Height = From springing line to crown unless noted. † Length = Distance over all.

(3a) Commenced 1898. Material penetrated mostly made ground, old masonry walls and foundations. Average progress 3.4 ft. in 24 hr., maximum 22 ft.

(3b) Material penetrated, see No. 3a. Average progress 10 ft. in 24 hr.

(4a) Commenced 1898. Employed on elliptical section. Material penetrated: made ground, decomposed limestone, marl, and foundation walls. Average progress 8.2 ft. per day, maximum 101.7 ft. per week.

(4b) Started 1898. Employed on circular section. Material penetrated, fine sand and gravel. Average progress 9 ft. per day.

(4c) Started 1898. Employed on circular section. Material penetrated, made ground, sand, foundation walls, etc. Average progress 7.2 ft. per day. Height = over all.

(5a) Started 1899. Two shields of this type employed on 1st section, 1 on 8th section, and 1 on 11th section. Material penetrated, made ground and soft sand, with some marl. Average advance 13 ft. per day on 1st section, 10 ft. on 8th, and 12 ft. on 11th.

(5b) Started 1899. One shield of this type employed on 2nd section, two on third section. Material penetrated, sand and gravel, some water-bearing. Maximum advance 29 ft. per week.

(5c) Started 1899. Two shields employed on 4th section. Material penetrated, sand and gravel. Shields proved unsatisfactory.

(5d) One shield of this type employed on 6th section, one on the 7th section. Material penetrated, sand, gravel, and marl. Average advance 6.5 ft. per day. Shield proved unsatisfactory.

(6) Started 1901. Material penetrated, blue clay and boulder clay, with some sandy and silty permeable clay. Air pressure, 18 to 20 lb. average, 25 lb. maximum; 1200 cu. ft. per man per hr. Average progress 4.8 ft. per day.

39. Cast-iron Tunnel Lining

The Lining for shield-driven tube tunnels has usually been cast iron. The reasons for its use are that it can be most quickly built; as soon as erected it furnishes a reaction for the shield jacks; it offers greater assurances of water-tightness, and being thin for its strength saves excavation. For subaqueous work done in compressed air all of these considerations are weighty. The number of segments forming a ring and the width of the ring depend on the economic weight that can be handled. Sometimes in small tunnels up to 13 or 14 ft. in diameter iron lining has been built by hand, but hydraulic erectors attached to the shields or to traveling platforms are generally used. The length of shield which can be conveniently used is another factor governing the width of segments, the length of the tail being affected correspondingly by increases in this width. Fig. 92 shows the cast-iron lining used in the Pennsylvania R. R. tunnels under the East River, New York. There has been built in compressed air at least one shield-driven tube tunnel lined with brick. In the construction of the 39th Street sewer in Chicago, segmental timbering formed a lining inside of which the brick was built. The timber was used to receive the reaction of the shield jacks.

The design of the cast-iron lining depends as much on the requirements of building, as upon the stresses involved, and the best guide is a study of precedents. The table gives principal dimensions and details of iron lining in existing tunnels.

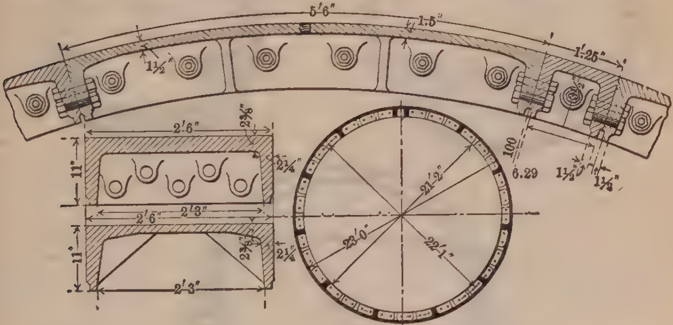

Fig. 92. Cast-Iron Lining, East River Tunnel

Stresses in tunnel lining can only be approximated by theoretical analysis, because they originate in earth pressures and the law of action of earth pressures is only imperfectly known. Although the designer should depend more on judgment and precedent than on theoretical analysis, such an analysis may be helpful by indicating the nature of the stresses.

Let C_1, C_2 (Fig. 94) be the line of centers of resistance (locus of centers of gravity if shell is homogeneous) of a unit length of tunnel shell which is taken circular but may have any other form. Let p_1, p_2, p_3, . . . to p_n be all forces acting upon the shell. These must satisfy the condition that the forces on opposite sides of any diameter must be equal and opposite, otherwise there would be movement. For example, the reactions and active forces, if any, on the bottom must balance the loads on top. It is assumed in Fig. 94 that the loading and the shell are symmetrical about the vertical axis $A-B$, which will usually be the case. The analysis would be similar in any case.

The load diagram a_1, a_2, a_3 . . . is constructed in the usual way by laying off the forces p_1, p_2, p_3 . . . to scale parallel to their direction. The position of the pole o is found by laying off on $a_1\ an$ the thrusts T_1 and T_n, which are found by taking moments of the horizontal components of p_1, p_2, p_3, . . . about C_1 or C_2. Then a_2, a_3, a_4, etc., are connected with the pole, and the line of thrust $T_1\ T_n$ is constructed in the usual way by drawing T_1, T_2, T_3, . . . parallel with oa_1, oa_2, oa_3, . . . But an infinite number of such lines of thrust may be drawn. The one to be used for computing stresses

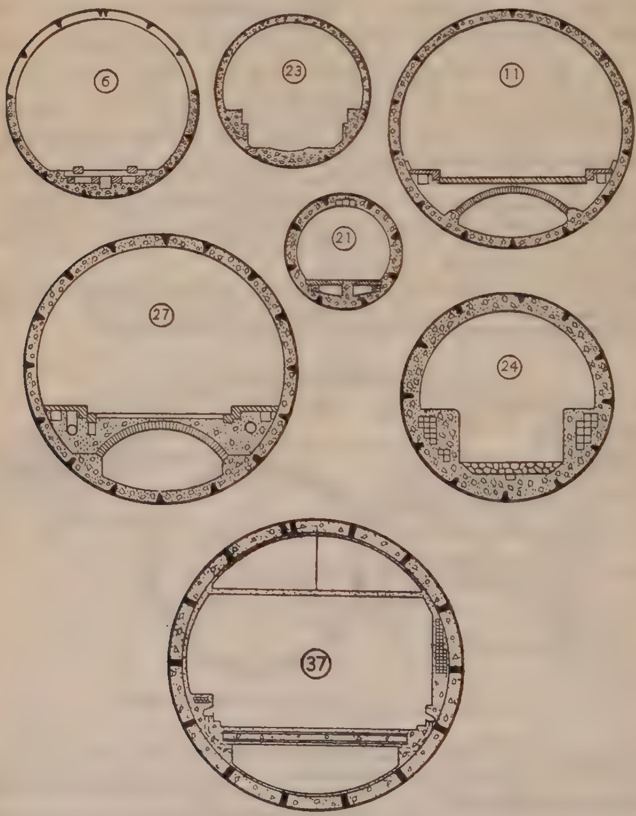

Fig. 93. Cast-Iron Lined Tunnels

in a ring of uniform cross-section may be found from the consideration that for any short length of bent member the bending moment is proportional to the angular deflection in that length, and, because in a closed ring the total change of angle of axis is zero, the sum of the bending moments integrated about the closed ring must be zero. The line of thrust to be used in computing the stresses in a tunnel ring may be found by choosing that one for which the positive and negative bending moments are zero. This may be done by trial. Divide the complete ring into small equal segments, multi-

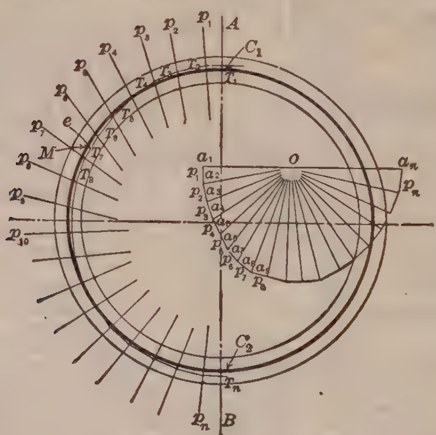

Fig. 94. Stresses in Tunnel Shell

ply the component of the thrust at right angles to the radius at the middle of each segment by e, the eccentricity of the thrust. The e is the distance from the center of gravity of the cross-section of the ring to the line of thrust measured on the radius. In this way find the line of thrust for which the sum of the positive bending moments equals the sum of the negative bending moments integrated about the complete ring.

40. Waterproofing and Grouting

Grummets. Bolt holes in cast-iron tunnel lining, being slightly larger than the bolts which are placed in them, permit water to seep into the tunnel unless a tight calking material is carried around the bolt hole or some form of grummet is placed under plate washers at the head and nut. Three principal types of grummets have been used. In the Baker Street and Waterloo, the North River Pennsylvania, the Battery, and for a time in the East River Pennsylvania tunnels rings of hemp saturated in red lead and oil under plate washers were used. In the East River Pennsylvania, where the bolts had rolled threads, the diameter of the threaded portion being larger than the diameter of the shank, greater success was attained by wrapping around the shank strands of hemp saturated in red lead and oil. In the Greenwich and Rotherhithe tunnels lead washers were used, and when the bolts were tightened the lead washers were forced into conical bolt holes.

Calking. The prevailing practice is to cast a small depression in the flanges at its inner edge which matches a like depression in the adjoining plate and forms a calking groove when the plates are bolted together; see Fig. 92. Into this is calked either soft lead or a rust mixture or sometimes portland cement. The grooves have usually been from 1/4 to 3/4 in. wide and about 1-1/2 in. deep. For lead it is desirable to make the groove much narrower, say 1/8 in. wide, but this is difficult to cast.

The rust mixture is usually one part by weight of sal ammoniac mixed with 400 parts of iron filings. The sal ammoniac is best dissolved in enough water to dampen the iron filings, which are then calked into the groove and well compacted either by hand tools or pneumatic hammer. The finer the iron filings the better. Rust mixture calking is not successful if there is water coming through the joint during calking. Even when the joints are made absolutely watertight slight movements of the flanges, such as are likely to occur from contraction in winter or in adjustment of bolts, are liable to cause a small amount of leakage. The table shows the practice in some of the more important tunnels:

Grouting. The shield being larger than the tunnel lining leaves an annular space which should be filled immediately after the shield has passed. This is especially necessary at the sides to prevent the lining from spreading. The material to fill this space must be ejected through holes in the lining. It must therefore be something that will flow and be permanent. A grout of equal parts of cement and sand is the most common material for the purpose, but simple pugged clay has been used as well as plain sand or gravel. These are probably all equally good so long as they are made to fill the space, although in rock the cement grout is preferred.

Waterproofing. Most subaqueous tunnels have had cast-iron or steel shells which are waterproof of themselves; the exceptions are those that are in nearly impervious clay, which prevents any quantity of water reaching the tunnel lining. There are a few such tunnels as the Severn, which has brick lining which is back drained to a sump which is kept dry by pumping. Numerous tunnels and subways in water-bearing ground are of masonry lining waterproofed by pitch in some form.

The most generally used form is a combination of pitch, usually applied hot, with sheets of some fibrous material used as binders; for this purpose burlap, building paper, and so-called felt have been used. These binder sheets are usually saturated with pitch by the manufacturer, and are applied to the outside of the wall in from 2 to 6 thicknesses, each layer being given a coat of hot pitch as it is placed. The specification for such work in the Pennsylvania R. R. land tunnels in New York call for "straight run

coal tar pitch which will soften at 60° F. and melt at 100° F., being a grade in which distillate oils, distilled therefrom, shall have a specific gravity of 1.05.'' Felt was coated and saturated with asphaltic products, and it was required that the wool in the unsaturated felt should be not less than 25% by weight and that the felt should weigh 0.05 to 0.06 lb. per sq. ft. unsaturated and 0.12 to 0.14 lb. saturated. Another type of waterproofing consists of an outside course of asphaltic brick laid in soft pitch or a mastic of soft pitch and fine sand.

41. Compressed Air

The Shield and Compressed Air generally go together, but there have been several exceptions. A portion of the Pennsylvania tunnels in Long Island City were mined, timbered, and lined in compressed air without use of shields, and the builders of the telephone tunnels in Chicago used compressed air but no shields. The amount of air required is very variable in different tunnels and at different times in the same tunnel. In the East River

* The shield cut into the permanent clay blanket placed on the river bed. The clay blanket is protected from washing by a rock revetment on the sides and top.

† Does not include clay blankets.

‡ Requirements for all contracts was 10 000 cu. ft. of free air per min. per heading; except in one case where one power house supplied 8 headings, the requirement was reduced to 8000 cu. ft. of free air per min. per heading.

tunnels of the Pennsylvania R. R. in open sand with a clay blanket 10 to 20 ft. deep and 350 ft. wide dumped upon the river bed, the capacity of compressors required was about 80 400 cu. ft. free air per min. The average used was about 3500 cu. ft. per min. per heading. In the Rotherhithe tunnel under the Thames it was specified that the minimum amount of air pumped into the tunnel should be 8000 cu. ft. of free air per man per hour.

The great difficulty in water-bearing sand or gravel when compressed air is used arises from the impossibility of balancing the water pressure at more than one elevation, with the result that if the water pressure is balanced at the bottom of the tunnel there is an excessive escape of air at the top, which is expensive, and there is always danger that a " blow," or sudden outrush of air, will occur at the top, which endangers the workmen and may cause delay by flooding the tunnel. If the water pressure is balanced at the top, the bottom may be so wet that the ground is unstable and difficult to handle. As a compromise the water pressure in such materials is usually balanced by the air pressure at about the center of the shield, and blows are guarded against by breasting and plastering the face with clay and depositing a clay blanket on the river bed above.

42. Subaqueous Tunnels Built from Surface

In cases where the top of the tunnel is desired to be close to the bed of the river thus giving insufficient cover for shield work, or if the tunnel is short,

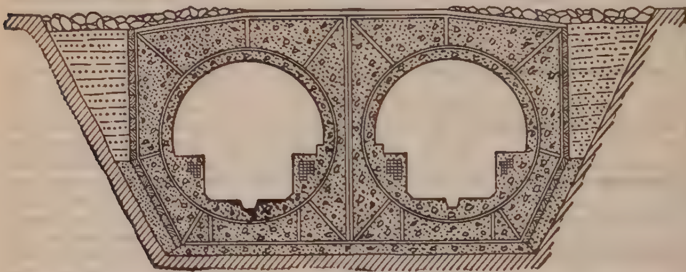

Fig. 95

making the plant installation required for shield work proportionately excessive, tunnels have been built successfully from the surface.

(1) Detroit River Tunnel, Detroit to Windsor. Trench was dredged to grade in the stiff clay of the river bottom. Twin steel tubes of 3/8-in. plate 23 ft. 4 in. in diam-

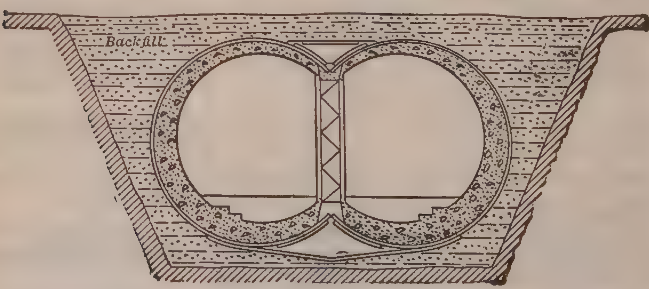

Fig. 96

eter and 262 ft. 6 in. long connected by structural steel diaphragms at 12 ft. c. to c. and provided with bulkheads were sunk in position on prepared foundations. Sections were connected up by divers with special bolting system. A timber form or sheathing was fastened to outer edges of the diaphragms. Concrete was placed by tremie between this sheathing and the tubes—completely encasing the tubes. This concrete was 3 ft. thick on the sides and 4 ft. 6 in. thick top and bottom. Reinforced-concrete lining having an interior diameter of 20 ft., was placed inside the steel tubes. (See Fig. 95.) Distance from water surface to top of rail in mid-channel 66 ft. Current in river over 2 miles per hr. Total length of river section 2667 ft. Built 1906-10.

(2) Chicago River Tunnel. Single length of two parallel steel cylinders with a longitudinal dividing wall; lined with reinforced concrete and sunk on prepared foundations in a trench dredged in the river bottom. Tubes of 3/8-in. steel plate, stiffened by plate and angle gussets above and below the central wall every 7-1/2 ft. Concrete lining 20 in to 40 in. thick. Central wall 3 ft. thick. Length of tubes 278 ft., width 41 ft., depth 24 ft. Weight when sunk 8000 tons. Backfill and cover sand. Connection to shore tunnels made by cofferdam. Built 1910-12. (Fig. 96.)

(3) Paris Subway under Seine, Pont Mirabeau crossing. The river portion is 644 ft. long and made up of 5 sections 116.8 ft. to 144.4 ft. long. Each section was a pneumatic caisson consisting of a structural steel frame covered inside and out with steel plates and filled with concrete, with a double-track tube of similar construction above the working chamber. Over-all width 29.9 ft., over-all height 30.1 ft. These sections were sunk in position 15-3/4 in. apart, this space filled with tremie-placed concrete through which an opening of required tunnel section was later excavated. A tunnel having a total caisson length of 1313 ft. was built under the Seine by a very similar method in 1906-7.

(4) Harlem River crossing, New York Subway, Lexington Avenue Line. Four-track tunnel built very much the same as the Detroit River tunnel noted above. The sections as assembled had an over-all width of 76 ft. and height of 24-1/2 ft. Four of the sections were 220 ft. long and the remaining one was 200 ft. long. Contract price $1500 per lin. ft. for four-track structure. Built 1911-12.

(5) Harlem River Tunnels, New York Subway, Lenox Avenue Branch. Twin tube sections 610 ft. long of cast-iron lining, inside diameter 15 ft. Across the river trench was excavated, bottom of which was a little below the middle of the finished tunnel. Two lines of heavy sheet piling were driven outside the line of the finished tunnel and cut off at the springing line of the arched roof. A floating timber box was then built in which the arched roof of cast-iron segments was erected and covered with concrete with proper internal bracing and bulkhead ends. The floating box was sunk from underneath and the roof left floating like a diving bell. This with steadying tackle was sunk and left resting on the sheet piling and bearing piles previously driven in the trench. After divers connected this to the section already in place, the lower half of the tunnel was built in compressed air. Built 1903-4.

(6) Oakland-Alameda vehicular tunnel, California, 1926-28. Single tube with 24-ft. roadway for two-way automobile traffic. 12 sections each 203 ft. long with temporary wooden bulkheads were built in drydock, floated to the site and sunk. The sections were reinforced concrete, 37 ft. outside and 32 ft. inside diameter. The arrangement of ventilating air ducts was like that in Holland tunnel.

43. City Subways

The Cut-and-Cover Method is usually cheaper than tunneling at depths less than 30 ft. and may be the more practicable method when the cover is shallow, as often with city subways for rapid transit. Attempts to excavate by shield within a few feet of street surfaces have not met with entire success because of disturbance to pavements and pipes. Where traffic will not permit an open cut, the pavement is taken up, if necessary at night, and replaced by a timber deck under cover of which the subway is built. Where wide cutting is objectionable, side-walls and interior supports are sometimes built in trench and roofed, after which the core is removed and the bottom placed. Where there is ground-water, its level frequently may be lowered by draining to sumps and pumping carefully. Where quicksand is met at subgrade, tight sheeting is driven to extra depth and it may be necessary also to excavate for and place the floor quickly in short sections. On the other hand, where the ground is dry and hard enough to stand with but little bracing and where decking is not required, steam shovels have been successfully used. Intercepted sewers may be depressed or under-siphoned, or the sewer system may be modified.

Adjacent foundations are underpinned, either temporarily or permanently, where required to prevent settlement. Finally, subsurface structures are restored or rebuilt and the street is backfilled and repaved.

Types of Sections are shown in Fig. 97. Earlier sections usually were of the single-arch type if headroom permitted; where close to the surface the roof was of beams with jack-arches between them. Later, beams came to be used also in sidewalls, forming bents, saving in width and facilitating construction. Reinforced concrete requires somewhat less and cheaper steel and permits the use of large forms, but bents continue in favor because better adapted to requirements of bracing, piecemeal construction, and support of subsurface structures. The single arch of concrete, plain or reinforced, is still used where conditions of head-room and lateral support are favorable. In soft or wet ground the floor may be formed as an invert or may be reinforced with beams or rods. Waterproofing is commonly felt or fabric saturated and laid with tar or asphalt, and in dry situations may be omitted from floor and sides. Stations are painted, plastered or tiled in white or light colors.

The New York Subway System, the largest, has 74 miles of underground structure in operation by two different companies. A new independent system now (1928) building by the city will add, it is estimated, 61 miles by 1933. Most of it is 2- or 4-track subway of bent type (3), Fig. 97. Portions first (1900-3) built are nearly all of bent type (1), and some later (1902-12) built are of reinforced-concrete type (2) or similar. Type (3) provides a partition between the middle tracks to promote ventilation by train movement. The roof and where necessary the sides and floor are waterproofed generally with felt or burlap and pitch. The inside tracks are for express, and the outside for local trains. At express stations the platforms are between local and express tracks, serving both, and at local stations at the sides. In some parts the four tracks are built in two tiers. Excavation was partly in rock. Groundwater and very fine quicksand were frequently met. Methods varied widely. The system includes several miles of arch tunnels in rock, cast-iron-lined tubes and steel viaduct extensions.

The Boston Subway System, the first in America, with 28 miles underground trackage, radiates to Cambridge, Dorchester, East Boston and Brookline. It is mostly 2-track subway and principally of bent type (4) and arch type (5) in earlier (1895-1908) portions and of reinforced concrete type (6) in a later portion. Where traffic was dense a short portion somewhat like (5) was tunneled with roof shield. The Cambridge portion (1909-12) is of arched, reinforced type (11), but where cover is shallow the roof is made flat. Excavation was nearly all in sand, clay and gravel. The system is for both surface cars and trains. It includes two shield-driven subaqueous tunnels and steel viaduct extensions or connections.

The Philadelphia Subway east and west in Market Street, built 1903-07, 2-1/4 miles long, is in about equal parts a 4-track (7) and a 2-track (8) structure. The walls of (7) and the roof and walls of (8) are rod-reinforced. The roof is waterproofed with asphaltic mastic and the sides with asphalted burlap. The outer tracks of (7) are for street cars and the inner tracks, con-

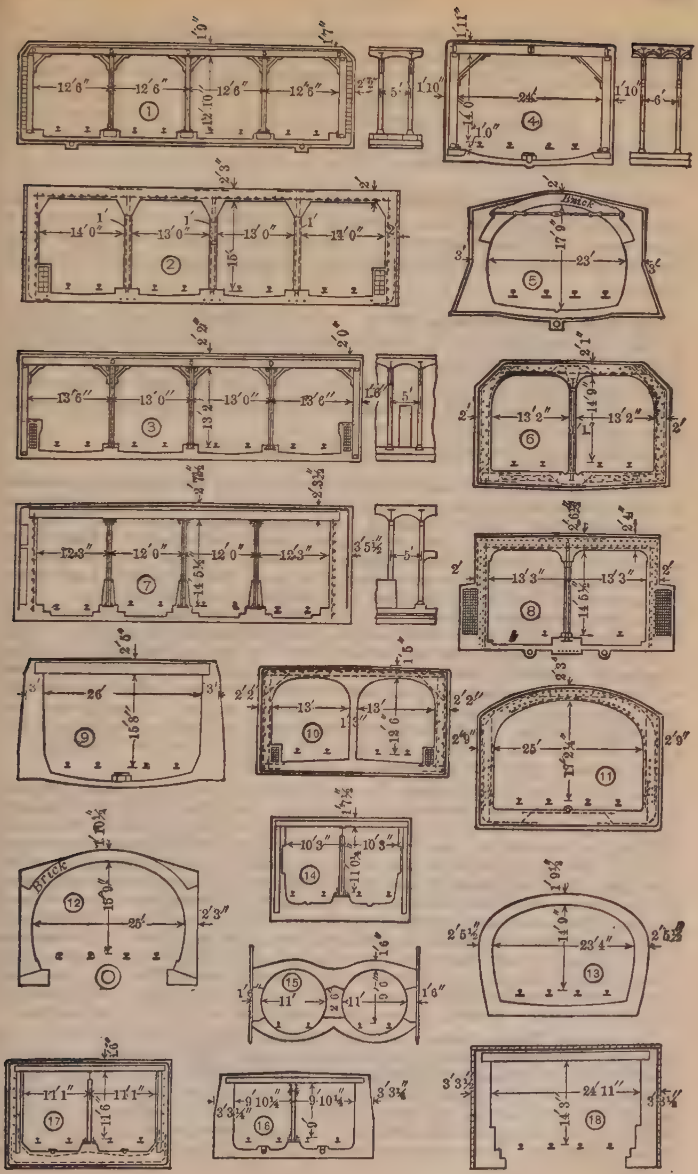

Fig. 97. Subway Sections

tinuous with those of (8), for trains. The columns of (7) are protected against derailment by low reinforced-concrete bulkheads. In 1924 the city began a 4-track subway 6-1/2 miles long north and south under Broad Street, to extend by a 2-track branch to the southwest. The new subway is of the bent type. Waterproofing is generally limited to the roof; the floor and walls are underdrained. Excavation is largely in gravelly soil. The system includes steel viaduct extensions.

The Atlantic Avenue Subway, Brooklyn (9), built 1901-7, 2 miles long, is for electric trains of the Long Island R. R. While not a city subway in a strict sense, it is structually such. The sides are retaining walls and with the roof are waterproofed with tarred felt. Excavation was mostly in sand and gravel.

The Sixth Avenue Subway N. Y. (10), built 1906-11, 1 mile long, is for Hudson and Manhattan R. R. trains entering the city by tunnel under the Hudson. Roof and sides and, where in earth, the floor, are reinforced. Waterproofing was mostly of asphalted burlap but in a short portion a waterproofing compound was mixed with the concrete. Excavation was partly in rock. Some quicksand was met.

Foreign subways generally are of smaller cross-section.

The London Metropolitan and District Subway, (12), an irregular oval line termed the Inner Circle, was the first city subway for rapid transit. It was built 1860-84 and later extended from its original length of 13 miles, part of which is open cut. The arch and walls are of brickwork. The extrados is waterproofed with asphalt. Where cover is shallow, cast- or wrought-iron roof girders were used. With soft or wet foundation, an invert was added. Excavation was mostly in gravel, sand and clay. Later extensive underground lines are in deep-level tubes, shield driven in London clay.

The Paris underground railway, (13), a network of belt and intersecting lines, begun 1898 and opened 1900, has in 1928 a length of about 60 miles, mostly subway. A link south of the Seine, begun 1912 and halted by the war, was resumed 1923. The plan in progress is to provide about 80 miles of double-track line within the city proper, in addition to a large mileage of extensions on viaduct or surface. Short portions first built were tunneled with roof shield or by the Belgian method. Watertightness was secured by grouting. Excavation was mostly in sandy soil and in some parts in soft rock. There are two operating companies—the " Metro " and the " Nord-Sud "—which exchange passengers by transfer at intersections.

The Berlin underground railway, (14), an original east-west trunk, begun 1896 and opened 1902, with later extensions or connections to suburbs, has about 25 miles of 2-track line, of which about half is subway. A new north-south trunk, 7.7 miles long, built by the municipality, was opened for operation by the existing company early in 1923. The section shown is that of the Schoneberg branch, opened 1910, of the bent type. The longitudinal girders are discontinuous, each supporting 5 roof beams, and rest on two columns over which they cantilever. A feature was the use of small I-beams, driven as piles at each side every few feet, to the inner flanges of which were clipped breast boards, retaining the earth and serving as back forms for the concrete of the sidewalls, in such manner as to permit the final withdrawal of the beams. The beam-piles were braced apart only at the top, leaving a free working cut. An earlier type has thicker walls without beams. A late type has no columns. Waterproofing is asphalted paper. Excavation was mostly sandy and much of it water-bearing.

The Glasgow District Subway, (15), an irregular oval line, built 1891-97, is 6-1/2 miles long, comprising subway, tunnel and open cut. For the subway, a heavily sheeted trench was excavated deep enough to build the roof, which was next waterproofed with layers of asphalt and covered with the restored pavement. The roof, supported by the sheeting, was then undermined with drifts in which were built the walls and floor, completing the structure. A short section in soft ground was built under air pressure. Excavation was in sand, clay, mud and rock. Traction is by cable.

The Budapest Subway, (16), for surface cars, a line 2 miles long, built 1894-6, was the first underground electric railway. The I-beams of the roof, which is close under the pavement, are supported at the middle on a continuous girder of two I-beams resting on columns spaced about 13 ft. apart. Waterproofing consists of sheets laid in pitch.

The Hamburg Subway, (17), begun 1907, forms 5 miles of a ring with external branches opened in part in 1912 and since extended. Excavation was in varied soil, in parts water-bearing. In dry ground, openings are left in the floor under the tracks and only the roof and sides were waterproofed. Beam piles were used at the sides, as in Berlin. Where depth permitted, a single arch section with invert was used.

The Buenos Aires Subway, (18), for surface cars, was begun 1911 and opened 1913 for a length of two miles, with extensions in progress or planned. It is of the earlier German type without steel in side walls. Waterproofing is tar paper and asphalt. Excavation was in hard clay. Electric shovels were used.

The Madrid Subway, opened in part in 1919 and extended by 1926 to a length of 9.3 miles, is roughly cross-formed in plan. The double-track arch and the rectangular section are both used. For the latter, the side-walls were first built in separate trenches, the pavement was then removed, the roof built and the pavement replaced, after which the core was excavated, and the floor and middle support placed.

The Sydney, Australia, Subway, a 2-track loop 3.6 miles long, from the Central Terminal station through the business district, with extensions, was opened in part late in 1926. Some viaduct and some open cut are included. Steel framing is used where headroom is restricted.

The Tokyo Subway was opened for a length of 1-1/2 miles late in 1927, and will connect the thickly populated districts of Uyeno and Asakusa. Other portions of the system are in progress or planned. The structure is 2-track and of the bent type.

The cost of subway work varies widely. The kind and depth of excavation, proportion of temporary decking required for traffic, size and number of sewers, pipes, etc., to be supported or changed, and the extent of underpinning to protect adjacent buildings, greatly limit methods and thereby influence cost. The accompanying table gives costs, per lineal foot of equivalent single track, of several New York subway sections put under contract between 1925 and 1928, all of a type resembling (3) of Fig. 97. The figures are based on contract prices which may be unbalanced, and preliminary estimates which may be large. They include nothing for station finish, track, equipment, engineering or inspection, and are not safe for use in estimates without fuller presentation of conditions than is possible here.

IRRIGATION AND DRAINAGE

BY

HORACE W. KING

PROFESSOR OF HYDRAULIC ENGINEERING IN UNIVERSITY OF MICHIGAN

IRRIGATION

SWAMP AND OVERFLOWED LANDS

FARM DRAINAGE

LEGAL AND ECONOMIC FEATURES

IRRIGATION

1. Fundamental Considerations

Definition. The practice of supplying water to crops by artificial means is called **irrigation.** Irrigation is essential in arid districts and may be profitable in semi-humid regions where the rainfall is occasionally insufficient to mature crops and for certain purposes in humid regions as an assurance against drouths. Irrigation water may be obtained by gravity flow by the diversion of natural streams or by pumping from surface or sub-surface supplies.

The Development of the Irrigation Resources of a country usually begins with the bottom lands lying close to the stream which provides the water supply. In the early days of irrigation, ditches were built to serve a single farm or a small group of farms. Later, community ditches were built and irrigation companies were formed which irrigated larger areas under a single system. In the United States and other countries whose irrigation resources have been extensively developed, the more accessible lands are under irrigation and the flow of streams during the irrigation period has been largely appropriated. There thus remains for development only the more inaccessible lands and those which must be supplied by the storage of flood flows and water not available during the irrigation season.

Operations of an Irrigation Project. In general, irrigation may be divided into four operations: the storage of water, the diversion of water, the conveyance of water, and the application of water to the land.

The Soils of arid districts extend to a greater depth and are commonly more fertile than those of humid localities. In the irrigated sections of the United States the soils are generally deep and of uniform texture. Hardpans are found near the surface of the ground in some localities, but they are usually dissolved by irrigation. Care should be taken to determine the crops to which an irrigated area is best adapted. This may depend upon the length of growing season as well as the soil formation. A strong growth of sage brush, bunch grass or other vegetation indicates fertile soil. Salt grass and grease wood are indicative of alkali. In general, the soils of arid districts are well supplied with lime, potash, and nitrogen, but are low in humus content.

2. Disposal of Irrigation Water

Soil Moisture occurs in three forms, usually termed hygroscopic, capillary, and gravity water. **Hygroscopic water** is the moisture which perfectly dry soil will absorb from the water vapor in the air. It either may form an extremely thin coating of the soil particles or may be held in loose chemical combination. It can not be removed without artificial heat and has no value in sustaining plant life. **Capillary water** exists as a thin coating of the soil particles. It moves from a wet soil to a drier soil in any direction. Capillary water is of chief value in supplying moisture for vegetation. **Gravity water** is the water contained by soil beyond its capacity to contain capillary water. It moves downward by gravity and is not retained by the soil, as such, if there is satisfactory drainage. After rains or if water is applied by irrigation, gravity water near the surface of the ground in passing downward may become capillary water in the lower strata.

The amount of hygroscopic water in the soil depends upon the temperature, humidity of the air, texture of the soil, and other less important factors. It varies from a minimum of about 0.5% of the weight of the soil for coarse sand to maximums of 8% and 17% respectively for silt and clay. The limit of soil to hold capillary water is usually reached when it contains 15% to 20% of its weight of moisture. Water will rise 0.5 to 2 ft. in one day and 0.7 to 4 ft. in one week by capillary action. The rate of capillary movement increases with the fineness of the soil particles. The distance which moisture may be drawn by capillary varies from about 2 ft. for sand to 5 ft. for fine silt or clay. Cultivated soils contain 30% to 50% of voids which marks the limit of their capacity to hold water.

Ultimate Destination. Irrigation water applied to land disappears in several ways: (1) **plant transpiration,** (2) **evaporation** from the ground, (3) **percolation** to strata beyond the reach of plant roots, and (4) **surface waste.** Only the water used in plant transpiration serves a useful purpose, and in successful irrigation disposal by the other three methods should be reduced to a minimum.

Plant Transpiration is the process by which growing plants obtain nutriment from the soil. Carbon, which constitutes about one-half of the dry plant, is taken by leaf action from the carbon-dioxide in the air. Plants contain 2% to 10% of mineral matter. The remainder of the plant is composed of the elements of water combined with the mineral matter and carbon. There is a continual upward current of water through the plant. The soil moisture, containing mineral matter in solution, enters the hair roots of the plant, the water being dispelled by the leaves into the air in the form of water vapor. The rate of movement of the water usually varies from 1 to 6 ft. per hour, but may be much greater than this.

The Amount of Transpiration, other conditions being the same, increases with the moisture in the soil, the amount of sunlight, and the temperature. Transpiration is practically zero for temperatures less than 42° F. The amount of water required to produce a given quantity of dry matter decreases as the humidity of the air increases. In general, for a given locality, the amount of water used in plant transpiration varies approximately as the quantity of dry substance produced. The average plant consumption and distribution of consumption on the Boise Project, Idaho, as determined by J. C. Stevens from statistical reports of the U. S. Bureau of Reclamation are given in the tables at top of page 1656.

The Amount of Evaporation from Soil depends primarily upon the available moisture. For saturated soil the evaporation is equal approximately to that from a free water surface. As the soil moisture is depleted the rate of evaporation decreases. The amount of evaporation is also affected by the character of soil. Fine soil has a greater capacity for capillary water and permits greater capillary movement and therefore affords a greater opportunity for evaporation than coarse soil. Cultivation reduces the amount of evaporation. A mulch of 6 in. will conserve 80% of the soil moisture. Other conditions being the same, the rate of evaporation increases with the wind velocity, the temperature, and the saturation deficit of the air.

Percolation. If the quantity of irrigation water applied to a tract of land is just sufficient to supply plant needs, there is no percolation to the deeper strata. With the irrigating methods ordinarily employed, however, percolation losses are 20% to 75% of the water applied. They increase with the porosity of the soil.

Return Seepage. Waters which percolate from canals and irrigated areas to underlying strata raise the ground-water level and eventually return to natural channels. Return waters may in some instances be used for irrigating other areas but they often become so heavily impregnated with mineral salts (see Art. 28) as to render them unfit to use for irrigation. In the San Joaquin valley of California large areas are irrigated by irrigation waters returned to the Stanislaus, Tuolumne, and Merced rivers. In some instances 40% or more of the water diverted is returned to streams through underground seepage.

Surface Waste is the irrigation water which runs off the surface of the ground and does not soak into the land being irrigated. It is not practicable to eliminate this waste entirely. An allowance for surface waste of 8% to 15% of the total water applied to the land is conservative. Without care in irrigating these percentages may be greatly exceeded. In general, the waste increases with the slope of the land to which the water is applied.

Average Plant Consumption, Boise Project

Crop	Acres	Yield per acre	Plant consumption	
			Depth in feet	Acre-feet
Alfalfa	39 090	3.9 tons	1.66	56 800
Barley	3 220	20.4 bu.	0.50	1 610
Clover	7 680	2.0 tons	0.84	6 430
Corn	1 410	37.9 bu.	0.97	1 370
Mixed hay	510	1.4 tons	0.62	320
Oats	3 210	25.5 bu.	0.48	1 540
Pasture	6 550	....	0.50	3 280
Wheat	25 680	21.2 bu.	0.63	16 100
Total	83 350	....	1.06	87 450

Distribution of Mean Plant Consumption

Month	Mean monthly temperature, deg. F = T	T − 42	Percentage of total	Inches

September	62	20	14	1.8
October	50	8	6	0.7
Total	....	137	100	12.7

3. Duty of Water

Units. The unit of volume commonly used in irrigated districts to express storage or the quantity of water required to irrigate a given area of land is the **acre-foot.** It is the amount of water required to cover an acre of land 1 ft. in depth, or 43 560 cu. ft. An **acre-inch** is 1/12 of an acre-foot. The unit used to express flowing water is the **cubic foot per second.** One **second-foot** (one cubic foot per second) flowing for 24 hours is equal to 1.9835 acre-ft. A unit of measure for flowing water that is becoming obsolete is the miners' inch.

Duty of Water refers to the relation between the quantity of water applied to the land and the area irrigated. It is commonly expressed as: (a) the area which can be served by 1 cu. ft. per sec. of water, (b) the volume in acre-feet used during one irrigation season to irrigate 1 acre, or (c) the depth of water in inches per irrigation season that is applied to the area irrigated. The term is ambiguous and could well be dispensed with, but because of its extensive use and common acceptance by engineers it must be recognized. The **net duty** of water for an irrigation project is based upon the average use per acre measured at the borders of farms. The **gross duty** is based upon the total diversion at the intake of the main canal, thus including conveyance losses in main canals and laterals. In using the term, duty of water, it should be clearly understood at what point the water is measured.

The Factors Entering into Duty of Water, exclusive of conveyance losses (see Art. 4) together with quantities of water ordinarily chargeable to each during one irrigation season, are listed below. Extreme values may be greater or less than those given.

Plant transpiration..........	0.50 acre-foot to 1.75 acre-feet
Evaporation................	0.75 acre-foot to 2.00 acre-feet
Percolation................	0.25 acre-foot to 6.00 acre-feet
Surface waste..............	0.25 acre-foot to 0.50 acre-foot

Only water used in transpiration serves a useful purpose. Losses resulting from evaporation, percolation, and surface waste should be prevented insofar as practicable. Evaporation is reduced by cultivation but cultivation is impracticable for hay and grain crops. Percolation losses result from applying too much water to the land and permitting seepage to depths beyond the reach of plant roots. In general, percolation losses increase with the coarseness of the soil. Percolation losses are reduced by irrigating only a small tract at a time and using a large head of water so that the area can be covered quickly. Surface waste can be reduced or even entirely eliminated by having the ground well prepared to receive water and by care in irrigating.

The Kind of Crop has an important bearing on the duty of water. Excepting fruits, the water required will vary with the length of the growing period. Alfalfa which, with an adequate water supply, produces successive crops during the growing season, requires more water than other crops.

Water Requirements for Different Crops

Crop	Soil	Water requirements in acre-feet per acre		
		Average maximum used	Average minimum used	Average for most economic use of water
Alfalfa (three cuttings)	Clay and sandy loam.	4.0	1.5	2.5
	Porous sandy soil....	10.0	4.0	6.0
Grain...............	Clay and sandy loam.	3.0	1.0	1.5
	Porous sandy soil....	5.0	1.5	2.5
Potatoes............	Clay and sandy loam.	3.0	1.0	1.5
	Porous sandy soil....	5.0	2.0	2.5
Sugar beets..........	Clay and sandy loam.	3.0	0.5	1.2
	Porous sandy soil....	5.0	1.2	2.0
Deciduous fruits......	Clay and sandy loam.	2.0	0.7	1.0
	Porous sandy soil....	4.0	1.5	2.0
Citrus fruits.........	Clay and sandy loam.	3.0	1.2	1.7
	Porous sandy soil....	5.0	2.0	3.0

The Times to Irrigate to secure the best results from a given water supply will be the times which come nearest to fulfilling the ideal condition that the soil shall have an adequate and uniform moisture content throughout the growing period. Since transpiration from large plants is greater than from smaller ones, and also because maximum growth is obtained late in the summer when evaporation is greatest, more water should be applied during the latter part of the growing season. After vegetation has attained its full growth and becomes well matured, but little water is required. When water is obtained directly from streams this ideal condition is not usually attainable, since the water supply, plentiful during the early part of the growing season, usually decreases rapidly as the summer advances. If the source of supply is from storage reservoirs water is available when needed. An important consideration is that the ground should be thoroughly moist at seeding time or when plant growth begins. To accomplish this, fall, winter or early spring irrigation has been practiced with excellent results. If the fall and winter rains are heavy enough to supply adequate spring moisture such irrigation is unnecessary. In localities where water is not available during the growing period, short-season crops such as grains and early fruits have been grown successfully with fall and winter irrigation only.

If the soil is moist at the time plant growth begins in the spring, the first irrigation of the crop should be deferred until the need for more water is apparent. This permits the roots to obtain a more vigorous growth. After the first irrigation successive irrigation should follow as required. As a rule frequent irrigations using comparatively small quantities of water are advisable. The usual practice, for fine soils, is to apply 3 to 5 in. of water at each irrigation. A smaller quantity of water should be used for coarse soils, if practicable, but irrigations should be more frequent.

The Number of Irrigations varies with the crop and the character of the soil. For fine soils, alfalfa should be given one or two irrigations for each cutting; potatoes, sugar beets, corn and similar crops are usually irrigated 3 to 5 times, the greater part of the water being applied from July 1 to August 15 in the northwestern states; grains are given 1 to 3 waterings near the time of seed formation; deciduous fruits require a fairly uniform distribution of moisture, with rather more at the time fruit is forming; citrus fruits require irrigation throughout the year, with the maximum requirement in the fall. Coarse soils require more frequent irrigations than the finer soils.

The Economical Use of Water has been investigated by the United States Department of Agriculture and by many of the western states. It has been found that while the use of water up to a certain amount is beneficial, beyond this amount little if any apparent increase in the productivity of the land results. It has also been found that where the supply of water is insufficient to irrigate all of the available land lying under it, there is an economical limit to the amount of water which should be applied. In other words, a greater profit from a given quantity of water may, in some cases, be obtained by spreading it over a larger area. This point is illustrated in the following example by Widstoe (Principles of Irrigation Practice, p. 337), assuming that sugar beets are worth $5 per ton and the cost of producing them, including interest on investment, is $60 per acre:

30 acre-inches spread over	Inches of water on each acre	Yield of beets per acre (tons)	Total yield of beets (tons)	Price paid for ton of beets	Gross income from beets	Cost per acre	Total cost	Net income from beets
1 acre........	30.0	21.0	21	$5	$105	$60	$60	$45
2 acres........	15.0	19.5	39	5	195	60	120	75
3 acres........	10.0	18.6	56	5	280	60	180	100
4 acres........	7.5	16.3	65	5	325	60	240	85

The above table shows that the greatest yield per acre is obtained by applying the 30 acre-inches of water to 1 acre of land, but the greatest net income for this quantity of water is obtained by spreading it over 3 acres.

4. Conveyance Losses

Seepage and Evaporation losses from canals are usually considered together under the term conveyance losses. In earth canals, seepage losses are much greater than evaporation losses. The coarser the soil the greater the seepage. If canals carry much silt, seepage may in some instances be gradually reduced by sedimentation but extensive investigations by the United States Bureau of Reclamation on many projects have failed to indicate that canals after long periods of use show any decrease in rates of seepage losses. Inseepage of ground-water, such as may occur when there are irrigated areas at higher elevations, may reduce apparent seepage losses. Conveyance losses are usually considered to vary directly with the area of the wetted surface.

Canal Linings of various types have been used to reduce seepage losses. The best type to use depends largely upon the materials available and other local conditions. Canal linings are expensive and are used most extensively

Irrigation Water Losses

Irrigation Water Lost in Canal Seepage, Delivery, and Waste in Canal Waste-ways and Spillways on Federal Reclamation Projects, 1916 to 1926

* The following are names of projects and numbers which correspond to the numbers in column 1, together with soil classification for canals: (1) Belle Fourche, clay and sandy soil; (2) Boise, volcanic ash and sandy loam; (3) Carlsbad, sandy loam and gravel; (4) Grand Valley, pervious—puddle lined; (5) Huntley; (6) King Hill, volcanic ash and sandy soil; (7) Klamath, sandy loam; (8) Lower Yellowstone; (9) Milk River, river bottom; (10) Minidoka—South Side Pumping Div., sandy loam; (11) Newlands, 60% sandy, 40% clay; (12) North Platte, sandy loam; (13) Okanogan, gravelly soil; (14) Orland, clay and loam; (15) Rio Grande, silt; (16) Shoshone, Frannie Div., sand and clay loam; (17) Shoshone, Garland Div., gravel and 'oam; (18) Sun River, Ft. Shaw Div.; (19) Sun River, Greenfields Div., gravel-clay; (20) Umatilla, sandy loam; (21) Uncompahgre, 1/2 adobe-shale, 1/2 sand and gravel; (22) Yakima, Sunnyside Div., sand and volcanic ash; (23) Yakima, Tieton Div., sandy loam and gravel; (24) Yuma, fine sandy loam.

where water is valuable. In California many canal systems are lined throughout, but in other localities only those portions of canals are lined in which seepage losses are greatest. Canal linings are beneficial in reducing operation costs and also in reducing friction losses.

Concrete Linings range in thickness from 1/2 to 5 in. Fine aggregate should be used for the thinner linings. Proportions of cement to aggregate vary from about 1 to 8 for the thicker linings to 1 to 4 for the thinner linings. Concrete linings should reduce seepage 75 to 95%, the thicker linings being more effective. The slopes of banks should not be less than the angle of repose of the material in which the canal is situated. Canal linings of cement mortar 1/2 to 1 in. thick in western United States have given excellent service. By using a comparatively dry mixture, concrete can be placed without forms on banks having a slope of 1 to 1. For steeper slopes, forms are necessary.

Losses Per Day in Canals of the United States Bureau of Reclamation

Depths in feet per square foot of wetted area

Soil	Number of observations	Maximum	Minimum	Mean
Gravel and sand	2	3.62	1.44	2.53

Approximate Costs of Concrete Canal Linings in Western United States

Thickness of lining, inches	Cost, cents per sq. ft.	Thickness of lining, inches	Cost, cents per sq. ft.	Thickness of lining, inches	Cost, cents per sq. ft.
1/2	3.1 to 4.4	1-1/2	5.3 to 7.5	3	8.3 to 12.1
3/4	3.8 to 5.1	2	6.3 to 9.0	4	10.5 to 15.4
1	4.3 to 6.0	2-1/2	7.3 to 10.8	5	12.6 to 18.5

Gunite Lining, 1 to 1-1/2 in. thick, has proved to be very effective in preventing seepage. Wire-mesh reinforcing is usually placed near the center of the lining. Satisfactory proportions of cement to aggregate are 1 to 4 or 5. All stone in the aggregate should pass a 1/2-in. screen. The cost of such lining, including reinforcing but not including grading, varies from 7 to 11 cents per sq. ft.

Oil Linings are made by sprinkling 1 to 3 gal. of crude oil per square yard on the sides and bottom of the canal. Several light applications are used, and in some cases the surface is worked with a rake or harrow after each application. Good results have been obtained, however, by leaving the surface undisturbed after applying the oil. The oiled surface is generally rolled or otherwise compacted. Experiments indicate that oil linings when new will reduce seepage losses in canals 50 to 75%. They deteriorate, however, and their effectiveness diminishes with age. The average cost of preparing oil linings in the United States, not including the cost of the oil, has been about 1.5 cents per gallon of oil used.

Clay Puddle Linings have been used in localities where suitable material is available within a reasonable distance. The clay is deposited in a layer 3 to 6 in. thick along the bottom and sides of the canal, after which water is turned into the canal and the material is puddled by harrows or the tramping of animals. A good clay puddle lining will reduce the seepage loss 60 to 80%. It does not deteriorate, but becomes more effective with age. Fine surface soil thrown into a canal containing water and thoroughly stirred up by teams dragging heavy chains or otherwise agitated has in some cases been quite effective in reducing seepage.

Hydraulic Sluicing has been used to stop bad leaks in canals. Fine material for sluicing must be available. The sluiced material should be deposited directly on the porous area so as to cover it with a thin blanket. Very bad leaks in shale, gravel, and seamy rock have been successfully treated by this process.

5. Water Supply

Total Water Supply. One of the first considerations in the investigation of an irrigation project is the determination of the amount of water available for the project. The discharge of the stream or streams forming the source of supply should be carefully investigated. A knowledge of the distribution of the flow as well as the total annual discharge for a period of years is essential. The best data on which to base an estimate of future discharge are continuous discharge records covering a period of years. Such records, for many streams in the United States, are published in the Water Supply and Irrigation Papers of the U. S. Geological Survey. They may also in some instances be obtained from state engineers' offices or from private sources. On many streams, however, available discharge records cover only a comparatively short period or they may be entirely lacking. It also may be found that discharge measurements on a stream have been made at a place quite remote from the proposed point of diversion. Precipitation records are valuable for supplementing incomplete stream discharge data. Such records, published by the U. S. Weather Bureau, are available at one or more points for practically every drainage basin in the United States.

The safest data for estimating future discharges are actual discharge measurements, near the place of diversion, covering a period of not less than ten years. A record for this period will probably include ordinary high- and low-water stages of the stream, and show the general distribution of flow throughout the year. If a project is under investigation and discharge records near the place of diversion are not available, a gaging station should be established at the first opportunity. If there is any doubt as to the adequacy of the water supply for a proposed project, construction work should be delayed until supplementary data sufficient to provide a satisfactory estimate of discharge have been obtained. In general, at least two years of continuous discharge records should be available near the place of diversion and these should be supplemented with such additional data that a reasonably reliable record for a period of at least ten years may be estimated.

Prior Rights to Water. In estimating the water available for irrigation from a given stream, all prior rights should be investigated. In western United States the streams are controlled by the states and the laws regulating the use of the streams are not uniform and are continually being changed by new statutes and court decisions. The state laws governing the stream should therefore be understood. The waters of some streams have been adjudicated by the states and in such cases records of prior rights are obtainable at state engineers' offices. In many instances it will be found that the records of water rights are in such a condition that an examination of each canal diverting from the stream must be made to determine the amount of water actually used and the area of land under it that is entitled to water.

Water Supply Available. The difference between the total water supply and the quantity of water represented by prior appropriations gives the water supply available. The estimate of available water supply is usually prepared by months by deducting from the discharges for each month of the period covered by measured or estimated discharges, the water represented by prior rights for corresponding months. These differences give the estimated amount of water that would have been available for each month during the period considered and if the period is long enough (preferably at least ten years) they may be taken to represent the available future supply.

The Water Supply Required for a given area will be that necessary to provide for the irrigation of crops and in addition all seepage and evaporation losses in canals and reservoirs. (Arts. 3 and 4.) An estimate of the water supply required should be prepared for each month by adding the estimated seepage, and evaporation losses. By comparing the water available with the water required, the deficiency for any month of the period covered by records may be determined. If storage is to be provided, such deficiencies will give the amount of storage required. About 20% of an irrigable area will be occupied by roads and buildings or for other reasons will not be irrigated. This area should be deducted for purposes of estimating water requirements for an irrigation project.

6. Conduits

The Conveyance System which delivered water from the place of diversion to farm laterals may include canals, flumes, pipes, and tunnels as well as many auxiliary structures such as drops, wasteways, and turnouts.

Canals (See Sect. 15, Art. 24). The canal section of a given area which will have the greatest capacity, other things being equal, is the one having the greatest hydraulic radius. Such sections are usually not practicable for earth canals. As commonly constructed (Figs. 1 and 2), $b = 3d$ to $4d$, $a =$

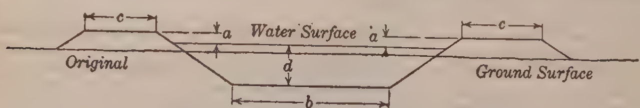

Fig. 1. Canal Section for Level Ground

$0.4d$ to $0.6d$, $c = 1d$ to $2d$. Canal banks in level ground and on the downhill side of sloping ground are usually given a slope of 1 on 2 or 1 on 1-1/2. The uphill slope may be made as steep as 1 on 1 to reduce excavation. There should be an allowance of 10% for waste and shrinkage in embankments.

Velocities in Earth Canals. Canals should ordinarily be designed to carry water at the highest velocity that can be maintained without erosion. This is the most economical velocity since it gives the smallest canal section and therefore the lowest construction cost practicable, and permits a minimum deposition of silt. The velocity at which erosion begins varies with the size of soil particles and the cohesive properties of the material forming the canal surfaces. Colloidal matter either in the material in which the canal is situated or in the water carried by the canal tends to cement soil particles in such a way as to resist erosion.

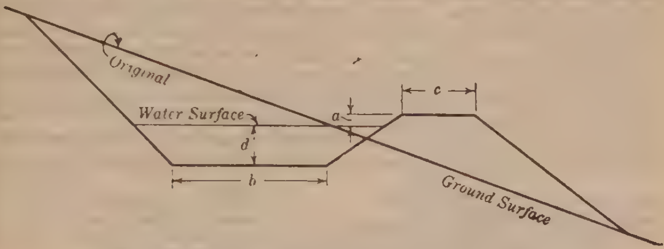

Fig. 2. Canal Section for Sloping Ground

The Age of a Canal has an important bearing on the velocity at which erosion occurs. The erosive velocity may be twice as high in a canal after several years of use as it was when the canal was new. Seasoned canal beds contain particles of different sizes and when the interstices are filled by the smaller particles the mass becomes more dense and stable, and less subject to erosion.

Permissible Canal Velocities after Aging

Recommended in 1926 by Special Committee on Irrigation Research, American Society of Civil Engineers

Velocities in feet per second

Original material excavated	Clear water, no detritus	Water transporting colloidal silts	Water transporting non-colloidal silts, sands, gravels, or rock fragments
Fine sand, non-colloidal	1.50	2.50	1.50
Sandy loam, non-colloidal	1.75	2.50	2.00
Silt loam, non-colloidal	2.00	3.00	2.00
Alluvial silts, non-colloidal	2.00	3.50	2.00
Ordinary firm loam	2.50	3.50	2.25
Volcanic ash	2.50	3.50	2.00
Fine gravel	2.50	5.00	3.75
Stiff clay, very colloidal	3.75	5.00	3.00
Graded, loam to cobbles, non-colloidal	3.75	5.00	5.00
Alluvial silts, colloidal	3.75	5.00	3.00
Graded, silt to cobbles, collodial	4.00	5.50	5.00
Coarse gravel, non-colloidal	4.00	6.00	6.50
Cobbles and shingles	5.00	5.50	6.50
Shales and hardpans	6.00	6.00	5.00

Canals in Rock are excavated with steep side slopes, commonly 1 on 1/4, and with bottom widths not more than two times the depth. They are also sometimes built with a semicircular cross-section. Canals excavated in rock are usually lined with concrete. For canals in hardpan or other indurated material the conditions are intermediate between those for earth and rock.

Flumes (see Sect. 15, Art. 15) are used to convey water across streams, ravines or other depressions of the ground, and also around hillsides to avoid difficult excavation. They are built of wood, steel and concrete, or of combinations of these materials. The substructure may consist of piers or posts of concrete or of wooden or steel posts or trestles. Trestles should be braced longitudinally and posts should be well tied together with both transverse and longitudinal bracing. Concrete bases or mud sills may be used for supports. Flume channels usually have rectangular cross-sections when constructed of wood or concrete and semicircular cross-sections when constructed of steel. Fig. 3 shows a steel flume with wooden substructure and concrete pedestals. Short flumes have been built more than 100 ft. high, but as a rule flumes are

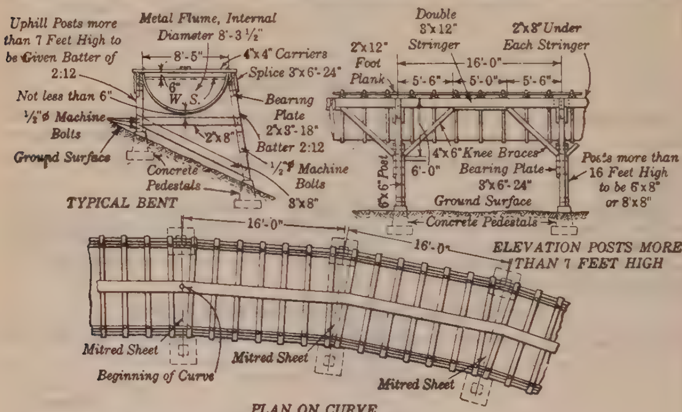

Fig. 3. Steel Flume with Wooden Substructure

better adapted to conditions where the height is not much over 20 ft. For greater heights, especially for long depressions, pressure pipes will usually be more economical.

Pressure Pipes (see Sect. 14, Art. 21 and Sect. 15, Arts. 13 and 14) for irrigation purposes are usually built of wood, steel, or reinforced concrete. For small quantities of water, if the pressure head does not exceed 20 ft., vitrified sewer pipe and plain concrete pipe have proved satisfactory. Pressure pipes are used to carry water across depressions or around steep hillsides; small pressure pipes may be used as laterals for distribution systems.

Reinforced-concrete pipes are best adapted to pressure heads of less than 100 ft. Wood-stave pipes have been used for heads of 300 ft. or more, though 250 ft. is probably very near to the economical limit of such construction. For the higher heads, steel is used exclusively. The average life of steel pipe is greater than that of wooden pipe, but the life of each is dependent upon the care with which it is maintained. (Art. 32.) Under ordinary conditions of use, concrete pipe should last indefinitely. Wooden pipe being smoother than concrete or steel has a greater capacity for a given diameter. Deposits will form on the inner surface of a steel pipe, which may reduce its capacity as much as 25% after a few years of service. In determining the most economical pipe for a given locality, where continuous service is required, the first cost, life, and carrying capacity of each kind of pipe should be considered. Fig. 4 is an example of a wood-stave pipe, as manufactured by the Washington Pipe and Foundry Company.

Tunnels (see Sect. 15, Arts. 32 to 41) may be constructed across points to shorten canal lines, or through divides to divert water to a different drainage basin. They are also built in the sides of rocky canyons where canals, flumes, or pressure pipes would be expensive to maintain. In difficult side-hill location, the water may be carried successively in canals, flumes, tunnels, or pipes, following each other in any order.

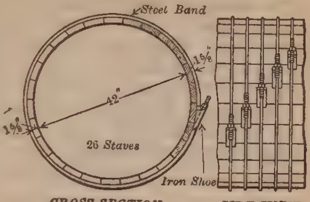

Fig. 4. Wood-stave Pipe

Tunnels for irrigation purposes are usually lined with concrete, though short tunnels in firm rock are sometimes left unlined. Concrete linings serve the double purpose of preventing caving of tunnels and of reducing resistance to the movement of water, thus increasing their capacities. The minimum dimension of the cross-section of a tunnel, except for the very short tunnels, should not be less than 6 ft. and preferably 7 ft. in order to allow free movement of the workmen. Beyond this limit they should be kept as small as practicable in order to reduce the cost. Velocities of 10 to 12 ft. per second in concrete-lined tunnels are permissible. Fig. 5 shows a cross-section of the Strawberry Tunnel, Utah.

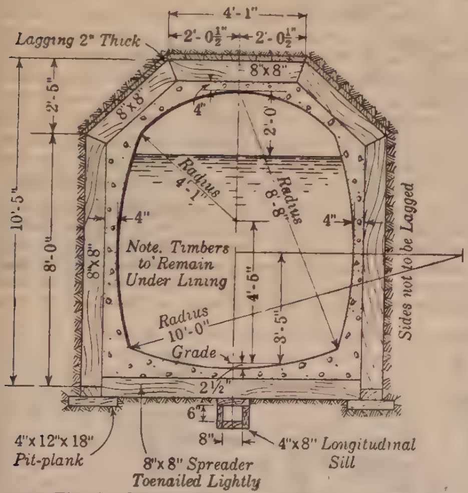

Fig. 5. Strawberry Tunnel, Shale Section

The Grade and elevation of water surface at the controlling points of a canal system should be thoroughly investigated. Special consideration is required wherever a change in the velocity of the water occurs. When water from a canal enters a pipe or culvert, changing to a higher velocity, allowance should be made for velocity head and head lost at entrance. A similar allowance should be made where a canal is changed to a smaller section. In this case the difference in elevation of water surfaces above and below the change in section represents head allowance for entrance conditions and change of velocity. If change from a higher to a lower velocity is made gradually some of the velocity head will be converted into static head.

In designing a canal or other structure for the passage of water the engineer should make liberal estimates of capacities. Uncertainties as to the proper values of coefficients necessarily exist and in general it will be safer to design a structure with a capacity slightly greater rather than less that required.

7. Drops and Chutes

The Grade in Earth Canals should be ordinarily that which will give the greatest velocity that may be carried without eroding the sides or bottom of the channel. When, therefore, it is desired to drop an earth canal to a lower elevation, the excess grade must be taken up by a structure designed for the purpose. The function of such a structure is to maintain the normal velocity of the water in the upper canal and deliver it at the normal velocity to the canal at the lower elevation. Two types of structures, commonly called Drops and Chutes, have been used for this purpose.

Drops are structures which concentrate the fall at one or more points. They usually are built of concrete or wood, the latter being satisfactory for temporary construction. The essential parts of a drop are the brest-wall, which extends across the channel and connects the upper and lower canals, the water cushion or platform on which the water falls, the various wing walls which connect the structure to the sides of the canal, and the canal linings, which prevent erosion immediately above and below the structure. The brest-wall extends from the elevation of the highest water surface in the upper canal to the bottom of the lowest part of the structure. Sufficient opening should be left in the portion of the brest-wall which extends above the bottom of the upper canal to discharge just the required volume of water while maintaining the normal depth of water in the canal. The opening in the brest-wall may be either a weir or one or more notches. Trapezoidal notches, having the narrower of the two parallel sides flush with the bottom of the canal, are frequently used. Such notches may have semicircular lips projecting from the base which cause the water to spread out and reduce the impact of the fall.

The notched form of fall crest with water cushion below has been used with excellent results. It appears to reduce the difficulties from erosion above and below the fall. Steel rails placed under the fall have not proved very satisfactory. Cutoff walls should be built into the backfilling, which should be moistened and thoroughly tamped to prevent the water from breaking through. Reinforced concrete has largely replaced other materials for the construction of drops. Fig. 6 shows a section of a 10-ft. drop

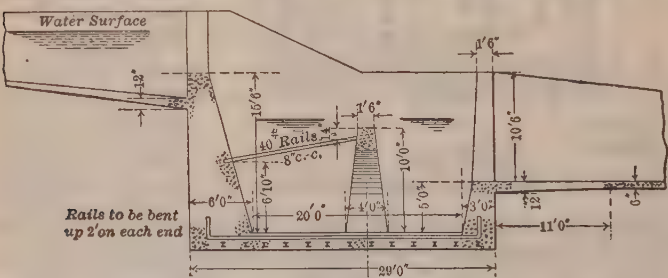

Fig. 6. Drop with Grating and Water Cushion

with grating and water cushion at Uncompahgre, Colorado. Ordinarily, drops are not built more than about 15 ft. high. For greater heights two or more drops in a series may be used. The amount of excavation for the canal leading from the drop increases as the slope of the ground decreases. In gently sloping ground a series of low drops may therefore be more economical than one higher structure.

Chutes are either lined canals or flumes, constructed on steep grades which connect two canals of different elevations. In addition to the conduit a chute must have a structure at the entrance to connect it to the upper canal and a structure at the exit to retard the velocity of the water before discharging it into the lower canal. The opening at the entrance to the chute should be just large enough to discharge the required volume of water while maintaining the normal depth of water in the canal. The conduit usually discharges into a water cushion in which baffles may be built to help break up the high velocity of the water. Canals should be paved for a short distance above and below the chute. The conduit may be of any length, and chutes several hundred feet long are not uncommon. Chutes with short conduits built on steep inclines are used in place of drops Fig. 7 shows a reinforced concrete chute with a short conduit, of the Okanogan project, Washington.

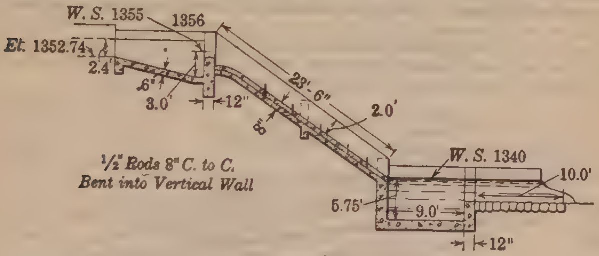

Fig. 7. Reinforced Concrete Chute

The velocity of water in a chute will accelerate until it is just great enough to overcome the frictional resistance. To determine the required dimensions of the conduit it should be divided into short reaches and the hydraulic computations made for each reach. The rate of reduction in area of the cross-section of the conduit will be more rapid at the upper end.

8. Minor Structures

Canal Crossings for Natural Waterways. At every place where a canal crosses a natural drainage channel, whether such channel carries water continuously or at infrequent intervals, provision must be made for conveying the natural drainage to the lower side of the canal. This may be done in either of the following ways: (1) by carrying the water under the canal; (2) by carrying the water over the canal; (3) in the case of small flows which may be expected only at rare intervals, by allowing the water to flow into the canal with provisions for it to escape over the opposite embankment; (4) by intercepting ditches above the canal which collect the drainage from small channels and convey it to some other channel for which a crossing is provided. Before designing a structure for this purpose a careful estimate of the maximum flow that the channel may be expected to carry should be made, and a liberal waterway should be provided in all cases.

If the bottom of the canal is high enough natural drainage waters in small quantities may be carried under the canal in culverts or pipes. For crossing streams where large flows may be expected, it will generally be safer to convey the canal water over the stream in a flume, preferably supported by a truss, or under it in a pressure pipe. Short flumes or overchutes are sometimes used to carry small quantities of water over canals. Where drainage water is allowed to enter a canal a depression should be left in the upper embankment which, together with a short section of the canal, is usually lined with concrete. The objection to this method is that sediment is washed into the canal.

Wasteways are structures which may, in an emergency, divert the entire flow of a canal into a natural drainage channel. They are intended primarily as a safeguard to the canal and should preferably be located above the weaker portions where breaks are most likely to occur. In case of a break or other trouble, if there is a wasteway above, the water may be turned out of the canal more promptly than if the headgate alone must be relied upon for this purpose and the resulting damage will be less.

The essential features of a wasteway are a system of gates in the lower embankment of the canal and provision for diverting the water through them. Many different types of wasteways have been built. Usually the gate sills are placed at an elevation lower than the bottom of the canal in order to increase the head on the gates. A low submerged weir is sometimes placed across the canal below the gates to help divert the water through them. A similar weir upstream from the gates will retard the velocity of the water in the canal when the gates are open and reduce the erosion above the structure. If built in earth, the canal for a short distance above the wasteway and the channel leading from it should be concrete lined or paved. Fig. 8 shows a wasteway of the Umatilla project, Oregon, with a tunnel outlet.

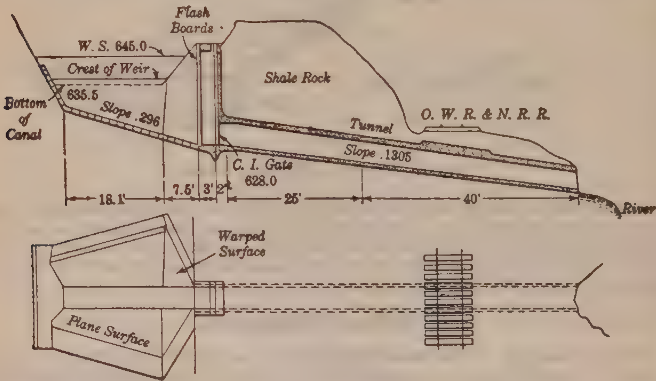

Fig. 8. Wasteway from Canal

Spillways are constructed by depressing the lower embankment of a canal to the elevation of the highest water surface which the canal is designed to carry. A spillway in an earth canal should have its crest and both slopes of the embankment lined with concrete. Spillways protect a canal against overflow, when drainage water enters it, when the water is backed up by an obstruction in the canal, or when a sudden rise in the stream from which the diversion is made allows too great a volume of water to enter the headgates.

Bridges must be provided where a canal is crossed by road or railway. Highway bridges may be built of wood or steel, or concrete arches may be used. Wooden bridges resting on concrete piers and abutments are in very common use. For earth canals, where the velocity of the water is low, piers or posts in the channel are not objectionable except that they create a slight tendency to erosion in their vicinity.

At Railway Crossings if the roadbed is too low to allow clearance for the water under a bridge, short pressure conduits are used. Fig. 9 shows a crossing of the feed canal of the Umatilla Project under the O. W. R. & N. Railway. To secure minimum loss of head in changing from one cross-section to another the transition should be made gradually and all corners should be rounded.

Where large changes in velocity are involved, the practice of the United States Bureau of Reclamation is to make the length of transition structures (particularly outlets) such that a straight line joining the flow lines at the two ends will make an angle of about 12-1 2 degrees with its axis; and to so design the structure that the computed water-surface profile through the transition shall be a smooth, continuous curve, approximately tangent to the water-surface curves in the channels above and below.

See: Julian Hinds, The Hydraulic Design of Flume and Siphon Transitions, Proc. Am. Soc. C. E., October, 1927.

Sand Gates and Sand Traps. Streams used for irrigation frequently carry large quantities of silt, especially during flood stages. Diversion works on such streams may be designed to exclude a portion of the silt, but some of it

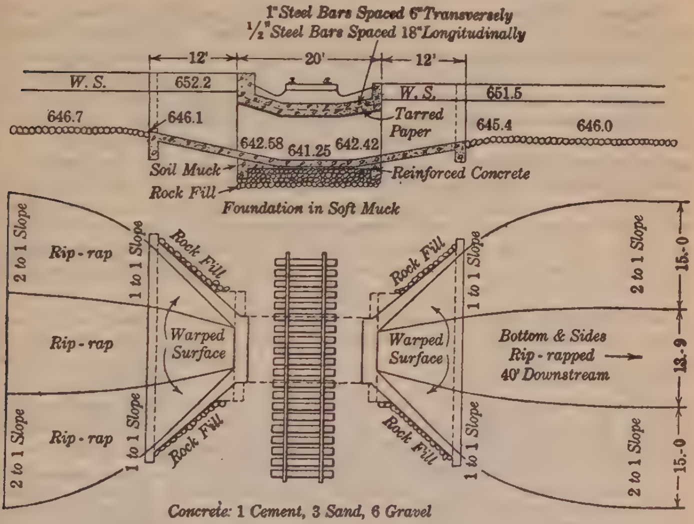

Fig. 9. Canal Crossing under Railroad

will usually enter the canal. The finest sediment is carried in suspension through the canals to the land being irrigated whereas the coarser material is rolled along the bottom, finally depositing in the canal and reducing its capacity. The water in canals acting as feeders to reservoirs should be made as free from silt as practicable in order to reduce to a minimum the deposition of silt in the reservoir.

Different types of structures have been designed to remove the coarser material carried by canals. In general such structures consist of an enlarged canal section which terminates in a low weir placed across the channel or a basin having its bottom depressed below the subgrade of the canal, with sluice gates at the lower end. Owing to the retarded velocity of the water at this place the coarser sediment will move closer to the bottom or be deposited and a portion of it may be scoured out or allowed to pass out through the sluice gates. Frequently sand traps are built a short distance below headgates to remove the sediment as soon as possible after it enters the canal. In such cases, when there is more water in the river than is required for the canal, the sluice gates may be left open allowing a continuous discharge through them. If there is no surplus water, the gates are opened only occasionally for sluicing out the sediment which has been deposited. Sand traps built on this plan may also serve as wasteways, or regulating works.

Telephone Systems are essential for the proper operation of large irrigation projects. Telephone booths should be placed at intervals along main canals and at other critical points and should be connected to the operator's house at the headgate. This enables the water to be shut off promptly in case of a break in the canal or other trouble and also assists in the economical distribution and delivery of water.

9. Diversion Works

Purpose. Wherever water is diverted from a natural stream into an artificial conduit some form of diversion works is necessary. This usually consists of a diversion dam or weir, which controls the elevation of the water surface in the stream, and a headgate, just above the diversion dam, which regulates the amount of water allowed to enter the canal. Sluice gates through the dam and adjacent to the headgate or other devices to prevent the entrance of silt into the canal may be provided. Structures, called *regulating works*, are sometimes constructed a short distance below headgates for the purpose of diverting surplus water back into the stream. With such a structure the amount of water entering the canal may be more effectively regulated than when the headgate alone is relied upon for the purpose. A sand gate is frequently combined with the regulating works. The laws of most states require that fish ladders must be constructed in dams across natural streams. In some cases logways must also be provided.

Low Diversion Dams. In general, when the diversion is made at a place where the stream lies in a flat sedimentary bottom, the natural regimen of the stream should be changed as little as possible. Under such conditions a very low dam or weir is preferable. If the stream has a flood plain subject to inundation, the diversion dam should extend across the natural channel of the stream and earth embankments several feet higher than the highest flood stage should connect the structure to the higher land on either side of the stream.

Low diversion dams are commonly built of concrete or wood or a combination of the two. Concrete dams are usually constructed on rock formations. For earth or gravel foundations, a substructure consisting of a rock and timber grillage or bearing piles tied together with walings and caps covered with a deck of heavy planking, will be satisfactory provided it is built low enough to be continually submerged. On this substructure either a wooden or concrete weir may be built. Fig. 10 shows a plan of the diversion works and a cross-section of diversion weir of the Umatilla project, Oregon.

High Diversion Dams may be built where a suitable site is available. Any type of dam may be used for this purpose, the problem being similar to that encountered in constructing a dam for other purposes. High diversion dams may be built in rock canyons to avoid expensive canal construction, the proper height being that which will result in the lowest combined cost of canal and dam.

Between the highest and lowest types of diversion weirs any intermediate height may be used. Each diversion presents special features and the height and type of dam must be chosen to conform to them. Collapsible weirs may be used when it is required to reduce the flood elevation of the water above the dam. Temporary brush and rock dams are sometimes used for diverting water into small canals.

Headgates control the entrance of water into the canal. They are preferably built on the line of the bank of the stream at right angles to the diversion dam. They should be joined to the diversion weir so as to form part of the same structure with it. Headgates usually consist of a series of gates separated from each other by piers. The piers rest upon a floor, of the same elevation as the bottom of the canal, which should be of sufficient thickness to give the required strength and stability. Cutoff walls should be provided to prevent erosion and excessive seepage beneath and around the structure. The

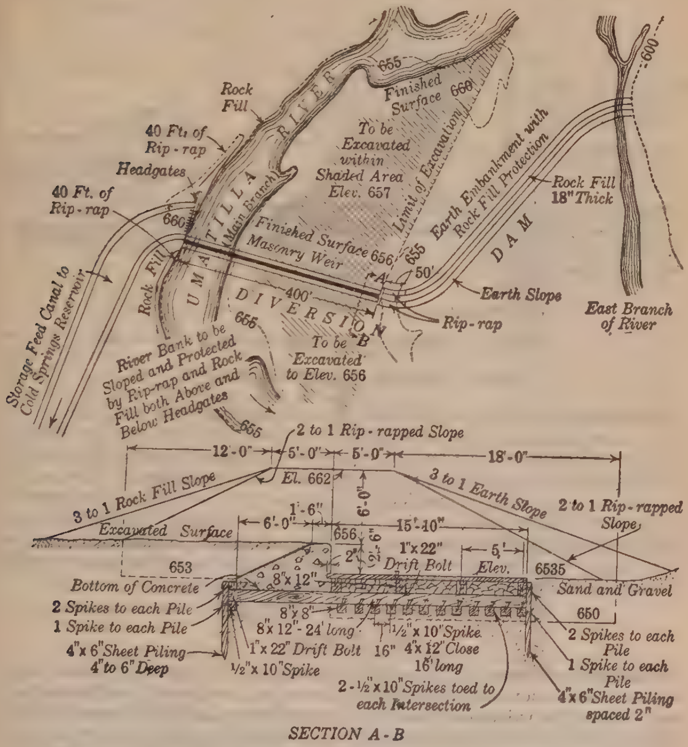

Fig. 10. Low Diversion Weir with Earth and Gravel Foundation

width of gate opening will be the distance between piers and the height of opening is regulated by curtain walls between the piers. A walk is usually built across the top of the structure and hoisting devices to operate the gates rest upon the walk. Gates should preferably be of such a size that they can be operated by one man. The total gate opening should be sufficient to discharge the maximum capacity of the canal in the contingency that one gate cannot be operated.

Headgates are commonly built of concrete, but wood may be used for temporary construction. Gates may be made of cast iron, steel, or wood. They are usually set in steel or iron guides embedded in the concrete. The bottom and sides of an earth canal should be protected by riprap or concrete lining for some distance below the headgate to prevent erosion. Headgates diverting from streams which carry drift during flood stages should have the noses of piers protected by fenders to prevent clogging of the gate openings. Fig. 11 is a cross-section of the headgate shown in Fig. 10.

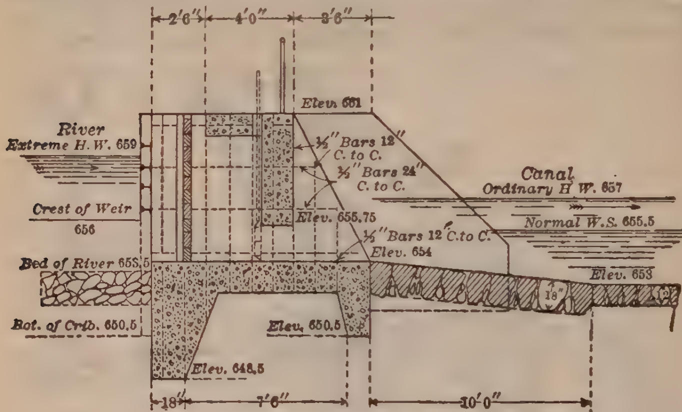

Fig. 11. Headgate for Low Diversion Weir

Sluiceways are openings in a diversion weir, usually adjacent to the headgate. They may consist of open panels in the weir or gates near the base of the weir. The latter are especially adapted to the higher dams. Sluiceways are necessary only on streams that carry considerable sediment. They serve to keep an open channel immediately in front of the headgates and to prevent the heavier sediment from entering the canal. They may also be used to regulate the elevation of the water surface above the dam. Sluiceways must be kept closed when it is desired to divert all of the water in the stream, but with a surplus of water they may be left partially or entirely open.

10. Storage

Necessity for Storage. Storage is essential to the complete utilization of a stream for irrigation purposes. Only those waters are directly available which flow during the irrigation period and are not in excess of the immediate requirements of the area which they serve. Without storage all water in excess of that which is directly available must be wasted. On many streams, further development for irrigation purposes is restricted to the use of stored waters.

Storage Reservoirs. The possibility of economical storage is dependent upon the availability of suitable reservoir sites. Natural lakes or basins may be used for storage when a suitable dam site exists at the outlet. A reservoir may be located on a stream from which water is diverted, or on a tributary of this stream. The water supply from a tributary may not be sufficient to fill a reservoir located upon it, in which case the flow may be supplemented by a feeder canal diverting from some other stream. If conditions are favorable water may be taken through a canal or tunnel from an adjoining watershed.

An investigation of the feasibility of storage for a stream should include a complete reconnoissance of the drainage basin. Each possible site should be first roughly investigated to determine approximate data relative to capacity, character of dam site, geological formation of the area to be flooded, availability of construction materials, value of rights of way and other information relative to the cost and value of storage. From these data the sites appearing to possess the greatest merit may be selected and a more thorough investigation may be made of them. Topographic maps of reservoir sites are indispensable in computing capacities.

Seepage and Evaporation from Reservoirs. One of the first considerations in investigating the feasibility of a proposed reservoir should be to make a careful study of the geological formation of the area to be flooded with a view to estimating possible seepage losses. Many instances can be cited where, after construction, reservoirs have proved worthless because of their inability to hold water. Such a condition results in great financial loss and humiliation to the responsible parties. The problem requires the mature judgment of the most experienced engineer. No rules can be laid down which will be safe guides in all cases. In general, it may be stated that seepage losses from basins lying in rock (not volcanic rock) or clay will not be excessive. Reservoirs built in formations of fine loam or volcanic soil have generally given satisfaction, although seepage losses from such reservoirs have been greater than from those lying in rock or clay. If any portion of the banks or bottom of the reservoir is formed of sand or gravel even though it may be overlain with a blanket of fine soil, and such sand or gravel might form an underground channel leading around or under the impounding dam or to some other drainage basin, there is grave danger of excessive seepage loss. On account of the large areas involved, efforts to reduce seepage in reservoirs by clay puddle or other methods have usually been unsatisfactory. If the water flowing into the reservoir carries much sediment, there will be a tendency for the reservoir to silt up and reduce seepage losses. Seepage losses from reservoirs in rock or clay formations should not be more than 5% of the inflow, and in fine loam or other soil probably not more than 10 or 20%. In coarse sand or gravel they may be anything up to the entire inflow. In determining the net supply of storage water evaporation losses should be deducted. These may be obtained from tables of evaporation losses from free water surfaces. (See Sect. 3, Art. 19.) The apparent capacity of a reservoir may be considerably increased by **bank storage.** (See Sect. 13, Art. 43.)

The following rules of caution are given by A. P. Davis (Engineering News-Record, April 4, 1918, p. 665):

1. Avoid reservoirs adjacent to gypsum deposits and to limestone deposits which show evidence of caves. 2. Examine critically reservoirs in volcanic rock, as a few have failed in such locations. Coarse-grained sandstone seems to be an object of suspicion and should be critically examined. 3. Natural depressions are treacherous and should be examined with care, and if they are near deep canyons or underlain with coarse material where water might readily escape, no superficial tightness will avail to make them effective.

Storage Problems commonly encountered in irrigation work are the determination of reservoir capacity to supply a given quantity of water at specified rates of use, and determination of the amount of water available for irrigation from a reservoir of given capacity. Where a reservoir receives all or a part of its water through a feeder canal it will also be necessary to determine the capacity of canal required to supply the storage. The solution of such problems may be readily accomplished by applying the principles of the mass diagram. (See Sect. 13, Art. 43.) In all cases irrigation water will be drawn from the reservoir at a variable rate and the use line will be curved.

11. Distribution Systems

The Function of a distribution system is to convey water from the main canal to each parcel of land to be irrigated. Water is usually diverted first into main distributing canals, then into main laterials and sub-laterals, and finally into the farmers' ditches, from which it is applied directly to the land. Because it is desirable to have as few openings as possible in the banks of main canals in order to reduce the danger from washouts, farm ditches should divert from laterals and sub-laterals rather than from main canals. The distribution is usually made through a system of earth canals, but where water has a high intrinsic value, or where seepage losses would otherwise be excessive, water may be delivered in flumes, pipes, or lined canals.

Location. Water should be drawn at proper intervals from main canals into moderate sizes branches so located as to command the greatest area and serve the land in the most direct manner practicable. The distribution is most economically affected when the main distributing canals are located along the tops of ridges so that they can supply water to laterals on either side. The laterals likewise should conform to the dividing lines between water-courses. It may not be found practicable, however, to conform rigidly to this plan. On flat areas distributing canals may be run along or parallel to property lines. Fig. 12 illustrates distributing canals and laterals diverting from a main canal.

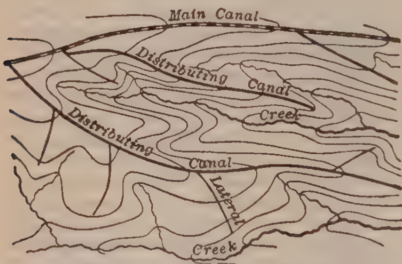

Fig. 12. Distributing System.

A Topographical Map of the area to be irrigated, with a contour interval not more than 5 ft., should be prepared before attempting the design of a distribution system. In addition to topographical features, this map should show non-irrigable lands and other areas to be excluded from the project. Special features, such as vegetation, property lines, improvements and soil formation, are in some instances required to be shown.

Design of Distribution System. In general, the entire distribution system should be planned, and the scheme for irrigating each part of the project should be worked out before any construction work is begun. This should be done even though the construction for a portion of the system is to be deferred for some time. As the plan is developed the position of all canals, flumes, pipes, and other structures should be projected on the topographic map, and the area to be irrigated under each should be determined.

Capacities of Canals should be based upon the water requirements for the period when the greatest amount of irrigating will be done. It is customary to determine the number of acres that will be served by 1 cu. ft. per sec. during the period of maximum requirements. The required capacity of main canals and distributaries may vary from 1 cu. ft. per sec. for each 120 to 150 acres irrigated, for fruit lands where the water supply is fairly uniform and maximum economy in the use of water is practiced, to 1 cu. ft. per sec. for each 50 acres irrigated, where the supply of water is available for comparatively short periods and conditions are otherwise unfavorable. For diversified crops where the water supply is regular a capacity of 1 cu. ft. per sec. for each 70 to

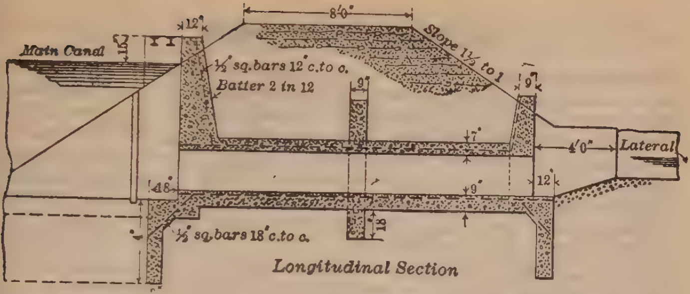

Fig. 13. Reinforced Concrete Turnout to Lateral

90 acres irrigated is commonly used. The capacity of farm laterals should not be less than the maximum head to be used in irrigating. This will vary from 1 to 2 cu. ft. per sec. where furrow irrigation is practiced to 5 to 10 cu. ft. per sec. for flooding methods. If rotation irrigation is to be practiced the capacity per unit area served should be greater for laterals than for main canals in order to provide flexibility in operation. In general, an allowance for seepage and evaporation should be added to the above figures.

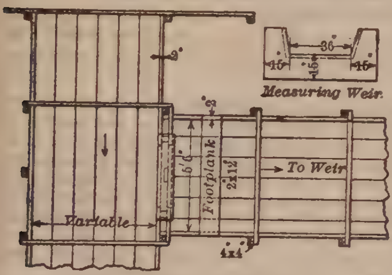

Fig. 14. Wooden Head to Lateral

Structures for Distribution Systems are similar to those for main canals. Turnouts must be provided where water is diverted from main canals to distributaries and at the heads of all laterals. Flumes or pressure pipes are constructed for carrying water across depressions. Drops are required in earth canals where the slope of the ground is greater than the allowable grade. These structures may be built of wood or concrete. Wood is more commonly used for the small turnouts and lateral heads. Measuring devices, generally weirs, are placed at the heads of farm laterals. Figs. 13, 14, and 15 are examples of structures for distribution systems.

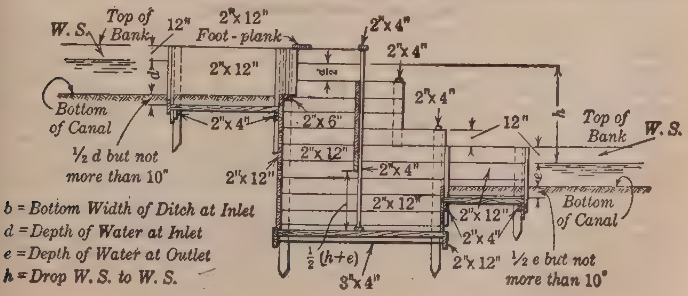

Fig. 15. Wooden Drop for Lateral

12. Irrigation by Pumping

Surface Water Supply. Water may be pumped from a natural stream or a canal. Areas lying above the main canals of gravity projects are sometimes irrigated from these canals by pumping. In some instances turbines are installed at drops in canals and either direct-connected to pumps or connected to generators from which power is transmitted to pumping plants. Such installations provide very cheap power for pumping. Often pumps may be considered an alternative to an expensive diversion and conveyance system. The comparative costs of irrigation by pumping and by gravity should be estimated on the basis of annual costs.

In 1923, about 150 pumping plants costing $2,360,000 were being operated for irrigation and drainage on projects of the United States Bureau of Reclamation. A statement of the cost of operation and maintenance of these plants, not including interest and depreciation (Berry Dibble; Engineering News-Record, July 26, 1923) is contained in the table on page 1677.

Wells. The essentials of a satisfactory pumping plant using well water are: (*a*) an ample supply of water of quality suitable for irrigation and near enough to the surface for economical pumping; (*b*) a pump adapted to the conditions as to lift and quantity to be pumped; (*c*) an engine or motor that will furnish the required power with the maximum efficiency and the minimum cost; (*d*) a plant carefully planned and installed.

The well casing should be of a standard type such as screw, riveted, or stovepipe casing, and the portion in contact with water-bearing strata should be perforated so as to admit water in sufficient quantities and to screen out gravel. Casing 6 to 24 in. in diameter are used, 16 in. being a common diameter for irrigation wells. Before pumping equipment is purchased the well should be thoroughly tested to determine its capacity and drawdown. Types of pumps commonly used for irrigation are the vertical and horizontal centrifugal, the deep-well turbine centrifugal, the plunger, and the air-lift. The height of lift is the chief factor governing the type of pump. The power may be supplied by an electric motor or by an internal-combustion engine. (See Farmer's Bulletin 1404, U. S. Dept. of Agriculture, by P. A. Ewing.)

The Cost of Pumping from Wells 100 to 200 ft. deep having capacities of 0.5 to 2 cu. ft. per sec., including 15% for interest, taxes, and depreciation in addition to all operating costs, varies from $2 to $16 per acre-foot of water pumped. Among the factors affecting cost of pumping are: cost of power, lift, capacity, and efficiency of plant. The effect of the last two factors on cost is shown in the table below.

Cost, for Power Only, of Raising Water per Acre-foot with Power at 1 Cent per Horsepower-hour

Pump efficiency	Head in feet									
	10	20	30	40	50	60	70	80	90	100

13. Preparation of Land

Clearing. Arid lands are usually covered to some extent with native vegetation. This may consist of grasses and small brush which can be plowed under, or heavy brush or scrub trees. All surface vegetation and roots that will interfere with the cultivation of the land should be removed and burned.

Sagebrush is the most widely distributed of all desert plants. It commonly attains a height of 2 to 5 ft. A substantial growth of sagebrush usually indicates fertile soil. Sagebrush may be removed by grubbing, or broken off by a team dragging a steel rail over it, or by other special devices. The cost of clearing land of sagebrush usually varies from $5 to $9 per acre. The cost of removing large brush and trees may be $30 to $90 per acre. The cost varies with the size of plant, thickness of growth, and labor conditions.

Grading. An accurate topographic map of the area to be graded should be obtained and the method of irrigation (see Art. 14) to be adopted should be given careful consideration. A study should be made of all factors affecting economy and efficiency in the use of water. A detailed plan for grading the tract should then be prepared. The cost of grading smooth areas may be less than $10 per acre. For rough or rolling areas the cost may be $20 to $80 or more per acre.

In many irrigated districts the soil is of uniform texture for some distance below the surface. Other localities have a comparatively thin surface soil which is underlain by a less fertile subsoil. Where the latter condition obtains, too extensive excavation may seriously affect the productivity of the soil, and it may be advisable to modify the plan of grading and system of irrigation from that which would otherwise be desirable. Where land is sufficiently valuable, it may be practicable to move to one side the surface soil from the areas to be excavated or filled, and after grading to recover them with the surface soil. Grading is usually done with scrapers. Buck scrapers and Fresno scrapers may be used to advantage if the haul is short, while wheeled scrapers are preferable for long hauls. Roads graders and various types of home-made levelers are used for smoothing the surface of the ground.

The First Cultivation of raw land is frequently difficult and expensive and the first crop returns will usually be less than later ones. Light sandy soils are especially difficult to subjugate, as they are apt to drift and allow the seeds to be removed by wind action. Such soils must usually be cleared and planted in small areas, and protection from wind provided as soon as possible. Straw or manure placed over the exposed surface may provide a satisfactory protection. Sometimes rows of sagebrush, about 50 ft. apart, at right angles to the direction of the wind, are left temporarily on the ground to act as wind breaks. A hardy grain, such as rye, is frequently used for the first crop.

14. Application of Water to Land

Methods. Water may be applied to land by surface or subsurface methods. Subsurface irrigation, or subirrigation, is usually more expensive than surface irrigation and is not commonly practiced. Surface irrigation may be accomplished by lateral percolation or by flooding.

Farm Conduits. Earth ditches are commonly used to convey water to the different parts of a farm. Where water is sufficiently valuable to justify the expense, flumes or underground pressure pipes may be used. Both flumes and pipes reduce seepage losses and prevent erosion, but flumes like ditches cut up a farm and interfere with cultivation and harvesting. Water is delivered from pipes through standpipes or "stands" as illustrated in Fig. 16. The permissible head is limited only by the strength of the pipe. Where open conduits are used, the water must be delivered to the highest point in the area to be irrigated. Fig. 17 shows a field lateral with distributing ditches. Farm ditches should preferably run parallel to property lines but often they must be curved the better to conform to topographic features.

Uncontrolled Flooding is a crude method of applying irrigation water. Parallel ditches are constructed across a field at intervals of 20 rods or less. The area between any two ditches is irrigated by opening the upper ditch at a number of places and controlling the flow of water to some extent by throwing up small dykes across depressions or by making small temporary ditches along the higher places.

The Border Method is best adapted to fields having a moderate slope. Small levees, or borders, are built 2 to 4 rods apart. The land should be so graded that the ground surface on any cross-section between borders will be level. The land is irrigated by letting water flow over the land between borders. This method of irrigating has the objection that the upper portion of the area receives more water than the lower portion.

The Contour Check Method. Distributing ditches lead from the supply canal and pass directly down the slope (Fig. 19). Check levees along contours and cross levees divide the land into areas of 1 to 3 acres. The size of checks that is desirable decreases with the porosity of the soil. Levees should be about 9 in. high and at least 6 ft. wide at the base. The land between levees should be graded to a level surface. Checks are filled with water from the ditch adjacent to them. On steep slopes the ground is graded to a series of level benches and terraces with a levee at the top of each terrace. The cost of grading becomes proportionally higher as the slope and roughness of ground increases.

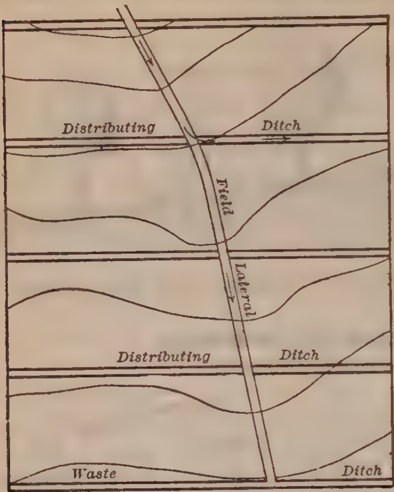

Fig. 17. System of Farm Ditches

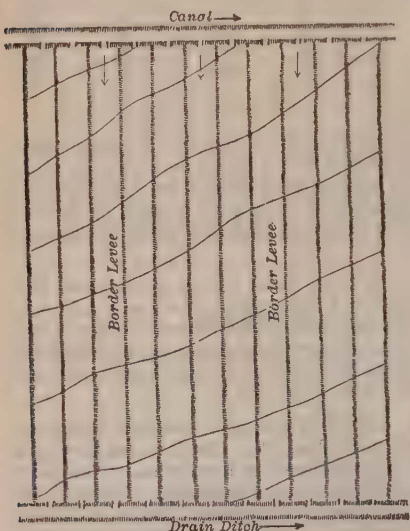

Fig. 18. Flooding by Border Method

The Square Check Method is suited only to gently sloping ground. It is similar to the contour check method except that the field is laid out in square checks. The best size of checks is 1 to 3 acres.

The Basin Method is best adapted to irrigating orchards. Levees are built around each tree, the land near trees being left high enough to prevent its submergence. The basins may be filled from ditches between alternate rows or water may be allowed to flow diagonally across basins as indicated in Fig. 21. Jointed pipes extending from the supply canal are sometimes used to fill basins. The lowest basin is filled first, then joints of pipe are removed and the basin next above is filled and the process is repeated until all of the basins in the row have been irrigated. This method is economical of water and is well adapted to the use of a small irrigation head.

The Furrow Method of irrigating by lateral percolation may be used for irrigating hay or grain (Fig. 22) and is used almost exclusively for crops planted in rows. Furrows, 3 to 6 in. deep and spaced 2 to 4 ft. apart, are made with a plow or special marking machine. Very little grading is necessary and the cost of preparing land is generally less than for the methods of irrigating by flooding. Furrows are made on slopes as steep as 10 ft. per 100 ft. but light soils may be eroded at this slope. The grade of furrows can be reduced by running them diagonally down a hill. The irrigation is accomplished by turning the water into several furrows at one time and allowing it to flow to the end of each furrow.

Subsurface Irrigation or subirrigation is the name applied to all those methods in which the water is applied below the surface of the ground. The

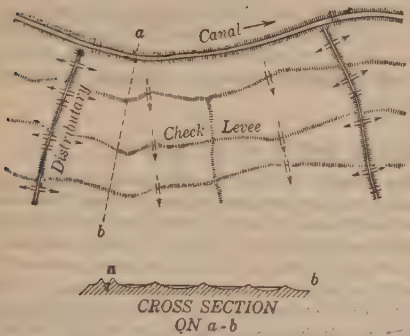

Fig. 19. System of Check Levees

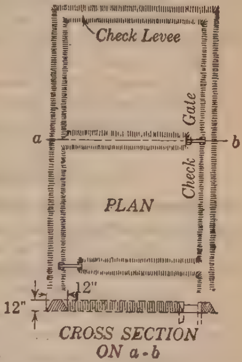

Fig. 20. Flooding by System of Squares

water is conveyed in underground channels containing openings, beneath the area to be irrigated, and through these openings the water percolates and is distributed through the soil by capillary action. The underground channels may consist of ordinary tile drains or perforated pipes. The cost of installation of such systems is high and in general the advantage obtained by them has

Fig. 21. Basin System of Irrigation

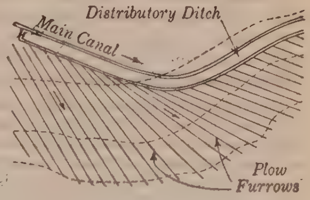

Fig. 22. Furrow Irrigation of Grain

not warranted the additional expense. In most localities surface irrigation is to be preferred to subirrigation.

Some lands are naturally subirrigated. Generally these are bottom lands underlain by gravel where the surface of the ground is but a few feet above the normal water surface of the stream. Water is drawn from this subsurface supply by capillary atraction to or nearly to the surface of the ground. Deep-rooted crops such as alfalfa are especially adapted to naturally subirrigated lands. Porous soils underlain by an impervious stratum quite near the surface may sometimes be subirrigated by simply digging ditches at intervals of 1/4 to 1/2 mile. Water flows down the slope between the two strata, and, if near enough to the surface, is available for plant growth.

Spray Irrigation has long been used in cities for watering lawns and small gardens. In certain humid districts it is used for supplementing the rainfall on larger areas devoted to the production of truck and small fruits. The essentials for this method of irrigating are a pumping plant and distributing pipe system. Hydrants may be located at suitable intervals over the field from which the water is applied to the land through hose, or parallel pipe lines 50 to 60 ft. apart, elevated a few feet above the ground and provided with nozzles at suitable intervals may be used to distribute the water over the field. An irrigation system of this kind is expensive, but the increased returns will often more than justify the expense.

15. Distribution and Use of Water

Distribution of Water among Users. At certain periods of the irrigation season the water requirements of crops are greatest and the demand for water may be excessive. The use of water cannot exceed the capacity of the irrigation system, and some adjustment in the use of water is usually necessary during certain portions of the irrigation season. On many large projects the farmer is required to give written notice 1 to 6 days in advance, stating when he will want water and the head that he desires. When it is not possible to deliver water to all users on the date requested without exceeding the supply of water, or the capacity of the irrigation system, the distribution is adjusted so as to accord as closely as possible with the requests of the various consumers.

Rotation in Irrigation. The consumer's right to the use of water is frequently expressed as a certain continuous flow, usually in cubic feet per second, throughout the irrigation season. As it is not economical to irrigate with a small head, it is customary for farmers whose rights to water are thus expressed, to rotate in its use, each taking a suitable head for such a time that the total water used will not exceed the allotment for the season. In many irrigated districts the right to water is expressed in some unit of volume, such as acre-feet per acre, or inches depth for the area to be irrigated. Such units are preferable for districts with an assured water supply.

Measurement of Irrigation Water is usually required at each farmer's intake. The ideal method of measurement would be with a meter that records the volume of water in cubic feet or acre-feet, but no practicable device for such measurement is now available. The present practice is to measure the rate and time of flow and to compute the volume.

Weirs of various types are used to measure the rate of flow of irrigation water. Headgates may be rated with a current meter to determine coefficients of discharge for different gate openings and heads. Discharge curves may be obtained from current-meter measurements for flumes or permanent canal sections. The Venturi flume may may be used where the head available is not sufficient for installing a weir. The control meter, reported in 1926 by the Special Committee on Irrigation Research of the American Society of Civil Engineers, is a modification of the Venturi flume that has the advantage of requiring only one head measurement.

Economy in Use of Water. In most arid districts the area of fertile land is much in excess of that which can ever be irrigated by the most effective use of all available waters. The limit of irrigation is therefore fixed by the water supply and not by the land area. Any water that is wasted or used in excess of that which may be applied to the land beneficially reduces the irrigable area. On the other hand, any improvement in methods of irrigation which reduces the water requirements, and all waste prevention, increase the area of land which may be reclaimed. Investigation of the use of water that will yield the greatest net return is therefore an important branch of irrigation engineering.

The Method of Payment for water has much to do with the economy of its use. Commonly the farmer's contract calls for a maximum quantity of water and there is no incentive for him to use a smaller amount. A better method of payment is for the farmer to pay for just what water he uses, or, if his contract calls for a fixed quantity of water, to allow a bonus for any smaller amount that he may use. Under such conditions the farmers will readily become interested in practicing economy in the use of water and in developing more efficient methods of irrigation.

SWAMP AND OVERFLOWED LANDS

16. Swamp Lands as Drainage Projects

Classification. Those areas which are covered with water or the soils of which contain an excess of water either continually or to an extent that renders them unfit for cultivation are commonly spoken of as swamp or overflowed lands. There are three general divisions: inland marshes, river-bottom lands, and tide lands. Most of these areas are susceptible of reclamation, and in many instances their development is of great economic importance.

Location and Distribution. Swamp and overflowed lands are distributed quite generally throughout the world and many such areas have been successfully reclaimed. The largest enterprises of this kind have been in Europe, where land values are high. Notable examples are the English Fens, where 700,000 acres of tide lands have been reclaimed, and Haarlem Lake, Holland, where a shallow lake 43 000 acres in extent has been converted into a fertile farming district. Large drainage enterprises have also been successfully completed in France, Italy, and other European countries. Of the large areas of swamp and overflowed lands in the United States only a small fraction have been reclaimed.

A compilation by the United States Department of Agriculture in 1922 gives approximately 57 000 000 acres of swamp lands, 31 000 000 acres of overflowed lands, and 8 000 000 acres of tidal marsh lands east of the 103rd meridian. Of this total of 96 000 000 acres, 18 000 000 acres are in Florida. In each of the following states there are: Louisiana, Georgia, and Minnesota, 6 000 000 to 7 500 000 acres; Michigan, North Carolina, Texas, South Carolina, Mississippi, Wisconsin, Arkansas, and Missouri, 3 000 000 to 5 000 000 acres; Alabama, Indiana, Illinois, Virginia, Kentucky, North Dakota, Tennessee, Kansas, Ohio, and New York, 1 000 000 to 2 000 000 acres.

Soil. Marsh lands are commonly covered with decayed vegetable matter and are usually very fertile. In many cases, however, some element of plant food is deficient and certain crops will not grow satisfactorily without artificial fertilization. This is especially true of peat and muck lands, which are usually lacking in potash. The subsoil of inland marshes is ordinarily similar to that of the surrounding country. Overflowed lands along rivers are composed largely of sedimentary deposits, silt and fine sand usually predominating. Tidal marshes may be formed of clay, sand and silt in any proportions. The soil formation of swamp and overflowed lands should always be carefully investigated with a view to determining is fertility, and its influence on construction methods and plan of drainage.

Subsidence of Muck and Peat Soils. Soils containing large percentages of vegetable matter subside when drained and cultivated. In the English Fens, at a place where in 1848 the peat was 18 ft. thick the ground surface has gradually lowered 10 ft. A shrinkage of 40% of the original thickness of peat soils is not uncommon. In the muck lands of Louisiana and Florida where the peat is impregnated with varying quantities of silt, a settlement of 2 ft. or more in five years has occurred. The amount of shrinkage decreases as the percentage of silt increases. In designing ditches and pumping plants for areas of deep muck land some provision should be made for the gradual but certain subsidence of the ground. For full discussion of this subject see Trans. Am. Soc. C. E., Vol. 82, The Subsidence of Muck and Peat Soils in Southern Lousiana and Florida, by C. W. Okey.

Natural Vegetation. Inland marshes frequently contain heavy growths of timber, or where the timber has been cleared they may be covered with dense underbrush, stumps, and fallen trees. Other marshes contain growths of coarse grasses, reeds, or moss. In all cases the expense of clearing must be included in the cost of reclamation.

Topographic Map. The general characteristics of a drainage project can best be studied from a topographic map, which should be prepared early in the investigation. Contours of the area to be reclaimed should ordinarily be shown for 1-ft. intervals, and natural drainage channels should be carefully indicated. Information as to soil formation, property lines, and source and amount of water to be disposed of may be recorded on the map. Existing maps may sometimes be of value in determining tributary areas which naturally drain into the area to be reclaimed.

17. Runoff

Surface Drainage. The channels and outlets of a drainage system should be of adequate capacity to provide for the removal of water at such a rate that the ground will be ready for early cultivation in the spring, and that the growth and harvesting of crops will not be seriously retarded. It is therefore the maximum or flood flows which must be considered in designing a surface drainage system, and the same principles apply regardless of the scheme of reclamation. Excessive runoff may result either from heavy rains, or the sudden melting of snows, but the most severe floods are caused by the former.

The Maximum Runoff per unit area that may be expected from any drainage basin decreases as the area increases. In general, the law of maximum discharge from flat areas, similar to those encountered in large drainage projects, may be represented by the equation

$$Q = KM^{0.75}$$

in which Q is the maximum discharge in cubic feet per second, M the drainage area above the point at which Q is required, in square miles, and K an empirical coefficient. If A is the area in acres, the formula may be written

$$Q = 0.00786\, KA^{0.75}.$$

Values of K obtained from measurements of maximum runoff of a number of drainage projects in the Mississippi valley range from 20 to 60. They correspond to rainfalls of 3 to 7 in. in 24 hours. The measurements were made on areas varying from approximately 2 to 200 square miles. The value of K depends primarily upon the maximum rainfall, but is influenced to a large extent by several other factors. It increases with the slope of the ground and the degree of imperviousness of the soil. The condition of the ground also influences the value of K. A heavy rain falling on wet ground will cause a greater runoff than the same rain falling on dry ground. If the ground is frozen or covered with ice, conditions will be favorable for a large surface runoff. Precipitation records covering as long a period as possible should be consulted to determine the maximum rainfall to be provided for.

The Total Annual Runoff from a given area is the difference between the annual precipitation and the water returned to the atmosphere through evaporation and plant transpiration, subject to modifications from ground-water conditions and possible deep seepage losses. The effect of the two latter considerations is commonly neglected in approximate calculations. Many factors affect the amounts of evaporation and transpiration, the more important being the mean annual temperature, and the amount and distribution of rainfall. The humidity of the air, velocity of the wind, character of vegetation, degree of cultivation, and soil formation are also important influences.

An accurate estimate of transpiration and evaporation losses for a given area involves a thorough investigation of the various factors involved. Rough estimates may be made by considering only the temperature and precipitation. Mean values of combined transpiration and evaporation losses, based upon observations in the United States, are given in the following table. The yearly runoff in inches is obtained by subtracting the proper tabulated value from the annual precipitation. Observed values may be expected to differ by as much as 5 in. from those given in the table.

Average Annual Transpiration and Evaporation Losses in Inches

Annual precipitation, in.	Mean annual temperature (Fahr.)								
	35°	40°	45°	50°	55°	60°	65°	70°	75°

70	25	26	27	28	29	30	31	32	33

18. Pumping Plants

Capacity. The removal of water may be accomplished by gravity or by pumping or by a combination of the two methods. A pumping plant should be of adequate capacity to remove water at a rate that will prevent injury to crops up to the point where additional capacity will cost more than the damage to crops that will result if the additional capacity is not provided. The time for which land may be flooded without serious damage differs for different crops, truck crops being more susceptible of damage than corn, sugar cane, grains and similar crops, but in general the land should not be submerged for more than 24 hours. The capacity of pumping plant must be based upon a consideration of maximum runoff (Art. 17) and also upon the storage provided by canals, the maximum length of time that crops may be submerged without damage, and the slope of the reclaimed area. Areas with considerable slope require greater pump capacity than more level areas, because of the tendency of water to collect and flood crops at the lower elevations.

In southern Louisiana pumping capacities sufficient to remove 1 to 1.5 in. per 24 hours have proved sufficient for areas of 5000 to 10 000 acres. One inch of runoff in 24 hours is equivalent to approximately 27 cu. ft. per sec. per square mile. In the upper Mississippi valley a pump capacity of 0.25 to 0.50 in. for similar areas has been found satisfactory.

The Period of Operation. Ordinarily pumps will be operated early in the spring to get the ground ready for cultivation, and after heavy rains during the growing period. In the lower Mississippi valley, where plant growth continues throughout the year, the pumping plant must be ready to operate at all times. In northern United States pumping usually is not required for more than 20 days, whereas in the extreme south it may be required 40 or more days in the year.

Location. Pumping plants should be located near the natural drainage outlet or, if the area is approximately level, so that the water will travel the minimum length of canal. Unless electric power is supplied from a central station the facilities for transporting fuel must be considered in selecting a location for the plant. The ground should also be explored with a view to obtaining a favorable foundation.

Buildings. The footings under machinery and buildings should be of concrete, and if built on earth they should be supported by piling. The pump should be mounted on the same block of concrete as the engine that operates it so that subsequent settlement will not throw them out of line. Buildings should be durable, of fireproof construction, and of sufficient stability to withstand the heaviest winds.

Power. The kind of power to be used in a particular case must depend upon local conditions, but each possible source of power should be investigated. The power finally selected should be that which requires the smallest operating expense, based upon interest charges, attendance, fuel, maintenance and depreciation. **Electric Power** requires a minimum expense for attendance. It is convenient and adapted to intermittent service and if the cost is low enough its use is to be preferred for plants of all capacities. **Crude-oil engines** provide a most satisfactory source of power and have been used extensively on many drainage projects of the southern states. **Steam-power plants** are quite generally used on large projects, but the large initial cost, the expense of keeping them continually ready for service, and the high grade of operators which they require are objectionable features.

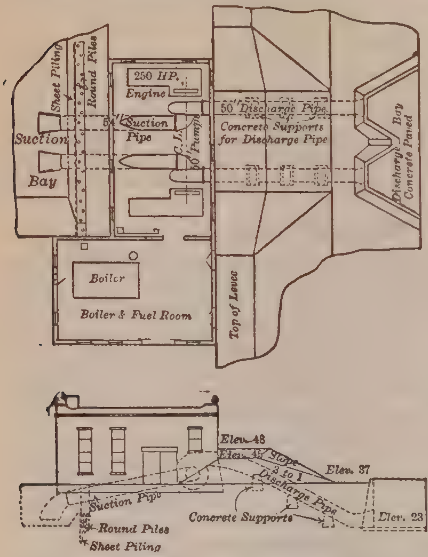

Fig. 23. Pumping Plant for Drainage System

Gasoline engines have been used to operate small plants. **Producer-gas plants** have not proved satisfactory for intermittent service.

Pumps should be selected and operated so as to secure the maximum efficiency practicable. The maximum lift will not usually exceed 10 ft. and the bulk of the water will not be lifted more than 3 or 4 ft. It is at the lower lifts also that the greatest pumping capacity is required. It is desirable, therefore, that the pumps should operate at very nearly their maximum efficiency for

Average Loss of Head in Feet per 100 ft. Length of Suction or Discharge Pipe of Pumps

* Acreage will be considerably increased later.

† Plant costs more than it would for an agricultural proposition, as two units must lift water 11 ft. if occasion demands it.

the lower lifts and operate at a satisfactory efficiency through the entire range of lift. Centrifugal pumps have been quite generally used for drainage reclamation work. Fig. 23 shows an outline of the plan and elevation of the pumping plant for Louisa-Des Moines Drainage District No. 4, Iowa.

The rated capacity of ordinary low-head centrifugal pumps is based upon a velocity through the discharge opening of 10 to 12 ft. per sec. The loss of head due to friction may therefore equal or exceed the static lift. For this reason the suction pipe and discharge pipe should be made as short as possible and sharp bends should be avoided. The outlet should be submerged so as to induce siphon action in the pipes, and the discharge pipe should be flared at the lower end so that the water will discharge at a velocity of not over 5 ft. per sec. The suction pipe must be air-tight and the water should be drawn from a concrete-lined intake several feet deeper than the minimum elevation of water surface to be maintained. Centrifugal pumps if properly designed and installed should give efficiencies of 60 to 70% throughout the range of lift ordinarily encountered in drainage work, but improperly selected pumps may give very much lower efficiencies. These figures refer only to the pumps, and friction losses in pipes and velocity head at exit must be added to the static lift to obtain the actual head against which the pumps must operate.

Cost. The cost of drainage pumping plants varies widely according to the type of machinery, expense of transportation, character of foundation and difficulities of erection.

Relative Fuel Costs of Several Types of Pumping Plants

For 1000 acres, 6-ft. difference in levels, 8-ft. total head. Amount pumped = 1 acre-foot per acre per season, at rate of approximately 1 acre-inch per acre in 24 hours or 42 cu. ft per sec.

Water horse-power	Type of plant	I.H.P. of steam engine B.H.P. of gas engine	Total cost of fuel oil per hr. at $1.25 per barrel	Total cost of gasoline per hr. at 12 cents per gallon	Total fuel cost per year of removing total 12 in. at pump efficiencies named

19. Levees and Ditches

Levees are required to prevent the entrance of outside water on lands subject to overflow. If subjected to current and wave action they should be designed on liberal lines with ample freeboard and they should be protected by rock riprap or other construction to prevent erosion. For the design and construction of river levees see Sect. 8, Art. 25, and Sect. 19, Art. 10.

Levees in Still Water may have a somewhat smaller cross-section than those subjected to current or wave action. They are commonly located on property lines without regard to the topography. This results in regularly shaped districts and minimum length of levee, but frequently the cost of construction and maintenance may be reduced by following the higher and firmer land and deviating somewhat from the more direct line.

Common dimensions for this type of levee (Fig. 24) are 1 on 2 or 1 on 3 for embankment slopes, a top width of embankment of 6 ft., a berm of 10 ft. and a freeboard above the maximum high water elevation of 3 ft. To reduce seepage, the borrow pit

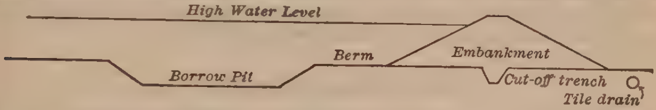

Fig. 24. Cross-section of Levee

should be on the outer side of the levee, but it is sometimes placed within the tract and thus serves as a drainage canal. All vegetable matter and humus should be removed from the strip of land on which the levee is to be built and as far as practicable only the better grade of material should be placed in the embankment. Carelessness in these regards may result in excessive seepage through the levee. Levees built of the mud commonly found in swamps will shrink 20 to 50% of its original volume, and allowance for this shrinkage should be made when the material is placed. The shrinkage will be less for sandy soils than for those in which clay predominates.

Ditches of various sizes must be constructed and so located as thoroughly to drain the area to be reclaimed. In pumping projects the larger ditches also serve for storing water after heavy rains and thus give greater flexibility to the pumping plant. In many instances the latter function is fully as important as the former, and quite commonly some of the main ditches are made much larger and deeper than would be necessary for drainage alone in order to provide more storage.

The size of each drainage ditch must be carefully determined from the duty which it has to perform. The general features are shown in Fig. 25. The side slopes are usually made about 1 on 1-1/2. When excavated with dredges it may be more con-

Fig. 25. Cross-section of Drainage Ditch

venient to leave steeper banks and allow additional width with the idea that the banks will cave in and eventually conform approximately to 1 on 1-1/2 slopes. Excavated material should be deposited in spoil banks on either side of the ditch, leaving suitable berms between the ditch and spoil banks.

Excavating Machinery. Either teams and scrapers or machinery can be used to construct levees and ditches on dry land but on wet land dredges are used exclusively. The use of power machinery for all drainage work has become general in the United States. New types of excavators have been put on the market in recent years and older types have been much improved. (See Bulletin 300 of the U. S. Dept. of Agriculture, by D. L. Yarnell.) The following excavating machines are used on drainage work: floating dipper dredge, floating grab-bucket dredge, dragline scraper excavator, dry-land dipper dredge, dry-land grab-bucket excavator, wheel excavator, hydraulic dredge, and various machines for cleaning old ditches.

The Cost of dredging drainage ditches in the United States is usually 12 to 16 cents per cu. yd. The cost of levees is somewhat higher depending upon the expense of selecting and placing material and the distance of the embankment from the borrow pit. The total cost of excavation for drainage projects where both levees and interior ditches are required varies from $20 to $60 per acre.

Maintenace of Levees and Ditches. Bushes and other vegetation of rank growth should not be allowed on levee banks since water will follow the roots and increase seepage. After the soft material in a levee has dried sufficiently it should be smoothed off and preferably seeded to Bermuda grass. It may then be mowed with a mowing machine, or the grass may be kept down by allowing stock to graze upon it. A heavy sod will assist in preventing erosion and in keeping out weeds and other objectionable vegetation. Grass and weeds should be cut out of ditches 1 to 3 times each year. At least once in 2 years the ditches should be cleaned of the accumulated mud and silt.

20. Inland Marshes

Source of Water. The first step in the investigation, preliminary to deciding upon the plan of reclamation, is to determine the source of the water or the reason why the land is too wet. The water may come from direct rainfall, from visible streams, from the runoff from neighboring hills, or from springs.

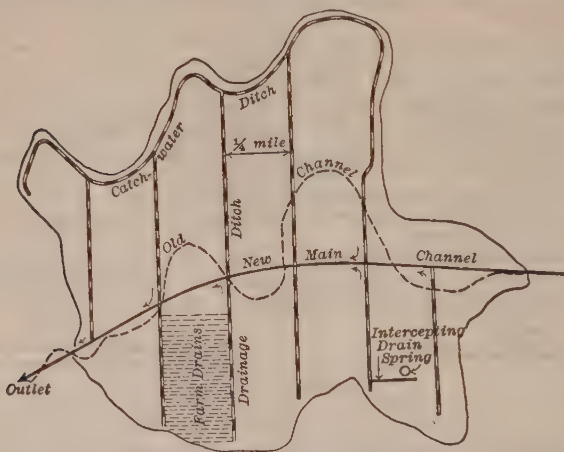

Fig. 26. Reclamation of Inland Marsh

The condition may be due largely to the fact that natural outlet channel is obstructed or of insufficient depth or capacity to drain the area properly.

Main Drainage Channel and Outlet. In order that a swamp area may be properly drained it is necessary that the outlet and main drainage channel should be deep enough and of sufficient capacity to carry the drainage of the swamp and all tributary areas while maintaining an elevation of water surface low enough to provide for effectively draining the area to be reclaimed. The natural drainage channel through an inland marsh may not be clearly marked or it may be very winding and obstructed with fallen timber and debris. One of the first requirements in such cases is to excavate or straighten and enlarge and deepen such channels and carry them to a natural outlet. If no satisfactory outlet exists, pumping may be resorted to, but inland marshes are usually drained entirely by gravity.

Auxiliary Drainage. The amount of drainage required in addition to that provided by the main channel will depend largely upon the size of the marsh, the natural slope of the ground, the soil formation, and the source of underground water. If the subsoil is sandy and especially if the ground has a fair slope toward the main channel no additional drainage may be necessary. Also if the marsh is small no additional ditches may be required. If the subsoil is of impervious formation auxiliary drainage ditches across the tract may be required at 1/4- or 1/2-mile intervals. When springs occur on the tract they should be cut off by intercepting drains, that is, drains which tap the source of supply before it reaches the surface of the ground. This result may usually be accomplished by means of an underground tile drain. If there is much flow on to the tract from surrounding hills a catchwater open ditch at the junction of the high and low land may be advisable. After the main drainage channel and principal auxiliary ditches have been completed, if further drainage is required it may be accomplished by open farm ditches or tile drains. Fig. 26 indicates the different methods of drainage that may be used in reclaiming inland marshes. In general the drainage should be adequate to assure a minimum depth to ground-water of 3 to 4 ft. after the subsidence following drainage has occurred.

21. Overflowed Lands

Classification. There are two general classes of overflowed lands: tidal marshes which are periodically submerged and uncovered by the rise and fall of tides, and river bottom lands which are temporarily inundated during high stages of the streams. The lower lying marshes in either case may be permanently submerged. Some lands, like those in southern Louisiana, may be subject to overflow from both causes. As regards topography, the area to be reclaimed may either adjoin high land on one side, or be entirely surrounded by overflowed land. In general, a similar plan may be adopted for reclaiming all overflowed lands, the details being changed to suit the particular conditions.

Protection from Overflow is secured by constructing levees around the area to be reclaimed. (Art. 19.) If the tract joins high land on one side, levees will be required on but three sides. In general the area of such lands that may be reclaimed by one levee system is limited to that which is included between the main stream or body of water and two of its tributaries. A levee runs along the bank of the main water and return levees follow the tributaries to the high land. Diversion ditches may be constructed near the foot of the slope where the hills join the flat land to deflect the hill waters and prevent their entering the tract. If the area to be rclaimed is surrounded by overflowed lands, levees must be built on all sides. Fig. 27 shows the system of levees and ditches of Area No. 7, Gueydan, Louisiana. Fig. 28 shows the method of reclaiming a tidal marsh near Dorchester, New Jersey.

Drainage. The drainage system consists of one or more main ditches with auxiliary ditches spaced as required, but usually 1/4 to 1/2 mile apart. Open farm ditches or drain tile may then be used to provide whatever additional drainage may be necessary. Open ditches should preferably be located on property lines or parallel to them, in order that they may interfere as little as possible with farming operations.

The Depth of Ditches should be such that the entire tract may be satisfactorily drained to a depth of 3 to 4 ft. The practice in the lower Mississippi valley, Fig. 27, is to dig farm ditches 4 ft. deep. The main ditches must have dimensions and slopes which will provide satisfactory outlets for the smaller ditches. Marsh lands will frequently settle 1 to 4 ft. after reclamation, and this settlement may continue for several years. The probable settlement of the ground should be considered in designing the drainage system.

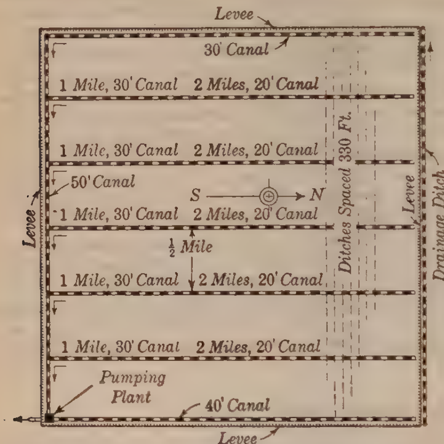

Fig. 27. Reclamation of Overflowed Land

The Outlet for the drainage system may be provided by gravity or pumping or by a combination of the two. If a natural gravity outlet is relied upon a sluice gate must be provided where the water passes through the levee. Sluice gates should act automatically and allow the water to pass out when the water surface is higher within than without the tract and close when the opposite condition obtains. A flap valve, hinged at the top, is ordinarily used for this purpose. A hand-operated gate should be installed in conjunction with the automatic gate to be used in case the latter

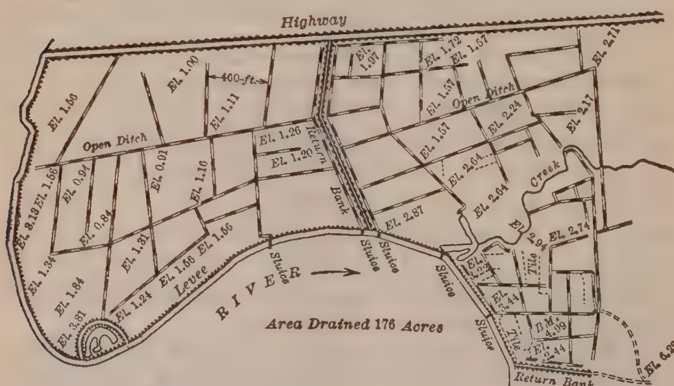

Fig. 28. Reclamation of Tidal Marsh

gets out of order. River bottom lands when subject to overflow for only short periods may be drained by gravity outlets if the water surface in the river is normally low enough, otherwise auxiliary pumping will be necessary to drain the tract satisfactorily. Tidal lands may be drained through automatic sluice gates, the gates being opened during low tides and closed during high tides. In localities where the tidal range is small and the elevation of the ground is low, reclamation can be accomplished only by pumping. In many

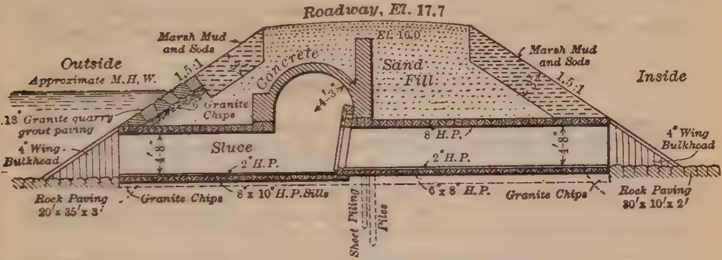

Fig. 29. Longitudinal Section of Levee through Sluice

instances where tidal lands are drained by gravity the expense of auxiliary pumping would be more than justified by increased returns from the land.

In general, tide lands drained only by gravity lying 1 ft. or less above mean low water have no value for agricultural purposes, those between 1 and 2 ft. above mean low water will produce hay, and those between 2 and 3 ft. above mean low water will produce rye, potatoes, corn and other crops. The best results are obtained from land 3 ft. or more above mean low water elevation.

FARM DRAINAGE

22. Drainage Possibilities

Soil Moisture. All water in excess of that required by vegetation is harmful (Art. 2). Air within the soil is essential to healthy plant growth and this is excluded by excess moisture. Air is completely excluded from saturated soil, and the land becomes cold, sour, and entirely unproductive.

Three Classes of Lands may be considered: (*a*) those that are entirely unproductive or that cannot be profitably farmed without drainage; (*b*) those that can be profitably farmed without drainage but that with drainage will give increased returns sufficient to justify the cost; (*c*) those that cannot be sufficiently improved to justify the cost of drainage. All lands not having a porous subsoil and especially clay lands can be improved by drainage.

Benefits of Drainage. Drainage benefits farm lands in the following ways: (*a*) By removing the surplus water, which is harmful to plants, and aerating the soil; (*b*) by warming the soil and thus decreasing danger from frosts, causing the seeds to germinate earlier, and grow more promptly, permitting earlier cultivation of the land, and increasing the length of the growing season; (*c*) by making the soil more granulated, porous, and friable, and thus increasing its ability to absorb rainfall. In general, the results of farm drainage are to make certain the production of crops each year and to increase the yields and profits.

Preliminary Investigation. Before laying out a plan of drainage for a given area a careful preliminary study should be made and a topographic map should be prepared showing contours and intermediate elevations at controlling points. It is important that natural drainage lines should be distinctly shown.

A soil survey of the area should be made and the character of the soil and subsoil at different points may be conveniently marked on the map, supplemented by additional field notes if necessary. The ground-water also should be studied, especially if there is evidence that it comes from some source other than precipitation upon the area to be drained. The position of the outlet should be determined from the field investigation and marked upon the map. The map and other data may then be used as a basis for the plan of drainage.

23. Drains and Drain Tile

Principles of Drainage. There are two kinds of drainage: Surface drainage, by which water is conveyed over the surface of the ground; and subsurface drainage, by which water is conveyed beneath the surface of the ground. Surface drainage removes the water that cannot percolate into the ground as fast as it is supplied by precipitation or melting snow. Subsurface drainage removes the water which cannot be retained as soil moisture.

Farm lands require surface drainage to remove excess precipitation but if slopes are too steep much of the water from heavy showers may flow off the surface before the ground has been wet as deep as is desirable. Surface drainage may be retarded by cultivating the land across slopes. Farm drainage is primarily a problem of supplementing natural subsurface drainage.

Open Ditches receive water from the surface of the ground and also water that passes through the soil. They therefore assist in surface drainage, which may be an advantage on very flat areas. In the lower Mississippi, where the rainfall is heavy and the land practically level, open farm ditches are used almost exclusively (Fig. 27). Farm ditches occupy land which might otherwise be cultivated and make it difficult to move farm machinery from one part of the farm to another. They are expensive to maintain and in clay soils they are apt to become puddled and prevent the free entrance of ground-water.

Subsurface Drains are conduits below the surface of the ground with openings of a size that will permit the ground-water to enter freely and will exclude the surrounding earth. Box drains have been used to a limited extent. They are made of four boards nailed together to form a rectangular cross-section with cleats between the top and sides to leave narrow openings for the entrance of water. Blind ditches partially filled with stones or poles were formerly used, but they were not permanent and have been abandoned. Tile drains have been found to provide the most satisfactory drainage, and they are used almost exclusively.

Kinds of Tile. There are two kinds of drain tile in common use: Clay tile and cement tile. Clay tile are sometimes made hexagonal or octagonal, but more commonly they are round. They range from 2 to 36 in. in diameter and from 12 in. in length for the smaller sizes to 30 in. for the largest. Cement tile under 12 in. in diameter are more expensive than clay tile, but in the larger sizes they are cheaper. The following comments on clay and cement tile are contained in Farmers' Bulletin 524 of the U. S. Department of Agriculture.

Clay Tile. Soft, medium, and hard-burned or vitrified clay tile are made. It costs less to make the soft-burned than the hard-burned tile and the selling price is lower, but the quality is not so good. Soft-burned tile have done good service, however, and when put under ground below the frost line have lasted indefinitely. The best tile are burned to a cherry red and when struck by a piece of steel give a sharp metallic ring. In the north, where they are laid above the frost line, only the hard-burned tile should be used. Hard-burned, or vitrified, tile are practically nonporous; thus, they absorb little moisture and unless water stands in them they are not injured by freezing temperatures. A tile that cracks and shatters in winter when lying in the yards unprotected from the weather is not fit to use above the frost line and is not the best under any conditions. Thick tile make the best joints. Those with thin sides, especially in the smaller sizes, are likely to slip out of place and leave openings. Some manufacturers who ship tile make them with thin sides to reduce the weight and the consequent cost of transportation. A 4-in. tile should weigh at least 6 lb., a 5-in. 8 lb., and a 6-in. 11 lb. Some factories make them heavier than this, which is better so far as utility is concerned.

Cement Tile. There are a number of machines on the market for making cement (or concrete) tile that cost from $50 to $100. One part of cement to about 3 parts of aggregate should be used. The largest pieces in the aggregate should not be more than one-half the thickness of the wall. The cement and aggregate should be well mixed and sufficient water should be added to make the mixture moist but not wet. After the tile are taken from the machine they should be placed in the shade. The longer the mold is allowed to remain around the tile the better. After the mold is removed the tile should be sprinkled twice a day for 3 or 4 days, or until thoroughly cured. A well-made and well-cured cement tile, like a good clay tile, when struck with a piece of iron will have a sharp metallic ring. Large cement factories are equipped with steam driers, with which the curing can be done to the best advantage.

24. Location of Drains

The General Plan of draining a given area should be determined before any drains are constructed, in order that all parts of the system when completed will work together effectively even though the construction is to extend over a long period. Details not pertaining to the general scheme of drainage may be worked out as required. When more than one farm will be benefited by the construction of main drains, each party interested should contribute in the investigation in so far as the work affects his property. State laws usually cover the legal points involved.

The Outlet is usually the first consideration. On rolling or hilly lands a natural outlet ordinarily exists. On low level land an artificial outlet is usually necessary. The elevation of the water surface in the outlet should be low enough to provide for the effective drainage of the area which it serves. It should be of sufficient capacity to take care of the requirements of surface and subsurface drainage. The expense should be assessed against all of the farms using the outlet in proportion to the benefits accruing to each. Outlets may be either open ditches or covered pipes. Tile up to 36 in. in diameter have been used for this purpose.

Drainage Systems. There are two general systems of drainage: Partial and complete. Partial drainage systems are used on rolling land when it is desired to drain only isolated portions of a tract, as illustrated in Fig. 30. The complete system is used when all of the land of a comparatively large area is to be drained. Examples of complete drainage systems are shown in Figs. 31 and 32. It will be noticed that certain areas adjacent to the main laterals are double drained, and for maximum economy this double drained area should be as small as practicable. For this reason long parallel field drains are preferable. The system indicated in Fig. 32 requires a smaller amount of tile than that indicated in Fig. 31.

Field drains should be laid in the direction of the greatest slope. This insures the greatest velocity and capacity. High velocities of water assist in scouring out the drains and in keeping them clean. It is very important that drains in sandy land should have velocities great enough to scour out the sand which filters into the drains between the tile. A 4-in. tile drain in sandy land should not be laid on a grade of less than 0.3 ft. to 100 ft. The laterals, submains and mains should preferably be located approximately in the lines of natural drainage, since the slope of the ground leads the water in this direction. The drains should be laid as straight as practicable and bends should be made by smooth curves. It usually will be found necessary to deviate somewhat from the natural drainage channel in order to improve the alignment.

The Depth and Frequency of Drains that will produce the most satisfactory results depends largely upon the character of soil. Where deep drainage can be used the drains may be spaced farther apart. The more porous the soil the deeper the drains can be placed. In heavy clay soils of close textures, drains placed 2 to 3 ft. beneath the ground surface have produced good results when deeper drains have failed. In other cases clay soils have been satisfactorily drained at depths of 3 to 4 ft. A depth of about 4 ft. appears to be the best for

Fig. 30. System of Partial Drainage

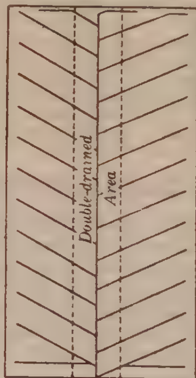

Fig. 31. System of Complete Drainage

Fig. 32. System of Complete Drainage

sandy soils. Practice also varies widely regarding the proper spacing of drains. In dense clay soils they should probably be placed 30 to 40 ft. apart, and in sand a spacing of 200 ft. may be used. For intermediate grades of material distances of 50 to 150 ft. may be selected to suit the conditions.

Before deciding definitely as to the proper depth and frequency of drains for a given area a careful study should be made of all factors likely to affect the problem. Conditions vary widely and results obtained in one locality may not apply to another locality, even though conditions appear quite similar. Local conditions especially should be studied, and if time is available and other conditions seem to warrant it, experiments with different depths and spacings of drains should be made before the completion of the work as a whole is undertaken.

25. Capacity and Size of Drains

The Required Capacity of a subsurface drain depends upon the rate at whch water will pass from the surface of the ground to the drain. The two principal factors affecting the rate at which water will enter a drain are the porosity of soil and the amount and rate of precipitation.

Drainage Coefficient. The inches depth of water which must be removed in 24 hours to drain any area satisfactorily is called the drainage coefficient of that area. Its value for different soils must be obtained from experiments. An investigation by the U. S. Department of Agriculture of a number of under ground drains in Illinois and Iowa that were doing satisfactory service showed maximum discharges in 24 hours of 0.11 to 0.27 in., most of the results varying from 0.15 to 0.20 in. These results were obtained on areas having fairly porous subsoils. Heavy clay soils and coarse sand soils will have respectively smaller and larger drainage coefficients than the above. It also appears that the drainage coefficient of rolling land is about 20% greater than for flat land. The following may be considered average values of drainage coefficients for different soils:

Compact clay soil, flat, 0.12; rolling, 0.14.
Medium porous soil, flat, 0.18; rolling, 0.22.
Porous sandy soil, flat, 0.30; rolling, 0.36.

With the drainage coefficient decided upon, the capacity of drain in cubic feet per second required to drain a given are can be obtained by multiplying the area in square miles or acres by the proper value in the accompanying tables:

can be used for computing the diameter. d_i is the diameter in inches, Q is the discharge in cubic feet per second, s is the slope or fall per foot, and n is the coefficient of roughness which has approximately the same value as n in the Kutter formula.

From a compilation of extensive experiments by D. L. Yarnell (published in 1922 as Bulletin 300, U. S. Department of Agriculture), the value of n for well-laid clay or concrete tile flowing full is approximately 0.011. This should be considered as the minimum value and should be used only under most favorable conditions. For poorly laid tile n may be 0.012 or even 0.014 or more. Values of d computed from the above formula with $n = 0.011$ are given in the accompanying table. For other values of n multiply d as given in the table by the following factors:

For n equal to........	**.012**	**.013**	**.014**	**.015**	**.016**	**.017**
Multiply d in table by .	**1.03**	**1.06**	**1.09**	**1.12**	**1.15**	**1.18**

Formerly 2-in. tile were used for farm drains, but modern practice is to use no tile smaller than 3 in. in diameter. The size of tile selected for a given case should ordinarily be the commercial size nearest to and larger than the computed size, excepting that no tile smaller than 3 in. should be used. The following are diameters in inches of common commercial tile: 2, 2-1/2, 3, 4, 5, 6, 7, 8, 10, 12, 15, 18, 20, 21, 22, 24, 27, 30, 33, and 36. For main drains above 15 in. in diameter vitrified sewer pipe is commonly used.

26. Construction of Tile Drains

Staking Out. Tile drains should be set true to line and accurately to grade. When curves are necessary they should be smooth and regular. Before beginning excavation stakes should be set 50 ft. apart parallel to and about 2 or 3 ft. from the center line of the drain on the side opposite to that on which the earth will be thrown. Elevations of tops of stakes should be taken with a level and the cut marked on each. These stakes will serve as guides for the rough excavation. After the excavation is approximately to grade, batter boards should be placed across the trench opposite each stake at the same distance, preferably about 6.5 or 7 ft. above grade. The center line is then marked on the batter boards and a string connecting these points will be directly above and parallel to the grade line. The center line at any point may then be obtained by dropping a plumb bob from the string, and the grade by measuring down from it with a pole of proper length.

Excavation should be begun at the outlet. The trench may be dug either by hand or with a trenching machine. If much work is to be done the trenching machine will prove more economical. For 6-in. tile or smaller the trench may be made 12 in. wide at the top and 7 in. at the bottom.

Fig. 33. Tile Hook

Trenching Tools and Machines. The special tools commonly used are tile spades, a shovel, pick, drain scoop, and tile hook. There are two kinds of tile spades, solid and open, the latter being used for wet sticky soils. Tile spades are 16 to 22 in. long and 5 to 6 in. wide. A drain scoop is used for finishing the bottom of the trench preparatory to laying the tile. It should be curved to a radius approximately equal to the outer radius of the tile. A tile hook, Fig. 33, consists of a bent 1/2-in. rod attached to a wooden handle. There are a number of types of trenching machines on the market. They vary from different styles of plows, which loosen the earth so that it may be more readily shoveled, to large machines of the wheel bucket and endless chain type, which do all the work of excavation. The larger trenching machines vary in cost from $2200 to $7500. Trenching plows may be obtained at $50 to $300.

Laying of Tile like the excavation of trenches should begin at the outlet. If the bottom of the trench has been properly prepared the laying of the tile should proceed rapidly. The smaller sizs of tile are usually laid with a tile hook by a man standing at the top of the trench. Care should be taken to see that the tile joints fits tightly, especially at the top. Crooked and imperfect tile should be thrown out and if used at all they should be placed together near the upper end of the drain. Curves are usually made by using crooked tile or by chipping off one edge of the tile. It is easier and better, however, to have special curved shapes, either drain or sewer tile, available for the purpose. Y-junctions should be placed where needed, the open end being plugged up until the connection is made. Before the tile are covered the work should be inspected to see that all joints are properly made and that the tile are laid true to line and grade.

Backfilling. Before the trench is filled the tile may be surrounded by coarse hay, twigs, burlap, small stones, or pieces of brick. This provides for a freer entrance of water and helps to exclude fine sand from the drain. The first earth should be put into the trench carefully so as not to movc the tile. The remainder of the backfilling may be done with shovels, scrapers, or a turn plow.

Outlets. Where a tile drain discharges into an open waterway, Fig. 34, the outlet should be protected by building a substantial retaining wall around it. The foundation should extend well below the bottom of the channel so that the wall will not be undermined by the current in the waterway or the water discharging from the drain. Only vitrified clay, concrete, or metal pipe should be used near the outlet, as soft clay tile may disintegrate under the alternate conditions of freezing and thawing to which they will be subjected.

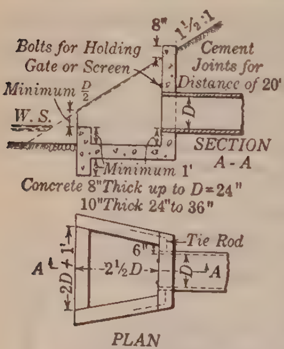

Fig. 34. Outlet Structures for Closed Drains

Surface-Inlets are sometimes constructed at low places to supplement surface drainage. They are commonly made of wood, concrete, or sewer pipe. They consist essentially of a small basin that extends to or below the bottom of the drain to which they are connected, with an opening at the top for the entrance of surface water. The surface opening should be covered with an iron grate which also should be protected by a covering of loose rock to prevent the entrance of dirt and drift.

Silt-Basins or Sand Traps are basins placed in drains or at the junctions of drains for the collection of silt and sand. They also afford an opportunity for the inspection of drains. The bottoms of the basins should be 2 or 3 ft. below the tile to provide a receptacle for the silt, which may be cleaned out as often as is necessary. These structures are not required for clay or loam soils, but are useful where drains are laid in sandy soils.

27. Costs and Profits

Cost of Round Drain Tile f.o.b. Factory

Prices quoted by manufacturers, subject to small discounts.

Size, in.	Length of one tile, ft.	Weight per linear ft., lb.	Price per 1000 ft.	Price of Y's, T's, ells and curves, each	Linear ft. per carload of 30 000 lb.
3	1	4	$30	$0.15	7500
4	1	6	45	.23	5000
5	1	8	60	.30	3750
6	1-1/2	11	82	.41	2760
8	2	16	120	.60	1875
10	2	23	172	.86	1300
12	2	31	232	1.16	970
14	2	38	312	1.56	790

22	2	100	850	4.25	300
24	2	110	950	4.75	280
27	2	140	1200	6.00	220

Amount of Tile per Acre. Where, over a considerable area, field drains are placed parallel and equal distances apart, the number of linear feet of tile required per acre may be obtained by dividing 43 560 by the distance between drains in feet. The following are linear feet for distances commonly used. An allowance of 4% should be made for breakage and imperfect tile.

Distance apart	25	30	33	40	50	66	80	100	150	200
Lin. ft. per acre	1742	1452	1320	1089	872	660	545	436	291	218

Cost of Drains. With labor at 40 cents per hour, for 6-in. tile or smaller, the cost of digging trenches 3 ft. deep by hand will be 3 to 5 cents per linear foot. On large contracts, the cost will usually be about 25% less with trenching machines than with hand labor. Trenches 4 ft. deep cost about 50% more than trenches 3 ft. deep. Laying tile and backfilling costs 1/2 to 3/4 cent per linear foot. If the ground is rocky or contains many roots the expense of excavation will be greatly increased. Very wet soil and especially quicksand may add to the cost of the work. The cost of laying a 12-in. drain will be about twice as great as the cost of laying a small drain to the same depth.

Profits from Drainage. The profits to be derived from farm drainage depend largely on the character of the land. The greatest profits usually result from the drainage of lands too wet for cultivation. The following examples are given in the Yearbook of the U. S. Department of Agriculture for 1914 as typical of results obtained from properly draining farm lands in the humid region of the United States.

In the Coastal plain of North Carolina about 25 acres that were producing nothing were tile drained for perhaps $250, probably not including costs of teaming and of supervision, and since then have produced a bale of cotton per acre. A field of 6 acres was drained for about $160, and the owner makes good crops on soil worthless without drainage. In the black prairie belt of Alabama, a field that had not been cultivated in years because too wet was drained with tile; then it produced one bale of cotton per acre and repaid the entire cost of drainage the first year. The following year the field yielded 50 bushels of corn per acre, twice the rate from other parts of the farm. Another drained field produced one bale of cotton per acre, whereas the undrained land produced only half a bale. A 10-acre field that yielded practically nothing in 1912 was tile drained, and in 1913 produced 60 bushels of oats per acre; in 1914 the rate was again 60 bushels of oats, in contrast to 10 bushels per acre from the adjoining 15-acre field planted to the same grain. The cost of most of the tile drainage in Alabama has been about \$25 per acre, some of it as high as \$30 to \$35, but increases of 50 to 200% in yields and the assurance of good crops every year instead of only in very favorable seasons are very satisfactory returns. The cost of drainage there has usually been repaid in 2 to 3 years by improved crops. In Iowa, a field of 40 acres too wet for planting was tile drained at a cost of \$24 per acre, after which it produced 60 bushels of corn per acre. Another field was drained for \$23 per acre, thereby increasing the yield from 15 bushels to 40 and 50 bushels of corn per acre. In Arkansas, on one of the state farms, 1 bale of cotton per acre was secured in favorable years, and nothing at all when the early part of the season was wet; the year following the installation of tile the yield was 1-1/2 bales per acre. In Nebraska a tract of more than 700 acres was tile drained at \$24.25 per acre, the pumping plant cost \$2 per acre, and as part of a larger district the cost of levees to protect from overflow was \$9 per acre. The improvement, at a total cost of \$35 per acre, immediately increased the crop on about 80 acres of corn 22 bushels, and on another part the increase in 2 years was from nothing to more than 30 bushels of wheat per acre.

28. Drainage of Irrigated Land

Necessity. More than 10% of the area in the United States, which has been under irrigation for a considerable period, has become partially or entirely unproductive through waterlogging or becoming impregnated with harmful mineral salts. These conditions are brought about by over-irrigation and inadequate natural drainage, and the remedy lies in supplementary artificial drainage. The necessity for artificial drainage or the system of drainage to be employed is not apparent usually until after several seasons of irrigation, but from a study of the topography and soil strata it should be possible to foretell approximately the future drainage requirements of a newly irrigated tract. Some irrigation projects do not require artificial drainage and others require it only to a limited extent, but in all cases the matter should be thoroughly studied in connection with the investigation and design of an irrigation system.

Alkali is the popular name applied to a number of mineral salts, harmful to vegetation, which are found in the soils of arid districts. The more common of these are sodium chloride, sodium sulphate, magnesium sulphate, calcium chloride, calcium sulphate and sodium carbonate. All of these except the last appear on the ground as a white crust and are called white alkali. Sodium carbonate, or black alkali, is the most injurious to plants. It is indicated by dark spots on the surface of the ground due to the dissolution of humus and vegetable matter which it causes. These salts are readily soluble in water and irrigation waters after passing through the soil become more or less impregnated with them. When the ground water reaches a sufficiently high elevation, moisture is drawn from it by capillary attraction to the surface of the ground, where the water is evaporated and the alkali is left as a thin deposit. After this action continues long enough sufficient alkali collects on the ground to injure or destroy vegetation. The height to which water will rise by capillarity varies from about 2 ft. for coarse sand to 5 ft. for fine clay.

Removal of Alkali. Lands which contain an excess of alkali either from natural causes or from irrigation usually may be cleansed by irrigation after adequate drainage has been provided. The water must be lowered below the limit of capillary action. and then by applying water the salts are dissolved and carried through the soil to the ground water. Usually two good irrigations will reduce the alkali on the surface to a harmless quantity, though in rare instances two years or more may be required for reclamation.

Objects of Drainage. The specific results to be accomplished by the drainage of irrigated land may be one or more of the following: (*a*) The lowering of the ground water to a level where it will not interfere with the penetration of plant roots to the required depth; (*b*) the removal of alkali from the surface of the ground; (*c*) the removal of excess soil moisture and the aëration of the soil. The problem differs from that encountered in humid regions in that alkaline soils are peculiar to arid districts and the amount of water which the land receives under irrigation may in a large measure be controlled.

Source of Water. A drainage system cannot be designed successfully until the source of the damaging water is known and its movement understood. The source of the water may be (*a*) irrigation water applied to the tract itself, (*b*) irrigation water applied to an area at a higher elevation, (*c*) a canal or reservoir at a higher elevation. In the first case the movement of the water will be downward through the soil. In the last two cases the water will move laterally either in porous strata near the surface or under pressure beneath an impervious stratum of hardpan or clay.

Methods of Drainage. The drainage of irrgated lands is accomplished by: (a) tile drains, (b) open ditches, or (c) pumping from wells.

Intercepting Drains are used to cut off the flow of water from higher areas. They are usually placed near the foot of a hill or at a change in slope. A secondary intercepting drain is sometimes placed below and approximately parallel to the main drain to collect water that passes the upper drain.

Parallel Field Drains, either tile drains or open ditches, are used where the water does not come from some clearly defined outside source. They should be designed to keep the ground-water level below the depth from which water will be drawn to the surface by capillary action. For fine soils the depth to ground-water should always be more than 4 ft. Drains are excavated to depths of 6 to 10 ft., and spaced 300 to 3000 ft. or more apart. The deeper the drains the greater the spacing that is permissible. The outlet may be either a natural channel or an irrigation ditch.

On the Rio Grande Project of the U. S. Bureau of Reclamation comprising 200 000 acres, about 1916, 3 years after beginning irrigation, 70% of the area was becoming unproductive through rise in ground-water. The soil consists of clays, fine sands and silt. The thread of the valley slopes 4 to 5 ft. per mile. This area was reclaimed by open ditches 1/2 to 3/4 mile apart and 10 ft. deep. After reclamation the ground-water sloped 1 in 1000 toward the drains, with an abrupt loss of head of about 1.5 ft. close to ditches. This loss of head must be considered in estimating the depth of drains. The discharge of the drainage ditches during the irrigation season is about 1 cu. ft. per sec. per linear mile. The cost per cubic yard of excavating by machinery over 10 000 000 cu. yd. of ditches was 8-1/2 cents. The cost of structures, engineering, overhead, and right of way including rebuilding of irrigation laterals was 7 cents per cubic yard of earth excavated. (See Engineering News-Record, Sept. 18, 1919, and Oct. 5, 1922.)

Fig. 35 shows a tract of land near Garland, Utah, that was reclaimed by a combined system of intercepting drains and field drains. Where water is carried from a higher area through a porous stratum the intercepting drain should extend down to the impervious material, as indicated in Fig. 36, otherwise some of the water will pass below the drain. Fig. 37 shows a method of intercepting water under pressure beneath an impervious stratum. This method may be used when the water is at a great depth.

Capacity of Drains. Where the water comes entirely from the irrigation of the tract being drained it is usual to provide for the removal of 0.05 to 0.1 in. of water per 24 hours. This is equivalent to 9 to 18 in. for a growing period of 6 months or a flow per acre of 0.0021 to 0.0042 cu. ft. per sec. If all or part of the water comes from other irrigated lands, their areas and the amount of water coming from them should be determined as accurately as possible. If it comes from irrigation canals the seepage losses in such canals

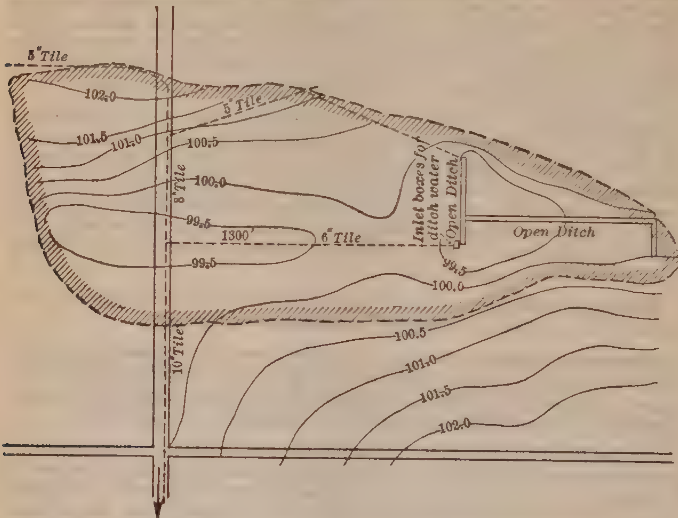

Fig. 35. Drainage of Irrigated Land by Intercepting and Field Drains

should be investigated. Nothing smaller than 4-in. drain tile should be used on irrigated lands.

The Cost of Trenching for the drains in irrigated districts will be relatively higher than in humid regions because of the greater depth of drains. If the banks cave, tim-

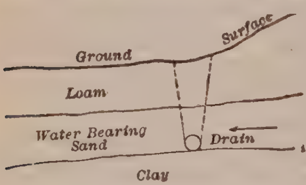

Fig. 36. Intercepting Drain

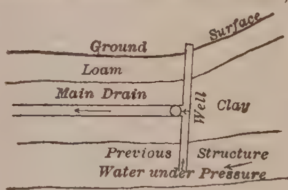

Fig. 37. Intercepting Drain for Water under Pressure

bering must be resorted to. In general the cost will be comparable to that of trenching for sewers and water mains at similar depths.

Drainage by Pumping from Wells has been in successful opration on the Salt River project to Arizona since 1922 and the success of this enterprise has influenced other districts to adopt the method. The method is particularly adapted to areas underlain by coarse water-bearing formations from which water may be pumped and to districts where cheap power is available. (See Bulletin 1456 of the U. S. Department of Agriculture, by J. C. Marr.)

In 1918, 64 000 acres of the 203 000 acres comprising the Salt River project were considered to be in immediate need of drainage. On this area 124 wells were driven to an average depth of 226 ft. The wells are 12 to 24 in. in diameter, most of them being 18 in. The total capacity of all wells is over 300 cu. ft. per sec., individual wells ranging in capacity from 1 to 10 cu. ft. per sec. The total cost of the drainage project was \$1 056 000. Of this amount about 90% was for pumping plants and power distribution system. During the year ending Sept. 30, 1923, 149 600 acre-feet of water were pumped. The cost of pumping was: Power, \$30 000; labor and materials, \$25 500; depreciation and overhead, \$56 500. The following are average data for the period: Lift, 33 ft.; power cost, 0.25 cent per kw.-hr.; total cost of pumping per acre-foot per foot of lift, \$0.023. A little more than half of the water pumped was used for irrigation. The remainder was wasted into natural streams, either because of the cost of conveying it to lands upon which it could be used or because of its unsuitability for irrigation. It is estimated that on the Salt River project the value for irrigation of the water pumped is as great as the cost of pumping. Economic conditions, especially the cheap power, were particularly favorable on this project.

Drainage Water for Irrigation. The outlets may be so situated that drainage waters can be used for irrigation. In many instances the value of such waters offsets to a considerable extent the cost of drainage works. All drainage waters are not suitable for irrigation because of the varying quantities of alkali salts which they dissolve from the soil. There is a diversity of opinion regarding the quantity of such salts that is permissible in irrigation water. The nature of the chemicals undoubtedly has an important bearing. It is generally conceded that water containing 0.1% by weight of solid material can be used safely. In some sections water containing twice this percentage of salts has been used without apparent injury to crops. Drainage waters containing salts in harmful quantities are often used for irrigation after mixing them with surface water.

Over-Irrigation. If water is applied to land only within the capacity of the land to contain capillary water the needs of vegetation are provided and no water is lost through seepage. The attainment of this ideal condition is not practicable but in general the use of less water will be beneficial in the following ways: (*a*) In saving irrigation water; (*b*) in reducing the amount of drainage required, and (*c*) in reducing the harmful effects of soil leaching. Whenever over-irrigation is practiced this process of leaching is in progress, and humus and nitrogen and various mineral elements of the soil which are valuable plant foods are washed away.

LEGAL AND ECONOMIC FEATURES

29. Water Rights

The Doctrine of Riparian Rights as commonly understood and interpreted is: "All persons owning land abutting on a natural stream have the right to demand that the waters of that stream shall pass their lands undefiled in quality and undiminished in quantity."

In the early history of the United States, the Common Law of England was generally accepted by the states and with it the doctrine of riparian rights. This doctrine is still in force in eastern United States. In western United States it is recognized only by California, Nebraska, Oregon, Texas, and Washington. In these states appropriation rights are also recognized and it is under the latter that most of the irrigating is done.

The subject of water rights is fully discussed by R. P. Teele in Bulletin 913 of the U. S. Department of Agriculture. The following is extracted from this bulletin:

Appropriation Rights. There has grown up in western United States a system of laws and customs controlling the use of water under which a farmer secures a " water right," that assures in greater or less degree his future water supply.

The use of streams for irrigation and like purposes is subject to control by the states, and must be in accordance with state laws. Actual use of water is necessary to hold a right and when the use ceases the right is forfeited. This is known as the doctrine of "beneficial use." Among users from the same stream the "first in time is the first in right." When there is not enough water for all, the rights are supplied, to the extent of the supply available, in the order of the dates on which they were acquired. This is known as the doctrine of "priority." Exceptions to this rule exist in a few of the states where, in cases of unusual shortage, the available water is apportioned among users either by state officers or by the courts. The date of a water right is fixed by the time of taking the first step to acquire it rather than by the time of putting the water to use. This is known as the doctrine of "relation."

Acquirement of Water Rights. In each of the western states except Kansas and Montana the acquirement of water rights direct from streams is under the control of state officials and any one wishing to get such a right must follow the procedure prescribed by law.

The Procedure is much the same in all the states and consists (*a*) in making application to some state official or board on forms supplied by the state, giving full information as to plans for irrigation works and use of water, (*b*) in carrying out of the plans as approved by the state, (*c*) in submitting proof of completion of work and use of water, and (*d*) in granting of certificates of license by the state, defining the right as to quantity of water, use to be made of water, and time during which it may be used. In Kansas and Montana it is required that a person wishing to acquire a water right shall post at the point of diversion and record with the County Clerk a notice showing the intention to take water, the amount to be taken, and the use to be made of it. The proposed work must begin within a reasonable time and must be prosecuted diligently to completion, and the water must be put to a "beneficial use." Anyone proposing to obtain a right to divert from a stream should consult the law of the state in which the land to be irrigated is located. The title to water is fully as important as title to land and it should receive the same careful attention.

Evidence of Title. Rights to water direct from streams are represented by the following evidences of title (*a*) filings in the county records; (*b*) filings in state engineers' offices; (*c*) certificates from courts, state engineers or boards; and (*d*) permits from state engineers or boards.

Rights to Underground Waters. Underground waters are divided into four classes: (*a*) underground streams flowing in known and defined channels; (*b*) underground streams flowing in unknown and undefined channels; (*c*) artesian waters; and (*d*) percolating waters. Although these classes are distinct in law, it is not always easy to tell to which class a particular supply belongs. Water which has long been considered in one class may later be found to be in another class and thus subject to a different law.

Subterranean streams flowing in known and defined channels are subject to the same laws as surface streams and one may not take water from such streams by means of wells or other means if it interferes with the rights of prior appropriators. Ownership of the land on which a well is located does nor give any right if the water is, in fact, a part of the stream. If a well draws water from an underground stream of which the channel is unknown and undefined, the ownership of land carries with it the right to take water. It is clear that the channel of such a stream may become known as a result of investigation, in which case a stream will become subject to the law of appropriation, and the prior user may stop use by later appropriators. Artesian water is held to belong to all the land overlying the artesian basin and each owner of such land is permitted to make any reasonable use of the water which will not interfere with a like use by all other land owners. In this respect, rights to artesian waters are similar to riparian rights. Percolating water, that is, water moving through the soil but not under pressure and not confined to a known and defined channel, belongs to the overlying land and the owner of the land may withdraw all he can get for use on his land. It is difficult to tell in which class the water found under any tract of land falls, but under the law all underground water is presumed to be percolating water unless it is proved otherwise.

Distribution of Water from Streams. Water from streams is distributed in canals in accordance with their right by public officials usually called water commissioners. Each commissioner has charge of the water within a certain district. He has a list of the rights showing amounts, dates, and locations, and distributes the water accordingly. In most states commissioners control diversions only when called upon by water users. When there is water enough for all, each takes it as he pleases. In the more highly developed communities, commissioners are on duty most of the time. Interference with the work of a water commissioner, by changing gates set by him, is a misdemeanor in most states.

30. Reclamation Laws

State and National Laws have been enacted for the purpose of encouraging or assisting irrigation development in the United States. Drainage statutes have been enacted by most of the states but there has been no national drainage legislation. There is, however, need for such legislation, particularly in connection with the reclamation of bottom lands along interstate streams where drainage is incidental to flood prevention and the problem is of national as well as local importance.

Federal and state policies with reference to land reclamation are discussed by R. P. Teele in Bulletin 1257 of the U. S. Department of Agriculture. Much of the material that follows has been taken from this bulletin.

Government Legislation for aiding irrigation began with the act of 1866. Difficulties had arisen regarding the right to divert water and the right to construct ditches over public land. This act recognizes rights acquired under local customs, laws, and court decisions and acknowledges and confirms rights of way for ditches over public lands. It stipulates that nothing in the act shall be " construed as affecting or intended to affect " state laws providing for the control of water used in irrigation.

The Desert Land Act as approved in 1877 provided for the procuring of title to 640 acres of arid land by conducting water upon it and the payment of $1.25 per acre. The entryman was required to spend at least $3.00 per acre in improvements and actually to reclaim at least one-eighth of the land. The area that may be taken by one person was limited by the act of 1890 to 320 acres. Under this act, a person may provide his own water supply or obtain a water supply from a system supplying many farms. In the latter case the entryman purchases a water right from the parties who build the irrigation works, and submits evidence of such purchase as proof of reclamation.

The Carey Act of 1894 grants to each of the states containing arid lands an area limited to 1 000 000 acres on condition that the states provide for its reclamation. The details are left to state legislation. The plan of operation under the Carey Act is for the states to contract with construction companies for building the works to reclaim specific areas of public lands. These contracts provide that the construction companies may sell " water rights " to reimburse themselves for the cost of construction, while the states sell the land to parties who have contracted for the purchase of water rights.

The United States Reclamation Act was authorized by Congress in 1902. It provides that all revenues derived from the sale and rental of public lands shall be employed in the construction of irrigation works for the reclamation of arid lands. Settlers acquire lands in areas that are estimated to support a family comfortably. Under some projects the farm areas are as small as forty acres. These are entered under the Homestead Act and the settler is given twenty years to complete his payments toward a proportionate interest in the irrigation works. **Water Users' Associations** are formed under each project and as the settlers make their payments they become active participants in the management of the irrigation works. Finally, the government withdraws and leaves all responsibility in the hands of the local organizations.

The Earliest State Legislation for aiding irrigation, as was the case with early federal legislation, was designed to remove obstacles to development rather than to provide direct public aid. State aid to irrigation development, with a few important exceptions, has been extended through irrigation district laws which provide means for making lands liable for the cost of their own reclamation.

Irrigation District Laws are similar in all of the arid states. These laws provide that a district may be organized only upon the petition of at least a majority of owners of land in the proposed district, who must also represent a majority of the acreage included; and upon a favorable vote (from a majority to two-thirds) of these land owners. If these conditions are fulfilled, land can be included in a district against the will of its owner and obligated for its share of the cost of providing a water supply.

California State Land Settlement represents a policy new in this country. The state buys land, provides irrigation and drainage works, subdivides the land, and sells the land on easy payments to actual settlers. The law authorizes the land settlement board, which administers the law, to prepare the land for cultivation, seed, plant and fence the land, and put up buildings or make other improvements. Settlers are required to pay at the time of purchase 5% of the price of the land and 40% of the cost of improvements. The balance is to be paid in amortized payments running not more than 40 years.

Federal Legislation Relating to Swamp Lands is limited in the main to the swamp land acts of 1849, 1850, and 1860. Under these acts the public swamp lands within their borders were granted to Alabama, Arkansas, California, Florida, Illinois, Indiana, Iowa, Louisiana, Michigan, Minnesota, Mississippi, Missouri, Ohio, Oregon, and Wisconsin. The total area conveyed to the states up to June 30, 1922, was about 64 000 000 acres. This granting of the swamp lands to the states explains the absence of any other federal legislation relating to the reclamation of swamp lands.

Drainage District Laws as enacted in various states are based upon similar principles as follows: (*a*) The consent of the majority of the interested land holders is necessary before a drainage district may be organized; (*b*) the drainage district may may not be organized unless it is clearly shown that the benefits to be derived will exceed the cost; (*c*) no drainage district may be organized unless it is shown that the work will be conducive to public health or general welfare. In general the state laws require the presentation of a petition by interested land owners, accompanied by a bond, setting forth the necessity and nature of the improvement. The drainage laws of some states provide for the appointment of county drainage commissioners and engineers.

31. Cost and Value of Project

The Cost of a Reclamation Project may be divided into five general divisions: (*a*) Preliminary costs, (*b*) the cost of construction, (*c*) the cost of financing, (*d*) the cost of colonization, and (*e*) the cost of preparation of land.

Preliminary Costs includes costs of surveys and investigations, rights of way, damages, legal fees, and all expenses incurred in perfecting rights and titles to water and land. In making preliminary estimates each of these items should be investigated with particular care.

The Cost of Construction includes the cost of labor, materials, supplies, equipment, supervision, overhead and all other expense required to complete a system of canals and structures that will deliver water to each farm in such quantities and at such times as is required. The cost of engineering is usually 5 to 10% of the construction cost. In preparing cost estimates provision should be made for unforeseen contingencies, particularly in connection with structures along streams which are liable to damage by floods. Unexpected difficulties are often encountered in excavating for subaqueous foundations.

The Cost of Financing. Interest on investment begins with the first expenditures and increases in amount as work progresses until the project is completed. As each tract of land is settled it carries its proportionate share of the interest charge. In order to reduce this expense to a minimum the construction work should be carried on without undue delay. If projects are financed by bonds the bond discount is a charge against the cost of the project.

The Colonization of a reclaimed area is expedited through the medium of an independent advertising and selling organization. The advantages of a newly reclaimed project must be advertised and opportunities for showing the land must be provided. Frequently free transportation from long distances is furnished by colonizing agencies to prospective settlers. It is important that a project shall be settled as promptly as possible in order to reduce interest and secure early returns on the investment. A vigorous colonizing campaign is therefore generally advisable even though a larger expenditure will be required than if settlement is extended over a longer period. The cost of colonization may vary from $5 to $25 per acre. It is usually included in the purchase price of the land and is thus paid by the settler. In any event it should be considered as a charge against the cost of the project.

The above comments refer more particularly to projects developed by private capital, but in general the same principles apply to government reclamation work. Under the terms of the U. S. Reclamation Act, the reclamation fund is available without interest and the expenses resulting from delays in construction and colonization, though just as real, are not so readily apparent. The government has provided no method of effectively advertising and colonizing its projects, and much of the available reclaimed area has not been settled.

The Cost of Preparation of Land for cultivation (Art. 13) includes the expense of clearing, grading, construction of farm ditches and drains, and all other work incidental bringing the raw land to a productive state. Interest on the investment during the non-productive period is an important item of the cost.

Value of Project. Unless the value of a project after the land has been colonized and brought to a productive state is greater than the total expense involved in the development the project is not a sound business venture.

Failure of a Reclamation Project may be caused by mistakes in engineering such as faulty designs, underestimating construction costs, or, for irrigation projects, over-estimating the available water supply. Failure may also result from poor business management, inadequate arrangements for financing, colonization difficulties, or the short-sighted policy of putting an exorbitant price on land. Another and perhaps the most common cause of failure has been the inexperience of the settlers and their inability to finance themselves through to the time when the revenue from their farm equals or exceeds expenditures.

Dr. Elwood Mead is of the opinion (Trans. Am. Soc. C. E., 1927, Vol. 90, p. 733) that any development scheme will break down that is based on the idea that settlers can be secured who have sufficient capital of their own. The records of the U. S. Bureau of Reclamation show that 70% of the applicants for farms have less than $1500 capital and only about 10% have more than $2500. If the settler with $2000 capital takes a farm that will require an expenditure of $4000 to make it a going concern, the additional $2000 that is needed should be provided from some source on terms entirely different from those which local banks will give. Money for changing the raw land into farms must be advanced on long-time payments at a low rate of interest.

In Australia preparing land for irrigation is regarded as a part of construction and the settlers take land that is ready for immediate cultivation. Payments are amortized. A small yearly payment keeps up interest and eventually pays off the debt. A few private projects in the United States and the state projects at Delhi and Durham, California, have been developed under this plan and have been successfully colonized.

32. Operation and Maintenance

Organization. The right to participate in the benefits of an irrigation or drainage system is inherent with every tract of land which it embraces. This implies that every land owner within a project is entitled to a voice in its management. In some instances reclamation works are owned and operated by companies who contract with land owners to provide the benefits of the system at a fixed annual rate. More commonly the ownership of reclamation works ultimately passes to an organization composed of the land owners each of whom participates in the operation of the system proportionately to the area of land which he owns. This may be accomplished by forming a stock company in which one share of stock is issued for each acre of land. Such an organization has general direction of the operation of the system.

Water Users' Associations are formed by the water users of the projects of the U. S. Bureau of Reclamation as soon as it appears probable that a project is to be constructed. The object of these associations is to facilitate dealings with the Department of the Interior and, after the construction work is completed, to participate in the operation of the project. The ownership, and operation of storage works remains in the hands of the Government while the distribution of water is left to the management of the Water Users' Associations.

The Operation of a reclamation system may be divided into three general divisions: (*a*) The operation proper, which includes the operation of pumps and other machinery, and for irrigation projects the delivery and distribution of water; (*b*) maintenance; and (*c*) clerical work. The force necessary will depend upon the size of the project. The organization should be such as to provide for effective and efficient service from the system, to keep the project maintained in a satisfactory operating condition, and to keep all records and accounts in a proper manner. General supervision will rest with the board of directors, or its equivalent, who determine the general policies of the system. Direct supervision is under a general manager, who is the responsible head.

The Head of the Operating Department of a drainage project may be the chief engineer of the pumping plant. On irrigation projects he is the water superintendent and has charge of the distribution of the irrigation water. Under the superintendent are ditch riders who apportion the water among the various users. One ditch rider can oversee the distribution of water for 2000 to 3000 acres, where water is controlled at the farmers' headgate. If delivered to lateral headgates he serves from 5000 to 10 000 acres. The water superintendent should be thoroughly versed in the principles of water measurement and the ditch riders should be sufficiently skilled to be able to make an equitable distribution of the water.

Maintenance as applied to reclamation projects includes the repairs and labor necessary to keep the system in successful operation. Repairs to canals or structures damaged by floors, cleaning canals, replacement of broken parts of machines and similar work belong properly to maintenance, and it may also include minor extensions and betterments and the replacement of inexpensive structures. A regular maintenance force should be employed to keep the system in satisfactory operating condition, except in case of unusual accidents, in order that the expense of maintenance for different years may, as nearly as practicable, be uniformly distributed.

Depreciation. There is a natural limit in the life of many of the parts of a reclamation system. Canals, levees, earth and rock dams and similar structures if properly maintained, and not accidentally destroyed, should last indefinitely. Also it cannot be said that there is any limit to the life of many properly constructed concrete or masonry structures. Wooden and steel structures, however, will eventually deteriorate to such a state that they can no longer be maintained in a satisfactory working condition. The depreciation of the different parts of a reclamation system should be estimated in advance and provisions for replacements should be made by an amortization fund created by equal annual contributions, which are included as a part of the operating expense.

The Average Life, in years, of various parts of reclamation systems is approximately as follows:

Wood flumes, redwood	15 to 20
Wood flumes, fir	12 to 15
Wood flumes, pine	8 to 10
Wood-stave pipe, fir, uncoated	12 to 20
Wood-stave pipe, fir, well-coated	20 to 25
Wood-stave pipe, redwood, uncoated	20 to 25
Wood-stave pipe, redwood, well-coated	25 to 30
Miscellaneous small wood structures	10 to 20
Steel riveted pipes, uncoated	20 to 30
Steel riveted pipes, well-coated	30 to 40
Centrifugal pumps	12 to 20
Steam engines	15 to 25
Boilers	12 to 20
Crude-oil engines	10 to 15
Pole lines for telephones or transmission	10 to 15
Electric motors	15 to 20
Buildings and improvements	25 to 75

The life of a structure depends largely upon the care that is taken to preserve it and the conditions of use to which it is subjected. Wood that is alternately wet and dry will deteriorate more rapidly than if kept continually wet. Structures above water may be preserved by keeping them well painted. Wood or steel buried in the ground or submerged or in contact with water for considerable periods will last longer if well coated with asphaltum or tar. The following relative to the life of wood-stave pipe (by D. C. Henry, Reclamation Record, August, 1915) was collected from a large number of installations:

(*a*) Under favorable conditions of complete saturation, fir well coated may have the same life as redwood uncoated.

(*b*) Either kind of pipe will have a longer life if well buried in tight soil than if exposed to the atmosphere. Such life may be very long, 30 years or over, if a steady pressure is maintained.

(*c*) Either kind of pipe will have a longer life if exposed to the atmosphere than if buried in open soil, such as sand and gravel and volcanic ash, provided in a hot or dry climate the pipe is shaded from the sun.

(*d*) Under questionable conditions, such as light pressure or partially filled pipe, fir, even if well coated, may have only one-third to one-half the life of redwood.

(*e*) Under light pressure the use of bastard staves should be avoided.

(*f*) The use of wooden sleeves in connection with wire wound pipe is objectionable and has caused endless trouble and expense.

(*g*) If wooden sleeves are employed they should be provided, at least for sizes from 10 in. up, with individual bands to permit taking up leaks.

Tar Paint has been found by engineers of the U. S. Bureau of Reclamation to be superior to any other kind of paint for all submerged metal work. It is also used exclusively for wood-stave pipe and the interior surfaces of metal flumes to prevent both erosion and corrosion. It is considered very satisfactory for use on wooden structures, or in any place where a black paint with a slightly sticky surface is not objectionable.

Specifications of Bureau of Reclamation for Tar Painting. All metal work, except as herein provided, shall be thoroughly cleaned of all loose scale and given one coat of water-gas tar followed by two coats of coal-gas tar. All coats shall be applied when the temperature of the air and metal is not less than 60° F. The water-gas tar shall have a specific gravity of not less than 1.05 nor more than 1.10 at 60° F., and shall be of such consistency that it can be applied with brushes. The melting point of the coal-gas tar, as determined by the cube method, shall lie between 105° and 110° F. Both the water-gas tar and the coal-gas tar shall be freed from moisture, and all fat shall extracted from the water-gas tar. If the water-gas tar is too thick to spread, the contractor may use suitable light oil, satisfactory to the engineer, for thinning. The water-gas tar may be applied without heating, but the first coat of coal-gas tar, which may be applied a few hours after the application of the water-gas tar, shall be applied hot and brushed out as thin as possible so that the coating will not run or peel after it is dry. The second coat of coal-gas tar shall not be applied until after the first coat has set. This tar paint shall be well worked into all joints and open spaces. Pin-holes, screw threads, and all machine-finished surfaces shall not be painted, but shall be coated with white lead and tallow as soon as they are finished. (Reclamation Record, Jan., 1921.)

Annual Cost of Operation includes all expenditures required to secure the benefits from the reclamation works and maintain them in working condition. There is a wide variation in costs for different projects. The following represent the annual range of costs on a large number of projects:

Cost per acre of distributing water..........	\$0.40 to \$1.00
Cost per acre of maintenance..............	.50 to 1.20
Cost per mile of canal maintenance.........	50.00 to 125.00
Cost per acre of general expense............	.40 to .80
Cost of pumping water. (See Art. 18.)	
Cost of depreciation; each part of system must be considered separately.	
Total cost per acre of operation.............	2.00 to 4.00

Other costs are taxes, insurance, interest on investment and sinking fund, any or all of which may be included as a part of the annual expense.

33. Engineering Reports

Purpose. A report on a land reclamation project should set forth, in clear and concise form, the essential characteristics of the enterprise. All data on which conclusions are based should be given, in order that the report will withstand a critical inspection by other engineers, but the controlling features, on which the feasibility of the project depends, should be intelligible to any good business man. Voluminous details, such as runoff, temperature, and precipitation records may be included in an appendix. Reports are always required in connection with the financing of reclamation projects, and their value in this regard may depend, in a large measure, on the standing and reputation of the engineer who makes them. In order to bring a project properly before investors, the promoters of the enterprise should have the report of a reputable engineer. Financial concerns, before investing, ordinarily require an independent report from their own engineer. Frequently several reports are made before a project is financed. Reports may be made at intervals during construction to determine whether work is progressing satisfactorily and in case of failure the creditors may require a report to determine the status of their securities.

An investigation must precede the preparation of a report. This includes a field examination and a search for all data bearing on the development or success of the project. Ordinarily all surveys and other data of the field engineers will be available and these should be scrutinized with sufficient care to justify conclusions as to their reliability. Information relative to land values, crops, market conditions and similar matters may frequently be obtained from interviews with reliable persons, but data obtained from such sources should be accepted with caution. Government reports should be used if possible for securing temperature, precipitation, and stream flow data. Information obtained from investigating other projects in the locality is always valuable. Frequently additional surveys, test pits or other work will be required, but these should not be of extensive character. If data sufficient for an intelligent report are not available, this fact may be stated in the report, or the investigation may be postponed until full and complete data are secured. The field investigation ordinarily should not require more than one or at the most two weeks.

The Contents of a Report should be such as will set forth clearly the feasibility of the project from both engineering and business standpoints. In general, the main points to be shown are: (*a*) the efficiency of the reclamation system, (*b*) the cost of reclamation, and (*c*) the value of the project after reclamation or the net profit to result from the development of the project. The material should be presented in logical order and each subject should be discussed under an appropriate heading. The following are headings, with outlines of subject matter to be treated under each. They will have to be modified to suit the particular conditions of different projects:

(1) **Introduction.** There should be a few introductory statements leading up to the main body of the report. These may include the authority for making the report, the data on which the report is based, the engineer's opinion of the reliability of such data, the period covered by the investigation, and other general information of a similar nature.

(2) **Location.** It is important that the general location of the project should be described. Principal boundaries, railway and water transportation facilities, and distances to the more important markets should be given. A small scale general map showing this and other information will be valuable.

(3) **General Description.** A general description of the project should be given before entering into details. This may include important topographical features, the area of the project and a comprehensive outline of the scheme of reclamation. A map of the project showing the general plan of reclamation should be included with the report and referred to in the discussion.

(4) **Climate.** Since the growth and time of marketing crops depends in a large measure on climate, this subject may be discussed in considerable detail. Tables may be prepared from government records showing maximum, minimum, and mean temperatures and amounts of precipitation for the different months of the year. Dates of last killing frosts in the spring and first killing frosts in fall should be given.

(5) **Soil.** The soil formation of the project from the standpoints of texture, fertility, adaptability to particular crops, and drainage conditions should be discussed. If the soil formation varies greatly a soil map may be included. Government and state publications give valuable data relative to soils for many localities.

(6) **Crops.** Information as to the kinds, yields, and values of crops to which the lands of the project are particularly adapted should be included in the report. The costs of growing, the times of marketing, and the net returns to be expected from producing different crops may also be given. Information of this kind may frequently be shown to advantage in tables.

(7) **Markets.** The market for crops is usually an important consideration, and this should be discussed. Transportation facilities and freight rates should be given consideration in this connection.

(8) **Water Supply.** The success of an irrigation project depends in a large measure upon the adequacy of its water supply and this subject should be treated with considerable detail. The two things to be determined are the water supply available and the water supply required, and the analysis of the problem should show the data used and

the steps taken in arriving at conclusions in regard to these matters. The discussion may be incorporated under the following headings:

(8*a*) **Period of Irrigation** showing the time when different crops will ordinarily be irrigated and the number of irrigations for different crops, with conclusions as to the approximate distribution in the use of water.

(8*b*) **Water Requirements** for crops or duty of water based upon a study of the needs for irrigation of the crops likely to be grown on the project.

(8*c*) **Water Supply Necessary** for the project determined from considerations of plant requirements, actual area to be irrigated, and seepage and evaporation losses in canals and reservoirs.

(8*d*) **Water Supply Available**, determined from a study of stream flow and other hydrological data, with proper deductions for prior rights to water. This phase of the problem will require careful investigation and all conclusions should be supported by as many records as practicable. If such records are too voluminous to be incorporated in the body of the report they should be put in the appendix.

(9) **Runoff.** The runoff from an area to be reclaimed by drainage should be discussed in detail and all precipitation records and other data necessary to support conclusions should be given. If pumps are to be used at the outlet the reasons for selecting a pumping plant of a certain capacity should be fully explained.

(10) **Cost of Project.** An estimate of the cost of developing a project, up to the point when it will become a going concern, should be included in the report and the main elements entering into the cost should be discussed. Estimates of this class should be made on a liberal basis so that ample allowance will be made for all contingencies.

(11) **Annual Cost.** An estimate of the annual cost of operating the project should be submitted. This, like the estimate of cost, should be on a liberal basis.

(12) **Value of Land.** The various conditions affecting the value of lands after reclamation should be discussed and an estimate of values should be submitted. It is important to distinguish between the value of raw lands after reclamation and the value of cultivated lands.

(13) **Net Returns.** An estimate of net returns on the investment may be submitted. This will be obtained by deducting the total expense of reclamation from the estimated value of land.

(14) **General Conclusions.** A few short, clear-cut paragraphs summarizing the main points brought out in the investigation should be given at the beginning or at the end of the report. The conclusions should contain definite statements of opinion regarding the value of crops, the adequacy of water supply for irrigation projects, the estimated cost of reclamation, the cost of operation, the value of land, estimated returns from the investment, and other important features. In some instances the report may be concluded with the engineer's recommendations.

SECTION 17

SEWERAGE AND SEWAGE DISPOSAL

BY
METCALF & EDDY
ENGINEERS

SEWERAGE SYSTEMS

DISPOSAL OF SEWAGE

SEWERAGE SYSTEMS

1. Definitions and Purposes

Sewage is a combination of the liquid wastes conducted away from residences, business buildings and institutions, together with those from industrial establishments, and with such ground- and storm-water as may be present. **Domestic Sewage** is that from residences, business buildings or institutions. **Industrial Wastes** are the liquid wastes resulting from the processes employed in industrial establishments. **Storm-Water** is that portion of the precipitation which runs off over the surface during and for a short time following a storm. **Ground-water** is that which is standing in or passing through the ground.

A Sewer is a conduit for carrying off sewage; a **Drain**, one for storm or ground water. A **Combined Sewer** is one intended to receive domestic sewage, industrial wastes and storm-water. A **Separate Sewer** is one from which storm-water is intended to be excluded. **Underdrains** are sometimes provided beneath separate or combined sewers, for the purpose of removing ground-water and reducing the amount of infiltration into the sewers.

A **Building Connection** is a pipe leading from the plumbing system of a building to a sewer. A **Lateral Sewer** is one receiving sewage from building connections only; a **Submain** or **Branch Sewer**, one receiving the discharge of two or more laterals; a **Main** or **Trunk Sewer**, one receiving the discharge of two or more submains.

An **Outfall Sewer** is one extending from a collecting system of conduits to a point of discharge or treatment. An **Intercepting Sewer** is a sewer provided to intercept the sewage from a number of outfall sewers, or the dry-weather flow of sewage from one or more combined sewers, and convey it to a suitable point for treatment or disposal. A **Force Main** is a conduit in which sewage is forced under pressure from a pump. An **Inverted Siphon** is a section of a conduit which is depressed below the hydraulic grade line, and which is always full and under pressure. Although the term is generally used, it is a misnomer, since siphonic action does not occur in an inverted siphon.

A **Sewerage System** is made up of a system of sewers with all necessary appurtenances, connected and in working order. If composed of separate sewers it is a **Separate System;** otherwise it is a **Combined System.** The separate system may have some advantage when it is necessary to treat the sewage before disposal. It is also likely to be desirable for small communities in which storm-water can be adequately cared for by street gutters and natural water courses, and storm-water drains are not required, or, at most, are needed for only part of the area served. Separate systems are subject to misuse from the connection of storm-water inlets and roof-water drains to separate sewers, resulting in their surcharge and the flooding of basements. This sometimes happens as the result of carelessness when storm-water drains are available. This is less likely to occur if it is made standard practice to use two sizes of pipe for connections, as for instance 5-in. for building connections to the sewer, and 6-in. to the drain. A similar result may be obtained by requiring all pipes of one system—for instance, the building connections for sewage—to have the socket painted with some conspicuous color, and insisting that only pipes so marked may be connected to the separate sewers.

2. Quantity of Sewage and Storm-Water Runoff

The quantity of domestic sewage and industrial wastes is generally related rather definitely to the population, and will increase substantially in direct ratio to the increase in population. It is necessary therefore to make a careful study of statistics of population and a forecast of the future population as a basis of estimating the total quantity of sewage. In the majority of cases the total daily volume of domestic sewage and industrial wastes approximates the daily consumption of water from the public supply. Some water used for sprinkling lawns, making steam, and other purposes is not discharged into the sewers after use; but ground-water and water from private wells and secondary supplies is likely to reach the sewers in sufficient quantity to make up for it. In some places the amount of water obtained from other sources than the public supply may be so great that the quantity of sewage may largely exceed the recorded water consumption.

The maximum rate of sewage flow is generally from two to three times the annual average rate of water consumption. In the smaller communities the per capita water consumption is generally less and the range between average and maximum rate is greater than in the larger cities. With water consumptions from 60 to 125 gal. per capita daily, the **Maximum Rate of Domestic Sewage Flow** may be expected to be from 200 to 250 gal. per capita daily.

The **Quantity of Industrial Wastes** and the rate of discharge may vary so widely in different communities and with different classes of industries that no general statement can be made. Data must be obtained locally for the conditions to be met. Frequently the total quantity of sewage other than ground- and storm-water from a community is not materially affected by the industrial wastes, and the maximum rate of flow may be estimated as a definite number of gallons per capita daily.

The **Amount of Ground-Water** entering the sewers varies widely, depending upon the extent of the sewers below ordinary ground-water elevation, and the type and excellence of construction; it also fluctuates with the season of the year and the conditions regarding precipitation. In general it is not practicable to keep out all ground-water, and allowance must be made for such a maximum rate of ground-water infiltration as is likely to occur under the circumstances. Data relating to actual infiltration are fragmentary, but indicate that maximum rates of 50 000 gal. per day per mile of sewer are not uncommon in systems supposed to be well built and maintained. In design it is best to allow for some quantity, such, for example, as 1000 or 2000 gal. per day per acre served by the sewer.

The **Maximum Rate of Sewage Flow** to be used as the basis of design of separate sewers is obtained by adding the rates for domestic sewage, industrial wastes, and ground-water. Assuming an area of 1000 acres, a density of population of 40 persons per acre, a rate of 200 gal. per day per person for domestic sewage, and 2000 gal. per day per acre for ground-water, the maximum rate of sewage flow would be 10 000 000 gal. per day, exclusive of industrial wastes. The conditions as to density of population to be expected will depend upon local conditions, zoning control and the like, and must be analyzed for each community. The probable average density of population is greater in small districts than in large ones, and therefore lateral sewers and submains should generally be designed for greater capacity in proportion to the areas served than the trunk sewers and intercepters. The design of separate sewers in a portion of Louisville, Ky., was based upon future densities of population as follows:

Extent of district, acres	10	100	500	1000	5000	10 000
Density of population, persons per acre	100	63	46	40	29	25

Storm-Water. The rate of storm-water runoff is best estimated by the **rational method**, expressed by the formula $Q = CiA$ where Q is the rate of runoff in cubic feet per second; A is the drainage area in acres; i is the average intensity of precipitation in cubic feet per second per acre (practically, the rate in inches per hour); and C is the "coefficient of runoff." The rate of precipitation i should be that which may occur in the period of time, called **"time of concentration,"** required for water to flow from the most distant point of the drainage area over the surface to the nearest inlet ("inlet time") and thence through the drains to the point for which the rate of discharge is required ("time of flow"). The inlet time can be estimated only on the basis of experience and local conditions; it will seldom be less than 3 or more than 20 minutes. The time of flow can be computed with sufficient accuracy by dividing the lengths of the several sections of drain by the estimated velocities of flow. It is seldom advisable to construct drains large enough for the maximum storm-water flows which may occur and it is assumed that the drains may be surcharged occasionally, say at average intervals of five, ten or fifteen years.

For the satisfactory determination of the rate of rainfall to be expected in any period of time and for a certain time of recurrence it is necessary to have at least 20 years' records of a recording rain-gage. Analysis of such records will show for any given duration of rainfall the rate of precipitation which has been equaled or exceeded, 1, 2, 3, and 4 times in the period covered by the record. If this is 20 years, the rates correspond approximately to those which have occurred at average intervals of 20, 10, 6-2/3 and 5 years. A smooth curve drawn to represent the points for various durations and a single

Meyer's formulas for value of i are as follows: (t = time in minutes):

District	Average Frequency, 25 years	Average Frequency, 10 years	Average Frequency, 5 years
1. Gulf Coast	$\frac{355}{t+40}$	$\frac{276}{t+32}$	$\frac{220}{t+27}$
2. Atlantic Coast from Narragansett Bay to Savannah; most of Georgia, Alabama, Mississippi, Arkansas, Missouri, Kansas, Oklahoma, and central Texas	$\frac{252}{t+28}$	$\frac{214}{t+26}$	$\frac{171}{t+23.5}$
3. Central New England and New York; region between District 2 and Great Lakes, as far west as 100th meridian	$\frac{181}{t+21}$	$\frac{150}{t+19.5}$	$\frac{122}{t+18}$
4. Northern New England and New York	$\frac{160}{t+20}$	$\frac{132}{t+19}$	$\frac{108}{t+17.5}$
5. Eastern Montana and Wyoming, Western Dakotas and Nebraska, Northeastern Colorado	$\frac{126}{t+14}$	$\frac{105}{t+13}$	$\frac{90}{t+13}$

frequency of recurrence may be taken as the curve of time-intensity relation for that frequency. If precipitation records are not available, recourse must be had to those of some neighboring locality, or general formulas like those of Meyer must be used.

The determination of the coefficient of runoff requires the application of judgment to a greater degree than any other element which enters into the estimation of storm-water runoff. No exact rules for computing it can be formulated. If an area were entirely impervious, and rain fell at a uniform rate, there would be a time when water was running off as fast as it fell, except for slight evaporation, and the coefficient would be 1.00; but comparatively few surfaces are absolutely impervious, and considerable water is required to wet surfaces, fill depressions, build up sufficient depth to provide for flow, and the like, so that the coefficient seldom reaches unity for so-called impervious surfaces. Pervious surfaces vary in character so widely that their coefficients may be almost zero, or nearly as high as for impervious surfaces. In estimating the rate of runoff for design of storm-water drains, it is necessary to allow for conditions as they are likely to exist some time in the future, and fix the runoff coefficients for such conditions, including the effects of varying proportions of impervious and pervious surfaces, the variation of precipitation from an uniform rate, the difference due to varying times of concentration, and all other influences which can affect the rate.

Values for runoff coefficients have been commonly assumed similar to the following:

Kind of surface	Duration of heavy rainfall, minutes						
	10	20	30	45	60	90	120
Impervious..........	0.60	0.80	0.85	0.90	0.95	0.95	0.95
Pervious.............	0.20	0.35	0.40	0.45	0.50	0.55	0.60

Values for pervious surfaces might vary considerably, depending upon kind of soil and character of cover. The coefficient for any given area would be

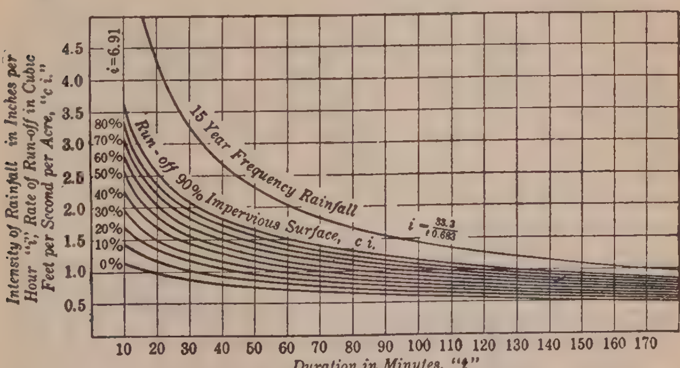

Fig. 1. Runoff Curve for Rainfall of 15-year Frequency at Louisville, Ky., corresponding to Various Proportions of Impervious Surface

obtained by combining the coefficients for impervious and pervious areas in accordance with the ratios of such areas, and further modified for the effect of any other factors requiring consideration.

In the application of the rational method to the estimation of storm-water runoff, it is convenient to construct curves similar to those in the following figure. The rainfall curve for 15-year frequency was adopted, and the run-off coefficients for pervious and impervious surfaces given in the table above were taken as basic coefficients, but were modified for the effect of time of flow—that is, allowance was made for the fact that at the end of any time of concentration the flow would be made up of water which fell at the beginning of the period upon the most distant parts of the area and has since been flowing to the outlet, and of water which fell in the last few minutes of the period on the portion near the outlet, so that various zones would be contributing water to the outlet at differing rates.

3. Sizes and Slopes of Sewers and Drains

Having estimated the maximum rate of sewage or storm-water flow, the sizes of sewers should be fixed to provide capacity for that flow. The practice

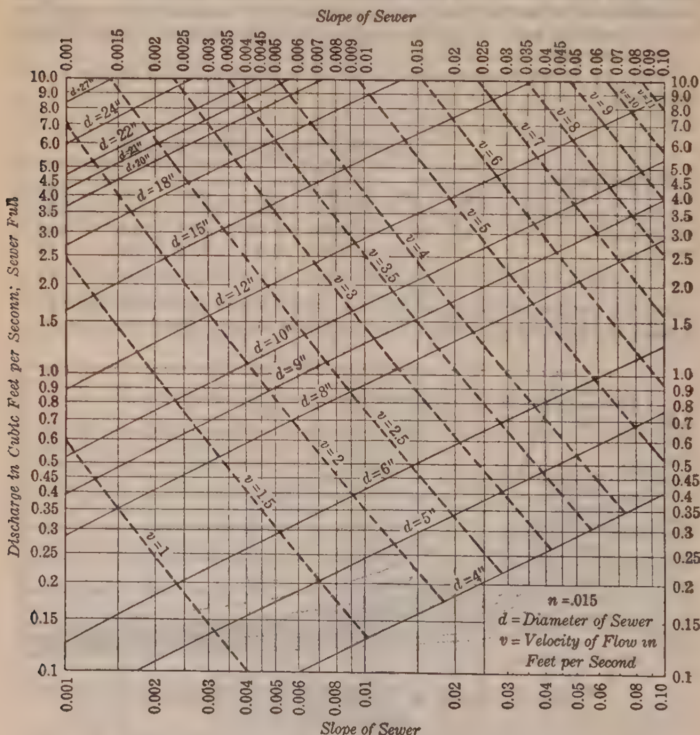

Fig. 2. Discharge of Circular Sewers for $n = 0.015$ and Steep Slopes

of providing sewers large enough to carry the maximum estimated flow when half full, especially in the case of separate sewers, was formerly widespread. This provides a 100% margin as a "factor of ignorance." While there are many elements of uncertainty in the estimation of capacity to be provided, it is now recognized as good practice to make all allowances in the estimate of quantity of sewage, and provide sewers large enough to carry these quantities when flowing full but not under pressure. In the case of separate sewers

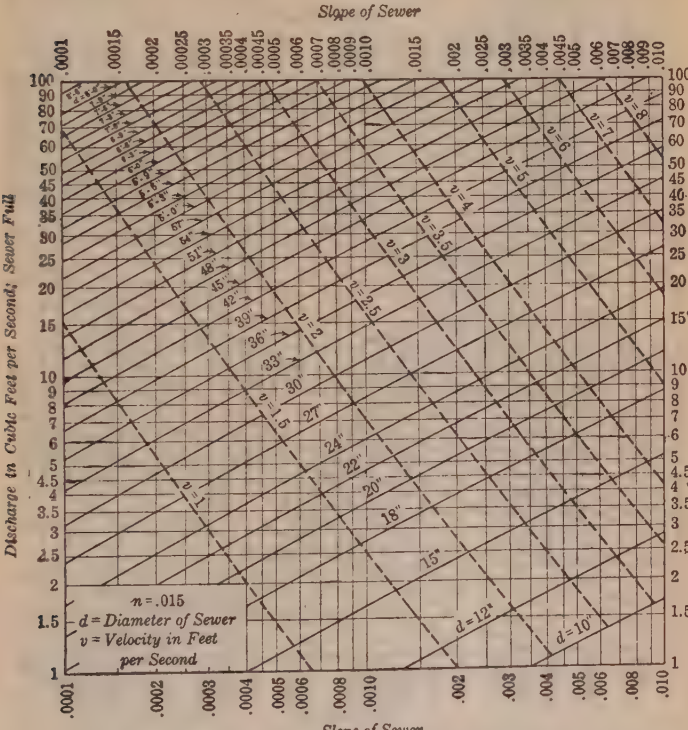

Fig. 3. Discharge of Circular Sewers for $n = 0.015$ and Flat Slopes

it may sometimes be advisable to make an allowance beyond the quantity of sewage and ground-water estimated as described above, for roof water which may be admitted by mistake or surreptitiously. In the case of combined sewers, the maximum rate of storm-water flow is usually taken as the basis of design, since the quantities of domestic sewage and industrial waste are so small in comparison that the size of sewer required is unlikely to be affected by their omission, except that in cases of unusual amounts of industrial wastes, the maximum flow should be taken as the sum of the maximum storm-water and the maximum industrial wastes.

Before determining the sizes of sewers, it is necessary to fix tentatively the slopes to which they shall be laid. In general, the topography will limit the possible slopes of the sewers. The depth at which sewers are to be laid is also an important consideration; they must be far enough below the surface to serve the lowest basements, unless the latter are so very deep as to make this impracticable, in which case the use of ejectors in deep basements may be necessary.

Having determined the capacity to be provided, and the slope, the size of

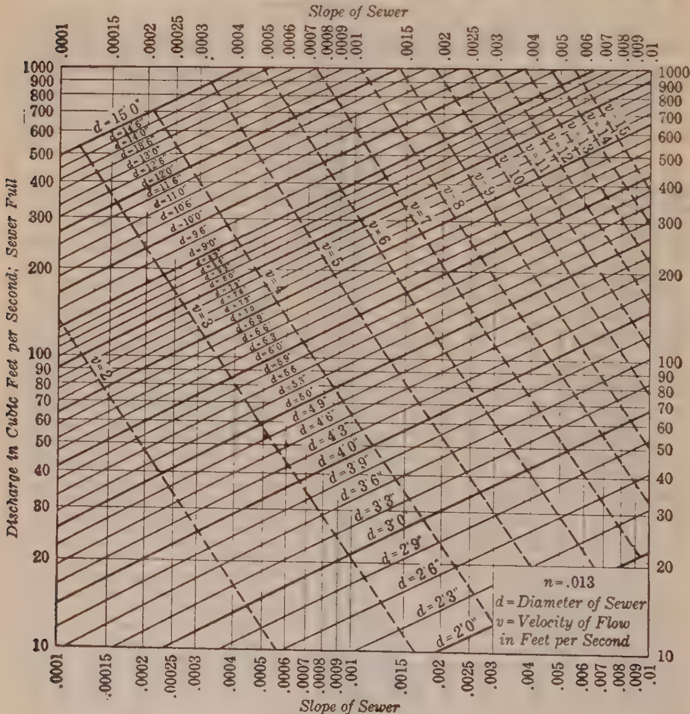

Fig. 4. Discharge of Circular Sewers for $n = 0.013$

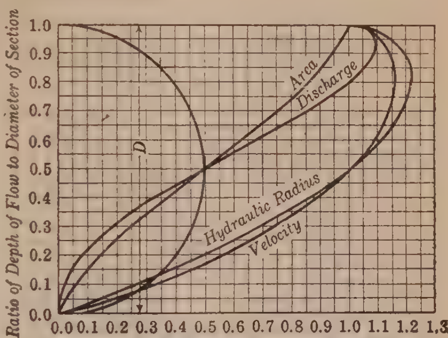
conduit required may be computed by any of the accepted formulas for flow in pipes, as the Hazen and Williams formula (*q.v.*).

It must not be forgotten that in hydraulic computations, the slope is the hydraulic gradient, which may not be the same as that of the invert of the sewer. This condition is particularly noticeable in the case of inverted siphons and submerged outlets.

The Kutter formula (*q.v.*) is most commonly used in estimating the flow in sewers and in fixing the size required for a given capacity. Since analysis of flow conditions when the sewers are partly filled is generally necessary, a formula for flow in open channels must be employed; and the applicability of the

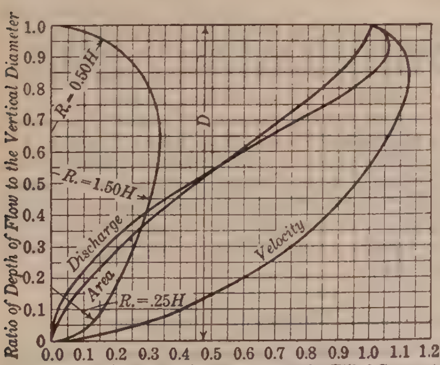
Kutter formula to full-sewer conditions is sufficiently accurate for practical use. Recommended values of n in this formula are, for pipe sewers 24 in. and less in diameter, 0.015, and for monolithic concrete of best workmanship 27 in. or larger in size or reinforced-concrete pipe of the same sizes, so jointed as to provide equally smooth interior surfaces, 0.013. Under test conditions with conduits clean and free from deposits and with no disturbances in flow due to the entrance of branch streams, enlargements, curvature and the like, the coefficients would be lower; but the values recommended are applicable to actual conditions likely to exist in sewers reasonably well cared for.



Ratio of the Hydraulic Elements of the Filled Segment to those of the Entire Section.

Fig. 5

In fixing the size of sewer required, the Kutter formula is most readily used by means of diagrams like those here given, from which the size of sewer and the velocity corresponding to a given discharge and slope can be read.



Ratio of the Hydraulic Elements of the Filled Segment to those of the Entire Section.

Fig. 6

For conditions other than full sewers, and for other shapes than circular, as well as for other values of n, the Kutter formula may be solved arithmetically by the aid of the tables in Sect. 9, Art. 15, interpolating for the proper values of R and n, or by the use of diagrams such as those in Metcalf & Eddy's American Sewerage Practice, Vol. I; Creager & Justin's Hydro-Electric Handbook, or Bulletin 852, U. S. Dept. of Agriculture. Hydraulic conditions for various depths of flow are compared most conveniently by means of diagrams showing the relations of the hydraulic elements, similar to those in Figs. 5, 6 and 7. The preparation of such a diagram is somewhat laborious but, once made, it can be used with sufficient accuracy for other sections of the same shape through a considerable range of sizes and slopes, although not for other values of n. This formula is only approximately applicable to part-full conditions, but no better method is available.

The **Minimum Size** of lateral sewers is generally at least 6 in.; many engineers consider 8 in. as the minimum. It is essential that the pipes shall be large enough not to be readily clogged by scrubbing brushes, mops and similar articles which sometimes enter the sewers through building connections.

The **Minimum Velocity** of flow which will prevent the formation of deposits in sewers is about 2.5 ft. per sec. in combined and 2.0 ft. per sec. in separate sewers. Higher velocities are desirable if the sewers are to be kept clean without frequent flushing. It is important to study the conditions which will exist at times of minimum flow; should it be found that the velocity at such times would be as low as 1.5 ft. per sec., it may be advisable to change the slope, dimensions, or form of section so as to ensure a more adequate velocity.

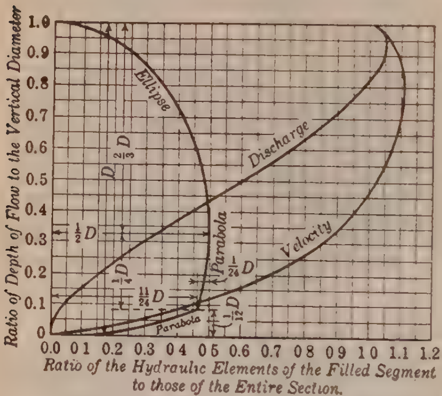


Fig. 7

Flushing may be resorted to in extreme cases, where it is impossible to provide sufficient slope to obtain self-cleaning velocities. This is frequently done by means of **Automatic Flush Tanks** located at the upper end of the laterals, and so arranged as to discharge a considerable quantity of water at least once a day.

Sewage Relift Stations or **Ejectors** are sometimes required to lift the sewage to a higher elevation, when the continuance of the sewers at reasonable slopes would involve excessive depth of trench, or to raise the sewage from areas too low to drain into available sewers. Such a station usually consists of a storage well or tank large enough to retain the sewage flow for a period of one or two hours, and a vault or steel tank containing one or better two vertical centrifugal pumps driven by electric motor and operated by float controlled switch. Such stations are so nearly automatic that they require attention not oftener than once a day.

4. Materials and Shapes of Sewers

Vitrified Clay or **Cement Concrete Pipes** are almost universally employed for sewers up to about 24 in. diameter. They are usually in lengths of 2-1/2 or 3 ft. and provided with sockets for jointing. The American Society for Testing Materials has adopted specifications for sewer pipes which are followed by the manufacturers of both clay and concrete pipe. Standard sizes are 4, 5, 6, 8, 10, 12, 15, 18, 21, 24, 27, 30, 33 and 36 in. **Joints** in such pipes are made by forcing a jute gasket into the socket, followed by either cement mortar, molten sulphur and sand, or a bituminous compound. **Cast-Iron Pipes** with lead or composition joints as in water works practice, are sometimes used for sewers when ground-water conditions are unusually bad and it is especially important to limit the infiltration of ground water.

Reinforced-Concrete Pipes are used to a considerable extent, in sizes from 24 in. to 72 in. or larger.

The **Load** to be carried by pipes depends not only on the depth of trench and the character of the refill, but also upon the width of the trench. If the width is kept as small as possible, a substantial part of the weight of the backfill may be carried by the sides of the trench.

The **Maximum Loads** on pipes imposed by backfill of saturated clay weighing 130 lb. per cu. ft., according to Marston and Anderson, may be as great as the figures given below (lb. per lin. ft.):

Width of trench at top of pipe	Depth of fill above pipe			
	8 ft.	12 ft.	16 ft.	20 ft.
2 ft.	1380	1730	1940	2090
4 ft.	3360	4560	5510	6280

When the pipe is laid substantially at the original ground level and an embankment is built over it, the loads to be carried would be very much greater than the above figures. In the case of a conduit 4 ft. wide outside and with a height of fill of 16 ft. over the top, and with saturated earth weighing 130 lb. per cu. ft., the load on the conduit might approximate 15 000 lb. per lin. ft., or nearly three times as great as that resulting from the backfill in a trench of the same width and depth.

The **Strength** of sewer pipe to withstand loads is dependent upon several factors in addition to the specific strength of the pipe itself—especially upon the manner in which the trench bottom is shaped to receive the pipe and the backfill is replaced at the sides and over the haunches. The provision of a concrete cradle to sustain the pipe enables it to develop much greater strength than if supported in any other way.

The specifications of the American Society for Testing Materials require that sewer pipes of either vitrified clay or concrete shall have a strength in sand-bearing tests at least as great as shown in the following tabulation (lb. per lin. ft. of pipe):

Size, in.	8	12	18	24	30	36	42
Strength	1430	1710	2200	3070	3690	4400	5030

The specifications of the American Concrete Institute for reinforced-concrete sewer pipe require the following minimum dimensions and strengths;

Size of pipe, in.	Shop-made pipe		Field-made pipe		Strength in sand-bearing tests, lb. per lin. ft.
	Thickness of shell, in.	Area of steel in longitudinal section 1 ft. long, sq. in.	Thickness of shell, in.	Area of steel in longitudinal section 1 ft. long, sq. in.	
24	2-1/2	0.15	3	0.065	4500
36	3	0.36	4	0.125	6300
48	3-3/4	0.46	5	0.210	7650
60	4-1/2	0.54	6	0.290	8700
72	5	0.62	7	0.360	9300

Investigations by Prof. Anson Marston have shown that pipe as laid in the ground, with the bottom shaped to fit the pipe for 60 to 90 deg., and with backfill loosely placed, may be expected to develop a strength about equal to that shown by sand-bearing tests: if the bottom is well bedded for at least 90 deg. and the backfill thoroughly tamped as high as the top of the pipe, about 20%

greater strength may be developed; and if the pipe is supported in a concrete cradle extending at least as high as 1/4 the diameter of the pipe, the resulting strength will be from 50 to 100% greater than that shown by sand-bearing tests. The depths of earth weighing 130 lb. per cu. ft. which can be carried by pipes having the strength stipulated in the American Society for Testing Materials and American Concrete Institute specifications, without any factor of safety or allowance for superficial loads, are very roughly as follows:

	Vitrified or concrete pipe		Reinforced concrete pipe	
	Without cradle	With cradle	Without cradle	With cradle
In narrow * trench.............	8–12 ft.	20–25 ft.	10–40 ft.	20 ft. or more
In embankment, filled over pipe.	4–6 ft.	6–9 ft.	9–10 ft.	10–12 ft.

* Assumed to be as narrow as practicable for any size of sewer.

The larger sizes of sewers may be built of brick, or of concrete with or without reinforcement. Reinforced concrete is generally employed. Many forms of section have been used; the circular, egg-shaped, and horseshoe or semi-elliptical are in most frequent use. The section must be designed of proper thickness and with sufficient steel to have suitable strength for the load to which it may be subjected. Where velocities are unusually high and erosion may be severe, or where the sewage is acid or otherwise corrosive, it may be necessary to line a concrete sewer partly or wholly with vitrified brick or liner plates.

5. Manholes, Catchbasins and Inlets; Building Connections

A **Manhole** is a shaft extending from the surface of the ground to the sewer, and large enough to provide access for inspection, cleaning, or repairs of the sewer. Manholes may be built of brick or concrete. It has been common practice to provide them on pipe sewers at each junction or change of direction or slope, so that the sewer may be straight between manholes; and not so far apart that jointed rods for cleaning cannot be effectually utilized: in general they have been placed at intervals of 300 to 400 ft. The wear of pavements adjacent to manholes and of the manhole frames and covers and the annoyance caused by them are so serious that care should be exercised to avoid unnecessary manholes. They should be large enough at the top so that a man can readily enter—not less than 20 in. in diameter; and at the bottom for handling rods, pails, and the like—about 4 ft. across. A channel or channels should be shaped in the bottom of the manhole to continue the sewer across it, and to provide for any change of direction or branch. The platform or bench upon which men may stand should be higher than the center of the sewer, preferably at the elevation of the crown, to minimize disturbance of flow conditions in the manhole when the sewer is full. **Manhole Frames and Covers** must be heavy enough to stand a great deal of wear and not to be displaced by traffic; the cover must be ribbed or covered with bosses to reduce slipperiness. In the past it has been common to perforate manhole covers to provide for ventilation of the sewers; this is generally unnecessary, and the holes have admitted much dirt and occasionally considerable storm-water; they are now frequently omitted, except one or two for the insertion of the point of a pick in raising the cover. **Manhole Steps** built into the masonry may be of cast or wrought iron; if the latter they should be heavily galvanized or well coated with asphalt or other coating to protect them against rust. **Inlets** are openings in the curb or in the street surface for admitting storm-water. They may include direct connections to the sewer or drain, or they may be built upon or connected with **Catchbasins,** which are brick or concrete vaults of considerable size, having sumps below the level of the outlet pipe for the purpose of retaining street detritus and trash and preventing their being washed into the sewers. If they are to serve this purpose efficiently the accumulated material must be removed regularly. **Building Connections** are usually of 5-in. or 6-in. pipe, and should enter a pipe sewer through a Y-branch set when the sewer was laid, or a masonry sewer through a slant built into the side. The direction of flow should be such as to cause the least possible disturbance to flow in the sewer.

6. Maintenance of Sewerage Systems

Sewers should be inspected regularly in order to have definite knowledge of their condition and to remove causes of obstruction before they result in stoppage. Many sewers require periodic cleaning for the removel of sediment, grease, rags, sticks, tree roots, and the like, all of which have effect in reducing the capacity of a sewer if no more serious consequences result. Tree roots may enter through defective joints; they have been known to form mats 20 ft. or more in length and practically filling 6-in. and 8-in. pipes. Grease is most likely to be troublesome in the neighborhood of hotels, restaurants and the like. It may be retained in large measure by adequate grease traps: ordinary commercial grease traps are likely to be much too small. Sediment may be of organic matter settling out of the sewage, or of mineral matter resulting largely from street wash entering the sewer through inlets, catchbasins, and perforated manhole covers. Rags, sticks, and other articles, sometimes of considerable size, occasionally enter the sewer, sometimes through building connections, sometimes thrown into manholes. Locked manhole covers afford some protection against this abuse. **Cleaning** of sewers is frequently accomplished by flushing, generally by a stream of water from a fire hose introduced at a manhole. If this is not sufficient, a rope may be put through a section between manholes, and a piece of heavy chain attached to it and drawn back and forth for the the purpose of scraping off the sediment; or a stiff brush or steel scraper may be necessary, particularly if accumulations of grease are to be removed. It is frequently necessary to use rods, which are made in sections short enough to be handled in a manhole, with joints for ready connection and yet providing some degree of flexibility.

Catchbasins must be cleaned frequently or they will either become stopped or the water and dirt will go through them into the drain. This should be done after each considerable rain, and in any event often enough to leave sufficient capacity for the detritus which may be brought in by a heavy storm. The usual method is for a man to enter the basin and shovel the dirt into pails which are hoisted to the surface; sometimes a specially designed grab bucket handled by a derrick mounted on a truck is utilized. Mechanical appliances such as regulators, backwater or tide gates, and the like, require very frequent inspection and cleaning in order to keep them in operation. Manhole frames and covers must be occasionally renewed or reset, from being broken, worn smooth, worn so that covers rattle, or sometimes because the roadway is worn down and the casting projects so much as to constitute a menace.

Explosions in sewers due to illuminating gas or gasoline have sometimes occurred. The probability of trouble from gasoline can be greatly reduced by requiring all garages and places using gasoline to install suitable traps. Even if gasoline or illuminating gas is present, there will be little danger of explosion if lanterns are not used and men are not allowed to carry matches into sewers. The use of electric torches where wired lights are not available will be an adequate safeguard in most cases.

DISPOSAL OF SEWAGE

7. Sewage Characteristics

Physical, Chemical and Biological Characteristics. Sewage consists of about 1 part of solid matter to 999 parts of water. Of the solid matter, about a third is in suspension and the remainder in solution. About half the solid matter is organic and half inorganic. Sewage contains large numbers of bacteria, some of which may cause disease. The harmful bacteria and the putrescible organic matter are the constituents which are responsible mainly for the sewage problem.

Constituents. The constituents of sewage vary with the character of water supply, habits of the population and kind of industrial wastes, and the concentration is affected by the per capita use of water and by ground-water leakage. Sewage from combined sewers varies greatly according to the presence or absence of storm water. Hourly, daily and seasonal variations in constituents also occur. Furthermore, the character of the constituents may be materially modified by the age of the sewage which tends to undergo decomposition while being carried or retained in the sewers.

Analyses of sewage and of sewage effluents are made according to "Standard Methods for the Examination of Water and Sewage" 6th edition, 1925, as adopted by the committees of the American Public Health Association, American Chemical Society and American Water Works Association.

Data relative to the analyses of sewage from 16 typical American cities are given in the following table:

Constituent	Parts per million *			Grams per capita daily		
	Average	Maximum	Minimum	Average	Maximum	Minimum
Organic nitrogen	15.3	28.0	6.6	5.78	10.6	2.5
Ammonia nitrogen	21.6	37.8	11.6	8.17	14.3	4.4
Oxygen consumed	134	154	25	50.7	58.3	9.5
Residue on evaporation:						
Total	686	1790	280	260	678	106
Loss on ignition	332	753	166	126	285	63
Fixed residue	354	1037	114	134	393	43
Suspended solids:						
Total	246	781	77	93	296	29
Loss on ignition	180	626	64	68	237	24
Fixed	66	155	13	25	59	5
Chlorides as chlorine	40.5	116.1	17.2	15.3	44.0	6.5
Biochemical oxygen demand † (5-day)	135	180	119	51	68	45

* Based on flow of 100 gal. per capita per day.
† From data in U. S. Public Health Bull. 132.

European sewages are usually much stronger than American due to the fact that the per capita water consumption in Europe is much smaller than in America.

The effect of industrial wastes is shown by the following estimates of the increase in certain constituents brought about by the discharge of wastes into the sewers of several cities:

City, and kind of wastes	Per cent increase, per capita basis	
	Suspended solids	Oxygen consumed
Akron, Ohio: rubber reclaiming plant wastes	120	140
Chicago, Ill. (packing house district only): packing house wastes	46	225
Dayton, Ohio: paper mill wastes	60	25
Fort Worth, Tex.: packing house wastes	65	....
Gloversville, N.Y.: tannery wastes	155	115
Milwaukee, Wis. (portion of city): packing house and tannery wastes	70	10

Suspended Solids. Solids carried in suspension may be roughly divided into three classes: First, the grosser solids, such as fecal matter, garbage, paper, rags, sticks, and leaves, which are capable of being removed by mechanical means, such as screens. Some of these matters should not reach the sewers but do so as a result of misuse of house plumbing systems and of the sewers. Second, the more finely divided solids, the specific identity of which is difficult to establish, but which are capable of being removed by sedimentation. Third, the grease and finely divided solids which do not settle out within any reasonable period of time. Among the grosser solids are those which produce visibly offensive conditions at the outlets of sewers and which are often difficult to handle and to dispose of in treatment plants. The solids capable of settling are those which may form offensive deposits in streams or other bodies of water and which in treatment plants produce the sludge which is so often the most troublesome feature in connection with sewage treatment. The finely divided and colloidal solids tend to produce discoloration and turbidity in the streams receiving the sewage and also effect a demand upon the oxygen content thereof. The organic solids in all three classes of suspended solids exert an oxygen demand.

Oxygen Demand. Inasmuch as the purification of sewage, both artificial and natural, is essentially an oxidation process, the demand for oxygen exerted by sewage is a characteristic desirable to measure. The biochemical oxygen demand (B.O.D.) of sewage, effluent, polluted water or industrial wastes is the oxygen required for the oxidation through biological or chemical agencies of the organic matter and oxidizable inorganic matter contained therein. For detailed information relative to the subject of oxygen demand and methods for determining it, reference should be made to Public Health Bulletin 175, "The Oxygen Demand of Polluted Waters," from which the following table relative to oxygen demand of the sewage of several American cities is compiled.

Putrescibility is the susceptibility of sewage or other polluted water to undergo putrefaction. This is measured by determining the time required for the sewage or other polluted water to exhaust the oxygen present therein. The ratio of oxygen available to oxygen required to satisfy the oxygen demand

Total Oxygen Demand of American Sewage

Pounds per capita daily

Alliance, Ohio	0.15	Dayton, Ohio	0.20	Peoria, Ill.	0.25
Baltimore, Md.	0.24	Detroit, Mich.	0.17	Pipestone, Minn.	0.38
Brooklyn, N. Y.	0.19	Edina, Minn.	0.26	Procter, Minn.	0.14
Buhl, Minn.	0.19	Fitchburg, Mass.	0.17	Reading, Pa.	0.15

Columbus, Ohio	0.25	Marshall, Minn.	0.07	Washington, D. C.	0.25
				Average	0.197

is designated as relative stability. The common test for this ratio is made by adding a small quantity of dye, methylene blue, to the sample and incubating the mixture at a constant temperature for a certain number of days or until the color of the dye is discharged which occurs when the oxygen is exhausted. The relative stability of the sample is determined by the number of days elapsing prior to decolorization according to the following table:

Relative Stability Numbers

("Standard Methods of Water Analysis," American Public Health Association)

t_{20}	t_{37}	S	t_{20}	t_{37}	S	t_{20}	t_{37}	S	t_{20}	t_{37}	S
0.5	.....	11	3.0	1.5	50	8.0	4.0	84	13.0	6.5	95
1.0	0.5	21	4.0	2.0	60	9.0	4.5	87	14.0	7.0	96
1.5	.....	30	5.0	2.5	68	10.0	5.0	90	16.0	8.0	97
2.0	1.0	37	6.0	3.0	75	11.0	5.5	92	18.0	9.0	98
2.5	.....	44	7.0	3.5	80	12.0	6.0	94	20.0	10.0	99

S = Relative stability or ratio of available oxygen to oxygen required for equilibrium; expressed in percentages.
t_{20} = Time in days to decolorize methylene blue at 20° C.
t_{37} = Time to decolorize at 37° C.

8. Disposal by Dilution

Pollution by sewage has several serious aspects in the following order of importance: contamination and infection with disease germs of public water supplies; contamination and infection of shellfish areas; contamination of bathing waters and beaches; contamination of water supplies for cattle; the destruction of fish life; and the production of generally objectionable conditions as regards appearance and offensive odors.

Few cities now take their water supplies from sewage-polluted streams without purification, but there are many streams so grossly polluted that water purification plants treating their waters can barely provide safe supplies. The contamination of shellfish areas is of significance only in coastal waters, but the matter has become one of considerable economic importance. Bathing in materially sewage-polluted waters is objectionable both from the esthetic standpoint and the public health standpoint. The use of sewage-polluted water for the watering of stock may not always be dangerous, but in some cases, such as pollution by sewage containing tannery wastes, there may be danger of the spread of anthrax among cattle. As regards fish life the effect of sewage is probably less than that of industrial wastes, except when the sewage pollution becomes so concentrated as to reduce the amount of oxygen below the limit required for fish. Locally objectionable conditions frequently occur at the point of discharge of sewers due to the presence of floating sewage solids, oil slick, the formation of banks of decomposing sludge, and the production of unsightly scum and offensive odors. Generally objectionable conditions with respect to decomposition and odors do not result until there occurs complete depletion of the dissolved oxygen normally present in the stream or other body of water receiving the sewage.

Natural Agencies of Purification. When sewage is discharged into a body of water, natural processes immediately begin its purification. Microscopic and other living organisms in the presence of the oxygen held in solution in the water tend to oxidize the organic matter and unfavorable environmental conditions as regards temperature and food supplies bring about the destruction of large numbers of harmful bacteria. If the dissolved oxygen supply is sufficient, the oxidation of the organic matter proceeds under aerobic conditions without creating offensive odors. If the oxygen supply is inadequate and becomes exhausted, putrefaction or anaerobic decomposition sets in and putrid odors result. Reaeration, fostered by turbulence and sometimes by oxygen-producing organisms, tends to prevent putrefaction.

Where the discharge of sewage is into a quiescent body of water or into a stream of low velocity, the suspended matters settle, forming deposits which in the absence of oxygen, and particularly in warm weather, undergo decomposition. In time, these deposits may become converted to a stable humus-like material and under certain conditions of flood they may be scoured out and carried down to the sea.

Dissolved Oxygen. At any temperature and barometric pressure a specific quantity of atmospheric oxygen can be dissolved in water, then said to be saturated. The saturation point in salt water is less than that in fresh and the quantity capable of being dissolved in warm water is less than that in cold. The solubility of oxygen in fresh water at a barometric pressure of 760 mm. (approximately sea level) and at different temperatures is expressed in parts per million in the following table:

Temp., C.	Oxygen	Temp., C.	Oxygen	Temp., C.	Oxygen
0	14.70	10	11.31	20	9.19
1	14.28	11	11.05	21	9.01

Deduct 1% for each 270 ft. of elevation above sea level. For sea water deduct 20%, and for mixtures of fresh and sea water in direct proportion to the amount of sea water.

Dilution Required to Avoid Objectionable Conditions. To maintain satisfactory conditions where sewage is discharged into a stream, lake or ocean the diluting water in proportion to the quantity of sewage must be at least sufficient to permit purification to take place under aerobic conditions. In temperate climates, self-purification and depletion of oxygen proceed rapidly in summer, but slowly in winter; consequently, the volume of diluting water required for a given quantity of sewage is much greater in summer than in winter.

The quantity of diluting water required to prevent offensive stream conditions estimated by various authorities has varied from a minimum of 2-1/2 cu. ft. per sec. to a maximum of 7 cu. ft. per sec. per thousand persons contributing sewage. The lower limit is applicable only in the case of rapidly flowing turbulent streams, and the upper limit to sluggish streams with mill dams or quiet reaches in which there are opportunities for the deposition of solids and the formation of sludge banks. As experience and knowledge have increased, there has been a tendency to set the quantity of diluting water required nearer the upper limit.

Prompt and thorough mixing of the sewage with the diluting water is essential. This can be accomplished by use of multiple outlets discharging into the main current of streams or into deep water of lakes or oceans. Care must be taken to select points of discharge to avoid possibility of tidal currents carrying sewage matters to bathing beaches.

The most notable example of sewage disposal by dilution is that of the Chicago Sanitary District whose drainage canal since 1900 has diverted sewage of the district, together with large quantities of diluting water, from Lake Michigan to the Illinois River and thence to the Mississippi. The growth of tributary population and the limitations of the volume of diverted water established by the Federal authorities, and the limited capacity of the canal, have now rendered it necessary for the District to undertake the construction of treatment plants on a large scale.

For exhaustive studies into the matter of pollution and self-purification of streams, reference should be made to U. S. Public Health Bulletins 139, 146 and 171, and to the Appendix on Sewage Disposal accompanying the report of the Engineering Board of Review of the Sanitary District of Chicago.

9. Screening

In cases where disposal by dilution may be practiced, but where the removal of floating solids is desirable, screens alone are used. Screening is also employed to protect pumps and in connection with more elaborate methods of sewage treatment. There are many types of screens, from the simple hand-cleaned, coarse, bar rack to the elaborate mechanically operated and cleaned screen of small apertures.

Racks and Coarse Screens. There are several types of racks and coarse screens used to protect pumps and treatment plant features. The type most frequently used is the inclined bar rack with spacing ranging from 1/2 in. to 6 in. These racks are usually placed across the channel, the individual bars being inclined to the horizontal at various angles, such as 30 to 60 deg. Cleaning is usually done by hand, the screenings being raked to the top of the rack. In a few instances, mechanical equipment has been provided for cleaning.

Another type of rack is composed of movable segments, in the form of an endless belt, which in operation convey the screenings out of the sewage to a point where they are removed by mechanical means.

At certain places, notably the Boston Metropolitan District and Milwaukee, screens in the form of movable cages have been employed for the coarse screening of large flows of sewage from combined sewers. These cages are usually installed in duplicate so that one screen can always be in place while the other is raised for cleaning. In the Ward Street station at Boston, the cage screen is about 9 ft. high and wide and 3-1/2 ft. deep, and is composed of vertical 3/4-in. round bars with 1-in. clear opening.

Screenings Removed by Racks and Cage Screens

Municipality	Date	Type of screen	Clear spacing, in.	Screenings, cu. ft. per m. g.
Boston, Mass.: Deer Island	1926	Cage	1	1.78
Nut Island	1926	Cage	3/4	4.77
Ward St.	1926	Cage	1	3.50
Fitchburg, Mass.	1918	Rack	1-3/4	0.62
Gloversville, N. Y.	1916	Rack	1-1/8	1.45
Schenectady, N. Y.	1927	Rack	1-1/2	1.94
Toronto, Ont.	....	Rack	1/2	2.8–3.7
Washington, D. C.	1918	Rack	5/8 and 1/4	12.5

The quantity of screenings removed by coarse racks varies with the spacing of the bars, and with the degree of comminution of solids. The table above gives data relative to the removals by different installations of various clear spacing.

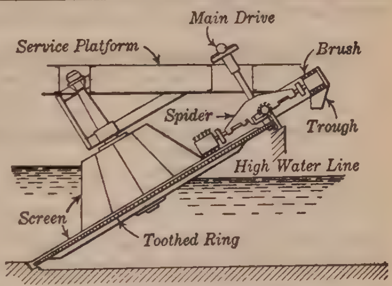

Fig. 8. General Arrangement of Riensch-Wurl Screen

Fine Screens. In recent years there has been a marked development in mechanically operated fine screens. At present the four leading types of fine screen in use in the United States are the Riensch-Wurl disk screen, the Dorrco and the Link-Belt drum screens, and the Rex band type. Other types are in use in Europe.

The **Riensch-Wurl** type of screen consists essentially of a slotted metal disk 8 ft. or more in diameter, revolving slowly around a shaft inclined slightly from the vertical in such a way that any particular portion of the disk passes alternately in and out of the sewage flow. Floating and suspended solids too large to pass through the slots are held back and are removed by revolving brushes which clean that portion of the screen out of the sewage.

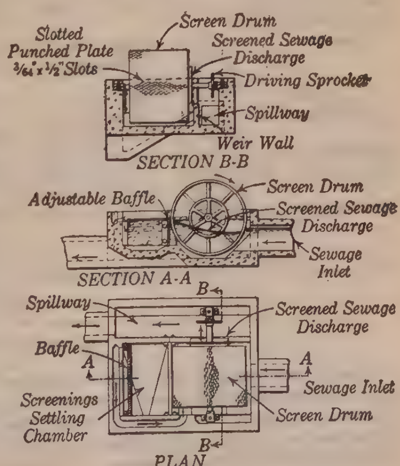

Fig. 9. Dorrco Screen

In the case of the **Dorrco** and **Link-Belt** screens, the slotted plates are fastened to a cylindrical framework rotated around a central horizontal shaft. The sewage flow passes from the outside of the cylinder to the inside and thence through an outlet at the end of the cylinder. The Dorrco screen is cleaned by washing the screenings off the drum by the outward flow of the sewage, which is carried slightly above the general water level by centrifugal action. The solids thus washed off, together with some which had never become attached to the drum, settle in the screen pit and are removed by means of a perforated bucket elevator. The Link-Belt screen is cleaned by revolving brushes travelling along the top of the drum.

The **Rex** screen consists of an endless band of slotted metal plates, moving in and out of the sewage flow, the screenings being brushed off just before the plates turn over the upper end pulley on their way back to the sewage.

The following table gives information relative to the quantity of suspended solids removed by several installations of fine screens. Under ordinary conditions a removal of 5 to 10 per cent is all that can be expected.

Sewage screenings are wet, odorous, putrescible and generally objectionable. Prompt removal and disposal are essential. In some cases excess moisture is extracted by presses or centrifuges and the partially dried material burned under boilers or in special incinerators. In other cases the screenings are buried or plowed into the ground. Unless precautions are taken, buried screenings are likely to attract rats.

10. Sedimentation

The removal from sewage of the settleable suspended solids is accomplished by sedimentation in suitable tanks. The degree of removal generally depends chiefly upon the period of detention, and but slightly upon the velocities prevailing in the tanks. Slight checking of such velocities as are common in sewers brings about the settling of some of the heavier solids, such as sand and grit, while in the case of solids of low specific gravity in a finely divided condition long detention at very low velocities is required. Sedimentation alone may constitute adequate treatment, in cases where the volume of diluting water is relatively large and where no public water supply is taken from the stream which receives the effluent. In most cases where a greater degree of purification is required, sedimentation is a valuable preliminary or preparatory treatment. Sedimentation is also utilized for the final clarification of effluents from trickling filters, and from aeration tanks in the activated sludge process. There are several types of sedimentation tanks differing from each other in function, design, and methods of operation.

Grit Chambers are small basins, shallow and narrow in proportion to their length, usually arranged in parallel units of two or more. Their function is to check the velocity of flow only sufficiently to allow the deposition of the heavier solids. The velocity usually provided for is approximately 1 ft. per sec. Grit chambers are cleaned by hand, by hose flushing or by grab bucket. A tank with mechanical equipment has been developed for continuous removal of deposits and separation of the lighter organic solids from the heavier inorganic solids.

Grit chambers are more necessary with combined than with separate systems of sewers, but they are commonly provided with the latter because exprience has shown that considerable grit such as cinders and sand finds its way into such sewers. The quantity and composition of the grit collected depends upon the composition of the sewage, the velocities through the chamber and the frequency and method of cleaning.

The following table gives data relative to the collection of grit in certain typical installations:

Volume of Grit Removed by Grit Chambers

Skimming Detritus Tanks are sometimes required to remove oils and grease which form unsightly scum on settling tanks or clog filters. The installation at Akron, Ohio, is typical. Two small circular tanks afford detention periods of about fifteen minutes. In these tanks the velocity is checked sufficiently to bring about the flotation of oil, grease and other substances lighter than water, together with the settling of a portion of the heavier suspended solids. The sewage flows out through two submerged openings, one a short distance below the water level and the other at the bottom. The portion discharged near the bottom, amounting to about one-fifth the flow, is somewhat concentrated by settling and passes through grit chambers and fine screens before reaching the Imhoff tanks, while the portion drawn through the upper opening goes directly to the tanks. Oil and floating solids are removed by skimming with a revolving scum board.

Plain Settling Tanks are usually rectangular in plan and section with the inlets so arranged as to permit fairly uniform distribution of flow through the cross-section of the tank. Detention periods range from 1 hour to 6 hours and baffle and scum boards are usually provided to aid in regulating flow and to retain scum. Cleaning is accomplished by drawing off the supernatant liquid and then removing the sludge by gravity or by means of pumps. The more common type of settling tank utilizes horizontal flow. Care must be taken to secure proper inlets and outlets. In some instances (Dortmund tanks) vertical flow is employed with the inlet for the sewage at the center of a cylindrical tank and the outlets arranged around the periphery. This type of tank permits the use of a hopper bottom from which the sludge can be drawn under the pressure of the supernatant water without interrupting operation of the tank. Plain settling tanks are cleaned at frequent intervals. The quantity and character of the sludge depend upon the characteristics of the sewage and the design and efficiency of operation of the tank.

Clarifier Tanks have been adapted for the settling of sewage. These are comparatively shallow circular or square tanks, equipped with mechanism for continuous removal of the deposited solids. The mechanism consists primarily of revolving arms just above the bottom of the tank to which are attached plates or plows so directed as to move the sludge slowly into the center as the arms revolve. From the center the sludge can be pumped to the point of disposal.

Septic Tanks are essentially sedimentation tanks so designed and operated as to permit the anaerobic decomposition of the deposited solids. It was originally claimed that this decomposition would proceed so far that the sludge would be completely gasified and liquefied, but experience has shown that this cannot be accomplished. The disadvantages of the tank are such that few are now installed for municipal treatment plants, although their use for residences is common. The septic tank is operated for much longer periods without the removal of sludge than plain sedimentation tanks. This has the disadvantage of producing a floating mat or scum of considerable thickness which becomes difficult to remove. The effluent of a septic tank is often offensive to both sight and smell.

Septic tanks are usually similar in construction to the ordinary type of plain rectangular settling tank. The detention period varies according to the wish of the designer, as from 18 to 24 hours or longer, and the velocities are correspondingly low. Many septic tanks are covered, but this is not essential to proper biological action, and may be a source of danger due to the collection of explosive gases. Sludge is allowed to remain in the tank long enough to secure the benefits arising from the digestion of a large proportion of the accumulated organic solids. Under favorable conditions the sludge when drawn off is generally denser and less odorous than that from plain settling tanks.

Two-Story Tanks. In order to secure in a single tank the advantages of plain sedimentation and the digestion of sludge by biological action and to avoid some of the disadvantages of the septic tank, two-story tanks have been quite commonly used. This type of tank, usually known as the **Emscher or Imhoff Tank,** consists essentially of an upper compartment for sedimentation and a lower one for sludge storage and digestion. The compartments are separated from each other by a sloping bottom provided with slots so arranged that solids settling in the upper chamber can pass into the lower chamber while sludge or gas cannot easily rise through these slots into the

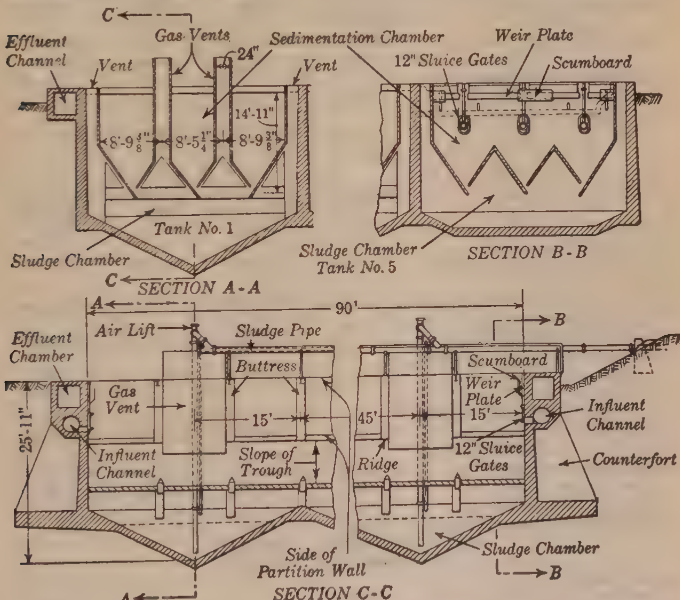

Fig. 10. Sections through Imhoff Tanks

settling compartment. This type of tank permits the sewage to pass through it without becoming seriously affected by the septic action taking place in the sludge.

In the sludge compartment the rate of digestion of organic matter varies according to the temperature, being very rapid at from 65° to 80° and practically ceasing around 40° Fahrenheit. Consequently the accumulated sludge is generally found to be substantially free from odor and in good condition for drying in warm weather, when the sludge should be drawn off frequently and the tanks left in the late fall with only enough sludge in them to provide for seeding. During periods of low temperature the sludge must be stored in the digestion compartments for decomposition during the next warm season. The storage period has often been taken at six months in the northern part of this country. Methane gas is produced in large quantities during normal digestion and gas vents are provided for its escape into the atmosphere

or in some cases for its collection and use. The sludge produced in these tanks is usually distinctly less offensive than that from plain settling tanks or septic tanks, with a lower moisture content and of such a nature as to dry more easily.

There have been operating difficulties with this type of tank due to the tendency for the gas-filled solids to rise in the form of scum and in some cases to form a foam, due in part to rapidity of decomposition, which has overflowed the gas vents. In the laboratory and in practice it has been found possible to control the proper digestion of sludge by the use of lime, a hydrogen-ion concentration (pH) of 7.2 or 7.3 being found most advantageous.

Data relating to four typical American Imhoff tank installations are given in the table on p. 1738 from "Imhoff Tanks—Reasons for Differences in Behavior," p. 465, vol. LXXXVIII (1925) Trans. Am. Soc. C. E.

Of these four installations those at Fitchburg and Rochester have been operated practically without difficulty, while those at Plainfield and Schenectady have experienced considerable trouble.

Imhoff tanks are usually from 20 to 35 ft. deep, relatively deep ones appearing to function better than shallow ones. Sludge is ordinarily removed by hydrostatic pressure through pipes extending to the bottom of the sludge compartments. Sometimes water piping is placed at the bottom of the sludge compartment to permit stirring of the sludge by water jets to facilitate removal and to improve biological conditions by mixing the new with the older sludge. The bottom may be arranged either as a long trough or as a series of hoppers. The detention period in the sedimentation compartment varies, according to design, from one hour to six hours, depending upon the degree of removal desired; a period of two hours is commonly adopted. The slope of the bottom is usually at least 1.5 on 1, and often steeper, to prevent retention of solids. The clear width of these slots may be 6 in. or more. Influent and effluent systems are arranged so that the direction of flow through the sedimentation compartment may be reversed at frequent intervals, except in small tanks. Scum boards may be useful in front of the outlets. Inlets and outlets should be designed to provide as uniform distribution of flow through the sedimentation compartment as possible.

In some installations, provision is made for collecting and utilizing the gases given off in the gas vents. The principal gases given off and their approximate proportions are as follows: Methane 75-85%, Carbon dioxide 5-15%, Nitrogen and miscellaneous gases 5-10%. The mixture of gases has a calorific value between 600 and 900 B. t. u. per cu. ft. It has been estimated that on the average the volume of gas produced by the digestion of sludge from sedimentation tanks is from 0.5 to 1.0 cu. ft. per capita daily.

Partial oxidation of colloidal and dissolved organic matter has been accomplished by placing brush or lath filters in the sedimentation compartments of Imhoff tanks, and introducing air underneath these filters. It is claimed that this method produces an effluent intermediate between that of a plain Imhoff tank and that of a trickling filter.

Humus Tanks or secondary settling tanks are used to improve the effluents from trickling filters by sedimentation of the suspended matters which periodically are flushed out from the filters. They may be of the ordinary horizontal-flow type, or of the vertical-flow type, and may or may not be provided with mechanical appliances for the removal of sludge.

Chemical Precipitation may be employed to increase the quantity of solids removed by sedimentation. It requires the addition of chemicals to the sewage prior to its entrance into settling tanks. Lime and sulphate of iron are

* Capacity. † Based on the number of tanks in use.

most frequently used, producing a flocculent precipitate which upon settling carries with it much suspended and some colloidal matter. This method is capable of bringing about a more complete removal of suspended solids than plain sedimentation. The sludge produced, however, is considerably greater in bulk, not only as the result of a more complete removal of sewage solids, but also because of the precipitation of the added materials. For treatment of sewage, chemical precipitation is now used by but a few cities in this country, although for treatment of certain industrial wastes it is a valuable process.

Tanks for chemical precipitation are usually similar to those used for plain sedimentation. Provision must be made for the addition of the chemicals and their thorough mixing with the sewage. In the old plant at Worcester, Mass., baffles of the fish-ladder type in the inlet channel were employed for mixing. The quantity of precipitants required varies with the character of the sewage and may range from 500 to 2000 lb. of lime per million gallons, and about one-half these quantities of ferrous sulphate. In some cases the sewage contains enough iron salts from pickling liquors to make the addition of ferrous sulphate unnecessary.

11. Sludge

Sludge is the material settled from sewage, exclusive of heavy inorganic matter or grit. Its characteristics depend largely upon the manner in which it is produced and the changes occurring during its retention. In general each type of settling tank produces a distinctly characteristic sludge. Sludge from plain settling tanks is grayish brown in color, coarse in texture and ill-smelling. Such sludge contains a large proportion of undigested sewage solids. Chemical precipitation sludge is fairly heavy, gray, brown or black in color, and more or less offensive in odor, depending upon its stage of decomposition. The proportion of chemicals used affects its characteristics considerably.

Imhoff tank sludge or **Digested Sludge,** if digestion has proceeded properly, is black. moderately uniform but granular in texture, full of entrained gases and has a comparatively unobjectionable tarry odor. The material has been so changed by the digestion process as to give little indication of its original constituents. The sludge from the activated sludge process is very bulky, high in moisture content, brown in color and with an earthy odor. Humus sludge, as its name implies, resembles humus and is composed of coagulated sewage solids and of bodies of organisms which are unloaded from the filter medium of trickling filters. It is brownish black in color, smooth in texture and of an odor which varies according to the condition of the sludge. At times when such sludge contains large numbers of decaying worms, the odor is distinctly offensive.

The quantity of sludge produced, per million gallons of sewage treated, varies with the kind of treatment, the strength and character of the sewage and the efficiency of the settling tank. The following table ndicates typical quantities and densities of the several kinds of sludge produced from sewage of the same characteristics.

Typical Volumes of Sludge Produced by Different Processes of Sewage Treatment

Treatment process	Nominal volume of sludge, gal. per mil. gal. of sewage treated	Proportion of solids in sludge, per cent	Specific gravity of sludge	Weight of dry solids in sludge, lb. per mil. gal. of sewage treated
Activated sludge	10 000	2.00	1.005	1675
Chemical precipitation	5 000	7.50	1.040	3250
Sedimentation	2 500	5.00	1.020	1060
Septic tank	500	5.00	1.040	220
Imhoff tank	500	15.00	1.070	670
Trickling filter—Humus tank	500	7.50	1.025	320

Separate Digestion of Sludge. In order to secure the benefit resulting from storage and digestion, while avoiding the difficulties sometimes experienced with Imhoff tanks, the sludge may be settled in plain settling tanks and removed to separate tanks for storage and digestion. Such separate digestion tanks are sometimes equipped with mechanical devices for agitation to mix the sludge and reduce scum formation. In some cases the sludge is heated to promote digestion, and sometimes the gases given off from the digesting sludge are collected and utilized for heating. The sludge from such tanks resembles Imhoff tank sludge.

Sludge Disposal. In all processes of sewage treatment, disposal of the sludge is a problem of primary importance. Except where sludge is lagooned or barged to sea some form of dewatering is necessary. The most important methods are: draining on sand beds, filter pressing, and complete drying for sale as fertilizer. The dewatered sludge from the first two methods is usually disposed of as fill, although in certain cities, notably Rochester and Schenectady, N. Y., dewatered Imhoff tank sludge is sold to local farmers at a nominal price for use as fertilizer.

Sludge drying beds consist of level areas of underdrained sand upon which the wet sludge is applied to a depth depending upon the kind and character of sludge. The applied sludge drains and dries with a rapidity depending upon weather conditions and character of sludge. The dried sludge reaches a moisture content of about 50-60% and shrinks about 65% in bulk. Ten days to three weeks may be required for the sludge to reach a spadable condition. To facilitate drying, particularly during adverse weather conditions, sludge beds are sometimes covered with glass roofs of greenhouse construction. The area of sand beds required may vary from about 0.5 to 2.0 sq. ft. per capita, depending on production of sludge, climatic conditions and whether covers are provided.

Several types of filter presses have been used for dewatering sludge. Usually conditioning of the sludge by acid, alum or lime is required to facilitate pressing. The resulting sludge cake contains about 75% water. Filter pressing is employed in relatively few places.

Lagooning consist in discharging wet sludge into relatively deep natural or artificial earth basins and allowing the material to compact as the result of drainage and evaporation. This method is applicable only when ample areas of isolated land permit. Lagooning of excess activated sludge is practiced on a large scale at Houston and Indianapolis.

The large volume and high moisture content of activated sludge cause a difficult dewatering problem where utilization as commercial fertilizer is attempted as at Milwaukee. Experience has demonstrated that before attempting to dewater the sludge it is essential to condition it by means of chemicals, such as sulphuric acid, aluminum sulphate and ferric chloride. At Milwaukee three chemicals and combinations of the three are used. After conditioning, the moisture content can be reduced by means of filter presses or by vacuum filters, the latter being used on a large scale at Milwaukee. The vacuum filters produce a thin cake with a moisture content of about 85%. Further reduction, to less than 10%, can then be accomplished by means of heat drying. The dried material is ground, screened and sold as fertilizer or fertilizer base.

Recent experiments have shown that activated sludge when mixed with fresh sludge from plain sedimentation or Imhoff tanks can be satisfactorily digested either in separate tanks or in the digestion compartments of Imhoff tanks. The mixed sludge after digestion may be dewatered on sand beds. At Chicago it is now planned (1928) to pump the excess sludge from the North-Side activated sludge plant to the West-Side Imhoff tank plant for digestion in the sludge compartments of the latter. At Fitchburg humus tank sludge is pumped to the sludge compartments of the Imhoff tanks for digestion with the primary sludge.

Fertilizer value of sewage sludge is not great as the most valuable fertilizing constituents of sewage are soluble. The following table gives the results of analyses of typical sludges.

Typical Analyses of Sludges

Per cent—Dry basis

	Nitrogen as ammonia		Potash	Phosphoric acid (P_2O_5)
	Total	Available		
Fine screenings*	2.5	....	0.5	0.5
Fresh sludge from plain sedimentation	4.0	....	....	1.5
Septic tank sludge	2.0	....	....	1.4
Imhoff tank sludge	2.5	1.3	trace	1.2
Chemical precipitation sludge	2.5	....	....	0.5
Humus tank sludge	3.5	2.5	trace	3.5
Activated sludge	5.5	4.0	0.2	2.5

* Included for comparison with sludges.

In addition to the chemical constituents noted, sludge contains humus material of some slight value.

Screenings and sludge from plain sedimentation are likely to be so ill-smelling and to contain so much valueless trash as to prevent farmers from using such material. Digested sludge is less open to these objections but there has been little demand for it, the sales at Rochester and Schenectady being exceptional. Humus sludge alone is hard to dewater, but it has some fertilizer value. Sludges dewatered by drainage and evaporation and as ordinarily handled contain so much moisture as to render them less valuable than stable manure. Activated sludge contains a relatively high per cent of nitrogen and for this reason is more valuable than digested sludge which has lost some nitrogen. A composite analysis of Milorganite, the trade name under which the product of the Milwaukee activated sludge plant is sold, is as follows:

	Per cent
Moisture	4.08
Total nitrogen	5.42
Equivalent to ammonia	6.58
Water-soluble organic nitrogen	0.30
Water-insoluble organic nitrogen	5.12
Nitrogen insoluble in neutral permanganate	0.71
Availability of water-insoluble organic nitrogen by neutral permanganate method	86.13
Active nitrogen by alkaline permanganate method	3.22
Availability of water-insoluble organic nitrogen by alkaline permanganate method	62.89
Total phosphoric acid	3.08
Insoluble phosphoric acid	0.65
Available phosphoric acid	2.43

This material is being produced (1929) at the rate of about 100 tons per day and sells for approximately $16 per ton f.o.b. cars Milwaukee.

12. Oxidation Processes

A large portion of the putrescible organic solids of sewage are in solution or in the form of colloids not removable by sedimentation. To change these solids to inert organic and mineral substances is the object of oxidation processes such as filtration through fine or coarse material and the activated sludge process. These oxidation methods are comparable with the action of the lungs in which the impurities of the blood are oxidized by bio-chemical processes.

Broad Irrigation was the earliest method adopted on a large scale for the treatment of sewage in which oxidation is involved. This method consists of applying sewage to relatively level areas of land and allowing the soil to absorb it. In some cases farming of land thus treated was attempted, to utilize the manurial value of sewage. Large areas of land are required, approximately an acre to each 10 000 gal. of sewage daily, and objectionable conditions with respect to flies and odors are often brought about. The use of this method in this country has been practically abandoned except in arid or semi-arid regions where the water content of sewage is valuable for irrigation purposes.

Intermittent Sand Filtration is a distinct advance over broad irrigation. The filters consist of beds of sand or fine gravel 2 to 6 ft. in depth, usually underdrained by tile pipe laid with open joints at intervals of about 40 ft. The effective size of the sand should preferably be between 0.20 and 0.35 mm. and the uniformity coefficient as near unity as practicable. Sewage is applied fairly evenly to the surface of the beds in doses from twice a day to once every

3 or 4 days. Application should be at a rate of about 1 cu. ft. per sec. per 5000 sq. ft. and the depth of dose should be about 3 in. The sewage per-

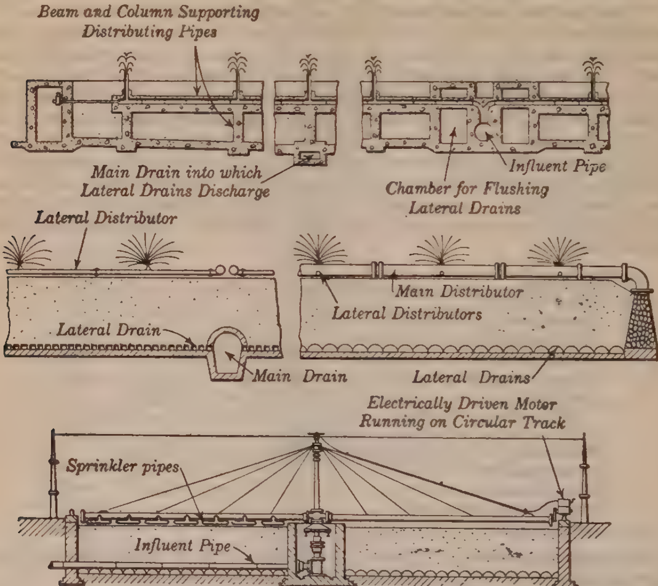

Fig. 11. Three Types of Trickling Filters

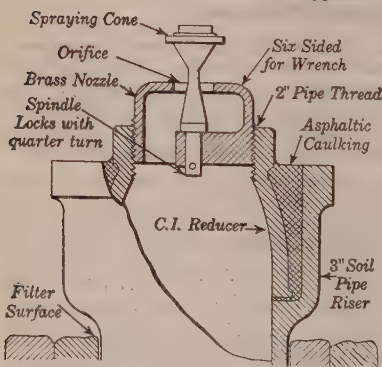

Fig. 12. Riser and Worcester Nozzle

colates through the sand to the underdrains. Application of the sewage may be through trough distributors or at the corners of the beds.

The action of this type of filter is partly to strain out suspended matters upon the surface and partly to oxidize the dissolved organic solids by the micro-organisms living upon the surface of the sand grains. At intervals weeds and the mat of solids accumulating on the surface of the filters must be removed. After cleaning, the beds should be harrowed and leveled by brush drag. Intermittent application of sewage and reasonably clean surfaces are essential in order that air may be admitted into the voids of the sand. For winter operation in cold climates the beds should be furrowed to permit the formation of a protective ice roof.

Effluents from properly operated filters are practically clear and colorless, non-putrescible and of low bacterial content. An acre of filters will treat about 30 000 gallons of sewage daily. Preliminary sedimentation increases the capacity of such filters to about 50 000 gal. daily.

Contact Beds are tanks filled with broken stone to a depth of 4 to 6 ft., the stone being from about 1/2 to 1-1/2 in. in size with 40 to 50% voids. The beds are filled with settled sewage, the effluent promptly drawn off and the beds allowed to rest for some hours with the voids full of air. In some cases it is necessary to apply the sewage to two or more beds in series. Automatic filling and emptying can be accomplished by timed siphons or similar devices.

In time the voids of the filter stone become clogged and the material has to be removed and cleaned, or replacement may be necessary as a result of disintegration. Contact beds can be operated at rates as high as about 100 000 gal. per acre-ft. or 500 000 gal. per acre per day with 5 ft. of depth. Effluents from carefully operated contact beds are usually non-putrescible, but rather turbid and of high bacterial content.

Trickling Filters are primarily beds of broken stone, 1 to 2-1/2 in. in size, 4 to 10 ft. in depth, laid on concrete floors covered with systems of underdrains for rapid discharge of effluent and for ventilation. Sewage is applied to the surface of these filters in the form of fine spray through spray nozzles or with mechanical traveling distributors. Traveling distributors may follow a circular or a rectilinear course. In the case of spray nozzles the sewage is discharged through them from automatic dosing apparatus under varying pressure, so as to secure uniform application of the sewage. This application takes place intermittently with a few minutes for dosing and a somewhat longer period for resting. The sewage sprayed through the air absorbs oxygen and as it passes down through the filter medium the film of micro-organisms on it utilizes this oxygen to oxidize and mineralize the organic matter.

Due to the practically continuous application of sewage and the abundance of oxygen in the voids of the filter media and sometimes in the applied sewage, this type of filter may be operated at high rates, 200 000 to 500 000 gal. per day per acre-ft. being typical. Usually the effluent is turbid, brown, non-putrescible and contains materially less bacteria than the applied sewage. Sedimentation of the effluent improves its quality by the removal of readily settleable suspended solids.

Data with respect to filter media may be found in "Progress Report of the Committee of the Sanitary Engineering Division on Filtering Materials for Water and Sewage Works," Proceedings Am. Soc. C. E., 1928, p. 243.

13. Activated Sludge Process

In this process large quantities of air are forced in fine bubbles through sewage as it passes through a tank having a detention period of 4 to 8 hours. After aeration the sewage is settled for the deposition of sludge. The sludge thus formed contains numerous micro-organisms similar to the biological film on the media of trickling filters, and is said to be activated. Part of the sludge deposited is returned to and mingled with the entering sewage. As the sewage is agitated by the air the activated sludge mingling with the sewage acts both to absorb and coagulate suspended solids and oxidize the organic matter.

The plant requires a comparatively small area of land and construction cost is relatively low. More elaborate mechanical equipment is necessary than in other processes and very careful operation is essential. The disposal of the bulky excess sludge is attended with some difficulty and considerable expense. The effluent is clear, sparkling, somewhat yellowish-brown in color and with relatively few bacteria.

Tanks are usually 10 to 15 ft. deep. The air is forced through porous plates set in the bottom of the tanks. Inclined deflector baffles placed longitudinally near the top and along one wall of an aeration tank produce a spiral motion in the sewage flow with a resultant improvement in mixing and a decrease in the quantity of air required for agitation. Washing and filtering of the air is necessary to prevent clogging of the pores of the diffuser plates.

The amount of air required varies with the character of the sewage, but for ordinary domestic sewage from 1 to 1-1/2 cu. ft. of air per gallon of sewage is required. For supplying air at a rate of 1.5 cu. ft. per gallon in a 10-ft. tank, approximately 30 hp. per hour are required per m.g.d. of sewage. The volume of activated sludge returned to the tanks may amount to from 20 to 25% of that of the sewage. The quantity of excess sludge removed is equivalent to from 1 to 1-1/2% of the volume of sewage treated.

Sedimentation after activation is generally accomplished by the use of tanks equipped with mechanical scrapers for continuous removal of the deposited solids. In the design of these tanks an allowance of 1 sq. ft. of tank is made for each 1600 gal. daily of flow at maximum rate.

Instead of compressed air for agitation of the sewage, surface stirrers have been devised consisting essentially of paddle wheels which when revolving agitate and aerate the sewage.

The economy of the activated sludge process depends mainly upon the net cost of disposal of sludge. Recent (1928) results at Milwaukee are encouraging.

14. Chlorination

Disinfection. None of the foregoing methods of treatment brings about the complete destruction of bacteria. Under certain conditions where water supplies or shellfish may be affected by the discharge of effluents, it is important to obtain practical freedom from disease germs. To accomplish this result, resort is frequently had to disinfection by means of hypochlorite of lime or liquid chlorine, the latter being most frequently used. The equipment used for application of chlorine is similar to that used for chlorination of water supplies. The quantity of chlorine required to effect satisfactory disinfection varies from about 10 to 15 p.p.m. for settled or screened sewage to 1 to 3 p.p.m. for the effluents from intermittent sand filters. A short period of contact, usually not over 15 minutes, is necessary to bring about proper disinfection.

Other Applications. Attempts have been made, apparently with some success, to minimize odors at treatment plants by chlorination of the sewage as it arrives. Attempts have also been made to reduce by chlorination the number of small moth flies frequently prevalent around trickling filters, but conclusive results have not been obtained. Chlorine is also used to deodorize the vapors given off by heat driers for activated sludge. Ferric chloride used for conditioning activated sludge is produced by chlorination of solutions of ferrous sulphate. Chlorine has also been found useful in reducing excessive growths of micro-organisms upon trickling filter media.

15. Small Sewage Disposal Systems

In the absence of a municipal sewerage system, the simplest method for meeting the sanitary needs of a single residence is the privy, in some cases fitted with removable containers or pails. Chemical closets are also used in which deodorization and disinfection are accomplished by caustic chemicals. Such methods are safe if suitable care is used, but are not applicable for houses provided with water supply and plumbing fixtures, for which a common means for disposal of sewage is the **Cesspool.** There are two types, the tight cesspool and the leaching cesspool. The former has the serious disadvantage of filling up rapidly, necessitating frequent emptying if overflow and objectionable conditions are to be avoided. The leaching cesspool permits the seepage of excess liquids into the surrounding soil and constitutes a satisfactory method of disposal where the soil is porous and the ground-water level below the bottom of the cesspool. Usually the earth around a leaching cesspool becomes clogged in course of time and emptying becomes necessary as in the case of a tight cesspool. There is also danger of the contamination of ground-water supplies derived from wells in the vicinity of such cesspools.

Where cesspools alone cannot be used, tight settling tanks followed by secondary means for the disposal of the excess liquid can be adopted.

The commonest form of settling tank for small disposal plants is the so-called **Septic Tank.** Such a tank is usually constructed of reinforced concrete, of capacity sufficient to provide a detention period of from 12 to 60 hours, the usual allowance being about 24 hours. The effluent from these tanks is discharged intermittently to the secondary treatment plant, by means of a dosing tank equipped with an automatic siphon. Ready-built commercial septic tanks of tile or iron should be used only if of adequate capacity and suitably arranged, particularly if no provision is made for intermittent application of the effluent to subsurface filters or trenches. The following secondary means of treatment are applicable: leaching cesspools, filter trenches, subsurface sand filters and open sand filters.

Filter trenches contain a series of pipes laid from 1 to 2 ft. below the surface of the ground, with open joints so that the settled sewage may pass out into the gravel with which the trenches are refilled, and thence into the surrounding soil. The length of pipe necessary is estimated at 20 to 100 ft. per person, depending upon the porosity of the soil. Where the soil is so dense and impervious as to make the use of filter trenches or leaching cesspools impracticable, subsurface filter beds may be used. Such beds are constructed by excavating a suitable area to a depth of about 4 ft. and backfilling with sand and graded level to a depth of about 3 ft. covering the top with about a foot of loam. The settled sewage is discharged through tile pipe laid with open joints at the surface of the sand, and the whole bed is underdrained. The size of bed should be sufficient to provide from 1 to 2 sq. ft. of surface area for each gallon of sewage per day, depending upon the strength of the sewage and the fineness of the sand. For residences, the area should be between 25 and 90 sq. ft. per capita and for day schools the requirement will be generally between 12 and 20 sq. ft. per capita.

Open intermittent filters can be adopted for large residential and institutional plants providing proper isolation can be secured. These filters are similar to the intermittent sand filters employed for the treatment of municipal sewage. The loading adopted for residential filters is usually less per acre than in a municipal plant because of the greater percentage of sediment carried upon the bed and the likelihood that it will receive less careful operating attention. The usual allowance for rate of treatment is in the neighborhood of 40 000 gal. per acre per day, the population served ranging from about 650 to 1000 persons per acre.

16. Industrial Wastes

There are almost as many kinds of wastes as there are industries and each industry has its characteristic wastes varying in quality and in quantity. In some industries the wastes are relatively unobjectionable or small in quantity. In other industries the wastes may be large in volume or extremely objectionable, or both. A convenient classification of industrial wastes is according to the nature of their principal constituents, namely animal, vegetable or mineral. The putrefactive quality of the several kinds of constituents are approximately in the order given.

As a matter of fact, many wastes are combinations of more than one class. Silk mill wastes contain animal gums from the silkworm cocoons, vegetable oils from the soaps and tin salts from the weighting process. Tannery wastes contain animal fleshings, tan bark extractives and spent lime.

The effects of pollution by industrial wastes are similar to those of sewage. Generally speaking, danger of infection from industrial wastes is probably less than from sewage, because many industrial processes involve treatment by heat or by chemicals which are germ-destroying. Furthermore, apart from the sewage from the industrial buildings, the materials in wastes are not such as are likely to carry bacterial infection. On the other hand, some wastes, like tannery wastes, may constitute a greater hazard to cattle than does sewage, due to the possible presence of anthrax germs.

Some industrial wastes contain quantities of froth-forming constituents, which when discharged into streams produce unsightly and persisting scum, objectionable to bathers and to boat owners. Other wastes high in coloring matter bring about unsightly discoloration. Wastes containing highly putrescible organic matter, animal or vegetable, decompose and exhaust the dissolved oxygen content of the stream, with resulting production of offensive odors. Wastes with large quantities of settleable solids form sludge deposits, which if organic in character undergo decomposition, and as this decomposition proceeds masses of offensive slimy material rise to the surface. Chemical wastes may have a direct destructive action upon fish life, either as a result of poisoning or by clogging of gills. Oil wastes form unsightly sleek and scum and hinder the natural reaeration which exposed water surfaces normally undergo. Phenol wastes from gas plants or from coke by-product recovery plants, reaching water supplies even in minute quantities, have frequently been the cause of medicinal tastes, particularly where the water is chlorinated. This type of pollution has been of great annoyance in the case of the Great Lakes cities of Milwaukee, Chicago and Cleveland.

Treatment of Industrial Wastes requires much the same methods as for sewage, although with some particular types of wastes special adaptations are required. Chemical precipitation, although now practically abandoned for the treatment of sewage, remains a very valuable method for the treatment of certain wastes, such as those from tanneries and paper mills. Screening and plain sedimentation are also employed for the removal of solids. Where a high degree of purification is required intermittent sand filters are used, and trickling filters, also, are of value. The activated sludge method has been tried experimentally and found capable of satisfactorily treating certain wastes such as tannery, packing house and beet sugar wastes. The acid crackling process for the treatment of wool scouring liquors has been employed successfully for many years. Chlorination has been practiced with tannery wastes for the destruction of anthrax germs. Controlled dilution, using storage ponds for conserving flood flows, has been employed in some cases, with a view of reducing the extent of treatment otherwise required.

The disposal of the sludge produced in the treatment of industrial wastes constitutes a serious problem. It is sometimes found feasible to utilize some of the sludge, as for instance cellulose fibres from paper mill wastes or from rubber reclaiming plants. In certain cases the treatment of industrial wastes has resulted in the recovery of materials of value, and the possibility of such recovery should always be considered in connection with wastes treatment problems. It is important, however, to avoid overstressing the profit possibility of wastes treatment, to the extent of overlooking the fact that the primary purpose is to prevent stream pollution, not to make profits.

REFUSE COLLECTION AND DISPOSAL

BY
METCALF & EDDY
ENGINEERS

REFUSE COLLECTION AND DISPOSAL

REFUSE COLLECTION AND DISPOSAL

1. Municipal Refuse

Municipal refuse consists of the following classes of waste material: garbage, rubbish, ashes, street sweepings, stable refuse, offal or market refuse, dead animals, and industrial refuse (including waste building materials). The first three classes are those with which householders are concerned chiefly and they constitute the principal part of municipal refuse.

The municipal refuse of North America and Europe differ so greatly in composition that data from one continent should be used in design problems on the other only after making certain that conditions are comparable. This is due to differences in climate, habits of diet, methods of house heating, wrapping of merchandise and thrift of the inhabitants of the two continents. In England, for example, all three types of household refuse are stored in the same receptacle and collected in the same vehicle. This mixed refuse is known as "dust" and the collectors as "dust men." The contrast between this material and wet American refuse in the watermelon and corn season in the middle West is marked. In order to avoid misleading American engineers, no data regarding European practice are given herein.

Garbage is defined by the Committee on Collection and Disposal of Garbage (Sanitary Section, Boston Society of Civil Engineers) as the solid animal and vegetable waste matter produced wherever food is handled raw or prepared for consumption. The report* of this committee defines the principal terms used in dealing with collection and disposal of garbage. Frequently, as collected in municipalities, garbage includes more or less rubbish. There is a marked variation in the character of garbage produced in different cities, owing to differences in local conditions. It is difficult to secure representative samples for analysis because of the heterogeneous character of the material. Few available analyses cover periods of more than a few weeks and the results, therefore, show the composition only under stated conditions, and, due to the wide variation in character with the seasons and according to the localities collected, such analyses may differ widely. Garbage reaches the municipal collection vehicle in varying degrees of decomposition depending upon the frequency of collection, the state of the weather and the degree of cleanliness of the household. **The Moisture Content** in general lies between 68 and 80% by weight. The quantity of **Grease** in garbage varies approximately from 1 to 7% of the weight of raw garbage. As grease is derived principally from animal matter and as less meat and more vegetables are ordinarily eaten in warm weather, the proportion of grease in the garbage varies with the seasons, climate and habits of eating. The **unit weight** of garbage varies widely, due to the differences in habits of the population, the season, rainfall and the character of the collection service. In general the weight of a cubic yard of garbage lies between 900 and 1200 lb. An average unit weight frequently assumed is 40 lb. per cu. ft. (1080 lb. per cu. yd.).

Rubbish includes many kinds of waste material, such as newspaper, wrapping paper, boxes, cans, crockery, rags, rubber, leather, wood, brick, glassware, tinware, lawn and brush clippings, much of which material is combustible. The bulk of individual pieces varies greatly, from dust to articles as large as bedsteads and automobile fenders. Frequently, as collected in municipalities, rubbish includes more or less garbage and ashes. Much of the

* Jour. Boston Soc. C. E., 1927; **14**, 305.

material is of light weight and is easily blown about by the wind. The **Unit Weight** of rubbish is much less than that of either garbage or ashes, generally ranging from 125 to 250 lb. per cu. yd. An average unit weight of 200 lb. per cu. yd. is frequently assumed.

Mixed Refuse is a term used in this country to include garbage and rubbish but not ashes.

Ashes, as collected in municipalities, commonly have mixed with them more or less rubbish, especially tins and bottles, and frequently some garbage, but the major portion of this material consists of household ashes. The character varies with the geographical location, type of fuel used in houses, the seasons, the degree of separation and method of storage of household refuse and the frequency of collection.

Ashes as collected are generally dry and very dusty. Where stored in the open in wet weather the moisture content is greatly increased. The **Unit Weight** is usually slightly greater than that of garbage, lying between 980 and 1350 lb. per cu. yd.

Street Sweepings consist of the refuse which accumulates on the surfaces of streets and sidewalks, including the droppings from horses and other animals, miscellaneous litter thrown upon the streets, material carried by wheels from unpaved to paved streets, leaves, and sweepings from buildings and sidewalks. Street sweepings may be used as fertilizer due to their content of nitrogen, phosphoric acid and potash, but their value is not great, and they are most commonly utilized in covering over the surface of dumping grounds.

Dead Animals, Offal and Market Refuse must be promptly collected and disposed of to avoid their giving rise to offensive odors. Offal from fish markets is offensive even when handled promptly. Frequently the parties producing offal and market waste can be required to attend to its collection and disposal.

Industrial Refuse is of many kinds; some partly combustible and some non-combustible. Examples are boxes and package materials, steam cinders, blast furnace slag and waste excelsior. Little of this type of refuse enters into the problem of municipal collection and disposal because it is commonly considered the duty of the manufacturer to dispose of such refuse. The same is usually true of stable refuse, which, is of some value and generally can be sold.

2. Quantity of Refuse

Garbage. The quantity of refuse produced varies widely in different cities and from day to day and from season to season in a single city. The table at top of next page gives the annual per capita production of garbage, rubbish and ashes in several municipalities.

A reasonable figure for the average production of garbage in the larger cities in the northern portion of the United States which are not affected by peculiar local conditions, is about 180 lb. per capita per year or 0.5 lb. per capita per day.

Other things being equal, it is evident that the quantity of garbage in southern cities where fresh vegetables and fruit are cheap and abundant will be greater than in northern cities. The wealth of the population has a marked influence on the production. The following table which shows the difference in this respect between three manufacturing cities and three residential cities in Massachusetts is taken from the 1926 report of the Massachusetts Department of Public Health.

Quantity of Municipal Refuse in Pounds per Capita per Year

Municipality	Year	Garbage	Ashes	Rubbish

Garbage Production in Manufacturing and Residential Cities in 1924

Manufacturing Cities	Pounds per capita per year	Residential cities	Pounds per capita per year
Fall River	185	Brookline	337
Lowell	123	Newton	278
New Bedford	206	Watertown	276
Average	171	Average	297

Economic conditions have a marked influence, more garbage being produced in good than in bad times. Nationality may also affect the garbage production, since most foreign-born inhabitants are less wasteful of food than native born citizens. In stormy weather uncovered receptacles collect rain and snow, thereby increasing the weight of material to be collected. In rural communities a portion of the garbage is sometimes disposed of on the individual premises by burial or feeding to hens or pigs, thus reducing the amount to be collected. With efficient service and frequent collections, a greater quantity of garbage is collected than where service is inefficient and collections infrequent. When garbage is wrapped in paper in the household a greater volume is collected due to the wrappers which are included. On the other hand a substantial amount of moisture is drained off before wrapping which tends to reduce the moisture content and weight.

There is a great **seasonal variation** in production due to the consumption of fruits and vegetables, particularly melons and green corn. This seasonal

Monthly Variation in Quantity of Garbage Collected, Expressed in Per Cent of Average Monthly Weight Collected in 1926

variation is illustrated by the table above, in which minima and maxima of 60% and 167% occur. The range differs materially in different cities. The variation in the quantity of garbage collected in short periods is illustrated by the next table.

Variation in Quantity of Garbage Collected in Short Periods
(In per cent by weight)

	Buffalo	Rochester	Akron
Daily average for year	100	100	100
Maximum four weeks	135	155	171
Maximum week	150	162	181
Maximum day	169	167	197

Rubbish. The quantity of rubbish collected varies substantially in different cities, as is illustrated by the table on page 1752. The per capita production of rubbish is greater now than it was a generation ago, due to changing customs such as the use of package goods and the great increase in size and circulation of newspapers and magazines. Furthermore, the average American family is probably more wasteful and discards more materials now than formerly. Other things being equal, a well-to-do residential city will produce more rubbish per capita than a manufacturing city. The amount of rubbish to be disposed of by municipalities increases with the efficiency of the collection service. The seasonal variation is not great. It is shown for several cities in the table at top of page 1754.

Ashes vary in quantity with the climate and the season, although practically every city will produce a considerable quantity of ashes even in summer. The type of fuel used for heating and cooking has a marked influence on the ash production; for example the production is high in New England where anthracite commonly is burned, while it is low where bituminous coal is used and even lower in the natural gas districts.

The number of small **dead animals** (mainly cats and dogs) to be disposed of

varies widely in different cities, as well as from month to month in the same city. In general, there will be more dead animals during the summer months, owing chiefly to the detrimental effect of hot weather upon dogs. Humane societies frequently deliver large numbers to the city for disposal. The following table gives the number of small dead animals collected by the municipal forces in three cities:

Number of Small Dead Animals Collected

City	Year	Population (estimated)	Number of dead animals	
			Total	Per thousand population
Akron, Ohio..................	1926	215 000	3 101	14
Milwaukee, Wis..............	1919	450 000	3 536	8
Rochester, N. Y..............	1926	320 000	20 865	65

The following table gives some data concerning the quantity of **street sweepings** collected and the area of streets cleaned:

Quantity of Street Sweepings Collected per Year

City	Year	Estimated population	Total quantity of street sweepings, cu. yd.	Per capita quantity of street sweepings, cu. ft.	Million square yards cleaned
Columbus, O.......	1926	285 000	37 604	3.56	203
Boston............	1926	790 140	77 350*	2.64*	243*
Chicago...........	1926	3 074 382	354 953†	3.12†	2092†
Washington, D. C...	1927‡	500 000	....	....	2736

* Figures refer to paved streets and macadam gutters only.
† Figures refer to streets cleaned by hand only.
‡ Year ending June 30.

3. Household Handling and Storage

It is essential to the maintenance of sanitary conditions for each householder to fulfill his obligations with respect to the care of garbage, rubbish, and ashes. Of primary importance is the separate storage of the different classes of refuse. Their mixing may give rise to offensive, insanitary conditions and to serious fire hazards. Wrapping of garbage in paper is desirable from the standpoint of household sanitation.

Containers for each class of refuse should provide sufficient capacity to store the accumulation of that class of material between collections under conditions of maximum production. Garbage pails should vary in size according to the number of persons in the family, but, as a rule, no pail should be used having capacity in excess of about 12 gal. Where greater capacity is required, additional pails should be provided. For ashes, no container should have a capacity exceeding about 4 cu. ft., as this represents the maximum weight that can readily be lifted by two men into the collection vehicle. It is generally advisable for each householder to have not less than two ash cans. Galvanized iron is probably the most suitable material for garbage pails and rubbish and ash cans, since it can be kept clean with comparatively little difficulty. Garbage pails should be provided with tight covers. On account of the serious risk of fire, ashes should never be stored in wooden barrels or other combustible containers.

It is usually advisable to store garbage pails on the rear porch or in the back yard, where they are readily accessible to both householder and collector, and where sunlight and fresh air have access to the surroundings. Ashes and rubbish, on the other hand, are generally stored in the basement, but combustible rubbish should not be kept near the heating plant on account of the fire hazard.

It is not wise to place ashes and combustible refuse in the same container, because of the danger of fire. Neither is it desirable to mix garbage and rubbish, because of the increased volume of foul material stored and the increased number of containers to be kept clean. The admixture of hot ashes with garbage may result in offensive odors; moreover, if the mixture of ashes and garbage is disposed of by filling waste land, the dumps may become infested with flies, rats and other vermin.

Regulations. In order to promote cooperation between householders and collectors, simple regulations for the household care of garbage, rubbish and ashes should be printed on cards and delivered to every household. If such regulations set forth clearly the conditions under which refuse collections are to be made, the number of needless complaints on the part of the householders will be greatly reduced, and the disposal of refuse will be simplified. All complaints should be investigated immediately, and if they prove valid, prompt remedial measures should be taken.

4. Collection

Separate vs. Mixed Collection. Collection of municipal refuse may be classified either as separate or mixed collection. Separate collection necessitates independent storage in separate containers by the householder and independent collection of each of the different kinds of refuse. Mixed collection does not require household separation, although it can be adopted even if the different classes of refuse are separately stored by the householder. Which collection method should be adopted by the municipality depends upon several factors. Each method has both advantages and disadvantages. Separate collection is essential if attempt is made to obtain profit by salvage of material and recovery of by-products, or if disposal of the three principal classes of refuse involves use of ashes and non-combustible materials for fill, the incineration of combustible rubbish and the reduction or feeding to hogs of garbage. Mixed collection brings about a thorough mixture of garbage and rubbish, which may be of some advantage where disposal is by incineration, although the whole mass of material may become moist and difficult to burn. In some cities, particularly those with large foreign populations, it is difficult to secure proper separation of refuse by householders.

Separate collection has the advantage that a much smaller bulk of offensive material accumulates in periods of interrupted service. After such interruptions concentrated effort upon the collection of garbage alone would be much more effective as a measure of household sanitation than if a much larger accumulation of mixed refuse had to be collected.

With separate collection the methods of handling by the city as well as the householder and the equipment used in collection must be adapted to the kinds of refuse. Collection vehicles can be made of such material and so designed as to be easily and quickly cleaned and covered. In the case of mixed refuse the collecting vehicle must conform with the sanitary requirements incidental to the collection and transportation of the wet offensive garbage, whereas with separate collection the vehicles for rubbish and ashes may be of a different type suited to the much greater bulk of light rubbish,

Number of Collections of Garbage per Week in Twenty-six New England Municipalities

and with less rigorous requirements as regards ease of cleaning, watertightness and covers.

Frequency of garbage collection should be governed by considerations of sanitation, householders' convenience and cost. In winter it depends more upon conditions of storage on the householder's premises than upon decomposition and odors. In cold weather frozen garbage often occupies a portion of the outdoor containers, thus reducing their effective capacity. In disagreeable weather the collector occasionally skips some houses, and during very severe storms or heavy snows the collection service may be interrupted. In many municipalities daily collections of garbage are made from restaurants, hotels and markets, because of the large quantities produced. Such collections are frequently made by crews and equipment specifically assigned to that duty. The general practice as regards frequency of garbage collection in New England municipalities is indicated in the table on page 1756.

Practice in regard to rubbish and ash collection is not nearly as uniform as in the case of garbage collection. While many cities have frequent and regular collections of rubbish and ashes, both in winter and summer, many others do not collect either of these types of refuse. In many cases periodic collections are made from once a year, generally in the spring or the fall, to three or four times per year. The table below shows the frequency with which ashes and rubbish are collected in the residential districts of various cities.

Frequency of Collection of Ashes and Rubbish in Residential Districts

Municipality	Number of collections per month		
	Ashes		Rubbish
	Summer	Winter	
Buffalo, N. Y.	4	8	4*
Indianapolis, Ind.	2	4	....
Milwaukee, Wis.	1	1	....
Montclair, N. J.	4	4	4
Richmond, Va.	4	4	4
Rochester, N. Y.	2	4	4
Salt Lake City, Utah	4	4	4
Seattle, Wash.	4	4	4

* 8 Collections per month in summer.

Frequently ashes and rubbish are collected daily in business districts.

Collection Districts. In devising a system of refuse collection for a given municipality, it is generally wise to divide the territory from which collections are to be made into a number of districts, each one of which shall represent the area to be covered by one collection crew in the course of say a week. If ashes, rubbish and garbage are to be collected separately, it may be necessary to have different numbers of districts for the several classes of refuse. Moreover, if the frequency of collection of any class of refuse is to vary with the seasons, it will be necessary to have, for such refuse, a different number of districts in summer than in winter. The total number of districts for one class of refuse will depend largely upon the total production of refuse, the frequency of collection, the type and size of collecting vehicle, the number of men per vehicle, and the average length of haul to transfer station or point of disposal.

The relative sizes of districts will depend upon local conditions, involving such factors as density and character of population, number of miles of streets, grades of streets, and distance from transfer station or disposal site.

Each district may be subdivided into a number of routes, representing the territory to be covered by one collection crew on each day of the week. If each collection crew works regularly in the same district and follows the same routes, the men soon become familiar with the location of all refuse containers, which promotes speed and thoroughness.

Transfer Stations. Except in small municipalities or where refuse is disposed of at centrally located sites, it is necessary to provide transfer or loading stations, or to relay the refuse as by the tractor-trailer system. Such stations should be as centrally situated as is consistent with suitable isolation. Structures should be of durable, easily cleaned, material. Long storage of garbage at such stations should be avoided and cleanliness should be enforced. Grounds should be maintained in neat and attractive condition.

Vehicles. There are in general use throughout the country at the present time three types of vehicles for refuse collection; namely, horse-drawn wagons, motor trucks, and trailers drawn by horses during collection and picked up, when loaded, by motor tractor-trucks, for hauling in trains to the point of disposal. Local conditions determine in each case which type is best adapted to the collection of the class of refuse under consideration.

Consideration should be given to such factors as the time spent in actual collection, the time spent in transportation, the cost of motor trucks while operating at low speed with house to house stops and while operating at high speed fully loaded, expense of chauffeurs, whether or not chauffeurs help in collections, the number of men per vehicle, the size of vehicle, the traffic problem presented by trains of trailers, the necessity of brakemen or flagmen on trailer trains, criticisms by the public of parking of empty trailers and trailers loaded with refuse throughout the city. In some cases it may be desirable and economical to use different types of vehicles for the different services, and different types of vehicles for the same service in different portions of the same city.

Experience shows that vehicles of many sizes are used, varying from one cubic yard capacity up to as much as twenty-six cubic yards capacity in the case of rubbish wagons.

Express Service for isolated markets and lunch rooms requiring daily garbage collection and for the collection of small dead animals is often satisfactorily provided by one-ton trucks.

Organization. A comprehensive organization for the collection of refuse includes the following subdivisions under one or more superintendents: collection gangs respectively for garbage, rubbish and ashes, inspectors, clerks, repair gang, and either stable or garage force, or perhaps both. The collection gangs are made up of teamsters or chauffeurs and helpers; the repair gang includes mechanics and helpers; the garage force includes men who wash the vehicles, and the stable force consists of veterinarians, barn men, harness makers, blacksmiths and watchmen. The majority of the personnel is actively engaged in collection.

The principal duties of the clerks are those of receiving and tabulating complaints, time-keeping and record keeping. If such records are kept in considerable detail, they are valuable in checking the efficiency of the individual collectors and in studying ways to improve the collection system as a whole.

Fig. 1 shows a summer organization chart prepared in 1927 for Akron.

The following table from the report of the Boston Society of Civil Engineers Committee shows the equipment and personnel comprising the garbage collection gangs of 16 New England municipalities:

which the work is performed and methods of municipal accounting. In the more densely populated cities garbage collection costs are likely to range from $0.30 to $1.50 per capita under present wage scales (1928). Costs of ash collection are likely to have about the same range and costs of rubbish collection may be slightly lower per capita.

Costs of garbage collection per ton, except for unusual cases, range from $3.00 to $9.00, depending upon efficiency, length of haul, type of collecting vehicles and other local conditions. Per ton costs of rubbish collection are likely to run slightly higher and costs of ash collection may run considerably lower than those for garbage.

5. Miscellaneous Methods of Disposal

The **burial of garbage** by the individual householder is common practice in small municipalities in which no organized municipal collection and disposal service exists. If disposal by burial is made a municipal practice, the garbage should be placed in shallow trenches and covered with earth. In winter in the north this is difficult to accomplish. Isolated location for such practice is essential if conducted on a large scale. In order to keep the rate of application to land sufficiently low to bring about rapid and inoffensive decomposition of organic matter, large areas are required.

Although, if properly carried out, burial is a reasonably safe and sanitary method for small communities, it is an expensive method for large cities. It is also extremely difficult to carry out in such manner as to avoid nuisances from odors, rats, cockroaches and crows.

Filling. This method consists of the deposition of refuse on low lying ground. Filling differs from burial in that the depth of fill is limited by topographical considerations only, whereas with burial the depth is restricted to a few inches in order to foster active decomposition. This method has the advantage that several different sites may be utilized simultaneously in a municipality, thus reducing the cost of haul without greatly increasing the operating cost of disposal. It is the method most commonly used for ashes, and where ashes are collected separately it is a satisfactory method for their disposal. It is also frequently used for the disposal of rubbish and sometimes for garbage.

For sanitary reasons, garbage alone should be disposed of by filling only under exceptionally favorable conditions. If mixed with ashes, earth or other suitable materials, the use of garbage for filling may be less objectionable, providing proper operation of the dumps is secured, but even under the best operation, objections are likely to be raised due to the breeding of rats and other vermin in the filled material.

Dumps frequently catch fire, particularly where combustible refuse is present, thus providing a fire hazard to nearby buildings. The odor and smoke from burning dumps are highly objectionable.

Blowing papers and clouds of dust may cause annoyance to adjacent property owners and traffic upon nearby highways.

Some sea coast cities dispose of their efuse by **dumping at sea.** The chief objection to this method is the stranding of garbage or rubbish upon beaches which are used for recreational purposes. This method is used to a large extent by New York City. Recently a large number of bottles were discharged at the regular dumping ground containing addressed post cards, asking for information regarding the location where the bottles are picked up. The result of this investigation gave interesting data on the distance traveled by floating objects. A few of the bottles apparently floated southerly into the Gulf Stream and thence across the Atlantic to Portugal, France, England and Ireland.

Salvage. There is a substantial amount of material of value in municipal refuse, as for example, paper, rags, bottles and cans. In rubbish dumps some of this material is commonly salvaged by individuals, occasionally operating under concessions from the municipality. Several municipalities have practiced salvaging saleable material from rubbish prior t odumping or burning the unsaleable portion. In such cases the sorting is generally done on a traveling belt conveyor. Many cities have abandoned this practice but a few still carry it out, as for example, Washington, Baltimore and Rochester. Under recent market conditions salvage by American cities is of doubtful economy.

6. Feeding Garbage to Hogs

If properly carried out under suitable conditions, the feeding of garbage to hogs is a satisfactory method of partial disposal, particularly for the smaller communities. Under proper management and favorable market conditions, there may be an economic advantage arising from the conversion of garbage into pork.

The selection of a suitable site for a piggery is of prime importance. It should be at such a distance from the nearest dwellings that there will be no ground for complaint from aerial nuisances. It should be situated on soil which drains readily at all seasons, preferably sand or gravel. There should be plenty of water available for washing and flushing, and good sewerage facilities. The location of piggeries is usually comparatively remote from the municipality in which the garbage is collected. On this account, long haul transportation problems are involved, and legal difficulties may be encountered in transporting materials through municipalities other than that from which the garbage is obtained. It is important that the route traveled to the farm should be over good roads, but preferably ones without too much traffic.

The buildings where hogs are kept should be of substantial construction, well lighted and ventilated, and they should preferably be located on a southern slope.

The economical operation of a piggery requires that the number of hogs be varied with the seasonal production of garbage so that as large a proportion as possible of the garbage shall be eaten. This can be accomplished by regulating the farrowing season, or by purchasing new stock from dealers who in some localities specialize in raising and selling suckling pigs. The following table gives data regarding the relation between quantity of garbage collected and number of hogs fed with garbage.

Relation of Quantity of Garbage Collected to Number of Hogs Fed

City	Year	Average quantity collected per hog, lb. per working day	New stock obtained by
Akron	1926	27	Breeding
Buffalo	1922	49	Purchase
Los Angeles	1924	22	Breeding
Newton, Mass	1924	25	Breeding
Worcester, Mass	1926	23	Breeding

The ratio of the number of men employed in operating piggeries to the number of hogs fed varies with the degree of cleanliness maintained. At Worcester one caretaker is employed to feed, bed and clean the pens for each 250 to 300 hogs.

Data in regard to the costs of construction and operation of piggeries are meager. In the great majority of cases such cost figures are probably lower than they should be because the structures are too cheaply built and the premises are seldom maintained in a thoroughly clean and sanitary manner.

The feeding of garbage to hogs is not a process of complete disposal. There are three products of a hog farm, the pork, the uneaten garbage, and the manure. Experience indicates that the quantity of uneaten garbage and manure or piggery refuse may be equivalent to from 30 to 50% of the quantity of garbage received.

Disposal of Piggery Refuse is perhaps the most important sanitary problem connected with this method of garbage disposal. If not frequently and thoroughly removed from pens and buildings and properly treated it decomposes rapidly and produces offensive odors. Generally it is composted and then used on nearby farms. Compost heaps, unless properly cared for, give off offensive odors and are prolific breeders of flies. Furthermore, the material when spread upon land as a fertilizer disseminates odors broadly, at least until plowed under. Other methods of disposal of piggery refuse are burial, incineration and drying. With either of the latter two methods the total investment in the hog farm is greatly increased. Following is an analysis of dried piggery refuse from a test by the authors in a commercial indirect steam dryer at Buffalo in March, 1922:

Analysis of Dried Piggery Refuse

	Per cent
Moisture	7.70
Ammonia as NH_3	3.14
Calcium phosphate as P_2O_5	2.28
Potash as K_2O	1.15
Grease (ether-soluble matter)	12.33

Should epidemics of hoof and mouth disease, hog cholera or tuberculosis occur the whole process of garbage disposal will be interrupted for an indefinite period of time. Protective inoculations, however, will aid considerably in reducing the hazard of interrupted service from the common hog diseases. Foreign matter in garbage, such as phonograph needles, safety razor blades, nails and glass cause some casualties.

If objectionable conditions are to be avoided, every precaution must be taken in design, in operation and in disposal of piggery refuse to prevent the breeding of rats, flies and crows, which abound at garbage piggeries where preventive measures are not taken. Where nuisances from piggeries have become sufficiently obnoxious, injunction proceedings by aggrieved property owners have seriously embarrassed the continuance of operation.

7. Reduction of Garbage

In general the process of reduction consists of cooking the garbage under steam pressure for a number of hours, after which the water and grease are removed and the solid matter dried. The grease is separated and used generally for soap making, and the dry material, called "tankage," is used as a base for fertilizers. Recently in some plants some of the finer tankage has

been separated and sold for stock feed. Considerable grease remains in the tankage after cooking and usually is extracted by a solvent such as gasoline. In some processes the material is not cooked but is dried by direct heat or steam in revolving steel drums and the grease is recovered by extraction. Fig. 2 is a diagramatic outline of various reduction processes.

In the **Arnold process** the garbage is cooked in steel tanks for several hours, after which it is passed through a roller press to remove a portion of the grease and moisture. The liquor pressed out is known as "stick liquor." It contains a substantial amount of fine solids and grease and has a foul odor. The grease and stick liquor then flow through a series of tanks in which the grease rises to the top and is separated. The stick liquor is then discharged into a sewer or adjacent water course, or in some cases is evaporated and the residue added to the tankage. The solid matter, after the stick liquor has been pressed out, is passed through a direct heat dryer to remove moisture. Additional grease is then extracted by gasoline in a percolator. After extraction, the solvent remaining in the material is blown out with steam to avoid subsequent explosion. In a second direct heat dryer the tankage is given a final drying. The grease and solvent are separated by distillation and the solvent used again. Tankage is finished for market by screening and crushing and by the removal of metallic objects. The Arnold process has been in use for many years at Columbus and elsewhere.

The **Chamberlain process** is essentially identical with the Arnold, the chief difference being that in the Chamberlain process the stick liquor is pressed out of the cooked tankage through openings in the bottom of the cooking tank by steam admitted through the top of the tank, while in the Arnold process this is performed in a rotary press. The Chamberlain process has been in use for many years at Cleveland and elsewhere.

The **Morrison process** is similar to the Chamberlain process, the chief difference being that the steam for cooking is in a steam jacket on the outside of the tank, while in the Chamberlain process it is admitted directly to the tank. Some of the grease is removed by skimming from the top of the tank after cooking, some is drained off with the stick liquor and some extracted with solvent. Subsequent procedure is much the same in both processes. This method has been installed recently at Dayton and Indianapolis and a few other places.

In the **Cobwell process** the drying and grease extraction are carried on in the same tank in which the cooking has been done. The moisture is vaporized in the tank by heat from an external steam jacket and is removed by vacuum pumps. All the grease is obtained by extraction with solvent and separation of the solvent and the grease is by distillation. This method of removal of water takes a longer time than that required by the processes already discussed, and while two or sometimes three charges can be treated in a day in a single tank in the other processes, the Cobwell reducers can handle only one charge per day. The solvent loss with this process is considerably greater than with the other methods. The grease and tankage recoveries are, however, somewhat greater than in any of the other processes. The Cobwell process has been in use for many years at Rochester.

A modification of the Cobwell process which has been employed in some cities consists in removing a portion of the moisture in the raw garbage by direct heat drying in horizontal revolving drums prior to cooking in the Cobwell reducers. This method of moisture removal is more economical than that employed in the Cobwell process itself. This method is now in use at Syracuse, and is known as the **Cobwell-Merz process.**

Drying Processes. Many methods of drying garbage without cooking have been practiced from time to time. In Chicago there is a large plant using the **Merz process,** which consists merely of drying the garbage in direct heat dryers and extracting the grease with a solvent in percolators. In direct heat dryers a portion of the material may be burned or scorched, in which case very foul odors are created. If a moderate quantity of moisture is retained, scorching may not be extensive, but in any event the vapors from this process must be deodorized before discharge to the atmosphere if complaints from odors are to be avoided. This deodorization is effected by scrubbing the vapors by water spray, followed by chlorination.

Drying can be effected also by indirect heat dryers in which the heat is provided by steam, either in a jacket around the outside of the tank containing the garbage or in a series of tubes within a horizontal revolving steel drum through which the material passes. Vapors from indirect heat drying also must be deodorized to prevent the escape of objectionable odors.

Tankage is finished for market generally by screening, grinding or crushing and the removal of metallic objects by magnetic separators. In some cases, as at Indianapolis and Rochester, a portion of the finer material in the tankage is separated by suction and sold for stock feed. In Rochester the grease is extracted with solvent from that portion of the tankage sold as stock feed, but in other cities all the original grease remains in the stock feed except that which is removed by skimming or draining in the digestor. In cases where the grease is not removed by solvent extraction from the stock feed all revenue derivable directly from that portion of the grease is lost; consequently, in such cases the relatively high price obtained for the stock feed does not necessarily indicate that production of feed brings a greater revenue than the production of ordinary tankage and a larger quantity of grease.

Patents and Royalties. The older processes of reduction have been carried on for many years. Fundamentally many of the cooking processes do not differ greatly from one another, and they are similar in many respects to the process of rendering animal matter which has been used for years in the packing industry.

The Cobwell process is patented and royalties have been and are now being collected from municipalities for the use of this method. This royalty in some cases has amounted to about 25 to 30 cents per ton of garbage. Some items of equipment used in other processes have been patented, but in few cases is any attempt made to charge a royalty for the use of the equipment, patentees probably preferring to encourage the use of their devices by making a single charge for purchase. Patents and royalties do not offer a serious problem.

General Sanitation and Odors. Delay in unloading, with its consequent line of standing garbage vehicles, is one of the chief causes for complaints at some reduction plants. Therefore, provision should be made in design for prompt unloading.

During the reduction process the material should be handled with dispatch in closed equipment in so far as is practicable in order to minimize the liberation of objectionable odors. In design careful consideration should be given to questions of ventilation, deodorization of foul air, the effective control of dust in the tankage finishing process, and to the treatment of stick liquor and condensate.

In most cases reduction plants have been built in outlying locations away from dwellings with a view to avoiding complaints from objectionable conditions and odors. At Rochester, however, the reduction plant is located within a few hundred feet of an important business street and within three-quarters of a mile of the geographical and business center of the city, and it is said that no complaint has ever been received. Remote location is not essential, provided a plant is properly designed, is operated along sound engineering lines with the maintenance of rigid discipline and extreme cleanliness and provided adequate appropriations are made when required for operation and maintenance.

Explosion and Fire Hazard. Some reduction plants have been partially or completely destroyed by fires or explosions, in some cases accompanied by loss of life. Such accidents generally have been caused by solvent vapors coming in contact with flames in boiler plants or direct heat dryers. Careful design can reduce the probability of such accidents to a low point, but, even with a sound design, if maintenance is not taken care of and pipe lines and equipment containing solvent develop leaks, it may be possible for these fumes to form explosive mixtures with the air and become ignited. The explosion and fire hazard alone, however, need not be sufficiently serious to make it unwise for a city to adopt the reduction process.

By-Products. As previously stated, the principal by-products recovered in the reduction process are grease and tankage. In some cases an attempt is made to salvage bones and foreign materials but the revenue derived from such sources is comparatively small. Where large carcasses are handled, a slight additional revenue can be obtained from the sale of hides. As stated elsewhere, some of the tankage can be made into stock feed.

Recoveries of grease vary widely between the limits of 25 to 90 lb. per ton of garbage. With a high grease market and a low solvent market, it will be economical to extract more grease than will be the case where market conditions are reversed. It is seldom, however, that more than 60 to 65 lb. of grease are recovered.

The recovery of tankage also varies widely between limits of about 175 to 450 lb. per ton of garbage, depending upon the process employed and the effort made to obtain high recoveries.

Cost of Construction. So few reduction plants have been built in recent years that there is little available information on construction costs, and many of the existing plants apparently were designed with a view to minimizing the construction cost without adequate provision for sanitation.

The Rochester plant which was put in operation in 1921 has a maximum rated capacity of 180 tons per day. Its cost as reported by Mr. John V. Lewis, now Director of the Bureau of Maintenance and Operation, in his paper before the Sanitary Engineering Division of the American Society of Civil Engineers (Proceedings, October, 1926) was as follows:

Item	Cost	Cost per ton of maximum capacity
Land	\$47 140	\$262
Buildings	138 090	767
Equipment	568 960	3160

Actual bids received by the city of Buffalo in 1925 on detailed specifications were \$4940 and \$4150 per ton for buildings and equipment for the Cobwell-Merz and Morrison processes respectively, to which additional items, to provide a complete plant with all safeguards against fire and explosion hazards and with every provision for cleanliness and sanitation, amounted to 20 and 25%, bringing the total figures up to \$6060 and \$5170 respectively.

The Indianapolis plant is reported to have cost in the neighborhood of $2300 per ton of capacity, not including equipment for grease extraction.

Cost of Operation. The net cost of operation, or net profit from operation if there should be any, is dependent primarily upon the price received for grease and to a lesser extent on that for tankage, and consequently fluctuates widely. Not only are there uncertainties as to the trend of the tankage and grease markets, but there is doubt as to the permanence of the tankage market due to the advances being made in the chemical industry in the fixation of atmospheric nitrogen and the development of other sources of nitrogen. Activated sludge from the treatment of sewage also possibly may become a serious competitor. At several plants it has at times been impossible to sell the tankage at any price and huge tankage dumps have been built up.

The following table gives the cost of operating the Dayton plant:

Year	1916	1917	1918	1919	1920
Tons of garbage.....	16 330	15 930	15 380	18 720	13 800

* Profit. † Fixed charges.

8. Incineration

In most American cities mixed refuse, that is, rubbish and garbage, has sufficient heating value to evaporate its moisture and to actively and continuously support combustion at a suitably high temperature to avoid objectionable odors. This generally is not practicable with garbage alone. If garbage is burned on a slow fire the odors developed are disagreeable. On this account, incineration cannot be considered as a satisfactory means of disposal of garbage unless fuel is provided to help burn the garbage; municipal rubbish is the only economically available fuel for general use although coal or oil may be advantageously used in small quantities to meet emergencies.

The cost per ton of garbage of operating the plants at Columbus and Rochester has been as follows:

	Columbus, 1911 to 1926 inclusive	Rochester				
		1924	1925	1926	1927	1928
Operating cost.....	$3.62*	$8.80	$6.60	$7.31	$7.21	$6.19
Revenue..........	3.78	5.00	5.05	5.49	4.98	4.96
Net operating cost	$0.16†	$3.80	$1.55	$1.82	$2.23	$1.23
Fixed charges......	.55‡	2.50	2.40	2.41	2.42	2.40
Total net cost....	$0.39	$6.30	$3.95	$4.23	$4.65	$3.63

* Includes water furnished by city.
† Net operating revenue.
‡ Interest on bonds only.

The Columbus record covers the war period when prices received were abnormally inflated, and does not provide for adequate maintenance.

Methods of Incineration. Municipal refuse incinerators have generally been developed and exploited by manufacturers. Most makers have patents upon methods or devices, but the validity of many of them is doubtful because similar devices have been used in steam engineering practice and otherwise for many years. In most cases the purchase of the equipment carries the right to use the patents, and the payment of royalties is not required. The patent situation offers no obstacle to the adoption of incineration.

Most furnaces are charged from overhead by dumping through a hole in the arch. The refuse falls upon a grate or hearth on which it is burned or upon a drying hearth intended to evaporate some of its moisture before incineration begins.

Some furnaces are arranged with one to four grates in series, placed side by side so that the path of the flame is across all the grates into a combustion chamber at the end whence the products of combustion pass through the flue to the stack. Each grate is fed through an individual charging opening in the arch above and has an individual ash pit. In this manner the charging and draft conditions of each grate or cell, as they are commonly called, can be controlled independently. In such a furnace, when slow combustion is taking place in one cell due to the recent admission of a charge of cold, wet material, the heat and flame from the other cells and the radiant heat from the combustion chamber walls (provided the chamber is kept at a sufficiently high temperature) assist in raising the products of incomplete combustion from that cell to a deodorizing temperature.

In order to facilitate combustion of wet material and produce higher temperatures some furnaces are designed to operate under forced draft. A further aid to combustion is the use of preheated air. The air heaters are devices for transferring some of the heat in the flue gases to the cold air prior to its delivery under the grates, and generally consist of a series of tubes with hot gases on one side and cold air on the other. Maintenance charges will be reduced if air heaters are shut off when not required to raise the products of combustion to adequate temperatures.

Differences also exist in methods of charging. In some cases the entire contents of the collecting vehicle are dumped directly into the furnace, while in other cases small charges are admitted at frequent intervals. Under the latter system it is usually possible to select the material, varying the relative quantities of wet and dry material. Where large volumes of wet refuse collected in rainy weather are dumped directly upon the fire, the cooling effect is marked, and if the temperature of the products of combustion is reduced to too low a point, odors may be created.

There are furnaces having water-jacketed steel walls and a drying grate built in the form of a basket of tubes through which water circulates. The material in the basket becomes partially dried and is raked out or falls upon the fire on a second grate below. Such furnaces of necessity generate steam, which is available for power about the plant if desired. Where it is not economical to use the steam, it is discharged into the atmosphere.

In Germany, England and formerly in Switzerland a few vertical furnaces somewhat similar to the blast furnaces of the steel industry are in use. In such furnaces the refuse is admitted at the top, air is supplied through tuyères near the base of the furnace, and the residue is cut off by an hydraulic knife and discharged through the base. Waste heat from the top of these furnaces can be passed through waste heat boilers for the generation of steam. This is known as the Didier system.

Design of Incinerators. In the general design of incineration plants sanitary engineering principles should be rigidly followed, but the detailed design of the furnaces and auxiliary equipment are problems of mechanical and heat engineering. Draft provision, grate area, furnace volumes and combustion chambers should be adequate for proper combustion. Flue and stack areas should be proportioned to give reasonable velocities for the deposition of dust, the prevention of erosion of brick work and in order to assure reasonable draft losses. It is particularly important that expansion and contraction joints in the furnaces be properly located and designed due to the extreme range in temperatures encountered. There are of course many other details which should be carefully designed.

Specifications frequently have required average temperatures of 1400° F. and minimum temperatures of 1250° F. but in working out the designs provision should be made for the maximum temperatures which will be reached.

The design should be based on the material to be burned, for example, if it is intended to burn rubbish without garbage the calorific value and moisture content will be so different from those of mixed refuse that a simpler design may be justified. In the table below are given a few results of calorimeter tests and proximate analyses of refuse.

Average Results of Calorimeter Tests and Proximate Analysis of Refuse

(From "Municipal Refuse Disposal: An Investigation," by J. T. Fetherston *)

	Garbage	Rubbish	Ashes
Calorific values, B.t.u. per lb.:			
Original sample	2 233	6832	8 396
Dry sample	8 351	7251	8 510
Combustible portion	10 338	8503	14 296
Proximate analyses, per cent:			
Moisture	73.26	5.78	1.34
Volatile matter	16.89	65.66	3.73
Fixed carbon	4.71	14.69	55.00
Ash	5.14	13.87	39.93

* Trans. Am. Soc. C. E., 1908; **60,** 345.

General Sanitation, Odors and Smoke. The primary consideration in the sanitary disposal of refuse by incineration is the continuous maintenance of sufficiently high temperatures to prevent any odor from incomplete combustion. If a furnace is so designed and operated that a sufficiently high temperature is maintained at all times, there will be no smoke or objectionable odor given off with the stack gases, which, under such conditions, will have a faint bluish-white color and be noticeable only a short distance. If, however, the temperature drops too low, objectionable odors, smoke and bits of charred paper may be given off through the stack.

In some cases the ashes from incinerators have contained partly burned garbage which when placed on dumps has given rise to objectionable odors of decomposition, and attracted rats and flies. This condition will not obtain if the plant is properly designed and operated.

As in the case of reduction plants, provision should be made at incinerators for the immediate dumping of garbage collection vehicles. Properly designed and operated incinerators can be built in thickly settled neighborhoods, but objections often result in injunctions which forbid their location where planned. Experience indicates that the temporary storage of mixed refuse prior to incineration need not be objectionable, provided due care is exercised in thoroughly cleaning the storage facilities at frequent intervals.

Utilization of By-Products. With incineration the only possible by-products are heat, ashes and flue dust.

Considerable dust is carried over the bridge wall with the products of combustion and is subsequently deposited in the combustion chamber, flues and at the base of the stack. This material is somewhat similar to wood ashes and may contain sufficient potash to have some fertilizing value, although its utilization on a commercial scale is not practicable.

The ashes produced by incineration in North America have no value except for filling low land. In Europe on account of the quantity of household ashes contained in the refuse the residue from incineration contains considerable hard clinker. Sometimes this is ground and used as an aggregate for making concrete tile or for paving walks. The sale of ground clinker produces a slight revenue. Under recent conditions, however, this was not a profitable operation even in England. In this country ashes are seldom burned with mixed refuse, and consequently little hard clinker is obtained; and where ashes are burned there is no market for ground clinker.

In some furnaces sufficiently high temperatures are maintained so that it would be possible, were boilers installed, to generate steam in considerable quantity. In water-jacketed furnaces generation of steam is of necessity a part of the process. In other furnaces, lower temperatures render it inadvisable to attempt steam production.

If there is a market for steam at the site, as for pumping sewage or for operating a garbage reduction plant, or a municipal asphalt plant, it may be economical to install steam generating equipment at an incinerator. At some plants where steam is generated, it has been found impossible to synchronize the production of and demand for steam and the installation and daily use of coal fired boilers have been required. If a reduction plant is located outside the city, the additional cost of hauling the rubbish to an incinerator at such a site may exceed the value of the rubbish as fuel.

Steam can be used for heating the incinerator building in cold weather or for the generation of electricity for general use about the plant. Before purchasing equipment for this purpose, however, it is prudent to compare the additional fixed and operating charges due to such use, as for example, the employment of licensed firemen and engineers instead of unskilled labor, with the cost of purchased electricity or coal for heating. It is wise to consider also that some or all of the furnaces will be shut down over holidays, Sundays and frequently for longer periods due to necessity for repairs, interruption of refuse deliveries, and for other reasons.

Bids for incinerators with and without steam generating equipment received in Buffalo in 1925 indicated that in this case it would have been more expensive to generate electric current by the steam produced than to purchase the same current from the local power company.

It is probably true with some types of incinerators that if steam generating equipment is installed the depreciation of the flue and stack linings and the air heaters will be less rapid than if the hot gases do not receive the cooling thus afforded. On the other hand, the cost of the air heater will be greatly increased due to the much larger heating surface required on account of the lower temperature of the gases, and as stated above, more expensive labor may be required for operation.

Construction Cost. Bid prices for a few incinerators are given below. To estimate actual costs additions should be made for contingencies, such as paving at site, and water and sewerage facilities, and for engineering and other overhead costs.

Cost of operation of mixed refuse incinerators varies widely. In large plants a low figure may be taken at $1.00 per ton and an average figure at about $1.50 per ton of refuse burned.

HARBORS

1. General Information

A Harbor is a refuge for ships, a port or haven. From the very earliest understanding of the term, a harbor was a sheltered arm of the sea in which vessels could be built and launched, and taken for repair, or seek refuge in time of storm. One of the requisites was a good anchorage or holding ground. Such cargo as was carried by the vessel was transported to the shore by smaller craft or carried to the vessel by hand. Natural harbors are those which, in themselves, are usable without resort to engineering works of improvement. Primitive harbors were almost always of this character. With the increase in size and draft of vessels most of the so-called natural harbors have required works of extension and improvement. As a distinctive term, a natural harbor may now be considered as one located on an estuary or an enclosed bay. Artificial harbors, in a more restricted sense, are those requiring the construction of extensive engineering works, such as breakwaters for protection of the shipping from wave action, or harbors in which shallow or otherwise unsuitable areas have been excavated and deepened and other improvements made in order to make them available for the purpose intended.

Prevailing usage fails to distinguish clearly between the term "harbor" and "port." When to a harbor are added terminal facilities, the harbor becomes a port. A haven of refuge for shipping from storm and the elements would not be a port unless to the usage made of this shelter there are also added the facilities for loading and unloading the vessels and re-shipping or supplying the necessary cargo by land-drawn and water-borne supply lines and feeders. R. S. MacElwee suggests as a definition, "The harbor may be defined as consisting of the waterways and channels as far as the pier head lines, the port to include everything on the landward side of those lines, that is, the piers, slips, wharves, sheds, tracks, handling equipment, etc.," and suggests that this distinction, while technical and novel, tends to mark off distinctly the lines of the jurisdiction of the federal government as against that of the state and municipal authorities. This technically restricted definition would appear to have advantages, but it is believed that the term port should be considered the general one and includes the harbor whereas the harbor does not include the port.

Design. Harbors are usually located by force of circumstance over which the engineer has little or no control. This is especially so with natural harbors where the local geographical advantages and growth of population have resulted in the need for, and location of, harbors irrespective of the existence of better natural harbor facilities at points not far distant. The best natural harbors are probably, by reason of the very facilities they offer, often centers about which important interests and activities grow. In cases where the engineer has some voice in the selection, a thorough survey should be made of the neighborhood, including the foreshore and the depths of water in the vicinity. Borings and soundings should be taken to ascertain the character of the ground, both as to anchorage and as regards the readiness with which it will lend itself to economical dredging or deepening operations, should such be necessary. In an important harbor the depth of water should be sufficient to meet the requirements of the maximum draft of vessel likely to use the harbor, allowance being made for over-depth for the pitching and surging of vessels under wave action and the drag or set of vessels when underway. Borings on land should also be made to indicate probable subsurface conditions with a view to future location of the necessary harbor works. Observations should be made as to the meteorological phenomena, such as prevailing winds, frequency of storms, height and force of waves, establishment of mean high and low water and range of tide, direction and velocity of prevailing currents, evidence of silting and of littoral drift.

The large ports and harbors of the world, especially the older ones, were undoubtedly located to afford shelter and protection not only from the elements but from the enemy, and to protect the shipping, while laid up, from destruction and ravages of raids which were frequent in ancient, medieval and comparatively recent times. This condition was common in the Mediterranean and in the North Sea; consequently many old ports are located some distance up rivers, probably as far up as the vessels of those times could be navigated. The facility with which the river and its tributary branches could be used as a water highway by light draft craft for transporting cargo undoubtedly had an important influence, as water transportation had many advantages over the possible land transportation conveniences available in those times. As a consequence, certain large European ports, such as London, Antwerp and Hamburg, were river ports and to them later, with the change in times and the increase in size of vessels, the sea had to be brought by continuous expensive harbor and river work in order that they might retain their supremacy as ports; and there were also others which have disappeared or are no longer ports, as for example Paris.

On account of the facility with which land transportation, especially rail, can now be handled, the newer ports, especially of the United States, are located on the seacoast or on estuaries. This same condition has caused the development and construction in European practice of wet docks together with those reasons given in Art. 24 of this Section.

Tides. The tidal day is always of greater length than the solar day, two tides occurring, generally, in each day, high tide being on an average 50 minutes later every day. Although the tides on the coast line are produced by the sun and moon, this is not due to their immediate effect on the waters of the sea adjacent to the coast line, but is due to secondary tidal waves, resulting from primary waves in the wide expanse of the oceans. It is calculated that the primary effect of the moon on rise of tide is 1.34 ft. and of the sun 0.61 ft.; so that with the two together it is 1.95 ft. or against each other 0.73 ft., the velocity of the primary tidal wave being from 50 to 60 miles an hour. The momentum of this mass moving around the earth, taken in connection with the shoaling of the ocean and configuration of the coast line, explains the very great variation in range of tide found at different localities. The atmospheric condition, by reason of the pressure on the surface of the water, affects the tidal range inversely as the height of the mercury in the barometer. Sudden variations of the height of mercury in the barometer will give a difference of about 0.35 in. for each foot of tidal range for each inch of variation in height of barometer. Tidal range is affected considerably by wind, dependent upon location, and characteristics of the coast line, and the force, direction, and continuation of wind. In the open sea the tide is never slack, constantly changing its direction in a rotary movement, with varying velocity. When plotted the curve will be of elliptical shape. The fact that the directional change occurs clockwise in the Northern Hemisphere and counter clockwise in the Southern Hemisphere, shows very clearly the effect of the rotation of the earth.

Tidal Changes. Engineering works of improvement in harbors or rivers may result in quite surprising changes in tidal conditions. In the location and construction of harbors and harbor works, it is of the greatest importance to ascertain definitely the data of high and low water and range of tide, for which purpose automatic tide gages should be used. Elevation of mean high and mean low water at the various important parts of the United States can be readily secured from local authorities, or from the U. S. Coast and Geodetic Survey, but in important new harbor work it is advisable to establish these independently. Although the height to which the surface of the sea rises and falls at different points along the coast varies considerably, yet there is a mean level to which, at a certain stage of the tide, the water returns. This is known as mean sea level. Where possible, it is advisable to refer to this datum.

Tidal Prism. This is the volume of water represented by the area of the bay, river or harbor affected by tidal changes multiplied by the range of tide which would generally be the volume of water entering at the flood and leaving at the ebb. Harbor engineers are loath to permit the construction of any works that will serve to change materially this tidal prism, as a decrease in the tidal prism has a direct effect upon the quantity and velocity of the water of the ebb and flood tide and a consequent effect upon the channel depth and direction by reason of the resulting tidal scour.

2. Waves

Wave Height. In the location of harbors and the design of harbor works, it is necessary to ascertain the probable maximum wave action and forces likely to be encountered. The height of wave to which an exposed entrance may be subjected will depend upon the greatest fetch or reach of open sea from the windward shore; for open exposed locations

$$H = 1.5\sqrt{d}$$

where H is the height of the wave in feet, and d is the length of fetch in miles. For shorter lengths of exposure in bays, or harbors, this height is represented by

$$H = 1.5\sqrt{d} + (2.5 - \sqrt[4]{d})$$

Extensive observations closely check the results obtained by the application of these two formulas, first proposed by T. Stevenson, and it is to be borne in mind that in the open sea the fetch is confined to the distance over which the wind acts continuously in one direction, the rotary character of ocean storms restricting the applicable fetch even in the broadest expanses of the Pacific Ocean to a distance of not over 1000 miles.

Formation of Waves. The direction of the wave crest in deep water is at right angles to that of the wind, but on approaching the shore it tends to become parallel to the shore line, due to the lagging effect, on the wave, of the rising bottom. Most waves are caused by the action of the wind, due to the wind blowing over the surface with varying velocity, acting by friction on the surface and by direct pressure on the rear of the wave crest. A confused sea existing during a heavy storm usually changes to a regular swell afterward, resulting in trochoidal seas. Waves formed in this manner in deep water are generally understood to be oscillatory waves, in which the particles of water forming the wave move through circular or elliptical orbits. This is not strictly correct, as, undoubtedly, all storm waves are to some extent waves of translation. Deep-water storm waves on reaching shallow water become waves of translation, the friction of the rising bottom on the lower portion of the wave tending to retard this portion to the point where the front of the crest of the wave becomes steeper and steeper, and finally breaks and becomes a breaker or comber.

Wave Velocity in deep water is dependent upon the velocity of the wind, taken together with its continuity, and the extent of the surface of the sea over which it acts, which in turn affects the height of the wave and the wave length. The velocity may be given by

$$V = \sqrt{5.123\ L} \text{ for deep-water waves}$$

$$V = C\sqrt{5.123\ L} \text{ for shallow-water waves}$$

in which the coefficient C is the square root of the ratio of the axes of surface orbits b/a, as it is recalled that the shoaling depth changes the orbits from circular to elliptical, V being the velocity in feet per second, and L length of wave in feet. It is necessary to use the coefficient C only in cases where the depth of water is less than one-half the wave length. The following are values of C:

d/L = 0.05	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45
C = 0.552	0.746	0.858	0.922	0.958	0.977	0.988	0.994	0.997

in which d = depth of water, or distance from the center of the surface orbit to the bottom, and L = distance from a wave crest to the next.

The relation between wave height and length is dependent upon wind, sea and other local complex influences; in general, the proportion between length and height may be taken as: 33 for moderate wind and light sea, 20 for strong wind and rough sea, 18 for storm and heavy sea.

The wave pressure varies greatly; pressures as high as 7840 lb. per sq. ft. have been recorded. A series of observations at Skeeryvore Rocks and at Tyree gave these results: 6-ft. swell, 3041 lb.; 10-ft. ground swell, 3041 lb.; 20-ft. heavy sea, 4562 lb.; strong gale, heavy sea, 6083 lb. per sq. ft.

Wave Energy of a wave of one unit width, with length L and height H is

In deep water, $E = 8\ L\ H^2\ (1 - 4.935\ H^2/L^2)$

In shallow water, $E' = 8\ L\ H^2\ (1 + 19.74\ a^2/L^2)$,

in which a is the semi-major axis of surface orbits, H and L are in feet, and E is in foot-pounds. This energy is for salt-water waves; for fresh-water waves reduce amount by 2-1/2%.

Values of a in Terms of Wave Height H

d/L = 0.10	0.15	0.20	0.25	0.30	0.35	0.40
a = 0.91 H	0.68 H	0.59 H	0.55 H	0.52 H	0.51 H	0.504 H

When a wave enters a bay, or arm of the sea, between natural or artificial barriers its height tends to decrease on account of friction of the shoaling bottom and the retardation due to barriers; and on emerging into open, interior water, it further decreases in height due to distribution and the tendency of the wave crests to diffuse parallel to the shore line.

Wave Action. The percentage of wave height above water level is important as indicating the height to which harbor structures may be subjected to direct wave action. Observations indicate that, in general, about two-thirds of height of the wave is above mean water level, and about one-third below. Due to the action of high winds, opposing currents and further unknown causes, deep sea waves may break partially in water of sufficient depth for their free propagation, so that a barrier opposed to them in water of great depth may at times be subjected to the direct action of breaking waves. It is known, however, that waves invariably break on reaching water of insufficient depth. Considering the height of the maximum wave as determined by actual observation, or by application of Stevenson's formula, the ratio of depth of water to wave height in which waves may break will vary from 1 to 2.71; or 1.67 is a mean ratio taken from 134 observations. Where wave action is arrested by barriers, a portion, at least, of the wave energy will be exerted against this barrier. It is important in designing harbor works that such artificial barriers shall be made strong enough to resist the successive attacks of maximum sized storm waves. Wave force is exerted and transmitted against such barriers in divers ways, some of which are: (a) The force may be static pressure due to the height of the column of water. (b) It may result from the effect of rapidly moving particles of the liquid. (c) It may be due to the impact of floating bodies on the surface of the water hurled by the wave against the barrier. (d) It may result from the rapid subsidence of masses of water thrown against the structure, producing a partial vacuum and causing sudden pressure to be exerted from within. (e) Destruction of the structure may result from the falling on it from above of large and heavy masses of water thrown up by the wave action.

The interior of such barrier structures is also often affected by forces transmitted through joints or cracks, by hydraulic or pneumatic pressure. The most destructive effects of waves are exerted at or about sea level. The result of wave action may be apparent at considerable depths, although it diminishes considerably in force and extent. In the design of structures subjected to wave forces it should be considered that the material entering into the structure is at least partially submerged and that, therefore, the weight of the mass submerged must be considered. Consideration should also be given to the presence and movement of ice where harbor works are located in colder climates.

3. Breakwaters

Uses of Breakwaters. A breakwater is a work or barrier constructed around or in connection with artificially sheltered harbors in order to protect the interior water areas from the effect of heavy seas, and make it possible for this area to be used for the safe mooring, operating, handling, loading, and unloading of shipping. Breakwaters are almost invariably a most prominent and essential feature of artificial harbors, and are employed to convert an open area or roadstead into a harbor or to render more secure and usable harbors that are enclosed and protected, excepting against the sweep of the sea with prevailing winds coming from certain directions. Breakwaters on a smaller and less important scale are sometimes constructed in the interior areas of large natural harbors to protect shipping from wave action under conditions of heavy storms from an unfavorable direction. A breakwater the protected side of which is used as a quay for wharfage is also known as a **Mole.**

Design. There are three general types of breakwaters: 1, that in which the exposed face is vertical; 2, partially vertical and partially inclined; 3, inclined. The type to be selected is dependent upon local conditions. Claims in favor of the vertical type of breakwater are that because the action of deep sea waves is purely oscillatory, the wave force encountered is due to water head pressure, dependent upon the height of waves. As has already been stated, nearly all waves are to some degree waves of translation, and since breakwaters are usually located and constructed in comparatively shallow waters, the wave forces to be encountered are more complicated than those due purely to hydrostatic pressure; therefore, vertical face breakwaters are undoubtedly subject to severe wave impact. The combination of the inclined and vertical face often results in the throwing up, vertically, of large masses of water which, in turn, fall on the top of the breakwater directly behind the parapet. In crib breakwaters, with heavy timber decks, structures have often been seriously damaged by such action. In inclined breakwaters there is danger, if they are not carried high enough and surmounted by a vertical wall, with heavy storm waves, that the waves will sweep entirely over the breakwater, resulting in a disturbed effect and an appreciable secondary wave action behind the breakwater. When waves impinge obliquely in the direction of the breakwater, they often accumulate size and energy as they travel along its front. In the design of harbor breakwaters, information should first be obtained concerning the direction and force of prevailing winds, character of coastal currents, probable maximum height of waves, character of bottom or foundation and cost and availability of materials to be employed in construction.

Rubble-Mound Breakwaters are a more or less heterogeneous assemblage of rubble, riprap, or cobble, deposited without any particular regard to bond or bedding. This is the simplest form of breakwater and is usually constructed by the dumping of material into the sea from barges or cars run out on trestles or staging. This operation is carried on until the mound or heap emerges from the water and is carried up a distance above the same, the action of sea and waves being depended upon to give the sides a natural stable slope. It is usual in constructing extensive works of this character to make some attempt at grading materials and to control the slopes, the interior being composed of cobble or smaller riprap and the sea side of the breakwater of heavier and more massive stone. As the force of the wave decreases with the depth, in deep water the slopes are often steeper and smaller stones are used. Such a structure is often supplemented by placing heavy massive stone or concrete blocks on the sea side, whereas the slopes and faces above the sea level are roughly paved with blocks of stone or concrete.

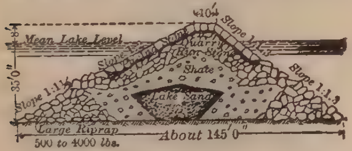

Fig. 1

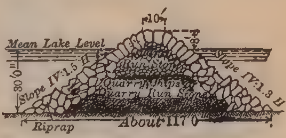

Fig. 2

Rubble-Mound Breakwaters

Figs. 1 and 2 show typical sections of rubble-mound breakwaters, Fig. 1 illustrating the first modification made in the Cleveland, Ohio, breakwater. The earlier breakwater had a complete sand core or hearting; during heavy storms this hearting was washed out, resulting in the subsidence of the rubble top and eventual disruption. The work was finally built as shown in Fig. 2 with all sand omitted from the core and with rough instead of smooth stone covering.

Timber Breakwaters may consist of timber cribs floated out to place and loaded and sunk by being filled with rubble, or may be built of close round piles or sheet-piles driven into the bottom, framed, braced and backed up with rock or concrete blocks. Timber cribs of this character are sometimes superimposed on rubble-mound breakwaters. Breakwaters of timber are more or less temporary structures and are principally used in shallow water for unimportant barriers. They have, however, been extensively used on the Great Lakes.

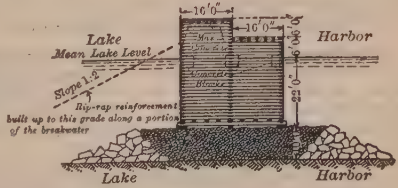

Fig. 3. Timber Crib Breakwater

Fig. 3 shows a typical timber crib breakwater built at Cleveland, Ohio. This work was damaged by storms, masses of water projected upward by storm waves fell on the top timber work, breaking the cross members and planking. The work was reinforced by backing the structure with riprap.

Fig. 4 shows a low-coursed stone wall breakwater surmounting a rubble-mound, at Dog Bar, Gloucester, Mass.; a somewhat similar breakwater at Sandy Bay, Cape Ann, Mass., was considerably strengthened by preventing the large blocks from sliding by inserting steel dowels into the stones on the harbor side against the toe of the course directly above.

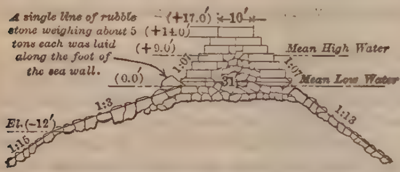

Fig. 4. Mound Breakwater with Wall

Masonry Wall Breakwaters are, in whole, or part, constructed in a regular and systematic manner of coursed stone masonry or concrete with vertical or inclined faces. Such walls are constructed in cofferdam in the dry or under water by divers or diving bells. This character of breakwater is often built from the tide level up surmounting a rubble-mound substructure or capping a timber crib.

Figs. 5 and 6 show typical sections of the mole breakwater at Harbor Beach, Mich., consisting of a timber crib, capped with concrete blocks. The section shown in Fig. 6

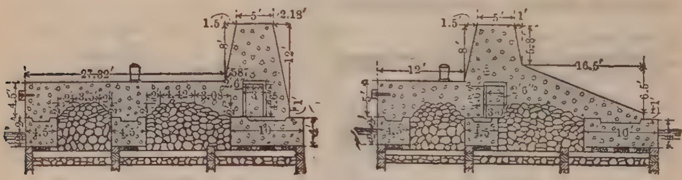

Fig. 5 Fig. 6

Timber Breakwaters Capped with Concrete

was damaged by storm by having the concrete capping lifted and cracked. The cost of wall and composite wall breakwaters varies widely.

Reinforced-concrete Breakwaters may be built by means of caissons built on shore, or in floating structures, launched or lowered into the sea and sunk to place, and settled upon a prepared foundation of rubble or piles, the breakwater being formed by filling the compartments with stone or sand; or they may consist of reinforced-concrete piles and sheet-piling banked or filled with sand, riprap or rubble. See Sect. 11, Art. 57, p. 1108. In the following examples of breakwaters the numbers refer to Fig. 7.

(1) Zeebrügge, Belgium, 1905. Breakwater or mole 6560 ft. long, lower course built of monoliths, set in floating caissons of structural steel and plating with concrete lining arches. Lower sections 82 ft. long, 24-1/2 to 29-1/2 ft. wide, 28 to 36 ft. deep. Built in graving dock and floated out. Sills for setting 20 in. deep. Sections sunk at low water by flooding, and then filled with concrete. Blocks weigh 1500 to 1600 long tons light and 4000 to 5000 long tons when filled.

(2) Barcelona, Spain, 1906. Section of floating caisson for monoliths for extending the breakwater. Blocks 39 ft. long divided into five pockets, which were filled with pre-molded blocks.

(3) Touapsé, Russia, on Black Sea, breakwater 1400 ft. long, largest caissons 56 ft. long 21 ft. wide, and 21 ft. deep, divided into 21 divisions, 7 sets longitudinally. Caissons of reinforced concrete. Large boxes weighed 268 long tons when launched and 1600 long tons when filled.

(4) and (5). Talcahuano, Chili, 1908. Breakwater 1750 ft. long, section (5), dam (4), each caisson 33 ft. long, built of reinforced concrete and filled with sand and stone.

Breakwaters have been constructed employing floating caissons at Bilboa, Bizerta, Algoma, Wis., and Welland Canal, Canada. (See Sect. 11, Art. 57.)

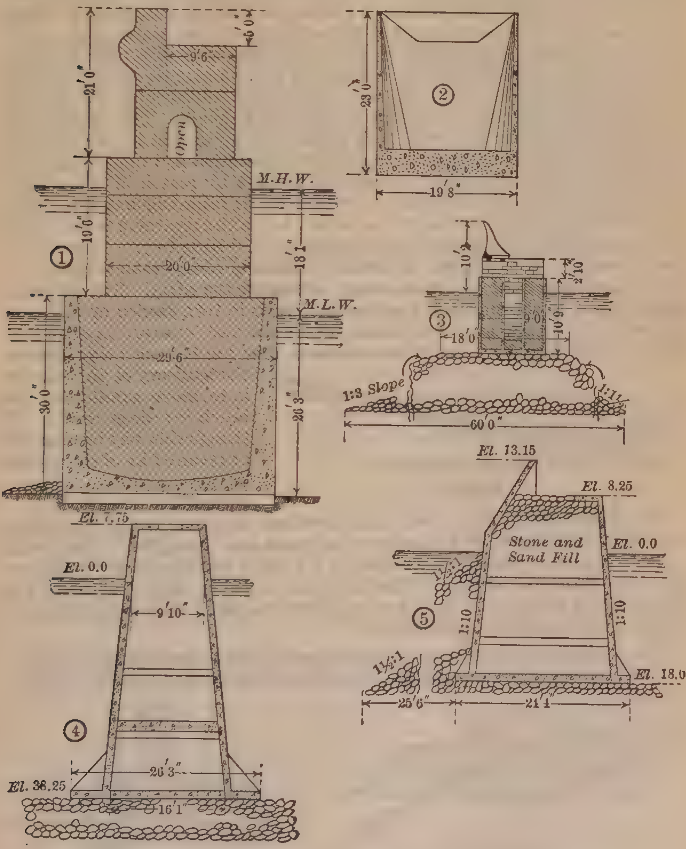

Fig. 7. Reinforced-concrete Floating Caisson Breakwaters

4. Bars. Sea Encroachment

Littoral Drift. The coast line of all exposed foreshores indicates a gradual but continual change, in some locations in the direction of retrogression or washing away, and in other locations in deposition and accretion, the carrying away and depositing of materials being due to wave action in connection with current flow. The breaking of waves on a beach or foreshore serves to stir up loose material and also to break up solid material by direct erosion or by the impact or wearing away, due to the carriage by the water of particles of sand and shingle; the lighter particles of such material remain in suspension long enough for them to be projected some distance along the shore by the resultant of combined wave action and littoral currents. The heavier particles are rolled along the beach and partake of a zigzag movement, the principal action being generally confined to the reach between high and low water mark. Littoral drift is generally attributable to the prevailing wind direction, although it is modified by onshore currents. Breaking waves acting on a beach or foreshore by reason of their velocity are carried some distance up the sloping beach, mixing with, and stirring up, the sand and shingle. The wave having spent itself, the water then runs back by gravity, but is met by the next oncoming wave, the returning water carrying in suspension and rolling down the beach some sand and shingle, the oncoming wave by reason of its greatest velocity being at the top or crest is carried over the returning water, building up a hydraulic head at the beach line which forces the returning water down and outward thus setting up what is known as the "undertow." The undertow in some instances becomes an outshore current of considerable importance, owing to peculiar local conditions which accentuate the effect. The material carried down, as the undertow loses its velocity, is in turn carried up again on the beach by returning waves moving backward and forward, as shown in Fig. 8. The quantity of sand in suspension near the bottom being greater the tendency of wave action is to move sand from the beach to deep water, although this may be retarded or reversed by offshore gales setting up surface offshore currents.

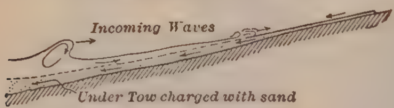

Fig. 8

The general effect of the wind on the foreshore, as shown in Fig. 9, tends to carry this drift of sand and shingle up the beach in a zigzag line. The actual action, as can be readily understood, is far more complex, but the general principle illustrated obtains. The drift varies, being dependent upon the direction and force of the wind, but in general the result follows the direction of the prevailing winds of the locality.

Bars. Bars at the entrances of harbors are of four general classes: (a) Natural bars, consisting of hard material not affected by scour or current; (b) those

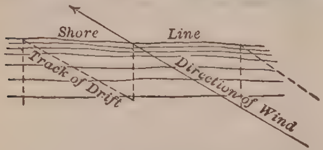

Fig. 9

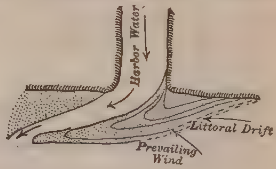

Fig. 10

due to the deposition of alluvial material brought down by river drainage; (c) casual bars occasionally and irregularly heaped up by storm wave action and afterwards dispersed by similar action, or by one or more currents; (d) bars consisting of sand or shingle of certain general features and permanent direction, but constantly subjected to alteration by action of winds, waves and varying currents. It is generally concluded that the last-given type of bar is that most usually encountered at harbor entrances, and is due, principally, to wave action and the littoral drift engaged in depositing material across the mouth of the outfall channel and the constant tendency of the ebb and flood currents to remove and disperse the drift. The result of such drift action and harbor ebb current is shown in Fig. 10, which is typical of the conditions that have affected the entrances to interior bodies of water on sandy coast lines.

Influence of Coast Line on Formation of Bars. Where the bed of the sea decreases in depth rapidly, the drift moving along the coast line is less readily carried into the channel by flood tide and is more readily transported by the ebb tide to deep water. Under such conditions bar formation is unlikely. Harbor entrances on precipitous foreshores of rock materials are not liable to bar formations. Prominent projections of the coast line on the side from which the flood tide sets in cause the current to run around it with velocity sufficient often to prevent depositing of drift and formation of bars at harbor entrances.

5. Beach Erosion and Protection

Sea Walls, Dikes or Bulkheads are constructed along the shore line to prevent encroachment of the sea by direct wave action, and, as in the case of breakwaters, may consist of loose rubble-mounds or heaps, masonry wall work, usually, however, supplemented with timber, steel, or reinforced-concrete sheet-piling driven into the beach and strengthened by wales, guide and brace piles, fascines and mattress work held in place by piles and loaded with rock. The character or massiveness depends on the location and wave forces to which the work will be subject. In following notes of sea walls the numbers refer to Fig. 11.

(1), (2), (3), (4), Coney Island, N. Y. Section of sea wall.

(5) Governor's Island, N. Y. Sea wall, 1901–1911. Average settlement 0.8 ft., maximum settlement 2.4 ft.

(6) New York, Brooklyn Parkway, 1913. Masonry wall.

(7) Atlantic City, N. J.

(8) New Orleans, La., 2650-ft. wall, fill behind wall 8 to 12 ft. deep, piles 50 ft. long, expansion joint every 50 ft.

(9) Ocean Beach Esplanade, San Francisco, California. Length 2066 ft.; width 30 ft. 5 in.

Effectiveness of Sea Walls. In many instances large sums of money have been expended on sea wall protection with entirely unsatisfactory results. In exposed locations subjected to high wave action, with a sea current along the beach, on which the sea wall is constructed, the action of the waves, together with the current, will gradually, but continually, carry the beach material away until the foundation is exposed and undermined and the work destroyed. The most carefully constructed massive works of this character will not endure under such conditions.

The Board of Commerce and Navigation of New Jersey, through its Erosion Committee and Engineering Advisory Board, after a painstaking study of the New Jersey coast conditions, concluded:

(1) Neither bulkheads nor groins can be recommended for use separately except in special cases.

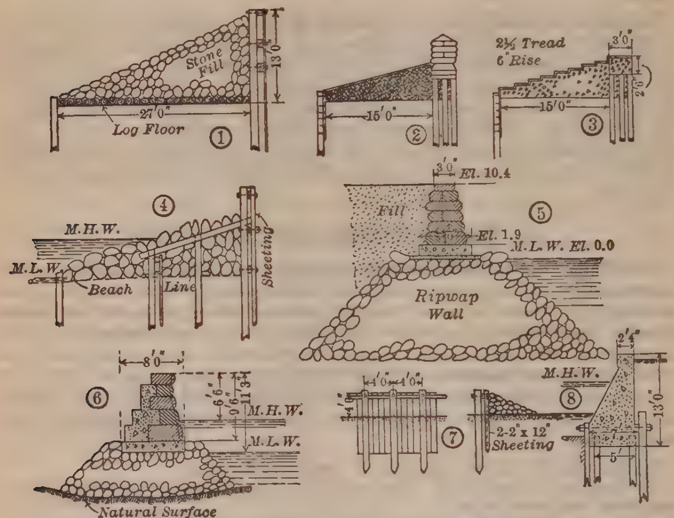
(2) The use of concrete for bulkheads is not recommended except for those heavier and more permanent types which may be classed as sea walls. Its use is highly hazardous where any serious settlement may be expected.

(3) Timber bulkheads should always be provided with rock protection. The rock should be of large size.

(4) The construction of shore bulkheads and sea walls seaward of the ordinary high-water line is to be permitted only when absolutely necessary for the immediate protec-

tion of existing structures such as buildings, roadways, etc. When the construction of such bulkheads and sea walls is unavoidable they should be supplemented by suitable groins.

(5) The distance between groins requires, for its determination, due consideration of many factors including the slope of the beach, height of waves, distance to offshore bar, proximity of ocean inlets, etc. If the space between groins is too great, the front-



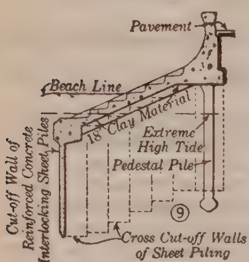


Fig. 11. Sea Walls

age to the leeward of the groins will be left without protection. If this space is insufficient, scour may result from back-wash and interference of the two groins. In general, groins should be spaced from one to one-and-one-half times their length.

(6) Groins must always be securely and tightly connected to a bulkhead or must extend well inshore to points beyond the reach of the highest waves. Disaster will almost certainly follow if the water is permitted to pass the inshore end of the groins. Any breach or poor connection between a groin and a bulkhead on a sandy beach is almost certain to nullify the effect of the structures.

(7) In groins sheet piles should have a minimum penetration of 10 ft. Even this will be inadequate in some situations. The groins must be of tight construction, preferably of tongued and grooved sheet piling well lined and braced by wales and piles. The piles must have a penetration of at least 25 ft., and the timber should generally be treated with creosote. All bolts, rods, spikes, etc., should be galvanized.

The rock should be of large size. Stone less than 100 lb. should not be used. Even rock of such small units as 100 lb. is of very slight value. Where the exposure is severe, nothing less than one-half ton should be considered, and approximately 75% of the rock should be of units weighing two to six tons or more. In general, rock should have a least dimension at least equal to one-third its largest dimension.

The incorporation of a sandtight core in groins is essential. This should be ordinarily of timber piles and sheet piling. It may be of rock where sufficient material is used, in the class of large structures such as in the Longport Eleventh Avenue jetty, which contains a very deep, wide foundation of rock and foundry slag. The core must be a substantial structure. If of timber it must be supported by piling or by rock or by both.

(8) Groins or other structures designed to gather large areas of beach should be permitted only for special reasons and after careful study of the probable effect upon adjacent communities. What is to be sought is coast protection and not coast extension. Extension at one place is likely to be accomplished by recession at points in the vicinity.

(9) The height and slope of the groin with respect to the profile of the beach depend upon many factors. Structures of the type found to be necessary on the steep beaches of northern New Jersey would be needlessly expensive in many sections of the southern New Jersey beaches where the profile is much flatter and where greater fluctuation of the shore line may be permitted.

If the beach has been seriously lowered and the slope permits, it may be most economical to build a low structure, that is, some 3 ft. above the normal profile of the beach, but so design the core as to permit the addition of wales and sheeting to obtain higher level of the beach when the low jetties attain their maximum effect.

(10) The construction of curved groins should be permitted only after thorough investigation. There is no evidence that curved groins offer any greater promise of success than straight groins.

(11) Coast protective works must be adequately maintained. The tendency has been to pay little or no attention to maintenance until serious damage occurs. Where state aid is given to protect the shores, provision should be made for the maintenance of such works in good repair. Municipalities fronting on the ocean should adopt and maintain general programs for the adequate protection of their ocean front. Perhaps the best means to accomplish this would be the establishment of a fund into which moneys would be paid every year, the expenditures to be made therefrom as required. The almost universal tendency is to view with indifference the inroads of the ocean, making no effort to hold the beach until valuable structures are actually attacked.

(12) The growth of sand dunes along the coast should be encouraged and promoted. Unfortunately, in New Jersey the tendency has been to level the sand dunes as construction of roads and dwellings progresses. Public authorities should discourage the removal of sand from the beaches where this sand is used for construction purposes or for filling of low lands. The artificial removal of sand from the New Jersey beaches is a serious evil.

The best means of encouraging the growth of sand dunes is to plant beach-building vegetation, such as sea oats, sea wheat and other beach plants. In some places, particularly low spits, fences may be employed to gather the drifting sand.

(13) There is no evidence to justify the contention that the protection of the beaches can be well attained by means of heavy key works of great extent and massiveness, such as heavy outshore breakwaters or current deflectors.

(14) To control the location and navigable depth of inlets, tight jetties are necessary, and in the case of many inlets two parallel jetties are needed to carry the current into deep water.

(15) Twin jetties at inlets possess a superiority over a single jetty, whether straight or curved, and may be used with more confidence of results.

(16) In length jetties should always extend from high-water line, or form a proper bulkhead outward to such distances as may be required by the problem at hand. For navigation purposes they must necessarily extend out sufficiently far to obtain the low-water depth sought. For fixation of location of inlets and for beach protection purposes an extension to or only slightly beyond low-water mark is necessary. It should be borne in mind in all cases that long jetties may temporarily cut off from the leeward beach the supply of drifting sand upon which its maintenance in normal conditions depends.

(17) The northern beaches of New Jersey, that is from the vicinity of Long Branch northward, are relatively steep. This is a situation which requires the application of substantial structures, that is, heavy rock breakwater jetties. Light wooden structures, not adequately supported with heavy rock, will not serve on this frontage.

The southern beaches are less steep, and here the construction of such heavy works is not ordinarily justified from the standpoint of economy, except in the vicinity of inlets.

(18) Every section of beach presents a problem with its own peculiarities. It is therefore impossible to give precise rules that can be applied offhand to particular localities, but the types of structures discussed and recommended in this report have proved their effectiveness as shown by the results obtained during the past few years, and consequently much of the confusion and uncertainty on this subject has been removed.

(19 For breakwater jetties of magnitude the tight sheet pile core type surrounded by large rock is recommended. The dimensions of the jetty should be suitable for the location.

(20) In extensive, or key construction of magnitude, as distinguished from local protection on the beaches, no small stone should be used. Contracts should call for large stone, say 85% of three tons and upwards, with no stone of less than one ton. In general, rock should have least dimension at least equal to one-third of its major dimension.

(21) Preparations for jetty contracts where rock is to be used should include, in addition to soundings, boring to locate a hard bottom, if one exists.

(22) Where hard or firm bottom exists, and a core wall is to be used, plans should call for piles and sheet piles to extend well into it. Where no hard bottom is found, then the longest piles and sheet piles should be used within reasonable expense.

Groins are built out from the shore line perpendicular to, or making an angle with, the shore line. They are generally constructed perpendicular to

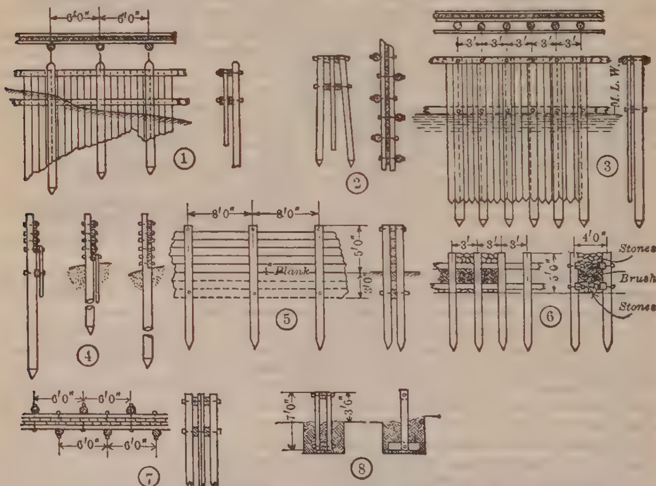

Fig. 12. Groins and Spur Dikes

the direction of the current or drift. Their object is to cut off and prevent the carrying of beach materials along the foreshore. They need not be of massive construction, and usually consist of close piling, or sheet-piling, driven between guide wales and piles, or horizontal courses of plank held between vertical timbers or piles driven into the beach. They should be built so as to offer the least resistance to wave action, follow closely at a few feet height the general slope of the beach, and extend from high to low water. When of more massive and stronger construction on a steep beach they should, if built out below low water, extend out into water of depth so that wave action will not seriously disturb bottom conditions, such as would result in scour and undermining and the destruction of the outshore end. When built in this way they are also known as **Spur Dikes** or **Jetties.** Groins should cut off the lateral sweep of waves. The distance between groins should equal their length and may be one and one-half times the length. In following notes, the numbers refer to Fig. 12.

(1) New York, N. Y., foot of Bay 22nd, Brooklyn. Wales 5 × 10, sheeting 4 in.

(2) Bath Beach, N. Y. Sheeting 3 in., 11 ft. long. Top wales, 6 × 6; lower wales, 6 × 8 in.

(3) Coney Island, N. Y. Wales 4 × 10, 4-in. sheeting 22 ft. long.

(4) Telewana Park, N. Y. Horizontal planking 3 × 10, wales 4 × 8, sheeting 3 in., 6 ft. long, piles 15 to 20 ft. long.

(5) Atlantic City, N. J. Planking was put in, sand as littoral deposit, raised beach, all lumber creosoted.

(6) Atlantic City, N. J.

(7) Asbury Park, N. J. Placed 1908; successful up to 1914. Beach protected and extended.

(8) Type of low groin adopted by E. Case on English coast with entire success.

Groins of reinforced concrete have been extensively used on the English coast, consisting of grooved reinforced-concrete piles and horizontal slabs added as the beach rose in height. On the Holland coast spur dikes consisting of brush piles covered by pavement of stone have been successfully used, length about 350 ft.

Principle of Action of Groins. The object of groin construction is to confine the action of the breaking waves on the beach to moving the sand and shingle composing the beach up and down locally in the confined space, and at the same time prevent the current along the beach from carrying this sand away to other locations, the beach current being compelled to seek a path outshore of the extremity of the groins at a depth where the wave action will be insufficient to stir up a sandy bottom, so that it may be carried away by the beach current. On the other hand, this current will carry, in suspension and along the bottom, sand or shingle from more distant points not protected by groin construction, and deposit this in the pockets formed by the groins resulting in beach accretion, as indicated in Fig. 13.

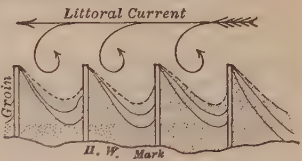

Fig. 13

The windward accumulation will be more pronounced, the deposit on the leeward side being materially reduced by eddies caused by the lee side of the outer end of the groins; as the pockets between become filled up, it becomes necessary to raise the height and extend the groin seaward. In most instances it is possible by this method to add considerably to the foreshore where, previous to the work, it was being steadily and continuously carried away. Groins are advantageously employed in connection with sea-wall protection.

Offshore Breakwaters. In certain instances breakwaters constructed parallel with the beach and outshore have been effective in stopping beach erosion and have resulted in accretion behind the breakwater. See Transactions Am. Soc. C. E., Paper 1541 by H. C. Ripley, and discussion.

Dunes. Besides the retrogression or deposition of materials by direct water action of breaking waves, coastal currents and littoral drift, the air currents or the winds frequently have a direct effect of considerable importance, as is evidenced by the erosion, carrying away and deposition of sandy beach materials in the building up and constant movement of dunes. Such action may often become of so important a character in connection with foreshore protection as to require stabilizing.

On the Holland coast this is accomplished by resorting to planting of coarse grass and the placing of brush to protect the sand surface from wind action and also to catch the flying particles of sand and artificially build up dunes or embankments at predetermined places.

The fixing of sand by the planting of grass, weeds, shrubbery, although an effective permanent method where applicable, requires time. For more immediate results and as a preliminary, fences are frequently employed; if they become buried in the sand deposit they may be built up and the height increased until protection is afforded by permanent artificially built-up dunes. It is important in channel construction between lagoons and the open sea to bear in mind the sand drift, inasmuch as frequently in the case of jetties built to the open water where the bottom is beyond the influence of wave action and where the littoral drift is not properly provided for, the wind-borne sand is carried over the jetty into the channel, obstructing it.

6. Channel Regulation

Variation in Channels. In bay or estuary harbors on coast lines subject to appreciable tidal ranges, it is quite frequently the case that the ebb current in finding its way to the sea has a tendency to scour out a channel for itself in the line of least resistance, water from the sea entering the harbor at flood tide, eroding for itself a different channel-way, sometimes across the channel-way of the ebb tide, with a consequent inclination to fill up this channel. The influence of littoral current and drift at the entrance of such harbors, together with that of gales and storms at intervals, often seriously complicates the problem of maintaining navigable channels. However, there is a constant tendency toward an equalization of forces looking to the establishment of a more or less fixed channel-way. The navigable channel need not necessarily follow the natural channel eroded by the ebb or the flood tide, but may be established by crossing a series of deep pockets, availing itself, in whole or part, of either or both tidal channels. For methods of marking channels, see Art. 11.

Dredging. Such navigable channels are often established and maintained by excavating shoal reaches between natural channel-ways and deep holes, or by straightening out and making more direct the natural channels, by cuts through bends, and cross-bars. A description of the different processes of excavating under water will be found in Sect. 8, Art. 15. Dredging operations of this character are frequently sufficient in themselves although, to some extent necessary as a continuous operation for maintenance of channels. In other cases, dredging operations are necessary in conjunction with other works of channel control and regulation.

Jetties. In cases where there is considerable littoral drift, resulting in the formation of bars across harbor entrances, or formation of bars from deposit of sediment, jetties are built out from the harbor entrance into deep water. In the construction of jetties, attention must be given to the natural conditions or inclination of the channel to establish itself in a certain direction, with a view to not unnecessarily disturbing the equilibrium of forces.

Single Curved Jetty. Where a heavy littoral drift is constantly forcing to leeward, the outflow of water should be directed into the sea by a curved channel having its convex side presented to the direction from which gales are prevailing, a single jetty of curved section being used on the windward side of the channel. In such construction it will often be necessary to extend the jetty seaward from time to time, as the foreshore is built up on the windward side of the jetty; under some conditions such a jetty would be likely to carry the drift beyond the entrance into deep water, and not require seaward extension.

Single Straight Jetties have been constructed but, unless designed for a special purpose to fit in with definite geographical conditions, are not likely to be efficient.

Twin Curved Jetties. The jetties built by Eads at the South Pass of the Mississippi River are an example of this type.

Twin Straight Jetties were built at the mouth of the Rhône, France. These were built so slowly that the bar advanced more rapidly than the jetty extension. The work was abandoned as a failure. Similar jetties were built at Tampico, Mexico. In this case, the extension seaward was rapidly performea and the work was successful.

Jetties Open at the Shore End were built at Charleston, S. C., but were ineffective.

High and Low Jetties. These two types have their advantages and disadvantages. High jetties are carried up several feet above high tide, and cut off the sand drift. They are the type now generally adopted in American and English practice.

Converging Jetties run parallel with the general direction of the ebb tide and are carried out from the land and converge, leaving a comparatively narrow opening. Jetties of this type tend to guide and restrict the outflowing tide, controlling and directing the scouring effect by increasing the velocity. The windward jetty serves to cut off the littoral drift, the leeward jetty assisting the windward jetty in directing the force of the ebb tide to scouring out the drift brought into the channel-way by flood tide. Jetties of this character often, from time to time, require outshore extension into deep water or the assistance of dredging.

Diverging jetties bring the entrance to a more natural condition, and afford a better approach for navigation, but have a tendency to scour out a deep hole in the inshore entrance-way.

Design and Construction. Jetties are usually constructed of mounds or heaps of large rubble in a manner similar to that of the construction of mound or heap breakwaters. The material is usually carried up slightly above the elevation of high tide. In estimating the quantity of material to be used, it is to be borne in mind that considerable is lost through settlement in soft bottom, besides which an excess of material must be allowed as the action of the waves will tend to wash down the stone to flatter slopes than would ordinarily obtain. From time to time, after completion, stone will have to be added to insure high enough elevation to keep cross currents at high tide from sweeping beach drift over the jetty into the channel. Fascine and mattress work with rubble loading is employed in jetty construction. Jetties are also built of wall work and also of reinforced concrete.

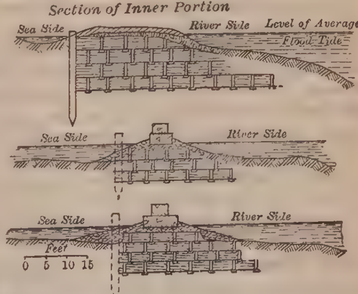

Fig. 14. South Pass, Mississippi River Jetties

A jetty built in 1913, at Shark River Inlet, N. J., consists of two practically parallel walls curved with concave side toward the south, the beach sands drifting toward the north. The jetties consist of a row of 16-in. reinforced-concrete sheet-piling, with counterforts at 10-ft. intervals, and with a braced reinforced-concrete superstructure; the pockets are filled with sand, the toe or apron is protected with riprap. Fig. 14

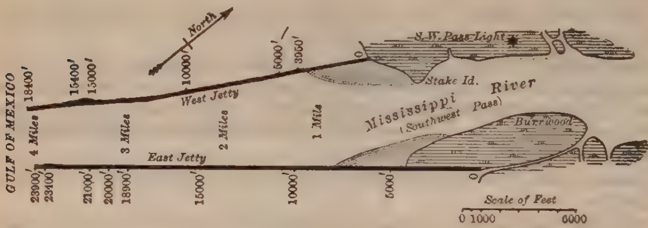

Fig. 15. South West Pass, Mississippi River

shows typical sections of jetties at the South Pass of the Mississippi River, and Fig. 15 a general plan of the jetties at South West Pass of this river.

RIVERS

7. Character and Description

Origin. Rivers owe their origin to the natural drainage or flow of water from the land to the sea, the development of their beds and their direction being due to the character of the soil, natural obstructions, inclination to follow the path of least resistance, and to certain modification in these characteristics due to influences, in some cases no longer existing, traceable to the breaking up of the Glacial Period. Their final formation and direction are the results of erosive action of the water, as balanced by soil resistance, resulting, in the cases of most older rivers, of an established equilibrium within certain limitations between the contending forces and the regimen as existing.

Sources of River Waters are in all cases, derived from tidal or rain water, the tidal water entering at the lower end, or mouth, and being directly due to the great primary or secondary ocean tidal waves, which, at high tide, pass up the estuary and the river, raising the level of the water and causing a flow of water up the river, and during the period of low water the process is reversed. The quantity of water passing up the river, due to such tidal influences, is, of course, on the average the same as the quantity flowing out on the reverse tide. The supply of fresh or rain water coming into the river at its source and constantly augmented by smaller supplies from branches and rivulets and the drainage from the banks along its course, travels solely in one direction from the source to the mouth and is subject to considerable variation in quantity and duration.

Tidal Rivers. Nearly all rivers emptying into a tidal sea are affected by tidal influences for some distance up from the mouth, depending principally upon the range of tide and the slope or fall of the river. At the crest of the tide, the salt water of the sea, by action of gravity, flows up the river; as the sea water is denser than the fresh river water, the flow has a tendency to take place by moving under the less dense fresh water and lifting this water up. On the trough of the tidal wave the flow is reversed, causing a continual oscillation in and out, the quantity of the ebb tide being augmented by the fresh water of the river. The volume of the ebb is under normal conditions always in excess of the volume of the flood, this condition being reversed at rare intervals by the occurrence of heavy onshore gales. The method of action of the tide is that, as the flood tide begins to make up the river, the current is at first slowed up, then entirely checked, and then reversed, banking up and preventing the flow and escape of the fresh river water into the sea. On the turn of the tide, the tidal water and the stored accumulated river water flow out into the sea, the greatest velocity occurring at about half flood or half ebb. At the periods of reversal, or of slack water, a short time elapses with no current existing. Contrary to the conditions generally prevailing directly on the coast line, the duration of ebb tide in rivers is longer than that of the flood tide, the difference depending upon the character of the river and the quantity of fresh water flowing down the river as compared with the volume of tidal water entering the stream.

Non-Tidal Rivers are rivers emptying into tideless seas or lakes or the upper reaches of tidal rivers beyond the effect of tidal action. The rise and fall of such rivers are entirely dependent upon the precipitation of rain on the areas drained by such rivers and their tributaries, the melting of snow and ice in such areas or as modified by the characteristics of the surface of the ground, growth of vegetation, and the peculiarities of the stream itself, such as depth, width, and slope.

8. Flow of Water in Rivers

Velocity of Current. The direction of flow and velocity of river water is due solely to the effect of gravity dependent upon the level of the surface of the water in the river. The difference in such level in any given length is termed "slope" or "fall." The particles of water at high level exert a pressure on those below them; these, being free to act in any direction, are pressed downward, forward, and upward toward the lower level, the whole mass being thus set in motion generally in the manner indicated in Fig. 16.

Fig. 16

The particles which come in contact with the bottom and banks of the stream are retarded by friction and do not move with the same freedom as the particles in the center of the stream section. Particles in contact with the bottom and sides are also deflected from their true course and cause disturbances in the stream action. As the stream moves forward, the particles describe orbits, varying in dimension with the section and depth of the stream; in large deep streams, the orbits being larger, the disturbing elements are less potent, the mean velocity being that obtaining in open channels as given in Sect. 13, Art. 15, and may be obtained more directly by

$$V = C\sqrt{2R \cdot F}$$

in which F equals the fall per mile in feet, R the hydraulic mean depth in feet, and C a coefficient of varying value, as follows:

For small streams of about	50 cu. ft. per sec.	$C = 0.65$
For larger streams of from 200 to	300 cu. ft. per sec.	$C = 0.75$
For tidal rivers of	1 000 cu. ft. per sec.	$C = 0.85$
For tidal rivers of	10 000 cu. ft. per sec.	$C = 0.95$
For tidal rivers of	100 000 cu. ft. per sec.	$C = 1.00$
For tidal rivers of	1 000 000 cu. ft. per sec.	$C = 1.50$

Transporting Capacity of Water. All rivers are charged with alluvial matter carried by them in suspension, the turbid conditions of many rivers during periods of heavy flow illustrating the extent of the work being carried on by them in the transporting of material. In addition to the materials actually carried in suspension, heavier and larger particles are transported by being rolled along the bottom of the stream. The sources of materials carried in suspension are the disintegrating effect of frost, breaking up and loosening of soil materials, the wash and erosion of rain, and the scour or eroding effect of the stream upon its banks. Under normal conditions the sectional area of the river is sufficient to provide for a velocity which will not cause undue erosion, the natural bed remaining in a state of equilibrium. However, any agencies which tend to increase such velocity tend to cause erosion with increase of sectional area and eventual decrease of velocity to the point of equilibrium. With a constant variation of volume of water flowing in rivers, detritus brought down at one time and deposited, is again taken up and transported farther downstream and so on. See discussion of Experiments by Grove K. Gilbert in Professional Paper 86 of U. S. Geological Survey, 1914; abstract in Eng. News, Sept. 10, 1914.

In a tidal river, the soil material carried by the stream is carried back and forth by the tide; the volume of ebb being greater than the flood, it is eventually slowly carried out to sea, or is deposited on the shores of the river mouth or estuary forming salt marshes. In non-tidal rivers, as the velocity of the current slackens on approaching and emptying into the sea, the material carried in suspension is deposited at the mouth of the river, forming deltas. The delta of the Mississippi River is a prominent example.

If a stream is loaded to its full carrying capacity it will tend to flow within the confines of its bank and the bed without further erosion; in some rivers more than 2% in weight of the total volume of water passing along the channel is solid matter. The ability of a stream to carry material is dependent upon the sixth power of the velocity as modified by the depth. Refer to Sect. 13, Art. 18.

Erosion and Scour. A non-tidal river with its flow constant in a downstream direction has an inclination to flow in a sinuous or meandering course. The particles of water moving in circular orbits or paths tend to impinge against one bank or the other; and on account of the lack of uniformity of the character of soil materials forming the banks, there is a constant tendency to erode or scour on one side or the other. A curved direction having once been assumed, the tendency is to increase the curvature, as illustrated in Fig. 17.

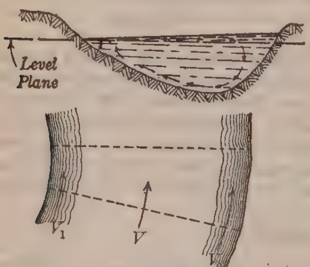

Fig. 17

The stream velocity is V. On account of the curved direction of the stream, the centrifugal force will tend to increase the velocity near the concave bank to V_2, and to decrease the velocity on the convex bank to V_1; the increased velocity on the concave bank, together with the dynamic pressure, due to the centrifugal force, will tend to deepen the stream bed at this side of the stream and erode and scour out the bank, these same forces tending to broaden a river at the bend by decreasing the mean hydraulic depth. The same force will tend to raise the elevation of the water on the concave bank and decrease it on the convex bank. The deflective force of the earth's rotation has a similar effect on both elevation and erosion. The right-hand bank in the Northern Hemisphere and the left-hand bank in the Southern Hemisphere clearly indicating by the bluff lines the small but continuous force directed against it. See Article in "The Military Engineer," Vol. XIX, No. 108, by G. T. Rude. Also Trans. Am. Soc. C. E., Paper 1599, by H. C. Ripley. The usual condition of a stream is illustrated in Figs. 18 and 19, the first showing a slight reverse bend, and the second a more considerable one.

The current, in each case, being close to the concave bank, has a tendency to scour out on this side deep channel-ways with consequent steep banks. Where material is

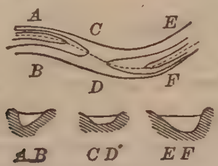

Fig. 18

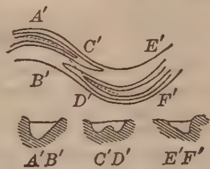

Fig. 19

carried in suspension the decrease in velocity on the convex side permits the deposition of detritus and the formation of flats, as illustrated in Fig. 20, and, eventually, the growth of the meandering effect of marsh land.

In some streams the bends become so great that the bights approach each other and a natural cut-off occurs, the bends soon taking the form of crescent lakes. The intersection having once occurred, the new channel is rapidly eroded as the shortest path and the one of least frictional resistance. This meandering effect is more prevalent in rivers with low velocity than in torrential rivers in which the increment due to centrifugal force is proportionately less. As the navigable distance is often naturally shortened by such cut-offs, these have been made by dredging; this should be done only after careful investigation as to water height and the consequent velocity through the cut-off; experience has shown that the shortening of the river course by this means often results in scour and bank caving.

Fig. 20

Channels and Bars. In non-tidal streams, the flow being constantly in one direction, the regimen of the stream flow is closely fixed and the flow, quantity and velocity vary with the precipitation of rain so that, within reasonable limitations of time, the location and direction of channels and flats are likely not to vary greatly. In tidal streams the conditions are different and more complex, the variation in fresh water flow being materially complicated by tidal flow as regulated and controlled by the extent and direction of storms. Fig. 21 illustrates the condition often obtaining at or near the mouth of tidal streams, the reversal of current due to the ebb and flood resulting in two or more variable channels with consequent formation of bars, very often shifting in character and extent.

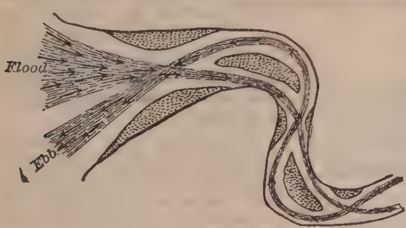

Fig. 21

The width and sectional area of channels in non-tidal rivers and in the upper reaches of tidal rivers bear a certain fixed relation to the drainage area and to the consequent quantity of water discharged. The width and depth of the tidal reaches of a tidal river do not appear to be so fixed, although the channels once fixed are usually maintained by the tidal flow. Any cause that tends to obstruct the free flow of tidal water and the propagation of the tidal wave is detrimental to the maintenance of the channel condition and frequently leads to shoaling. It is important to observe this effect in the design and construction of works of proposed improvement.

9. Training Works

Dredging. As with harbor work, the improvement of rivers, though often attempted by dredging, is not always effective as a measure of permanent improvement and usually entails continuous maintenance operations. Channels may be straightened out by cuts across bars and flats and the navigable distances along rivers decreased by excavating between the bends of meandering rivers. Dredging for the improvement of tidal or non-tidal rivers is principally useful in connection with other improvement works for stream regulation and control, and as a regular operation to maintain adequate depth and width of channels, slips, and basins.

Training Walls, also called dikes, are employed to direct the flow of the current in rivers with a view to the establishment of more favorable and fixed channels and often, also, to prevent scour and the erosion and carrying away of river banks. In the navigation of rivers it is important that the curvature of the channel should be of such radius as to permit the ready handling and movement of ships, this depending upon the depth of water and the size of ship to be considered. For large ships, if possible, it should be not less than 2500 ft. Single or double walls may be employed, the selection depending on the object to be accomplished. Two parallel walls may be used in a river flowing through a broad alluvial valley, in a wide bed and with an inclination to meander, the walls confining and directing the current flow, keeping the space between them open by sluicing and scour. The slack water area inshore of the training walls will tend to shoal and fill up. Such wall work in rivers is similar to and in many respects merely an interior continuation of jetty work at river mouths or harbor entrances.

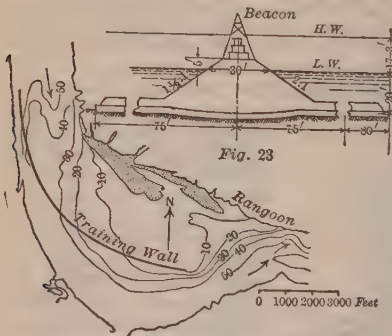

Fig. 23

Fig. 22. Training Wall, Rangoon River

At Rangoon, India, 1907, the Rangoon River (Figs. 22 and 23) was cutting out the concave river bank just above the city, causing formation of sand bars and shoaling of water on the opposite side, and on being deflected by a prominent point opposite the city was scouring out and undermining the foundations of wharves and piers. The training wall built was 2 miles in length and consisted of brushwood mattress 3 ft. thick, covered with a weighting layer of rubble, a rubble-mound wall surmounted by a concrete wall filled with rubble. Range of tide 20 ft. with 5 to 7 mile river current. River has scoured out new channel along wall and area behind wall has filled up.

In the case of the Mississippi River at Natchez, Miss., slides on the river banks were undermining the railroad tracks above. To relieve the situation, sedimentation was brought about by the use of a mud cell dike and when this was secured, the banks were permanently protected with concrete slab paving. See Trans. Am. Soc. C. E., Paper 1468, by W. C. Curd.

Construction of Training Walls or Dikes, as with jetties, may be of loose rubble-mound construction, with or without a surmounting masonry wall, or may be of timber, timber close piling, timber sheet-piling, steel sheet-piling, or reinforced concrete. In the employment of rubble-mound walls, considerable material will have to be used that will afterward be buried in the bottom, for as the wall is built and extended the scour of the stream at its end will tend to deepen the channel at this point, leaving deep holes to be filled with stone as the wall work is carried forward. Training walls should be carried up to the elevation of high tide, and when curved should be given easy curves so as not to cause sudden changes in the direction of channel currents. The area in back of the training wall eventually becomes filled up with sediment deposited by the stream in the slack water. A typical section of a loose, rubble-mound dike in use on Arkansas River is shown in Fig. 24, the rubble being deposited on fascines or brushwood mattress. Fig. 25 shows a typical solid, pile brushwood and stone dike in use on Arkansas River.

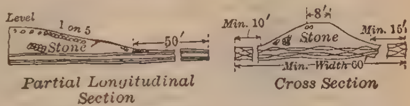

Fig. 24. Stone Dikes, Arkansas River

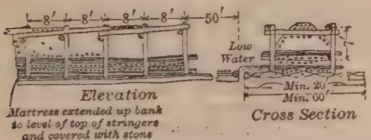

Fig. 25. Solid Pile Dike, Arkansas River

Spur Dikes, also called Spur Jetties, may be employed to regulate and direct the current of a river by contracting flow area and causing scour and lateral deposition of material behind or in between dikes. The influence of the spur dikes is similar to that of the groins employed in foreshore protection work, as described in Art. 5. Spur dikes are sometimes employed in connection with longitudinal dikes or training walls, or such longitudinal walls or bulkheads may be constructed connecting the end of the spur dikes after the space between them has become filled up with deposit.

Fig. 26 illustrates the improvement of the Upper Mississippi River by the employment of spur dikes which are built out perpendicular to or making an oblique angle with the direction of the current.

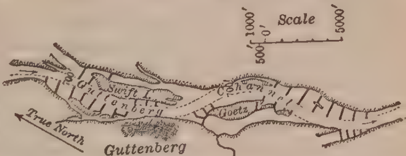

Fig. 26. Spur Dikes, Upper Mississippi

Permeable Dikes, instead of entirely cutting off or diverting the current flow, merely slacken and retard it. They consist of open-work construction, usually of timber piles and cribbing with rubble weighted brushwood mattress work hurdles. The velocity of the current being retarded behind or between such dikes, material in suspension is deposited and the area is filled up, the dikes themselves eventually become buried in a hydraulic fill dam of their own creation. On account of the initial increase in velocity at the contracted area of the dike itself, the fascine or mattress work is built with an apron on each side of the work to prevent scouring and undermining.

Fig. 27 illustrates the employment by the Chicago and Northwestern Ry. Co. of permeable dikes on the Missouri River at Blair Crossing. The river, as shown in (1), was following a cut-off and threatening the Blair bridge. The work was done in 1913. Permeable dikes were constructed across this cut-off, forcing the river into the old channel. (2) shows a section of the 2-pile dike; the main dike employed a 5-pile section.

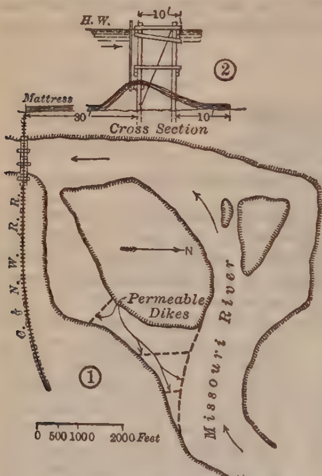

Fig. 27. Permeable Dikes, Missouri River

Bank Revetment is effected, when practical, by sloping the banks to stable slopes, protecting them from scour by brush mattresses, riprap, or block paving, timber planking, piling and sheet-piling. Such work is necessary, not only on rivers to protect banks from erosion due to the flow and velocity of the current, but at tide level to protect against wave action and wash of passing vessels. See Sect. 15, Art. 16.

In Fig. 28, (1), (2), (3), (4), (5), (6), (7) show typical methods of revetment on the Arkansas River. (8) and (9), typical methods, Upper Mississippi River. (10), typical methods, the Missouri River.

The standard revetment consists now of grading the bank on a slope of 1 : 3, laying a woven willow mattress 86 ft. wide from 3 ft. above low water and over the river bed, ballasting and sinking it, and paving the bank from the inshore edge of mattress to the top of bank. If the paving (riprap) fails by erosion, a substantial reinforced-concrete revetment is placed extending from the top to almost low water and from there a system of connected concrete flexible blocks about 24 in. square, extending beyond low water. This protects the bank and weak point of willow mattress.

10. Flood Control

Overflow. The causes which contribute to a river overflowing its banks are as a rule natural and seasonal in origin. In smaller rivers of limited drainage area these causes are found in exceptionally heavy precipitations of rain and in the melting of snow and ice in the early spring over the watershed; heavy precipitations of warm rain accelerate such melting. In a large river, with several tributaries discharging water from large drainage areas remote from each other and under different climatic, precipitation and other influences, the annual variation of flood in the main river is liable to be very great. The floods in the various tributaries might readily occur in such succession as not to tax the capacity of the main river, but the possibility is always present of these flood waters all reaching the main river at the same time or when it is, itself, under maximum flood condition. The Mississippi River is an outstanding example of such a possibility.

In most rivers draining a large alluvial valley, under normal conditions floods are to be expected annually. In the natural condition of the river, the river valley acts as a storage reservoir, the river overflowing its banks, the flat lands on either side being flooded and retaining the water, which is drained off and discharged at a later time. These annual floods have, in such cases as the Mississippi and the Nile, helped to enrich the flat agricultural lands along the stream by bringing down rich alluvial matter and depositing it as the water recedes after the flood period. This natural regimen has in some cases been upset by changes in these natural conditions through reclamation of the low lands on each side, by levees or dikes. Slowly but surely as this

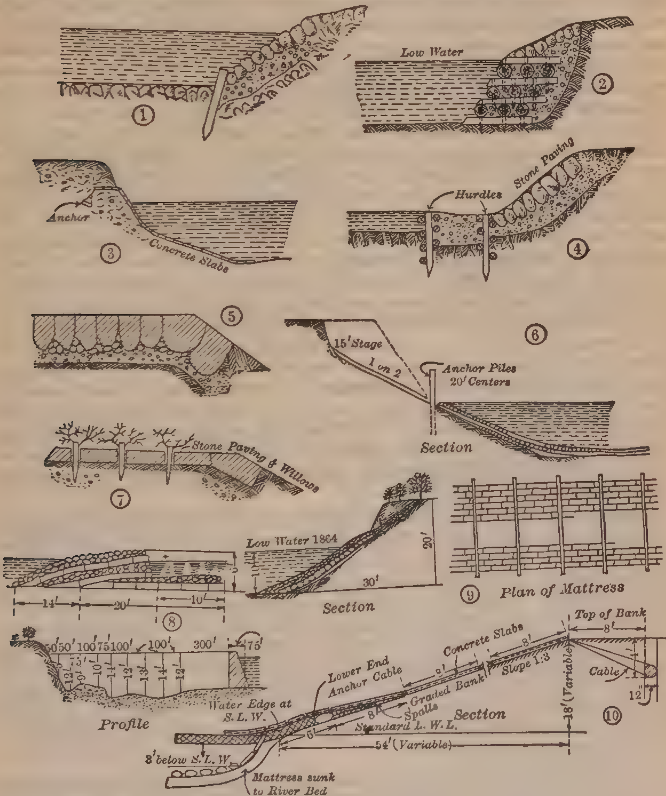

Fig. 28. Revetments

character of work advances, it confines the flooded river between these artificial barriers with resulting reduction in cross-sectional area, increased velocity and raised elevation of the river. This in turn requires increased height of embankments to prevent their being overtopped.

In addition to this cause of overflow or flood, it is frequently claimed that human inhabitation of the river valley results in a change in the character of the vegetation and various growth over the drainage area; the cutting of timber, removal of forest underbrush, and the placing of land under cultivation all serving to increase the rapidity of the runoff, with the result that periods of rainfall which would not ordinarily have caused serious floods will, under the change in the natural condition of the drainage area, have a tendency to hasten the drainage and outflow of rain water into the river.

An understanding of the causes of overflow of any important river is necessarily difficult and complex and can come only after thorough study of the special conditions under consideration, such study involving a complete topographical survey of the entire areas, rainfall and evaporation records over a long period of time, observation and gaging of stream velocity, cross-sectional areas, volume of discharge and various other features. The very voluminous records and reports in connection with the question of flood control of the Mississippi River indicate the difficulty of ready solution of the problem.

The conservation of forest growth, especially on the high lands where river tributaries have their source, has been advocated as a measure to reduce the rapidity of runoff and consequent flood, and at the same time by the retarding or storage effect to increase the flow at low stages. Forest growth undoubtedly does exert some regulating effect on flow and resultant floods, but such effects are materially changed and even reversed by altitude and frost, especially by snow and ice. The effect of forestation on flood would appear to be a local problem, and it can hardly be asserted, as a general proposition, that changes in such forest areas produce noticeable effects on river floods.

The control of floods by storage reservoirs has been found effective in certain cases hereafter referred to. In a river draining a large area this method involves such complex questions as the cost of the work and value of the land taken over for storage reservoir purposes. Another means of flood control is through relief afforded by diverting part of the flood flow through artificial or partially artificial channels. This frequently requires the construction of expensive controllable diversion spillways. It is often the case that no one of the means of relief mentioned herein can be effectively resorted to, but that a combination of all may be necessary.

Levees are embankments of earth built up on the sides of rivers to prevent the overflow of the banks. They should be built up 2 or 3 feet higher than the highest water recorded in the vicinity. In their design and construction, consideration should be given to the fact that the confining of the stream between the side levees will serve to decrease the stream area during flood flow, and probably entail increase in velocity and in elevation of the highest water over and above that recorded before the construction of the levees. The side slopes are dependent upon the character of the soil and vary from 2 : 1 to 4 : 1. The top width of the levee should be sufficient so that in case of settlement or unusually high water, the crest of the levee may be raised by additional embankment or by placing of bag extensions. Refer to Sect. 8, Art. 25, Levee Construction, and Sect. 16, Art. 19.

Fig. 29 shows typical sections for various heights of levees employed on the Mississippi River up to 1927; these are being increased in height and area as a result of the experiences of the 1927 flood. Revetment work is employed to protect levee slopes where river conditions are such as to indicate the necessity for such work.

The dikes of Holland perform a duty somewhat similar to that imposed on river levees, protecting the low lands from inundation by the sea. This system of dikes consists of the natural sand dunes, artificially built up sand dunes, and embankments. The rivers outflowing along the coast line have levees constructed along their banks. These sand dunes are protected against wind erosion by a growth of coarse grass and reed, which also serves to retard and hold the blowing sand and build up the dunes, fresh grass being planted on top of this. Where subject to wave action, the slopes are protected by fascine and mattress work, weighted with basalt or concrete blocks; short timber piles are driven to pin and hold down the work and to help break the force of the waves. In localities where lateral currents occur, spur dikes are built out perpendicular to the main dike.

Flood protection walls may be employed in connection with, or to replace, levee work. Such walls, consisting of two reinforced-concrete walls backfilled, were employed at Portsmouth, Ohio. The walls were fitted with flood gates which are closed when the elevation of the river reaches a dangerous height; the sewage discharge from the city must as a consequence be pumped instead of flowing through the wall.

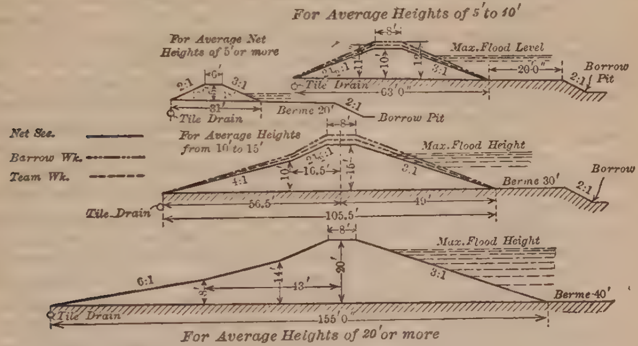

Fig. 29. Mississippi River Levees

Navigation. Most rivers at high stages usually afford the necessary facilities for navigation restricted within the known and expected local requirements. The low stages of rivers often make navigation impossible without the assistance of engineering works. At such low stages with the decrease in stream velocity and in the quantity of water discharged, bars extend diagonally across the river, especially at bends, blocking the fairway and making the passage of vessels difficult or impossible. With sudden rises, new channels are eroded through such bars, varying much in direction and location. Formerly in the Mississippi, when this river carried a large local river traffic, it was customary at New Orleans to hold frequent conferences between pilots of ascending and descending steamboats in order to ascertain the latest changes of channel. Rivers, especially during freshets, bring down large quantities of drift logs, developing snags or sawyers, which tend to obstruct navigation, raising barriers and sand bars and changing the channel conditions; it is important that such snags shall be removed as soon as possible.

Reserve Basins or Reservoirs. Under favorable conditions, river floods may be somewhat controlled by constructing in the upper reaches basins or reservoirs consisting of large areas with impounding dams as it is contemplated to hold in reserve in these reservoirs the excess flood volume which is to be released during the periods of low stages, and thus to increase artificially such low stage flow with a view to establishing an average flow. The fundamental principle involved is a sound one, but natural difficulties are generally encountered that render impracticable the obtaining of the desired results. The problem involved, for successful application for such works for flood control, requires special and careful study of local conditions, the areas available for reservoir sites, value of land likely to be submerged, and the existence of suitable sites for dam construction. The plan has been tried on the upper Mississippi River, the region being remarkable for the number of small lakes. A large Indian reservation presented conditions unusually favorable. Five reservoir lakes were immediately available and additional ones possible and in prospect. The watersheds of the five reservoirs constituted 11.8% of the whole area above St. Paul and 21.5% of that above Minneapolis. The actual result to navigation on the Upper Mississippi system was an average increase in low water depth at St. Paul of about 14 in. When the release of water was specially regulated, 22-in. increase was obtained; these figures are based on a record of 20 years, during which period the total outlay, including construction and operation, was about $1 500 000. From this it is concluded that, as a general proposition, such reserve reservoir work, though instrumental in controlling flood discharge and assisting navigation, is of use principally in connection with other engineering work of improvement. The difficulty of regulating the discharge from such storage reservoirs can not be overestimated. The release of reservoir water may be necessary and beneficial to one section, and have quite the opposite effect on other sections served by tributaries or branches which, due to local severe precipitation, are experiencing local floods.

Canalization or slackwatering is a method employed to afford a sufficient depth for navigation at all seasons of the year, and also to overcome rapids or falls that would otherwise make navigation impracticable. In this method a series of pools is formed by the construction of dams, and connected by locks. This method has been extensively employed in Europe on such rivers as the Fulda, Main, Oder, Elbe-Moldau and the Seine, and has been carried on extensively in the United States since 1840 on the Allegheny and Monongahela Rivers in Pennsylvania, the Ohio River, the Black Warrior and Tombigbee Rivers in Alabama, the Columbia River in Oregon, the Cumberland, Green and Kentucky Rivers in Kentucky, the Fox River in Wisconsin, the Hudson and Mohawk Rivers in New York, and the Kanawha River in West Virginia.

Its application to the Ohio River comprises a series of 51 locks and dams, overcoming a total fall of 424 ft. from Pittsburgh to Cairo, of which 26 ft. are at the Falls at Louisville. This system of locks and dams planned for completion in 1929 provides a minimum depth of 9 ft. for a distance of nearly 1000 miles during all seasons of the year.

11. Signals and Lighthouses

Buoys. Buoys are employed for demarcation of entrances, interior channelways, and for the location of dangerous shoals. They are placed at intervals at either side of the channel-way, the port and starboard boundaries being indicated by the shape and color of the buoy. Buoys must be moored to heavy anchors, either cast iron, such as the mushroom, or frequently large blocks of concrete are used with heavy iron eyes cast therein. Dependent upon the range of tide, the buoy is secured to an anchor by a length of cable two or three times the maximum depth in which it is to float. In channel demarcation the distance between buoys varies with the character of the channel as to width and straightness. In the interior of harbors mooring buoys are frequently provided at various fixed locations to enable vessels to moor without resort to ship's anchors. In harbors of restricted area, at times two buoys, one for bow and one for stern, are provided for mooring. Buoys are used for location of wrecks in outer harbors or in the open sea, also to indicate cable crossings.

Beacons are fixed signals or structures used for means of alignment or for indicating changes of direction. Frequently prominent objects or landmarks, natural topographical features, or prominent structures, are used as beacons.

Channel Lighting. The location of channels is often fixed for night use by luminous buoys lighted by means of oil or gas, or the range is fixed by two illuminated points, afloat on buoys or fixed on shore, or one afloat and the other ashore, the change in direction being shown by a similar line or range.

Sound Signals. Light being impracticable and useless during heavy mists or fogs, resource is had to sound or warning signals, a bell or whistling buoy being used for this purpose. In deep water where there is always some wave motion, bell buoys depend on this motion to actuate balls or pendent clappers. Whistling buoys depend on the taking in of air and its expulsion as the buoy rises and falls, or the bell may be struck or the whistle sounded by compressed air or gas carried in a tank that is regularly recharged. Sound transmitted through the air often gives a misleading idea of locality; resort is therefore had to submarine sound signals which can be heard a great distance and the direction of which can be identified.

Lightships. At locations where, on account of the natural conditions, it is impracticable to locate and maintain lighthouses, or at locations where luminous buoys would not be striking enough in character, necessary light for the assistance of navigation is placed on lightships. Signals of this character are more certain and reliable than are light buoys exposed to strong currents in heavy seas. The principal requirements are staunch construction and steadiness under severe storm conditions.

Lighthouses. (Lighting and Design.) Dangerous promontories, points, and bars are marked by lighthouses, especially at entrance to bays and harbors. The lights are fixed, revolving, or flashing, for purposes of identification. When a navigator has identified a light and knows its height above sea level, the distance at which it first becomes visible at sea is known. Let H be the height of light, h the height of the observer above sea level, both in feet, and D the distance from the vessel to the light in statute miles. When the light is seen exactly on the horizon, then

$$D = 1.32\left(\sqrt{H} + \sqrt{h}\right)$$

If the distance in nautical miles is required, 1.32 is to be replaced by 1.15. For example, if the height of the light is 100 ft. and the observer is 25 ft. above the water, he sees the light on the horizon when he is 19.8 statute miles or 17.2 nautical miles from the lighthouse.

The following statements regarding the lights of lighthouses and the structures themselves have been kindly furnished by J. S. Conway, Deputy Commissioner of the U. S. Lighthouse Service.

(1) **Intensity.** Lights are of classes heretofore known as "orders," based on the focal diameter of the lens, as "first-order," "second-order," etc., and miscellaneous smaller lights. Recent practice substitutes the candlepower of the light in place of the now more or less misleading term "order."

(2) **Ranges of visibility,** two classes: the geographical range of the light due to its height above sea level, and the luminous range due to the intensity of the light emitted by the illuminating apparatus.

(3) **Character** of the illuminating apparatus, three classes: catoptric or reflecting, dioptric or refracting, and catadioptric, in which the "lens" is provided with both reflecting and refracting media. The latter type is the most in use.

(4) **Characteristics** of the light, such as Fixed, Flashing, Occulting, Fixed and Flashing, or other combinations for distinguishing purposes. Fixed lights are liable to be confused with neighboring private lights and should be avoided if practicable. Fixed, combined with flashing, and lights with prolonged flashes should be avoided for the reason that the "fixed" and "prolonged" rays emitted by the lens are weaker than those of the "flashes," giving a misleading characteristic at a distance. Multiple lights, except for minor lights, are now considered obsolete, because they largely

increase the cost and are less distinctive than flashing lights. Lights of alternating colors should be so designed that the white and colored rays are of equal intensity.

(5) **Arcs of visibility,** two classes: single lights illuminating a large arc of the horizon and two lights in range illuminating a limited arc for purpose of marking narrow channels and passages. Often plates of red glass are introduced in the lantern so that the sector of rays passing through them will cover an outlying danger such as a reef, rock, or shoal, or to indicate the edge of a channel.

(6) **Attendance,** two classes: Watched and Unwatched lights.

(7) **Fog-signals,** four classes: the ordinary bell struck by hand or machinery and submarine bells struck by machinery, also whistles, reed horns, and sirens blown by compressed air. Some of the whistles and sirens are sounded by steam.

(8) **Materials.** Almost all the usual materials of construction have been used in building lighthouses in the United States Lighthouse Service: stone masonry, brick-work, reinforced concrete, framed timber, structural cast iron, structural steel, cast-iron plates, steel plates and piping.

(9) **Arrangement.** Light stations situated on land sites usually consist of the light tower, oil house, fog-signal building, keepers' dwellings, workshop, water supply and drainage systems, boathouse and ways, barn, and the usual outbuildings, roads and walks, although, owing to the restricted area of some sites, one or more or all of the buildings may be combined in one. On submarine sites the whole station is practically confined to one structure.

(10) **Foundations.** For land sites, the foundation for a closed tower of masonry, or metal work, is usually a single block of concrete resting upon the foundation soil. Occasionally these blocks are placed upon a timber grillage supported by piles for sites upon low or marshy land. In all cases the block is extended so as to bring the unit pressures within the bearing power of the soil. Occasionally a skeleton structure is placed upon a single foundation block, but usually each column or leg of the tower has its individual block. Where the site is subject to overflow, the buildings are sometimes grouped together, raised upon braced columns and connected by a system of galleries.

For submarine sites, the foundation may consist of a cylindrical cast-iron or sheet-steel caisson filled with concrete, or a masonry pier. Cast-iron caissons are in general use on the Atlantic Coast. When placed upon a ledge of rock, the latter is usually leveled up with concrete bags if below low water, or with tools if exposed, and the ledge or rock is then heavily ragbolted to the concrete filling. For soft bottom, the best method of procedure is to float the caisson out and sink it by the pneumatic process. Both timber and metal working chambers have been used and the depths from the cutting edge to high water have varied from 19 to 85 ft. Other foundations, consisting of timber cribs and concrete blocks, used in fresh water, have been placed either directly on good existing bottom, or upon a layer of small rock usually 3 or 4 ft. thick deposited upon the soft or dredged bottom prior to floating the crib out. These timber cribs are usually filled with stone and terminate about 2 ft. below low water level; the concrete blocks are then placed to the height of the deck.

(11) **Forces.** Structures upon land sites are exposed to wind pressures, and occasionally to waves in addition. Those upon submarine sites are exposed to wind, wave, currents, and ice. The usual procedure in determining the stability of tower is to locate the common center of effort of all the forces acting upon the structure to overturn it and so proportion the weights of the entire structure (the buoyancy of the water must be taken into account for submarine structures) that the resultant of the active forces and the net weight falls so far within the outer edge of the base that there is compression over its whole surface if the foundation soil is compressible. In seeking for this result it is proper to include the lateral resistance of the soil when the structure penetrates it for some distance for the reason that it is often heavily compressed by a large deposit of riprap and offers good support. The maximum unit pressures, both vertical and lateral, must not exceed the bearing power of the soil. In case the foundation is rock, the resultant must fall so far within the outer edge of the base that the maximum unit pressure does not exceed the compressive strength of the materials in contact.

The wind, wave, current, and ice pressures assumed should be the maximum in each instance, as lighthouses are commonly exposed to severe gales and flows of ice. It has been the practice to assume wind pressure for flat surfaces at 60 lb. per sq. ft., allowing two-thirds of this figure for rotundity. Maximum wave pressures of 6000 lb. per sq. ft. on flat surfaces are assumed, based upon Stevenson's experiments, the force of the wave being greatest at its crest and diminishing to zero at its base. The pressures exerted by currents vary with their rate of speed. The pressures due to ice have been assumed at 30 000 lb. per sq. ft. for a field of melting ice, 1 ft. thick, striking the pier and crushing its way past.

(12) **Superstructures.** The superstructures of all towers, whether separate or combined with other buildings, have certain features in common. There is a main entrance door at the base, a flight of winding stairs, broken by landings in high structures leading to the service room, which in the larger lights is usually separated by an airlock from the watchroom above, the latter supporting the lantern. Occasionally in large lights and usually in small ones the service and watchrooms are combined. The pedestal of the illuminating apparatus usually rests upon the watchroom floor, but in the small lights the lantern floor supports it. The clear glazed opening of the lantern is just sufficient to pass the horizontal rays from the illuminating apparatus, and if the latter is of a revolving type, showing flashes or occultations, the newel post of the tower serves as a weight shaft for the clock. There are railed galleries outside both lantern and watchroom. The tower should be thoroughly fireproof and isolated in this respect from the other buildings. For calculating the strength of closed and skeleton towers the manner prescribed for chimneys and viaduct bents is employed with the exception that great stiffness and rigidity must be provided, as vibrations are detrimental to the proper working of the lamps and clocks of the illuminating apparatus.

QUAYS

12. Design

Definition. Wharves are landing places or platforms built out into, or on to the water for the berthing of vessels. Wharves parallel to the shore, marginal wharves, are generally known as quays, and their protection walls as quay walls; wharves built into the stream or fairway perpendicular or oblique to the shore are generally known as piers.

Quay Walls, or bulkheads, are used for wharfage for retaining and protecting embankments or retaining filling. Their proper design and cost are largely dependent upon local conditions and the use to which they are to be put. The character of the foundation and the depth of water to be provided are important factors in the cost and design. Some data on design are given in Sect. 10, Art. 28.

Data on Design. It is important to observe the character of the foundation on which the wall is placed, whether the wall may be built directly on rock or hard-pan, or on a floating foundation on timber piling or grillage work. In the latter case, information must be secured as to the prevalence of marine wood-borers, and, if present and active, precautions must be taken to protect the exposed timber work by creosoting or other preservative or protective methods. Quay walls are designed in a similar manner to retaining walls with the difference that on the water side they are subject to the water pressure varying with the height of the tide, and on the land side to the earth and contained water pressure with a proper allowance for surcharge. The contained water on the land side of the wall will usually stand higher than the tide water, especially at low tide. A rapidly falling tide may result in a considerable earth and water pressure tending to push out or overturn the wall.

The Combined Pressure of water and earth upon a wall must be known in making a design. Let w_1 be the weight of a cubic foot of water, w_2 the weight per cubic foot of the submerged earth, ϕ the angle of repose of that earth, and h the height of the vertical wall. Then, for one foot in length of the wall,

$$\text{Water pressure} = 1/2\, h^2 w_1$$
$$\text{Earth pressure} = 1/2\, h^2 w_2 \tan^2 (45° - 1/2\, \phi)$$
$$\text{Combined pressure} = 1/2\, h^2 (w_1 + w_2 \tan^2 (45° - 1/2\, \phi))$$
$$\text{or, Combined pressure} = 1/2\, h^2\, W$$

To find W the weight per cubic foot, w_1 of sea water is taken as 64 lb. and w_2 may be found experimentally by taking samples of the earth as near as possible in its natural compacted state, and ascertaining its weight submerged in sea water, or may be fixed theoretically in approximate terms by taking the weight of the original material, such as limestone rock, granite, slate, and other materials less the weight per cubic foot of water multiplied by the percentage of solid material per cubic foot, that is, 100% less the percentage of voids in the material.

Combined Weight W of Sea Water and Earth, Lb. per Cu. Ft.

(Equivalent Liquid Pressure)

Slope of repose of earth	Weight w_2 of submerged earth, lb per cu. ft							
	40	44	48	52	56	60	64	68
1/2 : 1	66.2	66.4	66.7	66.9	67.1	67.3	67.6	67.8
3/4 : 1	68.4	68.9	69.3	69.8	70.2	70.7	71.1	71.6
1 : 1	70.9	71.6	72.2	72.9	73.6	74.3	75.0	75.7
1-1/4 : 1	73.2	74.2	75.1	76.0	76.9	77.9	78.8	79.7
1-1/2 : 1	75.4	76.6	77.7	78.9	80.0	81.2	82.3	83.5
1-3/4 : 1	77.5	78.8	80.2	81.5	82.9	84.2	85.6	86.9
2 : 1	79.3	80.8	82.3	83.9	85.4	86.9	88.4	90.0
2-1/2 : 1	82.3	84.2	86.0	87.8	89.7	91.5	93.3	95.2
3 : 1	84.8	86.9	88.9	91.0	93.1	95.2	97.2	99.3
3-1/2 : 1	86.8	89.0	91.3	93.6	95.9	98.2	100	102
4 : 1	88.4	90.8	93.3	95.7	98.1	101	103	105
5 : 1	90.9	93.6	96.3	99.0	102	104	107	109
6 : 1	104	108	112	116	120	124	128	132

This table gives the combined weight W, or the values of $w_1 + w_2 \tan^2 (45° - 1/2\, \phi)$, the weight w_1 being taken as 64 lb. per cu. ft. for sea water. It should be noted that the submerged weight of the earth will be dependent both on character of original soil rock and on the extent to which the soil is compacted, the angle of repose becoming greater as the soil is more compacted. See table A, p. 914, for values of angles of repose corresponding to various slopes.

It will be unusual in practice to find conditions where a combined weight W in excess of 90 lb. per cu. ft. should be used, although where a structure is built on soft mud, or is to be filled with, or retain, mud, especially if it is placed as a hydraulic fill, the combined pressure may reach or exceed 120 lb. per cu. ft. The total pressure in pounds against a linear foot of a vertical wall **h** feet in height is found by multiplying **W** by $1/2\, h^2$.

Some observations have been made at various depths on the weight "in situ" of soils immersed in sea water, and, as should be expected, they show wide variation.

The Overturning Moment is the product of the total equivalent liquid pressure on the rear side of the wall, and one-third the height, less the product of the water pressure on the sea side of the wall, by one-third its depth. In drydocks, canal locks, masonry quaywalls or bulkheads, the height to be taken would be the distance from the top of the fill down, whereas in walls with timber or other relieving platforms the height would be from the bottom of the platform. When the bulkhead or wall is founded on viscous or plastic soil, the depth or height to be considered will not necessarily be the height of the wall, but may extend some distance below the depth of water at the sea face.

Weight of Soils Immersed in Sea Water

Material	Pounds per cubic foot		
	Maximum	Minimum	Average
Gravel and marl	....	42.0	62.9
Gravel and sand	73	42.0	62.4
Sand	66	42.0	58.3
Gravel, sand and clay	80.9	51.2	70.0
Stiff clay	64.8	38.4	47.8
Stiff clay and gravel	70.3	44.8	52.6

Practice and Custom. It is too frequently the case in the design and construction of wharfage work that the designer is guided entirely by the accepted custom of practical wharfbuilders. It should be remembered that the same fundamental principles apply here as to other engineering structures. If the wall is a gravity structure, the safe bearing capacity of the foundation soil must be considered, and it must be remembered that the submerged part of the structure loses dead weight to the extent of the buoyancy effect of the water displaced by it.

Where piles are employed, their safe bearing capacity should be obtained by driving test piles and either applying a test load or making observations of weight and drop of hammer or penetration when bringing up, and these data are to be used in connection with one of the well-known piledriving formulas, the pile structure being examined as a column, and, if of timber, due allowance made for character of material used, the creosoting of timber reducing the strength and safe carrying capacity of the pile. If capped with timber, consideration should be given to the safe bearing power across the grain of the timber used. In wharf work under conditions generally obtaining, timber piles 14 in. in diameter at butts, with the usual framing, should not be counted on to give more than 18 tons carrying capacity per pile. If creosoted timber, not more than 15 tons. The safe bearing capacity of reinforced-concrete piles is frequently taken at twice this amount but is, of course, dependent on the pile section and the driving of the pile. In reinforced-concrete piling the bearing capacity at the top of the pile is reduced by the weight of the pile. In a reinforced-concrete pier built in Havana, Cuba, piles 20 in. square, and up to 85 ft. long, were used, and gross bearing capacity of 40 tons per pile allowed, or net capacity of 25 tons, 15 tons being allowed as the weight of pile. When employing batter, brace, or spur piles, this bearing capacity should be somewhat reduced, as the driving effect of the piledriver hammer will be less effective on account of the inclination and consequent friction on the leaders or guides.

Expansion Joints. In long quay or sea walls or bulkheads, expansion joints at intervals of about 50 ft. are necessary in order to avoid unsightly shrinkage and settlement cracks. It is desirable to design these so as to permit irregular vertical movement in adjoining sections, but to lock these sections so as to prevent a horizontal break. A simple and effective joint of this character is made by casting one or more V's or grooves in the end of one section, and coating this with pitch or tar, or the end of two adjoining sections may be built in this

Fig. 30. Expansion Joints

manner a few feet apart and the space filled up. The two methods are illustrated in Fig. 30.

For joint *A* tar is applied with brush to side first concreted. For joints *B* and *C* tar is applied with brush to body concrete after forms are removed and before key concrete is placed.

13. Foundations

Sheet Piling. When sheet piling is employed in quay walls or bulkheads in connection with or without relieving platforms, the sheet piling will act as a simple or partially fixed beam supported where driven into the bottom and at its anchorage or fastening at the platform. Due precautions should be taken to see that the sheet piling is driven deep enough into the bottom to secure a proper hold and to guard against being pushed out, for which purpose it must be driven to a depth so that the passive resistance of earth will take the bottom reaction. In reinforced-concrete sheet piling, steel can be placed accordingly, but in any case sufficient reinforcing steel must be placed on both faces so that the pile will be strong enough to be lifted and handled while being placed in the work. It is usually advisable to lift the piling at two points so that the negative and positive bending moments are equal, and to fix these points by casting gas pipe section or eyes in the piling.

A too frequent cause of failure of walls or bulkheads is the pushing out of the bottom or toe of the sheet piling, or, in very soft material where sheet piling is not long enough, the running out or mudwave effect underneath the bottom of the sheet piling.

Steel sheet piling is frequently used in place of timber or reinforced concrete, as it can be driven into and through materials that cannot be penetrated by either timber or reinforced-concrete sheet piling. Steel sheet piling has been driven into soft rock. The steel, although it rusts away where exposed to the air, or between tides, will nevertheless last a long time under water or where cut off from free oxygen. Steel sheet piling is now available with a small copper content in the steel. The effectiveness of this alloy in preventing corrosion is questioned.

Methods of Computing Depth to which Sheet Piling should be Driven, size of piles, struts or tension of tie backs.

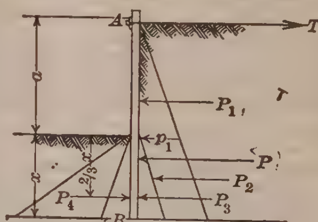

Fig. 31

In Fig. 31 the problem is shown in its simplest form.

AB is a sheet pile driven to depth x into the soil and a the known height above the soil to which it is retaining earth, assume it is held at *A* by a strut or tie *T*. P_1 is the known active pressure above the outside soil. p_1 the intensity at the level of the soil, p the increment of intensity per unit of depth for active pressure above or below outside soil. kp the increment of intensity per unit of depth for the passive pressure below the outside soil. $P_2 = p_1x$; $P_3 = 1/2\ px^2$; $P_4 = 1/2\ kpx^2$; $P_1 = 1/2\ pa^2$ or $P = P_1 + P_2 + P_3 = 1/2\ p\,(a + x)^2$.

Taking moments around A, $P \times 2/3\,(a + x) = P_4\,(a + 2/3\ x)$.

This is an equation with one unknown quantity x. Also $P_4 + T = P$ or T tension in tie or compression in strut $= P - P_4$.

Fig. 31a shows the usual trench sheeting, the two struts at D and C take the place of the tie, T, in Fig. 31 and under these conditions $P_4 + S_1 + S_2 = P$ and from this the size of sheeting and depth to which sheet piling is to be driven can be determined, and also the dimensions of struts and wales. Sheet pile

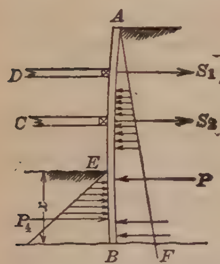

Fig. 31a. Length of Sheeting and Dimensions of Braces

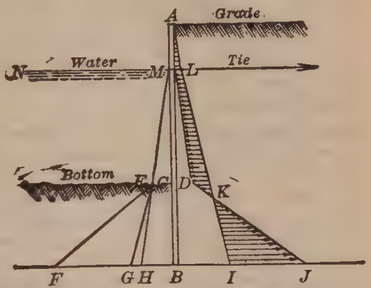

Fig. 31b. Bending Moment and Shear on Sheet Pile

AB is considered as a beam loaded as shown in ABF. The same analysis is applied to the general type of sheet pile bulkhead, Fig. 31b, where AB is the sheet pile, MN the elevation of water. The triangle ALM indicates the earth pressure above tide level and $MLIB$ indicates the total active pressure of submerged earth and water below tide level on the land side. MHB indicates the total water pressure on the water side, and EGH the total active soil pressure on the water side and EHF the total passive pressure. Superimposing the active and passive pressure on the water side on the active pressure on the land side $AMDKL$ represents the intensity of the forces outward. KIJ represents the intensity of the active and passive forces inward which with T equals the outward forces. From this may be constructed the moment diagram and the size and details of the sheet piling actually desired.

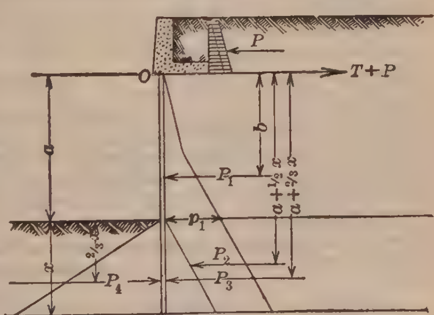

Fig. 31c

Fig. 31c is the general case of a platform wall with surcharge. The length and size of the sheet piling may be determined as follows:

Find the known active force P_1 extending from the relieving platform to the level of the outside soil. Find the intensity p_1 at the level of the outside soil. Find p the increment of intensity per unit of depth for the active pressure below the outside soil. Find kp the increment of intensity per unit of depth for the passive pressure below the outside soil. Then $P_2 = p_1x$, $P_3 = 1/2px^2$

and $P_4 = 1/2kpx^2$. Take the moment of all the forces below the platform about the point O, giving

$$P_4 (a + 2/3x) - P_3 (a + 2/3x) - P_2 (a + 1/2x) - P_1 b = O;$$
$$1/2px^2 (a + 2/3x) (k - 1) - p_1 x (a + 1/2x) - P_1 b = O;$$
$$1/3p (k - 1) x^3 + 1/2ap (k - 1) x^2 - 1/2p_1 x^2 - ap_1 x - P_1 b = O.$$

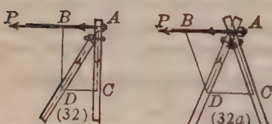
The last is an equation with one unknown x. Solve for x. Then determine P_2, P_3 and P_4 and $T = P_1 + P_2 + P_3 - P_4$.

In applying this method the table of equivalent liquid pressure in Art. 12 may be employed. kp the increment of intensity of passive pressure is dependent upon the character of soil bottom and must be obtained by experiment or experienced inspector.

Brace Piles, when driven with opposite inclinations, are subjected to a pull in one case, and a push in the other, and connection should be made accordingly. It is too frequently the case that brace piles, though provided for in ample number and of sufficient bearing capacity, have weakened and improper connections and that the full lateral effect is not secured from them.

A quay wall or bulkhead can be anchored against the thrust or horizontal pressure by deadmen or anchors buried in the embankment some distance back and below the plane of rupture made by the angle of repose, or by anchors of brace piles. Having determined the amount of this thrust, the anchorage can be readily designed.

Such anchorages are shown in Figs. 32, 32*a* and 33. In Figs. 32 and 32*a*, the amount of horizontal thrust is represented by $A\ B$, $A\ D$ would be the push or



Figs. 32, 32*a*. Pile Anchorages

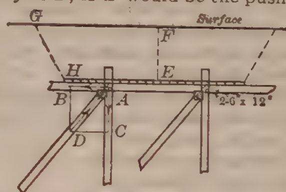


Fig. 33. Pile Anchorage with Platform

bearing on the brace pile, and $A\ C$ the uplifting effect or pull on the vertical pile in Fig. 32, and inclined pile in Fig. 32*a*; Fig. 33 is an anchorage in connection with a relieving platform, or might be used separately as anchorage for a bulkhead or wall. $A\ C$ is the uplifting effect, but the actual pull or uplift on the vertical pile shown is decreased by the weight of the soil or backfill surcharge on the platform, represented by $E\ F\ G\ H$.

Effective and Ineffective Anchorage details of brace or anchorage connections are shown in Figs. 34 and 35. Fig. 34 shows five typical brace pile anchors

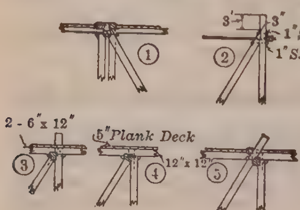

Fig. 34. Effective Pile Anchorage

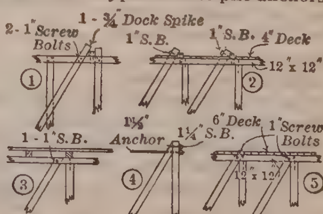

Fig. 35. Ineffective Pile Anchorage

for a quay wall or bulkhead. Fig. 35 also shows five typical cases of improper brace or spur, pile details or connections. Some of these have been taken from actual work, Fig. 35 (1) and (2) having been discovered and sketched only after the failure of the work by the outward movement and overturning of the wall. It will be noted that in these two cases the bearing or thrust in the brace pile is entirely taken by the bending in two 1-in. screw bolts and one 3/4-in. dock spike. These, apparently, held for some time, but, being submerged, even this support was greatly weakened by the corrosion of fastenings. In Fig. 35 (3) and (4) depend entirely upon the strength in bending of one screw bolt, as does (5), except that the deck planking directly above the piles furnishes an additional bearing. In designing work that will be submerged, or kept partially so, if the work is to be considered permanent, it is important, in so far as possible, to avoid entire dependence upon iron or steel fastenings. Galvanizing has been attempted with indifferent success, and, in one or two instances, extruded brass has been used for fastenings. As far as possible, work of this character should be detailed for dependence upon the fitting of timber joints and the use of wedges, dowels, and treenails. The general practice in engineering design should be applied to obtain dimension of caps and stringers, thickness of planking or decking, bearing surface in contact, and other details. Liberal allowance must be made, however, for the weakening of aged water-logged timber or the deterioration of timber, by rot, when exposed to successive wetting and drying out; and in reinforced-concrete construction to the possible disintegrating effect of concrete when submerged in salt water, especially when subject to the action of frost.

Safe Bearing Capacity of Groups of Piles. As stated in Sect. 8, Art. 10, the bearing capacity of piles is dependent upon the support at the bottom of the pile; if the pile penetrates a short distance to hardpan or rock, the strength of the pile as a column must be considered; when the pile penetrates some distance into soft materials, the bearing capacity depends upon the skin frictional resistance. It would be well, however, to note that the skin frictional resistance is the means by which the load on the pile is transmitted through the pile and through a vertical cone of earth, of which the pile is the center, to the subsoil at the plane of extreme penetration of the pile, the bearing capacity of the soil also being increased by being compacted by the driving of the pile. For this reason the safe bearing capacity of one pile is no criterion for fixing the safe bearing capacity of a number of piles driven closely together, as in the latter case the cones of resistance overlap and the bases of these cones at the bottom of the piles will, in cases of a group of piles driven closely together, each be required to carry the load, at least in part, of several piles. Whereas the bearing capacity of the subsoil at some distance beneath the surface, as at the foot of long piles compacted by pile driving, will safely carry considerably higher loads than the same character of subsoil at or near the surface not compacted, there is, nevertheless, a limitation which can be readily exceeded by placing piles too close together, expecting them to carry considerable loads. It is inadvisable in pile foundations, for harbor work, to place piles closer together than 2-1/2 ft. to 3 ft. It will be seen that at 2-1/2-ft. centers, in carrying loads of 18 tons each the interior piles of a large group will subject the subsoil to a load of approximately 3 tons per sq. ft. The same principle applies with equal force to any surface or subsurface loading, such as by means of spread footings.

Anchorage or Pull on Piles. Where brace piles are used for anchorage of quay walls or bulkheads, or in connection with pier work, as previously stated the bringing into play of these brace piles to resist lateral movements frequently results in an upward pull on some inclined or vertical piles. As a general rule, piles driven some distance into the soil and dependent upon skin friction for their carrying or bearing capacity can be safely counted on as giving an anchorage effect or resistance to pulling equal to the estimated bearing or carrying capacity. Experience in pulling up or attempting to pull up piles driven in harbor work fully confirms this statement. Observations made on piles 55 to 75 ft. in length, driven in 23 to 35 ft. of water, indicate that a pull of from 20 to 45 tons was necessary, in many instances tops of piles pulling off before the piles were moved. This resistance to up-pull is dependent upon the skin friction of the pile or actual mechanical anchorage in the case of types of concrete piles with enlarged bases, which, in turn, is dependent upon the weight submerged in water, of the cones or pyramids of soil engaged by the pile and having their small ends or apex at the bottom or foot of the pile and the enlarged bases at the river or sea bed. Hence the anchorage effect in a group of piles driven closely together will be less than the sum of the anchorage effect of a like number of single piles, because the anchorage is entirely dependent upon the weight of the mass of earth engaged by the group of piling and in no case should be expected to exceed the weight of the affected inverted prism of soil to the bottom of the piles of the group. The effective weight is, when below tide level, of course, the submerged weight of the soil, for which refer to Art. 12.

Relieving Platform Type of Quay Walls are those in which a platform is constructed at about the water level, and takes the weight of the fill and the surcharge as vertical loads carried in turn by timber or reinforced-concrete foundation piles. Structures of this type may be built having a platform of timber or reinforced concrete, a wall above the platform of reinforced concrete or gravity section and with timber, reinforced-concrete or steel, sheet piling in front or in rear of the platform, or with no sheet piling if the wall is carried back far enough.

The two types in general use are shown diagrammatically in Figs. 35*a* and 35*b*. Fig. 35*a* is the type generally employed on the sea coast in waters in

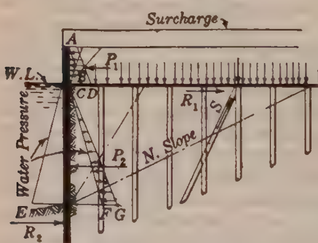

Fig. 35*a*

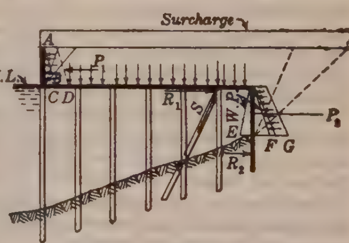

Fig. 35*b*

which the marine wood-borers are prevalent, the earth fill around the foundation piles protecting them. P_1 represents the horizontal thrust of earth fill and the surcharge on top of the platform. P_2 represents the horizontal thrust of the fill below the platform. The earth being submerged loses a portion of its weight due to the buoyancy effect of the water. The water pressure on the outside is counterbalanced by the water pressure on the inside and P_2 is represented by the triangle *BFG*. The two horizontal thrusts, P_1 and P_2, are resisted by R_1, platform tie, and R_2, the passive resistance of the earth at the bottom. R_1 equals the horizontal component of S, the bearing capacity of the inclined brace pile.

In Fig. 35*b*, the sheet piling is at the rear. The outward thrust is represented by P_1 above the platform, and P_2 at the rear, below the platform level. P_1, representing the earth thrust and surcharge, P_2, the earth thrust from the platform level down and the surcharge of the earth, etc., above the platform. These outward thrusts are resisted by R_1 and R_2. R_1 is the platform tie and is the horizontal component of the bearing on the inclined brace pile S, R_2, the passive resistance of the earth. It is evident that in Fig. 35*b*, if the natural slope of the bottom were steeper or the platform carried back further, no sheet piling at the rear would be required.

14. Timber Quays or Bulkheads

Inexpensive and Temporary Character. When work is to be of a more or less temporary character and of inexpensive type, timber is largely employed, often, where necessary, treated by one of the preservative processes. In harbors where marine wood-borers do not exist or are not active, timber work below mean tide level, where always kept wet, will last indefinitely and can be employed in the foundation and other parts of permanent harbor work.

Creosoted Timber. Available information shows that the life of creosoted timber, submerged in water where marine wood-borers are prevalent, varies a great deal and this is due to differences in quantity and quality of the oil used and to the method of treatment. A variation in quantity of 10 to 24 lb. per cu. ft. is frequently employed. Short leaf pine and fir, on account of their structure, readily take more oil per cubic foot than pitch pine, and while not possessing the same strength, are in many instances better materials to use where creosoted lumber is required.

Yellow pine piles treated with 16 lb. of creosote per cubic foot, after being in place in Charleston harbor 12 years, showed no evidences of having been attacked by marine wood-borers. In some of the other South Atlantic and Gulf ports, where the marine wood-borer is very active, there are examples of creosoted timber piles that have not been seriously damaged by the marine wood-borers, and have been in place over 20 years.

Examples of various timber quays are shown in Fig. 36, the numbers referring to the brief descriptions given below.

(1) Garrison Ave., Bronx River, New York City. Front close piling filled with riprap.

(2) Harlem River, New York City. Three-inch sheet-piling backed with riprap Anchor bents 10-ft. centers.

(3) Echo Bay, New Rochelle, New York. Close piling backed with riprap. Bents 6 ft. 6 in. on centers.

(4) Oak Point, New York.

(5) Hudson River, New York. Riprap embankment. Bents of platform 10 ft. on centers.

(6) Astoria, L. I., New York, Astoria Light and Power Co. Crib filled with rubble, pockets 8 ft. square formed by logs.

(7) Hudson River, New York, Interborough Rapid Transit Co. Slope paved with riprap. Bents 5-ft. centers.

(8) Harlem River, 171st Street, New York. Three-inch sheet piling, backfilled with riprap. Guide piles 5-ft. centers, two anchor piles every 10 ft.

(9) Rockaway Inlet, New York, Barren Island. Bents 10-ft. centers, one brace pile to each.

(10) San Pedro, Port of Los Angeles, California. Live load allowed 500 lb. per sq. ft. Piles creosoted, bents 15-ft. centers.

(11) Missouri River, Kansas City, Mo. Timber and piles creosoted. 526 ft. long.
(12) Chicago, Ill. Standard sheet pile bulkhead. Sanitary District.

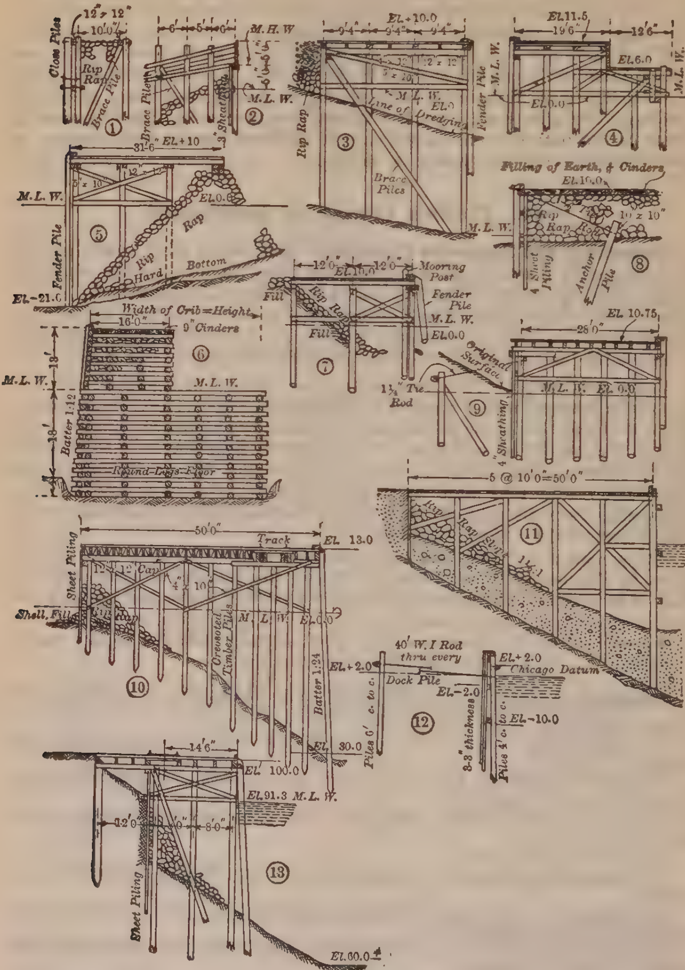

Fig. 36. Timber Quays

(13) Navy Yard, New York, 1912. 200 ft. long. Platform with 6-in. sheet piling. Bents 10-ft. centers.

15. Masonry, Concrete and Timber Quays

Foundations. In the construction of quays or bulkheads of more permanent character where rock of hard unyielding foundation can not be readily secured, timber piling and grillage work are often employed for the foundations or may be carried up to mean tide level, the work being surmounted by a masonry or reinforced concrete structure.

Riprap in locations where it can be secured in quantity and at a low cost is extremely valuable as a quay wall material, for the foundations of the wall, the protection of slopes, filling behind the wall, and for the underwater part of the wall itself. On account of the voids the material in mass submerged does not weigh more than earth fill and stands at a much steeper slope, less than 1 on 1.

Essential Details of various precedents are given in the following statements, the numbers referring to Fig. 37.

(1) Savannah, Ga. Standard Fuel Supply Co. 1912. Twelve-inch reinforced-concrete wall on timber piles, 15 ft. 6 in. on centers, reinforced-concrete deck slab. Live load 600 lb.

(2) Brooklyn, N. Y. Gowanus Canal. Timber platform, with concrete wall on piles and riprap.

(3) Chicago, Ill. Proposed plan for bulkhead wall alongside long pier.

(4) San Diego, California. 1912. 2675 ft. long. Concrete incased piles on 7-ft. centers.

(5) Iloilo, P. I. 1912. Cylinders on 12-ft. centers. Reinforced concrete on timber piles.

(6) Chicago, Ill. Long pier bulkhead.

(7) Charleston, S. C. 1911. 4000 ft. long. Untreated timber piles, sheet piling and concrete wall. Reinforced-concrete sheet piling, 3 ft. wide, to protect timber work from marine borers.

(9) New York (South Brooklyn), N. Y. One of several types of wall used by Department of Docks and Ferries.

(10) Boston, Mass. Northern Avenue. 1911. At Commonwealth Pier. Length 645 ft.

(11) Schenectady, N. Y. N. Y. State Barge Canal. (12) Amsterdam, N. Y. N. Y. State Barge Canal. (13) Utica, N. Y. N. Y. State Barge Canal.

(14) Providence, R. I. Fields Point. Bents 4 ft. centers, two brace piles to each bent. Sheet piling 6 in. and 8 in.

(15) New York, N. Y. Central R. R. of New Jersey, Bronx Terminal. Bents 8-ft. centers, two brace piles to a bent, sheeting 6-in.

(16) Boston, Mass. U. S. Navy Yard. (17) Norfolk, Va. U. S. Navy Yard. 1910. Timber platform, surmounted by concrete wall on reinforced-concrete sheet piling, 55 ft. long. Similar wall faced with granite ashlar, built at New York Navy Yard, 1912. Bents, 5-ft. centers.

(18) Berlin, Germany. Spree Canal. (19) Neufahrwasser, Commercial Railroad, Germany.

16. Masonry and Reinforced-concrete Quays

Foundations. Where the foundation is of rock or unyielding material, quay walls built up of large stone blocks, concrete blocks, or concrete monoliths are permanent and effective. In localities where granite is readily procurable at a reasonable price, this type of wall can not be improved upon both as to permanency and cost. With less satisfactory foundation conditions, especially where marine wood-borers are prevalent, reinforced-concrete piles or columns are effectively used. In masonry walls the underwater work, if of blocks, is usually laid by divers to elevation of low water. Where monolithic concrete

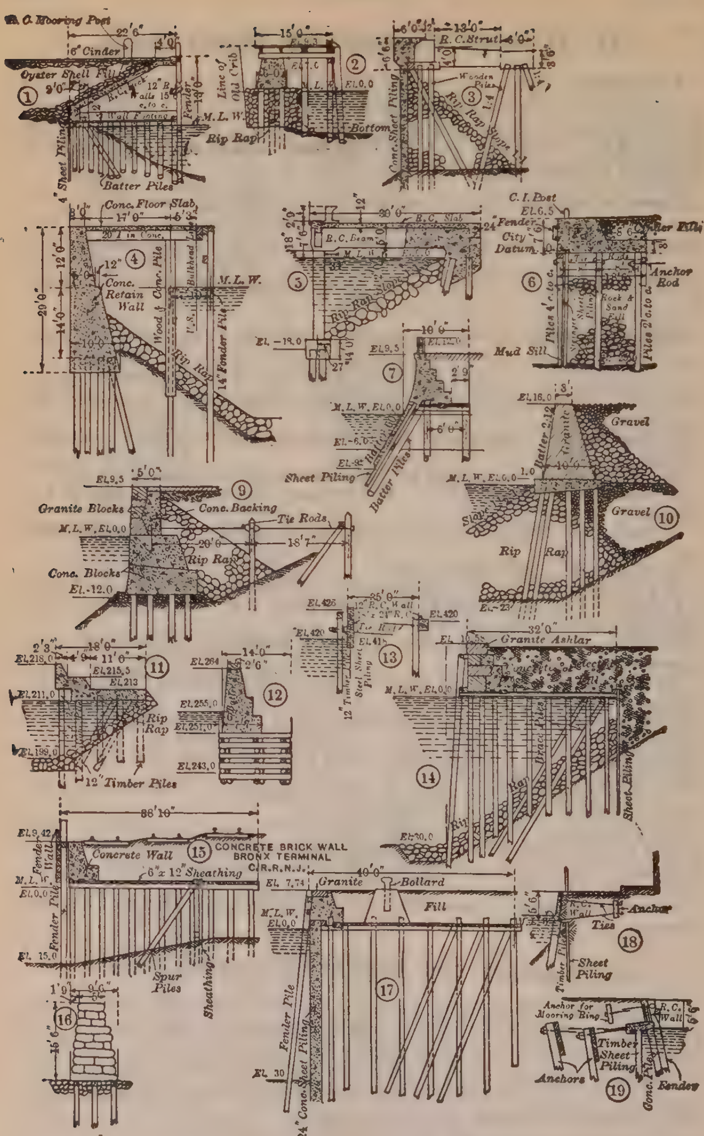

Fig. 37. Masonry, Concrete, and Timber Quays

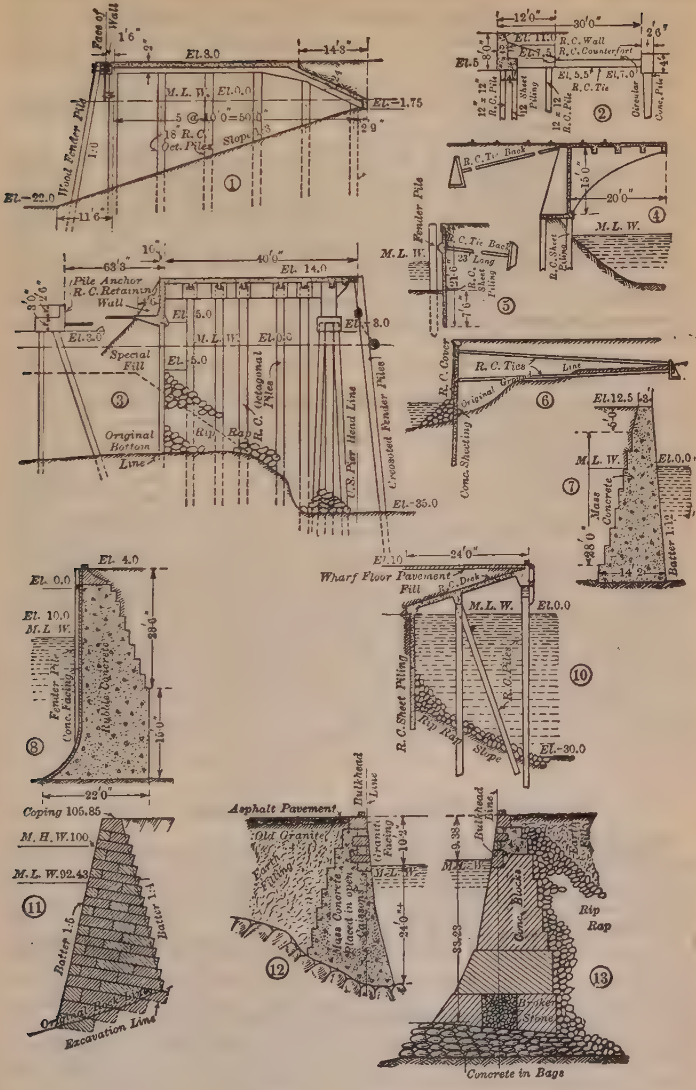

Fig. 38. Masonry and Reinforced-concrete Quays

blocks are used these may be premolded and lowered to place by heavy derricks, the foundation being prepared by the use of riprap and broken stone or concrete bag work. Concrete or stone masonry walls are also built in the dry in cofferdams, or use is made of reinforced-concrete or timber floating caissons or boxes, built on shore, launched, and sunk in place by filling.

Essential Details of various precedents are given in the following statement, the numbers referring to Fig. 38.

(1) Key West, Fla. U. S. Navy Yard. Reinforced-concrete piles and deck. Bents 10-ft. centers. (2) Albany, N. Y. State Barge Canal. (3) Los Angeles, California, 1914. Reinforced-concrete piles and deck. Bents 20-ft. centers; anchors, 4 vertical, 4 brace timber piles. (4) Nantes, on Loire, France. Reinforced concrete. (5) Spandau, Germany. Municipal Quay. (6) Nantes, France. (7) New York, N. Y. Port Morris, Bronx, N. Y. C. & H. R. R. (8) Oakland, California. 2005 ft. long. (9) Boston, Mass. Fish Pier. Wall around Pier 6. (10) Baltimore, Md. Proposed design. (11) Portsmouth, N. H. Navy Yard. Loose coursed granite laid by diver. A type of wall used along New England Coast. 1907–1912. 320 ft. (12) New York, N. Y. 116th Street, Department of Docks and Ferries. (13) New York, N. Y. Cedar Street. Department of Docks and Ferries.

The Department of Docks and Ferries of New York City has for many years employed large premolded concrete blocks for quay wall construction. With rock foundation within 40 ft. of the surface, if material over rock is soft, it is dredged off and rock cleaned, and the wall based on bag concrete brought up to level by divers. Upon this successive tiers of concrete blocks are laid up to low tide level; above this, granite ashlar, backed with mass concrete, is used. The blocks weigh from 25 to 95 tons. Where the foundation is such that piles can be driven to clay, sand or other firm bottom, soft material is excavated to 30-ft. depth, piles driven and cut off 15 ft. below low water and given lateral resistance by an embankment of riprap and gravel brought up to tops of piles. Upon these piles a single tier of concrete blocks is laid, each weighing 80 tons. A granite ashlar wall facing with concrete backing surmounts the blocks. Where the bottom is soft, the wall is provided with a relieving platform. In some walls in soft bottom, settlements as great as 4 ft. have occurred, which were remedied by adding courses of granite. The blocks are handled by scows and set in place by a 100-ton or a 40-ton crane. Cost has varied greatly from \$100 to \$750 per lin. ft.

Quay walls, in which monoliths are employed consisting of floating caissons, in a similar manner to their use in breakwaters (see Art. 3), have been constructed at Zeebrugge, Belgium; Rotterdam, Holland; Norresundby, Denmark; Talcahuano, Chili; and hollow reinforced-concrete boxes at Passau on the Danube. At Antwerp, Belgium, a quay wall was constructed using caissons launched and floated to place and then sunk by fixing over their upper part a pneumatic caisson or diving-bell handled by two floats, the section being then filled with concrete.

17. Failure of Quay Walls

Movement and Settlement of quay walls and their eventual failure in whole or part are not uncommon, even in well-designed walls or bulkheads where ample provision has, apparently, been made for the outward thrust; it is not unusual to find after work has been started evidences of settlement at the toe and irregular outward movement at the top. This may, in some cases, be accounted for by the slight settlement of the foundation under the front of the wall on account of the concentration of load and the outward thrust at that place and also in walls where timber platforms or anchors, employing brace piles, are used, to the slight movement allowed in the bringing up of bearings and connections. In most instances, this will not continue to any great extent, and may be corrected in so far as appearance goes, by resetting the coping. On walls or bulkheads having ornamental copings or balustrades, it is often advisable to postpone the placing of these until a short time after the wall or bulkhead has been built and has had an opportunity to take its set.

In gravity masonry walls, a not infrequent form of failure, or partial failure, is the moving or sliding out, in mass, of the wall on its base. It is customary, where possible, to lay the foundation and upper courses of masonry at an inclination to overcome this.

Examples of Failures and the corrective measures successfully applied in some instances:

(a) An outward movement was observed during the construction of the Fish Pier wall in Boston Harbor, the wall resting on an inclined riprap bed, laid on clay overlaying hardpan and rock. The movement was arrested by driving piles directly in front of and at the toe of the wall and constructing in the rear of the wall a relieving platform. 400 ft. of wall were involved.

(b) A section about 300 ft. long of a masonry and timber platform wall built at the New York Navy Yard failed by outward movement and overturning, the cause being, undoubtedly, improper brace pile connections, and as referred to in Art. 12.

(c) A somewhat similar wall in Washington, D. C., built on a very narrow platform without brace pile ties, moved outward 10 ft. when the backfilling had been carried only to mean tide elevation. When repaired, by constructing a timber relieving platform with adequate brace piles, backfilling was carried to grade and no further movement of importance found.

(d) A wall in Charleston, S. C., harbor, 4000 ft. long, was located on a salt marsh; the river silt of increasing compactness and density extended to a depth in excess of 90 ft. below tide. The depth of water at face of wall varied from 0 to approximately 8 ft. The support for the wall consisted of a timber platform and brace piles with sheet piling driven at an inclination. Filling of river silt was placed behind the wall by hydraulic dredging. In two locations the filling material blew out underneath the sheet piling, pushing out the bottom of the sheet piling. This was corrected by loading the toe of the wall with riprap and, in some instances, by driving heavy vertical sheet piling inside and back of the wall platform.

(e) A platform bulkhead built in New York Harbor, consisting of a timber platform with sheet piling on the inside with brace piles at 5-ft. intervals, with 15 ft. depth of water at the sheet piling, and 30 ft. depth along the face, gave evidences of outward movement when the depth of water was increased by dredging to 34 ft. This was corrected by placing 2-in. round steel anchors every 20 ft. and carrying these back 40 ft. inshore of the sheet piling to anchors of timbers, dead-men and piles, and placing riprap along the slope, decreasing the depth of water at sheet piling to 12 ft.

(f) A wall built at the Navy Yard in New York, about 1885, of gravity type, consisted of heavy granite blocks, with massive counterforts, laid by divers on a timber pile foundation, and of granite ashlar work above tide level. It was designed at a time when the draft of the vessels did not exceed 20 ft. With the increase in draft of vessel, the basin directly in front of this wall was dredged out, and, finally, to a depth slightly in excess of 30 ft. A somewhat similar wall in another locality failed by outward movement and overturning. The wall in question moved outward and gave every indication of early failure. It was repaired by the method indicated in Fig. 39, the ashlar work being stripped off to low water, sheet piling driven directly in front of the wall, and this tied back in turn by timber ties to a platform in back of the wall provided with vertical and brace piles, the space between the face of the wall and the sheet piling filled with riprap, and a new wall built directly on top of the sheet piling and the work backfilled.

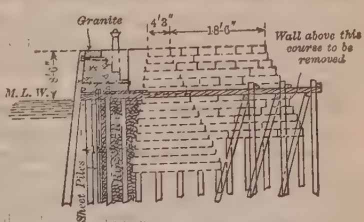

Fig. 39. Quay Wall Repair, New York

(g) A crib in D., L. & W. R. R. yard, Hoboken, N. J., the top of which had given way and needed renewal, was repaired as shown in Fig. 40.

(h) A seawall built on a timber platform, the protective face of which under water consisted of 3-lap, 2-in. yellow pine treated with creosote, began to fail on account of the destruction of the wood by the teredo. Eight-inch grooved and tongued reinforced-concrete sheet piles were driven and a reinforced-concrete face put on top of this and the structure tied back by tie rods.

Fig. 40. Quay Crib Repair, Hoboken, N. J.

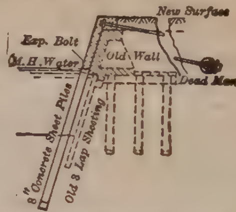

Fig. 40a. Wall Repair, Hampton Roads, Va.

There are numerous other examples, especially of walls or bulkheads constructed to retain filling that have failed by the outward movement of sheet piling at the toe or bottom, or by outward movement at the top, and overturning on account of insecure and insufficient anchorage.

The increase in the depth of harbors, due to the increased draft of vessels, has in some instances rendered insecure wall structures designed with sufficient strength and stability for the conditions existing when they were built.

LANDING PIERS

18. General Information

Harbor Lines. In the United States the Secretary of War is authorized to fix harbor lines for the protection of the harbor and its navigation, beyond which lines no wharves, quays or piers are allowed to extend. See laws for the protection and preservation of the Navigable Waters of the United States. In the interior of harbors and on navigable rivers, two lines are usually established by the government, or, outside of this jurisdiction, by local port authorities. The bulkhead line is the line to which solid or solid filled structures may be built. The pier-head line is the line fixing the boundaries of the fairway to which wharf or pier structures may be built, but when so built, they must be of open construction, permitting the flow through them of the full sweep of the current or tide, such open contruction being in the nature of pile or column bents. It is usually permissible, if desired, to make the structure from mean-low-tide up continuous or solid.

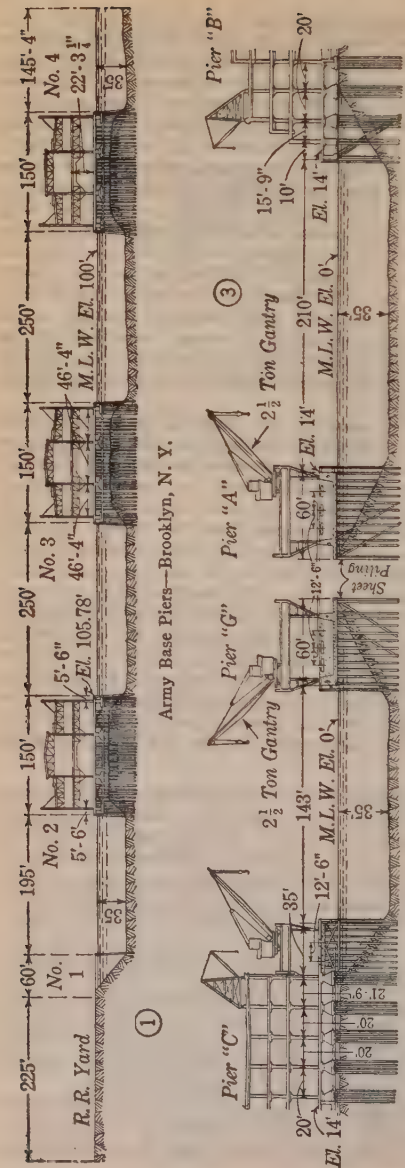
Length and Width of Piers. Piers should be of at least sufficient length to berth the longest ship likely to use them, and hence should project out into the stream a short distance beyond the bow or stern of the ship to protect the hull of the vessel from collision by passing navigation or floating ice. Piers are often built long enough for berthing two or more vessels on either side. Allowance should be made in determining the length of piers for the growth in dimension of shipping. The width of piers is largely dependent upon the use to which they are to be put, although a safe minimum width, in order to secure lateral stability by bracing, would be fixed by the depth of water and the length of the pier and the character and size of the vessels to which it will be required to afford wharfage. Piers to be used for the berthing of vessels, but not to any extent for the discharge, handling, or storing of cargoes, should be not less than 40 to 50 ft. wide. For piers in shipbuilding and repair yards, carrying standard-gage railroad track, and for heavy crane track service, requiring the handling of bulky material, the width is a local problem. For commercial pier work and in an important port where the largest ships are likely to be berthed, and cargo handled and rehandled, the width should, where possible, bear a relation to the volume of cargo to be handled and the time allowed for this. For a freighter pier or quay handling 10 000-ton ships, about 150-ft. width should be allowed, or for two ships one on each side, twice this, or 300 ft. Where four ships are to be berthed two on each side, an additional width of 50 ft. should be allowed for entrance and egress of cargo to the outer ships. No fixed rule can be given for the length of piers. Local conditions and the value of property must control. If piers are designed long enough for two or more vessels to lie alongside, the traffic congestion incident to handling and rehandling cargo at the entrance to the pier must be considered. As the width of piers, or transit shed erected on the pier, should afford storage space for at least one cargo outgoing or incoming, that is, considering whether a one- or two-story shed is used, the cargo capacity of the vessel at the pier and the necessity for aisles or passage ways through the storage space, and for roadways and railroad tracks to take in and bring out cargo, must be considered. There has been a tendency to increase the width of piers at cargo handling terminals.

The width of piers for handling incoming and outgoing cargo is directly related to the quantity of cargo to be accumulated on the pier for loading or the quantity to be landed in unloading while awaiting transfer and distribution. At a properly laid-out terminal vessels should be promptly loaded or unloaded. In determining the proper width the cargo carrying capacity and length of the largest vessel likely to use the pier should be taken. For man handling 5 ft. high would appear to be the highest economical height of stowage; while 60 cu. ft. can be allowed for a cargo ton, or with passageway, etc., allow 15 sq. ft. of pier or wharf per cargo ton. With mechanical stacking and handling this could be decreased or the width of piers can be decreased by using two-decked transit sheds, although in that case one deck is generally employed for incoming and the other for accumulating outgoing. On account of the increase in sizes of vessels and the importance of space for accumulating cargo in advance and discharging without delaying vessels, the tendency is to construct wider piers. The New York City pier and waterfront congestion is undoubtedly due largely to too narrow piers for the size of vessels using them.

Width of Slips. The berthing space or slip between two piers should be wide enough to accommodate two vessels readily, one lying at each pier, and also give room for the entry or departure of either. Sufficient space should also be provided for loading and unloading by barges or lighters on the off pier side of the vessel. The greatest beam of the largest ships is now about 100 ft., so that in slips where the largest vessels are to be accommodated the width should not be less than 300 ft., and it should preferably be more than this.

Depth of Water at Wharves. In former years the amidship, hull section of wooden ships was such that the maximum draft required was not necessary directly in front of quays or piers, but with the advent of steel hulls of practically rectangular amidship section, with bilge keels, the maximum draft is required directly in front of the wharf to be occupied, unless the vessel is kept off by spur shores, or floats, in which case there is a loss of space in the slip and inconvenience in the placing of gangways and the handling of cargo.

At the first-class piers on the Atlantic Coast 40 ft. appears to have been recently fixed as the desired depth for port approach channels. Several notable examples exist of transatlantic liners which have a depth of approximately



Army Base Piers—Brooklyn, N. Y.

Army Base Piers—Philadelphia, Pa.

Fig. 40b. Width of Slips

40 ft. at full load. It is doubtful if the tendency to increase full-load draft design of ocean-going vessels will continue beyond this 40-ft. limitation.

On the Atlantic Coast, in the important harbors, where possible, a usable depth of not less than 35 ft. should be provided, as some of the larger vessels in commercial use, when fully loaded, have a draft in excess of this. Provision should be made for this usable depth at extreme low water by allowing additional depth for silting up, and to provide for movement on account of wave action.

Naval vessels seldom have a maximum displacement draft in excess of 33 ft. An allowance, however, must be made for over-draft, especially in case of injury, such as the flooding of compartments.

Direction of Piers. In the prevailing American practice, piers are built out perpendicular to the shore line and to the direction of the channel. Some advocate placing piers obliquely, urging that the task of bringing vessels into and out of slips is thereby rendered easier. This is, of course, dependent upon tidal and current conditions. In a tidal harbor with the ebb and flood of the tides, this would be so under one of the two conditions of the tide, but it would be more difficult, or impossible, to bring vessels in or out with the reverse condition of current.

Laying Out of Wharf Work. The location of piles or columns in bents is usually fixed by batten ranges placed on shore, the spacing being laid off on two bases, a short distance apart, parallel with the bents, and the distance out to bents determined by similar ranges on adjoining structures, or by steel or cloth tape lines measuring out from a fixed base, the piles being held in place by stay-lathing or temporary braces below the cutoff or finished grade. The elevation of cutoff is given by level and carried from the given point by straight-edge and checked by instrument. Piles are cut off below water, by divers using a hand or power saw, or by using a horizontal circular saw operated from the surface.

Piers in Deep Water. When piers are laid out so that for the entire length or at the outer extremity they are in water of considerable depth, resort is sometimes had to raising the bottom, into which the piles are to be driven by making embankments of riprap. In pile piers, if placed after the piles are driven, there is likely to be a settlement in the structure due to the weight of the riprap or cobble. This method of construction has been employed along the New York City waterfront, and in the case of the New York Central pier, at Watt Street, resulted in a settlement of nearly 2 ft. Riprap embankments, under water, are also used to give the pier lateral strength, where the piles can not be driven deep enough into the bottom to insure good holding. The raising of the bottom by embankments of riprap or cobble is also resorted to to strengthen the pier laterally and especially to support the piling, which would otherwise involve consideration of the carrying capacity of such piles as an extremely long unsupported column.

19. Design

The Live Load carrying capacity of piers and quays depends largely on the use to which they are to be put, and ranges from 250 to 1200 lb. per sq. ft. The minimum should be used for piers intended solely for berthing light traffic and the support of oil and water mains, and the maximum for especially heavy work, such as the handling and storage of ordnance, armor plate, and heavy machinery. In commercial wharves, 500 lb. per sq. ft. should be used for piers, and 750 lb. for quays. The foundations are to provide for this live load and dead load of the structure itself. The foundation for standard-gage railroad track, or heavy crane tracks, shed or building foundations, require special treatment as in other engineering structures.

Prevailing Practice. In pier design it will be found that details frequently have to conform with established rules fixed by local authorities. Where this is not the case, the deck or slab should be designed to carry full live load and dead load, the stringers, rangers or beams to carry full live load and dead load; caps or girders, 80% of live load, and full dead load. Piles or columns 75% of live load and full dead load. For other structures such as sheds, railroad tracks, and special work, design in conformity with general building practice.

Timber Pier Framing is largely done by the methods used in ship framing. Pile caps, if not in one piece, are usually scarfed at such locations as to break joints in adjoining bents. In substantial work piles are usually tenoned and caps mortised. Frequently clamps are substituted for caps, these consisting of two timbers, the pile being shouldered out on each side to receive them. String pieces or rangers are either butted over caps and drifted, or spiked, to the cap, or if the joint occurs in the middle of the bay, the timbers being fish-plated. In heavy and important timber piers, the deck system usually consists of heavy planking with somewhat lighter wearing sheathing laid diagonally to the direction of traffic over it. Outshore corners on piers are usually rounded and heavily reinforced. In harbors where floating ice is prevalent, especially in tidal rivers, the bays at the outer end of the pier are made of double width, and the pile or column bents at either side protected between tides with steel or iron plates. The fastenings used are, in general, similar to those employed in timber, ship, and bridge work, and are frequently galvanized. Piers are often built with a slight crown at the center to facilitate drainage.

Fender System. Wharves, when used for berthing, are protected by fenders fitted so as to be readily removed for repair and replacement. The fender system is made up of vertical fenders or fender spring piles and horizontal wearing ribbons. The outer ends or corners of piers are usually protected by heavy clusters of fender piles, or by separate pile clusters or dolphins. In reinforced-concrete and masonry piers the fender system is often arranged on an elastic system with sufficient spring to save the main structure from the shock of vessels coming alongside. For this purpose the spring of the vertical and horizontal timbers is employed, or groups of heavy car springs are used. Frequently such fender systems are assisted or replaced by floating fenders, rolling logs or spars of single or made-up timbers sometimes served with old hemp line and fastened at the ends with lines or chains fixed to the side of the piers or quays.

In addition to the fenders employed it is sometimes customary to construct dolphins or clusters of piles along the side of a pier to breast off vessels with. Such dolphins are also used without the pier for mooring purposes while vessels are awaiting for pier or berthing space or being loaded or unloaded by lighters.

Moorings. Piers are provided with mooring posts or bollards, bitts, and cleats, one for each 50 ft. length of berth, the inshore and outshore moorings for bow and stern lines to be heavy bollards or posts fitted with horns or pins. Typical details of mooring fittings are shown in Fig. 41 When vessels are berthed alongside of quays, it often becomes necessary to spur them off so that at low tide the bilge keel will not rest on bottom slopes. Spur shores of heavy spars are used for this purpose, one end resting against the vessel's side, and being supported from it by lines or chains, the other end resting on wheels or rollers on the wharf platform, and made fast by lines or chains to bitts or mooring posts. The same object is accomplished by placing floats in between the vessel and the wharf.

Accessibility of Wharf Platforms. In harbors where the range of tide is only moderate in extent, the platform elevation of main piers and of second floors of pier sheds is usually so fixed that access may be had to cargo openings in sides of ships, for placing and transfer of cargo, by portable gangways. Where there is considerable range in tide, piers are sometimes built on two levels, the low one used at low tide, and the upper one at high tide, or inclines or ramps are built into the sides of the wharf, and sometimes these are provided with drop or adjustable gangways. A detail of such a gangway, in use at Philadelphia, Pa., is shown in Fig. 42.

Ocean Piers are generally built for passenger service, landings or recreation purposes. Ocean piers have been constructed for commercial purposes in locations where natural harbors were not available or convenient. Piers of the recreation type are found at resorts near populous cities, and are very often constructed of steel or iron piles or columns with steel and timber superstructure. The piles or columns are made up of pipe, or structural shapes, iron or steel disks or sections of screws being fixed to the lower end. The piles are put into position with the aid of water jets, an attempt being made to place them sufficiently deep so that the sand surrounding them will not be disturbed and washed away by wave action. These iron or steel piles or columns, when

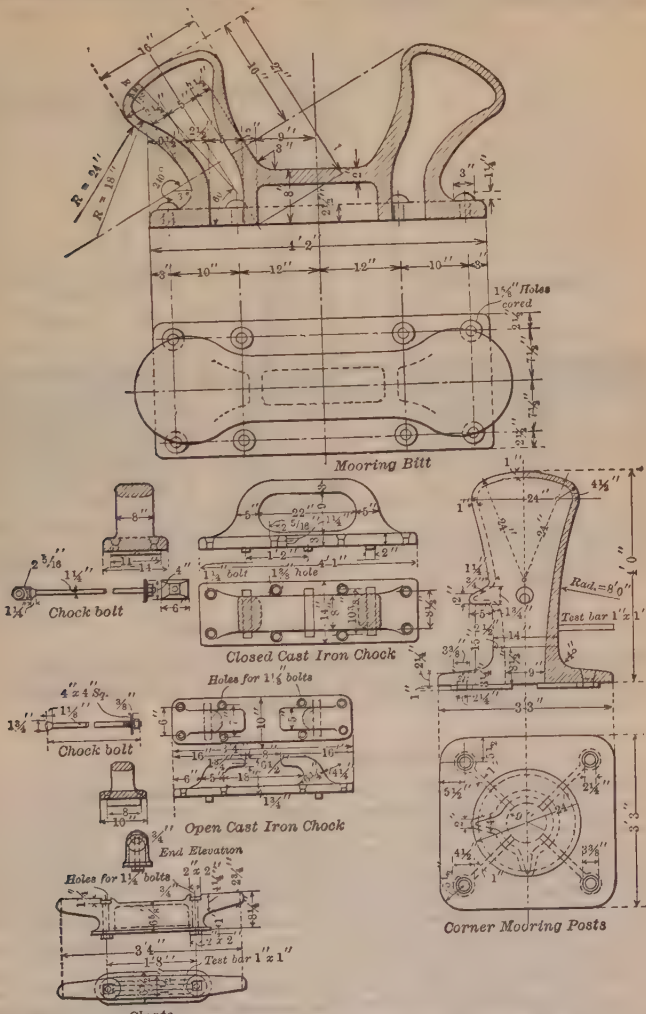


Fig. 41. Mooring Fittings

made of pipe, offer a minimum resistance to wave action; the requisite lateral stiffness is usually secured by cross bracing of steel rods. Piers of this character have also been built employing reinforced-concrete piles surmounted by a reinforced-concrete deck system. Ocean piers of the commercial type have been constructed on the southern coast of Cuba and in South America; in

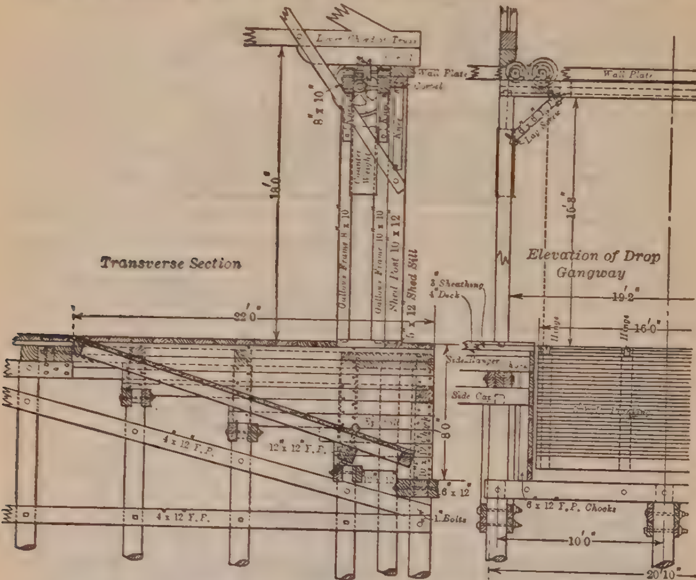

Fig. 42. Drop Gangway, Philadelphia

some cases, instead of being continuous piers built out into the sea, they consist of a detached platform or pier in deep water, the cargo being handled to and from the shore by means of overhead cableways.

20. Life and Cost of Piers

The Life of Piers is entirely dependent upon the location of the work and character of construction employed. Timber piers built in harbors where marine wood-borers are not active will last indefinitely below mean tide, but above this are subject to rapid deterioration and decay. Under such circumstances the life of a timber pier, in its entirety, could be probably fixed at 20 years. There are instances of work of this character requiring extensive repair, amounting to replacement, in 15 years, while in other cases piers after a life of 25 to 30 years are still in use. C. W. Staniford gives the following facts in Trans. Am. Soc. C. E., Vol. 77, 1914:

From the above it is derived that the average life of the entire pier is 21.6 years. The timber piles, however, below mean tide elevation, which are still in good condition, can be made use of by building a new superstructure above and resting on them. Climatic conditions, the care with which the construction work is performed, and the character of timber employed will materially modify length of life. Timber piers, with creosoted piles, in ports where

Description	Percentage of total original cost	Renewal required
Sheathing	12	Every 6 years
Backing log	1.8	Every 8 years
Fender chocks, including vertical sheathing	4	Every 10 years
Fender piles	4.7	Every 12 years
Decking	11.3	Every 15 years
Bracing	7.1	50% in every 20 years
Rangers and caps	24.4	50% in every 20 years
Piles, above mean low water	34.7	33-1/3% in every 20 years

marine wood-borers are active, may have a length of life between 15 and 25 years. In timber piers with reinforced-concrete decks, the length of life is dependent on the length of life of rangers and caps, and, when of substantial construction in a locality such as New York Harbor, can be taken as 30 years. Masonry, reinforced-concrete, masonry and reinforced-concrete on timber foundations or platforms where marine wood-borers are not prevalent or active, have practically an indefinite length of life, although under some conditions there is a possibility of deterioration of concrete work immersed in sea water requiring extensive repair and renewal. It seems safe, however, to fix the length of life of this character of structures at 60 years. Untreated, unprotected timber in harbors where marine wood-borers are prevalent and active, is destroyed rapidly, in some instances the piles being eaten away and destroyed in two or three years.

Costs of Piers. The data available as to the cost of piers are likely to prove extremely misleading. These costs are, of course, dependent upon details of construction, character of foundations, live load carrying capacity for which designed, the character and cost in the particular location of the material employed, availability and cost of labor and appliances. For general estimating purposes, for the cost per superficial foot of different types of pier work, in American ports, the following may be taken, the range between the maximum and minimum being dependent on location, foundations, and detail of design. These costs do not include auxiliary structures, shed foundations, railroad track foundations, subways, galleries, or other structures:

	Cost per sq. ft.
Untreated pine timber piers	$1.25 to $2.00
Creosoted pile untreated timber superstructure piers	$1.50 to $2.50
Untreated timber piers with reinforced-concrete deck	$1.30 to $2.25
Creosoted timber with reinforced-concrete deck	$1.65 to $2.75
Untreated timber platform with concrete cross-walls or reinforced-concrete columns and deck	$1.75 to $3.00
Creosoted timber piles with reinforced-concrete columns and deck	$2.00 to $3.25
Reinforced-concrete piles and timber system and deck	$2.00 to $3.50
Reinforced-concrete piles and deck and deck system	$2.40 to $3.75
Timber platform to low water and solid fill above	$2.00 to $4.00

On reinforced-concrete deck piers there should be added to the above figures, if asphalt wearing surface is to be placed, from 10 to 16 cents per sq. ft.; and if creosoted wood block wearing surface is to be placed, 20 to 28 cents per sq. ft. On filled piers, in addition to this, add 8 to 12 cents per sq. ft. for concrete base. It is to be noted that on the last type of filled platform pier, the enclosing wall structure representing the principal cost of the structure, the width of the pier would be a controlling feature in the cost. No cost can be given for solid filled piers, that is, piers enclosed by one of the various types of quay walls, as this cost will depend entirely on the cost of the wall and the width of the pier.

21. Timber and Timber Composite Piers

The Temporary Character of timber piers which, apparently, serves as a reason against their extensive use, in many instances loses much of its force in view of their low first cost, simplicity in design, and short length of time in which they can be built. Furthermore, in localities or harbors where a comprehensive and well-planned port improvement project has not been developed, the wharf work is often laid out and constructed to serve the immediate purpose, to be later torn down and rebuilt on new lines. The growth in importance of many American ports has been so rapid, and unforeseen, that no attempt at port planning in the past could have adequately provided for the future. The unprecedented and unforeseen growth in the size of vessels has also made necessary far-reaching and sweeping changes in port facilities. For these reasons timber piers of temporary character were as serviceable as more permanent piers, as it was easier and less expensive to remove them to make way for other more extensive work. The timber pier has played a not unimportant part in the rapid growth and expansion of American harbors. The engineer in planning pier work, when considering cost, is hardly justified in employing a permanent structure of a probable life of 50 or 60 years, when it is apparent that the wharf work will long before that time require extensions and improvements amounting to rebuilding.

Although timber wharf construction in American ports has played the part indicated in the development of such ports, and has made it possible to rearrange and rebuild without excessive cost, this very condition has brought about a more haphazard construction with very little serious and comprehensive planning for port problems and construction of port facilities. It is to be regretted that pier or transit sheds are frequently used in American practice for long storage periods and cargo is not expeditiously brought to and taken away from vessels. Vessels frequently lie at and monopolize wharfage space when they might as well be at anchor in the stream or be laid up at dolphins and thus make the wharves available for other vessels awaiting for loading or unloading cargo. As an illustration the area devoted to wharves at the port of New York is several times that devoted to similar purposes at ports such as Hamburg, Liverpool and London, all of which ports have in recent years handled about the same quantity and value of incoming and outgoing cargo.

Composite Piers, in localities where the under-water timber work will not be attacked by marine wood-borers, are practically permanent structures and, as a rule, are economical in first cost.

Crib Work may be employed for pier construction on a yielding or rock foundation. The crib, consisting of round or square timbers, is built in courses with pockets filled with riprap or rubble, in soft ground the crib being sunk to place on a prepared foundation of piles cut off to grade, on a level bed of broken stone or gravel, or directly on the bottom. On rock the crib is built up to rest and fit on the ledge, the contours of which have been previously determined by soundigs.

Essential Details of various precedents are given in the following statements, where the numbers refer to Fig. 43.

(1) Philadelphia, Pa. 1912. Pier 5. 657 ft. long; bents 10-ft. centers. Live load 500 lb. inner 400 ft., 300 lb. outer. Supports 40-ton crane track and standard-gage track. Reinforced-concrete top on timber piles.

(2) New York, N. Y. Navy Yard, Pier 3. 1905. 520 ft. long. Timber piles below water; 35 ft. depth of water.

(3) New York, N. Y. Department of Docks and Ferries, West 77th St. Timber piles and framing to mean tide elevation. Reinforced-concrete walls, 12 in. thick; 10-in. reinforced-concrete deck.

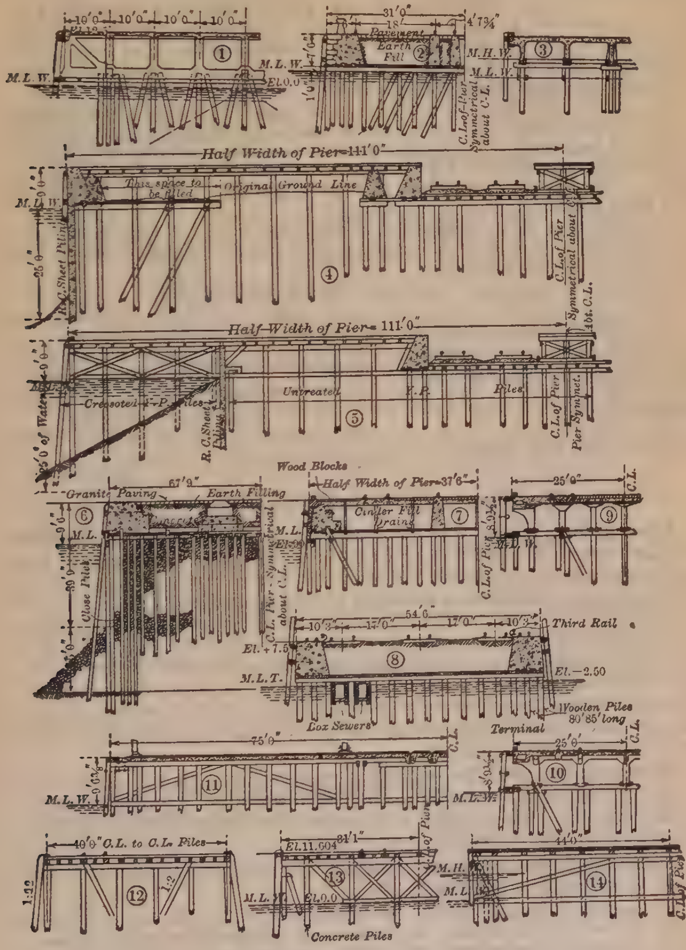

Fig. 43. Timber and Timber Composite Piers

(4) Norfolk, Va. Proposed Old Dominion Terminal. Untreated timber piles. Surrounding wall with reinforced-concrete sheet piling 16-in. 45 ft. long. Wall bents, 4-ft. centers; pier bents, 8-ft. centers. This type of construction to bulkhead line; open creosoted timber pile pier to pier-head line.

(5) Norfolk, Va. Proposed alternate plan, Old Dominion Terminal.

(6) New York, N. Y. Navy Yard, Pier 2. 1901. Timber low water platform, filled and banked with riprap, supports coaling plant. Length of pier 500 ft.

(7) New York, N. Y. Navy Yard, Pier D. 1912. Timber pile platform to low water; 34 ft. of water. Piles 55 to 60 ft. long. Granite ashlar faced surrounding wall. Paved creosoted W. B. pavement. Two standard-gage and one 50-ton crane track entire length of pier 440 ft. long. Live load, 600 lb. per sq. ft.

(8) Hoboken, N. J. D., L. & W. R. R. Terminal, Pier 1. 1909. 958 ft. long. Bents 10-ft. centers; 12-in. caps; 6-in. deck.

(9) and (10) New York, N. Y. Navy Yard. Alternate designs. (10) adopted. Two piers, each 500 ft. long. 1913. Timber piles and grillage below mean tide level. Piles 85 ft. long, depth of water 35 ft. Reinforced-concrete columns and deck system, columns premolded and set. Piers carry 2 lines of standard-gage track, subways, and piping. Paved in center, creosoted W. B. pavement. (9) Mushroom system, and (10) Beam system.

(11) New York, N. Y. Department of Docks and Ferries. Typical construction at present in use. Untreated timber structure with 10-1/2-in. reinforced-concrete deck with 2-1/4-in. asphalt pavement.

(12) Puget Sound, Wash. Navy Yard. Timber approach wharf.

(13) Charleston, S. C. Navy Yard, Pier 4. 1905. 650 ft. long. Reinforced-concrete piles, 16 in. square. Timber braces, clamps and deck system, 8 × 16 top clamp; 6 × 10 low water clamps; 3-in. deck; bents 10-ft. centers. Live load 500 lb. per sq. ft. Creosoted timber pile fenders. Similar approach wharf 45 × 920. 18-in. reinforced-concrete piles 40 to 50 ft. long; 10-in. reinforced-concrete deck. Similar construction employed in Railroad terminal pier, Brunswick, Ga.

(14) Philadelphia, Pa. Clyde Line. 1900. Pier 556 ft. long; bents 10 ft. Timber piling, bracing, deck system.

22. Masonry and Reinforced-concrete Piers

Filled-in Piers consist of walls similar to quay walls of masonry, or of the platform type, the interior being filled with earth; when properly built they are permanent and unyielding and require little or no repair work, other than that due to the settlement of the filling usually occurring only during the first few years of use. Such settlement prevents the pier from being paved or kept level during the period of settlement. They can only be employed inshore of the bulkhead line. On account of the cost of the surrounding wall work, narrow filled piers are not economical, except possibly at times when pier work is located on flats, in shallow water, or on high land, and the approach channels, slips or berths alongside require excavation or dredging, so that this dredged material can be used for filling.

Reinforced-concrete Piles and Cylinders are employed in pier construction where marine wood-borers are active, for economy in locations where the cost of timber piles is too high, or where the character of the pier foundation is such as to require the use of cylinders.

Essential Details of various precedents are given in the following statement. The numbers refer to Fig. 44.

(1) Balboa, Canal Zone. 1911. Lumber pier; live load, 400 lb. per sq. ft.; length 706.6 ft.; bents 30-ft. centers. Hollow concrete cylinders built in 6-ft. sections of 1 : 2 : 4 concrete. provided with steel cutting edge shoe; sunk to rock by jetting and interior excavation, filled with 1 : 3 : 5 concrete.

(2) Olongapo, P. I. U. S. Navy Yard, Pier B, 332 ft. long; bents 12-ft. centers; reinforced-concrete cylinders, 6 ft.; reinforced-concrete deck.

(3) Boston, Mass. Pier 6. 1912. 1200 ft. long; 300 ft. wide. Surrounding wall of courses of split granite 2 to 3 ft. high, laid by diver.

(4) Puget Sound, Wash. U. S. Navy Yard, Pier 8. 397 ft. long; bents 16-ft.

centers. Live load 400 lb. per sq. ft. Cylinders 3 ft. in diameter at top, 6 ft. at bottom, shell 4 in. thick, 23 to 52 ft. long; sunk to hardpan by interior excavation. Two standard-gage tracks full length of pier. In the same location a similar designed pier, No. 4,

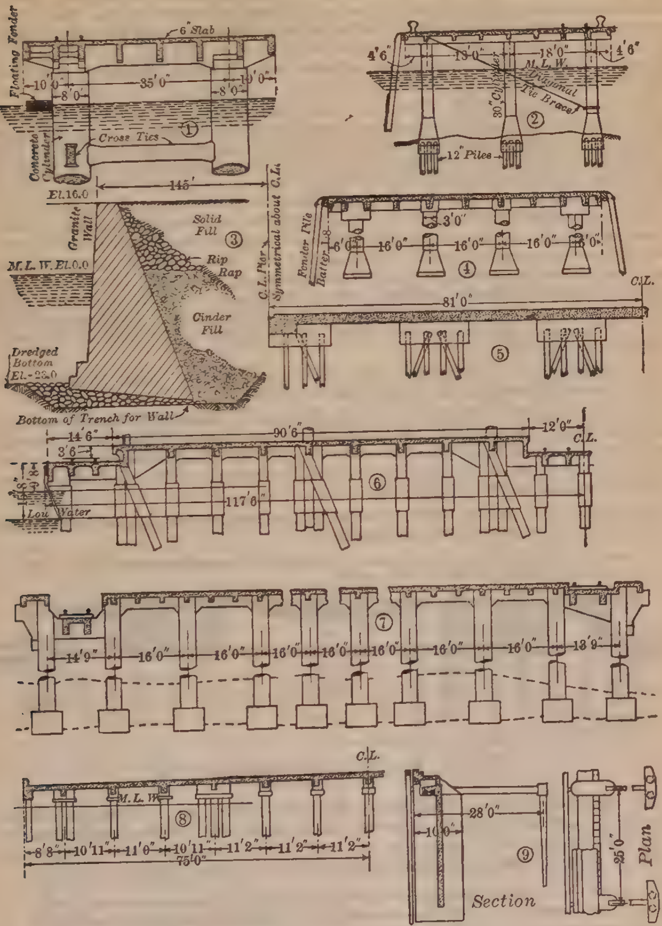

Fig. 44. Masonry and Reinforced-Concrete Piers

490 ft. long; cylinders 42 in. in diameter, 11 ft. in diameter at bottom, 43 ft. long. This pier was constructed by placing wooden shells, sinking these by interior excavation, sealing bottom with tremie concrete and filling with concrete.

(5) Havana, Cuba. Pier No. 1, 660 ft. long by 162 ft. wide, bents 20-ft. centers. A similar pier No. 2, 680 ft. long, was built, and a quay 800 ft. × 80 ft. Reinforced-con-

crete piles 16 in., 18 in., and 20 in. square. Water 20 to 40 ft. deep. Soft bottom. 12-in. reinforced-concrete deck, deck live load 250 lb. per sq. ft. and shed load.

(6) Halifax, N. S. Pier No. 2. 686 ft. long. 24-in. square reinforced-concrete piles, 45 to 77 ft. long; reinforced-concrete brace piles cambered 2 to 5-1/2 in. Special cement employed with minimum of aluminum to resist salt-water action. Bents 18-ft. centers; rock foundation 68 to 52 ft. below surface; area under pier filled by dredging to increase lateral stability. Piles loaded 80 to 90 tons each test load 120, 1 : 2 : 4 concrete. Piles protected against ice between tides by timber sheathing. Live load 1000 lb. per sq. ft.

(7) San Francisco, Calif. Pier 28, 677 ft. long; bents 15-ft. centers. Creosoted W. B. pavement 31 ft. wide down center, remainder of pier asphalt. Car springs fender employed. Types of construction general in this harbor, which is best given by brief abstract of specification: "The excavation for the cylinders shall be made inside of steel caissons which shall be driven into the hard bottom and sealed. The steel caisson shall be of such strength and rigidity as to resist external pressure, and of such size that they may be withdrawn without injuring cylinder bases. The forms shall be wood-stave forms of the diameter indicated. After the steel caisson have been set in place and the excavation made, as hereinbefore specified, the wood stave forms and reinforcement shall be set in place in the exact location shown on the plans. The concrete shall then be deposited through a tube or bottom-dump bucket. Under no circumstances will the placing of any concrete be allowed in or under water." Cylinders are sunk 12 to 14 ft. below dredge line, and where bottom is soft, timber piles are driven to support the concrete.

(8) Baltimore, Md. Broadway pier. Reinforced-concrete piles, 16 in. square; 8-in. reinforced-concrete deck. Bents 10-ft. centers.

(9) Baltimore, Md. Piers 4, 5, and 6; filled piers. Surrounding wall consists of flattened steel cylinders 25 ft. on centers, sunk, excavated and filled with concrete. Reinforced-concrete sheet piles between, achored by reinforced-concrete anchors and piles. Cylinders 27 ft. in length, built up in sections of 4 ft. Cylinders driven, excavation made by jet and pumping.

Two examples of piers of widely different types constructed during the period of the war in 1918 and 1919 are herewith shown.

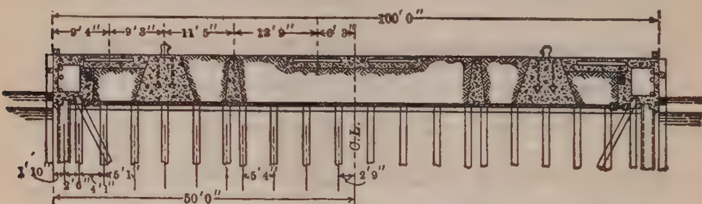

Fig. 44*a*. Filling-out Pier, Portsmouth, Va.

Fig. 44*a* shows Pier 4 at Portsmouth, Va., 1919, 1000 ft. long. Interior untreated pine piling, 4-ft. centers, live load 900 to 1200 lb. per sq. ft. 350-long ton fixed tower, revolving hammer head crane (see Fig. 91 *f*), inclosed space by 60-ft. reinforced-concrete sheet piles; 40-ft. depth of water at mean low water, range of tide 3 ft.

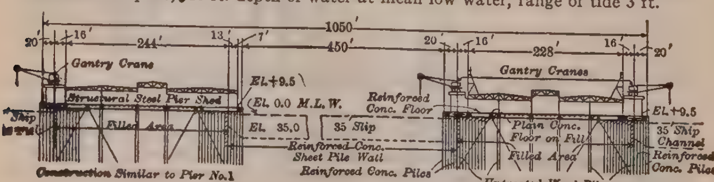

Fig. 44*b*. Freight Terminal Piers, Norfolk, Va.

Fig. 44*b* shows two piers for general loading and unloading of cargo of miscellaneous character, built 1919, 1328 ft. long. Filled center surrounded with reinforced-concrete sheet piles, interior untreated piles, exterior concrete piles.

23. Pier or Transit Sheds and Warehouses

Shelter from the Weather is provided on piers or quays used for the loading and unloading of cargoes, by the construction on the piers of sheds, one or two stories in height, the floor area covered by the sheds being devoted to the handling and distribution of incoming and outgoing cargo requiring protection and used for the storage of this cargo for a short time. Warehouses are usually provided on shore or directly behind transit sheds for goods to be stored for periods of more or less lengthy duration. When such warehouses are for the purpose of storing dutiable articles, remaining under custom seal until called for, and the custom imposed paid, they are known as Bonded Warehouses. Sheds are constructed of timber framing and siding with roofing covering of appropriate roofing material; timber framing with corrugated sheet metal siding and roofing; structural steel framing with corrugated sheet metal siding and roofing; of reinforced-concrete and other combinations of materials. On open pier construction, lightness of construction within safe limits is essential and the tendency is to make such structures fire retarding or resisting, especially where quantities of valuable cargo are handled. The width of the shed is, in most cases, fixed by the pier or quay width, allowing space in front for driveway or railroad tracks and a similar space in the center of piers, or rear of quays. An ideal arrangement on piers in general would be 25 ft. for driveway and trackage, 60 ft. for transit shed and 50 ft. for uncovered central space. A storehouse in the center for storage longer than 48 hours would require additional space and a greater pier width. Space must also be provided for open storage for cargo requiring no shelter such as steel rails, lumber, etc. The outshore end of piers is usually left open to permit ready handling of the bow and stern lines of incoming and outgoing ships.

Pier or Transit Sheds are of one or two stories dependent upon local conditions and practice and the availability and value of waterfront. On account of the conditions, pier or transit sheds should be capable of affording floor space for the storage of the cargo of incoming vessel or the accumulation of cargo ready to be placed in an outgoing vessel. Two-story sheds permit a narrow pier width, or the second story is utilized for passenger traffic.

Railroad Tracks, when carried out on piers, are as a rule run either directly through the center of the pier, at the sides of the pier, or in both places. Tracks are often laid in a depression, so that the level of the car platform will be at or about the level of the pier deck, or are laid on the deck level. When railroad tracks are run on the side, they are not usually covered by the main pier shed.

Details of Construction of Sheds are generally the same as those followed in building construction and it is often customary to give the sides of the shed a slight inclination inwards or "tumble-home." The second floor in two-story sheds is sometimes given a slight crown and the lower chords of roof trusses a camber. Openings should be provided at frequent intervals in the sides used for berthing, or should be made continuous so as to afford ready access to the various ship hatchways and side openings. Doors may either be swung from the top with counterweights employed to facilitate ready and rapid opening and closing, or slide horizontally on overhead trackways. (Various folding cargo doors and metal rolling shutters are also used.) When continuous openings are provided, several lines of overhead tracks are placed, so that the door leaves may be rolled by one another. When the siding of the shed is of light sheet metal, on either structural steel or timber framing, it is advisable to protect this on the inside to a height of about 6 ft. by cargo battens placed at a slight distance from the inside of the siding.

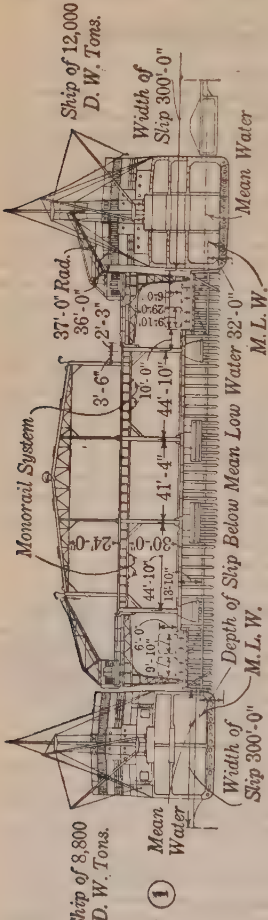

Fig. 45 Staten Island Piers

Lighting and Ventilation. In wide sheds the lighting arrangements are of considerable importance; natural light is provided by a continuous skylight or series of skylights, or by monitors constructed in the roof, or by both methods. The employment of monitors also affords opportunity for ventilation, but is likely to permit leakage in heavy driving rain storms. Circular sheet-metal ventilators of various types may be employed on the roof ridge spaced 50 to 100 ft. apart. As occasions frequently arise where the loading and unloading of vessels and handling of cargo must be done at night, proper artificial lighting is important, for which the practice is similar to that obtaining in general building lighting.

Miscellaneous Appliances. There have been many disastrous pier fires, therefore adequate fire protection and service systems are important adjuncts to properly constructed pier sheds. Piers, if of timber or timber composite, being highly inflammable, the fire insurance rate on the structure itself and on cargo stored is an item that can properly be fixed in the annual charge and capitalized cost. Important commercial structures should have installed modern fire alarm and indicator systems, automatic sprinkler systems, preferably of the dry pipe type, and fire service mains, laterals, riders, connections and fire hose on reels or racks readily accessible. If local fresh or salt water pressure lines are not available, elevated storage tanks, with pumps and overboard suction connections, must be included in the equipment of the pier shed. If water mains are carried out on piers, precautions should be taken to prevent freezing by means of proper insulation, or by draining the lines when not in use.

Essential Details of various precedents are given in the following statements, where the numbers refer to Figs. 45, 45*a*, 45*b* and 45*c*.

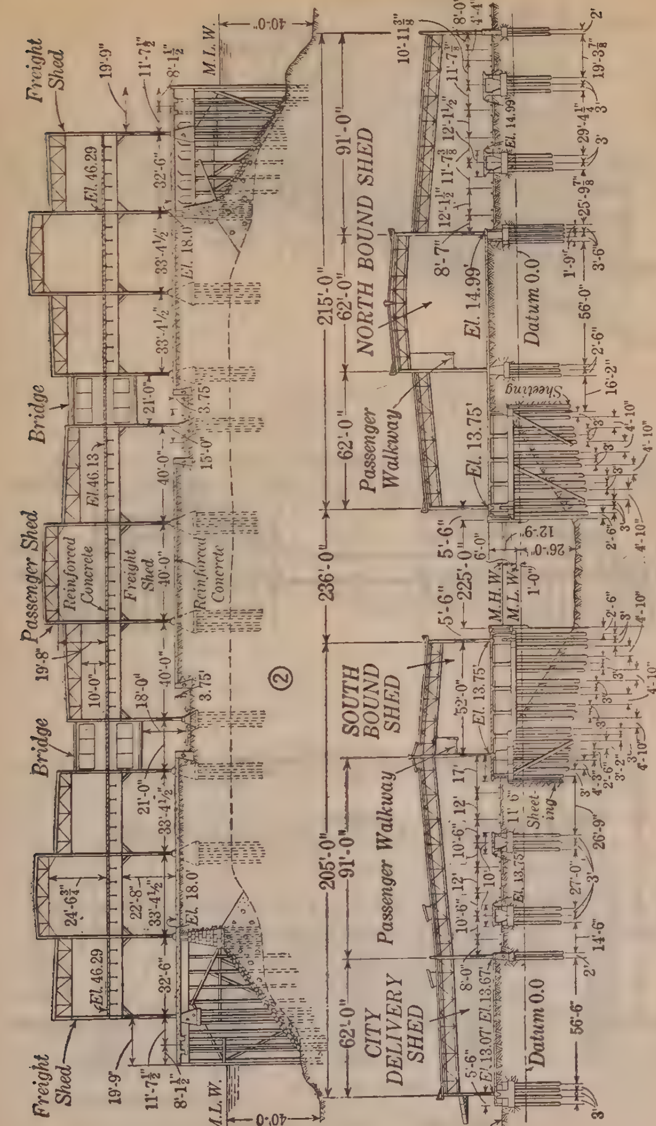

Fig. 45a—Pier Sheds—Continued

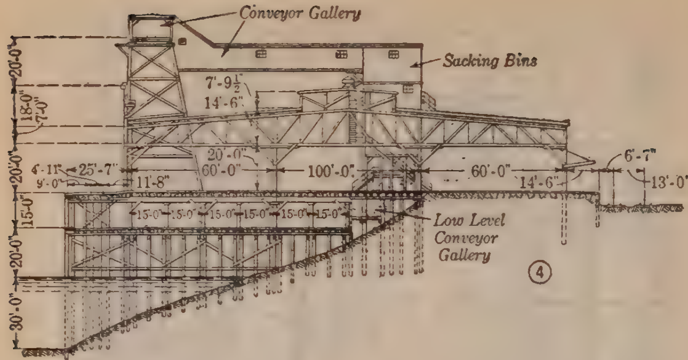

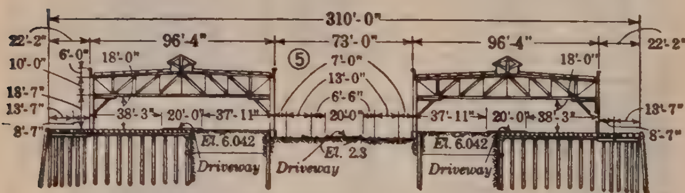

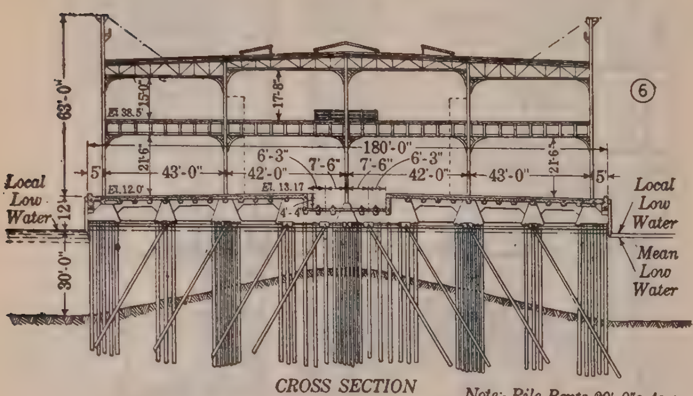

Fig. 45b—Pier Sheds—Continued

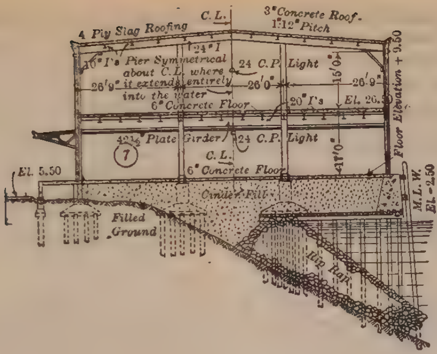

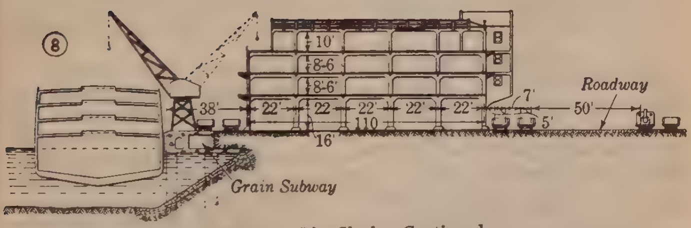

Fig. 45*c*. Pier Sheds—Continued

(1) Staten Island, N. Y. Pier 13.
(2) Boston, Mass., Pier 5. Open aprons both sides; ground floor, by means of bridges, is made available for freight in transit.
(3) Savannah, Ga. Construction is a combination of timber, reinforced-concrete and steel. Slip is a little too narrow for its length for loading and unloading large vessels.
(4) Portland, Ore. Timber construction.
(5) Seattle, Wash., Pier A, Smith Cove. Timber construction, combining open construction for the apron on each side of the fill confined behind sheet piling bulkheads, for the center portion of the pier.
(6) Philadelphia, Pa. Southwark Piers 38 and 40. Timber pile supports below permanent wet line. The two-story shed is of steel.
(7) Jersey City, N. J., Pier 9, D., L. & W. R.R. Steel frame. Reinforced-concrete roof, siding and floor.
(8) Manchester, England. Note grain subway.

WET AND DRY DOCKS

24. Wet Docks

Definition. Docks may be divided into two general classes—harbor docks and repair docks. The former, sometimes known as Wet Docks, are enclosed, or partially enclosed basins, usually, in European practice, provided with locks and entrance gate, similar to canal locks. They are sheltered basins for the receiving of shipping, so arranged that the water in the dock may be kept at more or less constant level to facilitate the loading and unloading of cargo.

The general term Dock is applied to such basins whether closed or open, and through a misunderstanding of the word is often, in general parlance, applied to the surrounding or bordering structure such as the quay or pier.

Use of Wet Docks. Their usefulness is apparent in harbors where there exists a considerable range of tide, and especially where under low tide conditions the approach to the harbor itself is not navigable for deep-draft vessels. They also have a special field of usefulness in harbors or rivers where considerable silting up takes place, the dock area being kept free of such silting by keeping out turbid river or harbor water and often by supplying water to the dock basin from other sources. This type of structure, in its restricted sense, is rarely found in American practice, although it is employed in some South American ports.

The reasons given for the use of wet docks are undoubtedly not the only ones that have occasioned their appearance in European practice, as otherwise they would undoubtedly have before this been employed in American ports where a considerable range of tide is involved. They have undoubtedly been resorted to in order to attain the maritime commerce of river ports, where the increase in draft of vessels has become greater than the normal navigable depth of the river. The wet dock has been developed as the instrument by means of which Old World ports have retained maritime supremacy.

Design of Wet Docks. It is apparent that in wet docks, where entirely enclosed and provided with entrance gates, as the surface of the water is to be kept at approximately a constant elevation, the sides and bottom of such a basin must be practically impervious, or arrangements must be made to replenish the water lost by leakage. This is especially so in all seas having a considerable variation in tide, and a consequent appreciable difference at times in the height of water inside and outside of the wet dock. Where the basin is located in a practically impervious soil, such as clay or clay soils, and many kinds of rock, these conditions are generally provided for. For this reason, a thorough exploration of the subsoils in locations where wet docks are projected is of the greatest importance. In locations where the subsoil is readily water bearing, the bottom must be blanketed with clay puddle or a masonry lining placed. The dock walls can be treated in a manner similar to that described under Quay Walls, in Art. 12; the walls, however, of dock basins are at times subjected to external hydrostatic pressure in excess of that to which they would be subjected if located on open basins. This is, usually, not a serious matter, as the combined earth and contained water pressure, together with the passive resistance of the earth backfill, will be found sufficient to provide for this condition.

Locks and Lock Gates. The condition governing the design and construction of these is, in all respects, similar to that found in canal work. Information on this subject will be found under Canals, in Arts. 17 and 19, of Sect. 15.

25. Marine Railways

Definition and Description. Repair docks may be marine railways, lift docks, graving docks, or floating docks. Marine railways are inclined slips or ways, extending out some distance into and under the water, and running up on the foreshore a sufficient distance so that the vessel when hauled out will be entirely clear of the water. A platform or cradle moves on these ways, usually on nests of rollers, and is hauled out of the water by means of chain or wire rope cable. Racking and pawls are usually provided, so that if the hauling device should break, the cradle and vessel will not slip back into the water.

It is apparent that even without considering the feature of range of tide, the application of this type of repair dock is limited to vessels of comparatively small size, as in long vessels of deep draft the ways would have to be carried out a great distance under water, approximately twice the length of the vessel to be docked, making the entire length of the ways over 3 or 4 times the length of the vessel to be docked. This condition is sometimes materially improved by use of a collapsible cradle. Although there is no reason why sufficient capacity of hauling device can not be designed, nevertheless important considerations would tend to limit this. This type of repair dock is, undoubtedly, valuable and economical for the docking of smaller vessels. Its application, however, appears to be limited. No marine railways have been built in excess of 5000 tons lifting capacity. Fig. 46 shows a marine railway of 2000 tons capacity. Estimated cost, $100,000.00 in 1919.

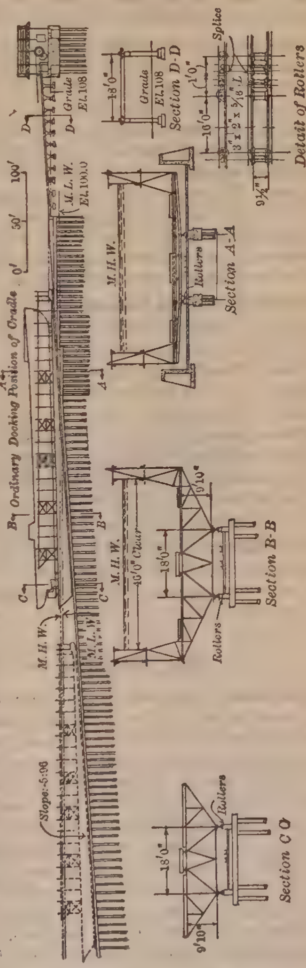

Fig. 46. Marine Railway

Marine Railways were designed in 1918-1919 of 3100 tons capacity; the estimated cost $300,000 or nearly twice the cost per ton capacity as that given hereinbefore.

The Foundation should, if possible, be incompressible. In many larger and more important marine railways the ways are built on piling. The intensity of pressure, though not great, is, nevertheless, in the form of a moving load, becoming greater as the vessel hauled out loses its buoyancy. The ways are in many instances similar to the ways employed in shipbuilding work, which, however, do not go out under water to the same extent, and besides this, the weight of a vessel when launched is usually considerably less than would be the docking weight of the same vessel.

Ways. The ways are laid at a gradient of between 1 on 13 and 1 on 25, 1 on 20 being the usual slope for large marine railways. The ways consist of 2 to 4 rails of iron or steel securely fastened to longitudinal bearers which in turn rest on cross-ties bearing on the foundation. The racking to receive the cradle safety pawls is usually placed in the center of the ways between the two central rails, if 4 rails are used. The under-water work is either performed in the dry by the construction of a cofferdam around the site, or by divers. If no foundation piles are used, the grading must be carefully done, working from over-water battens. If piles are used the under-water portion of the ways is built in sections, floated to place, lowered onto the foundation by weighting and fastened securely in place.

The Cradle or Platform is usually constructed of timber or structural steel, and is provided with keel and bilge blocks. The cradle is constructed on longitudinal sleepers, placed directly over the longitudinal ways, and provided on the underside with an iron track. The cradle is moved on nests of rollers placed in between the upper and lower lines of track. The rollers are usually of cast iron, double flanged, and held in place by flat bars or links; sometimes the rollers are fixed on the cradle and run on tracks on the longitudinal way-sleepers. In large marine railways, the cradle is built with side frame work, which is used for working platforms. Frequently, cradles, instead of having the same inclination as the ways, are built with the platform horizontal, or nearly so, in order that the ship being docked will immediately come to a bearing and not be lifted first by the bow.

Broadside Marine Railways. With a view to overcoming the difficulty as to length of marine railway, they are sometimes built so as to withdraw vessels from the water broadside on.

Power Absorbed in Friction. The power required to raise a vessel is dependent upon the inclination of the ways and the force required to overcome friction. Experiments made on the power absorbed in friction indicates a variation from 3.3% to 7-1/2% of the weight lifted. On larger and well-designed marine railways, the percentage is in the neighborhood of 4%, to which should be added 5% for initial friction in starting from rest. Thus in a marine railway having an inclination of 1 to 20, the hauling machinery would have to exert a pull of 14% of the weight of the vessel lifted.

Lift Docks are platforms lowered into and raised from the water. This type of structure is of limited capacity and has fallen into disuse. Hydraulic power was generally employed, applied through a series of cylinders placed on both sides of the platform and connected together transversely by girders.

26. Graving or Basin Dry Docks

Definition. Basin dry docks, often called graving docks, are basins generally made by excavation in the foreshore of the harbor, having entrance-ways closed with gates or portable caissons, and are usually of such dimensions as to be capable of receiving, with sufficient clearance, the maximum sized ship to be docked therein. After the ship is floated into the dry dock, the opening is closed by means of a gate or caisson and the water in the interior is removed by pumping, the ships settling on blocks provided for that purpose. In some graving docks advantage is taken of the fall of tide to reduce pumping or eliminate it entirely. In nearly all cases the graving dock must be pumped out twice for the docking of the vessel. The dock is usually left unwatered so that when word is received that a certain vessel is to use the dock, the blocking may be arranged to conform with the profile of the keel and the character of the vessel. The dock is then flooded and the vessel is floated in and centered and held in the proper position, the opening closed and the water removed. On completion of the work on the ship, the dock is flooded and the ship removed, the opening again closed, and the water removed from the dock.

Foundations. In large graving docks, water at considerable head must be excluded, and for that reason the character of the subsoil and foundations are of considerable importance in locating structures of this type. A graving dock can, although at times at a prohibitive cost, be constructed in almost any location, but, where possible, it should be located at a site where sound bedrock will be encountered at some elevation not below the subgrade of the structure or in locations where marl, stiff clay, or mixtures of marl or stiff clay, sand and gravel are encountered. Suitable foundation conditions, other than rock, sometimes result in less expensive and more expeditious construction. Fig. 47 shows a half transverse section at the entrance sill of a graving dock on pile foundations.

Graving docks have been constructed in unstable water-bearing soils, but at high cost. With a view to securing a suitable site, or to enable proper precautions to be taken in design and in method of constructions, if selection of a site

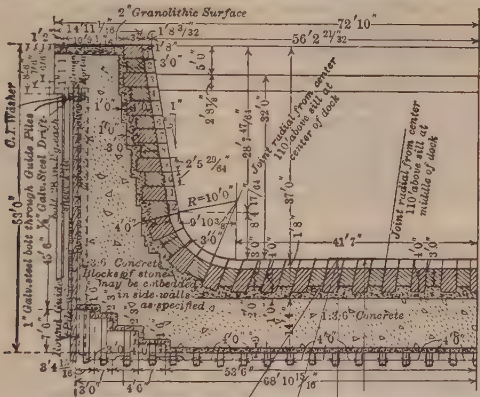

Fig. 47. Section of Graving Dock with Pile Foundation

is restricted, an important preliminary step is the taking of exploration borings, operations for which are described in Sect. 15. Arts. 29 and 30. It is advisable, where possible to do so, to secure core borings showing the condition of the soil " in situ " and, in special cases, to supplement these with test pits. See Sect. 15, Art. 31. In water-bearing soils such test pits may have to be made by employing the pneumatic process.

Masonry Graving Docks. In the design and construction of such docks, provision must be made for counterbalancing the hydrostatic pressure by sufficient weight of masonry or other anchorage effect. In porous water-bearing soils, the hydrostatic pressure to be considered will be at least the full hydrostatic pressure due to maximum tide elevation, and under certain conditions, on account of the presence of ground, surface or artesian waters, a pressure in excess of this. Where the dock is located on a solid rock ledge without water-bearing fissures, this condition will not obtain, although ideal foundation conditions of this character are seldom, or never, encountered in practice, and it is therefore customary on this character of foundation to provide for relieving the water pressure by under-draining the floor of the structure. In some soils, such as tenacious marls or clays, or hardpan, the same precautions may be taken, the walls of the graving dock being designed as retaining or quay walls. In graving docks built in water-bearing soils, full hydrostatic pressure should be expected and provided for. A number of graving docks have been constructed in which the weight of the masonry mass is somewhat less than the uplifting force due to full hydrostatic pressure, their integrity depending upon the friction of the backfill on the back of the side-walls, and, in some cases, to anchorage or pull on foundation piles. In stable water-bearing soils where the uplifting forces are clearly defined, dependence can be placed on the anchorage effect of the foundation piles, where such exist. This anchorage effect, however, should not exceed the submerged weight of the mass of subsoil engaged by piling, as stated in this section, Art. 12. The friction of the backfill on the rear of side-walls, being indeterminate at best, should not be given a definite value, and should be considered merely as a factor of safety. In a dry dock completed at the New York Navy Yard in 1912 the anchorage effect against hydrostatic uplift was secured by deep piers with flared-out basis, secured into the floor by a system of anchor rods, the anchorage provided in each being in the neighborhood of 1 000 000 lb., these piers being sunk to position by the pneumatic process.

A masonry graving dock is subjected to three following conditions:

(a) When empty: The bottom or floor is subjected to hydrostatic pressure, usually considerably in excess of the weight of the floor itself. This excess is transmitted to the heavy side-walls by actual or virtual inverted arch action, the abutments of the arch being furnished by the weight of the side-walls taken together with the thrust of the earth and water on the rear of the wall and the passive resistance of the earth itself. When this abutment action is insufficient, reinforcing steel should be provided in the floor.

(b) The dry dock empty with a ship of maximum tonnage in the dock: The conditions are the same as (a), except that there is concentrated at the center line on keel blocks, and on the side blocking, the weight of the ship, for which concentration, where the foundation is somewhat yielding, special provision must be made by distribution of this load by reinforcing the masonry with steel, or the foundation directly under the blocking designed accordingly.

The loading per running foot of dry dock is dependent on the length, depth, and width of the structure and the character of ships to be docked. For war vessels of the largest size weights as high as 90 long tons per running foot should be allowed, as the concentration under machinery and gun turret locations is liable to run this high. For commercial steamers the loads will be less. Under ordinary docking conditions 5/8 of this load will come on the keel blocks and 3/16 on each side, docking keel or bilge block. In the work of bottom repair, as blocking is removed the concentrations are shifted, this, however, only occurring locally over small areas.

(c) Dry dock full of water. Under this condition, the foundation, considered in its entirety, is subjected to the greatest load, consisting of the submerged weight of masonry to tide level, plus the weight of masonry above tide level, the conditions being somewhat altered with the presence of surface or artesian ground-water in the soil. Under this condition the thrust on the rear of the wall is due to submerged earth pressure to ground or tide water level, tide or ground water pressure and surcharge of earth pressure above tide or ground water level, and surcharge on wall, reduced by water pressure on the interior of the dry dock. It is often customary to use combined liquid pressure to the coping of the structure and neglect surcharge (Art. 12). Under this condition, very often little or no virtual or actual arch action can be counted on, and the foundations under the side-walls should provide for the weight directly above them, or provisions for distribution made by employing reinforcing steel. In yielding foundations, if this is not done, settlement at the side-walls will be in excess of the settlement under the center of the floor, causing cracks at the toe of the walls, and along the center line of the dry dock. It should be noted, as between Conditions (a) and (c), that there is likely to be a complete reversal of stresses in the floor.

To these three conditions a fourth may be added, that is, of the dry dock while under construction. This should be given careful consideration and analysis, the omission of which has, in some instances, resulted in damage to the uncompleted structure. Many older masonry graving dry docks have been constructed of rubble or ashlar stonework, faced with ashlar work. Nearly all the the more modern graving decks are constructed of concrete, unlined, or lined with granite ashlar work, or, as in the case of the graving dock built at the New York Navy Yard in 1912, vitrified brick, in either case caisson or gate seats consisting of granite stonework with radial joints for the bottom and lower parts of the side steps, the contact faces of which are fine cut work, or, at times rubbed. The beds and joints of caisson-seat stonework should not exceed 1/4 in., and, in some cases, are limited to 1/8 in.

Examples of recent graving docks are shown as follows:

Figs. 47*a* and 47*b* show a plan and a transverse section of a group of four dry docks at the Norfolk, Va., Navy Yard. Dry Dock 3 was built between 1903 and 1911 while

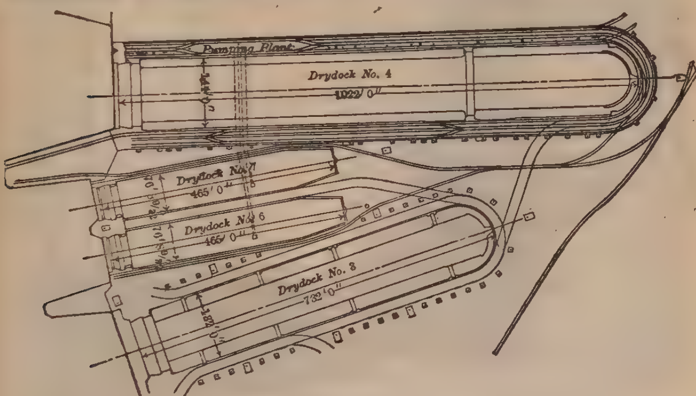

Fig. 47*a*. Group of Four Dry Docks for Norfolk, Va.

Dry Docks 4, 6 and 7 were completed in 1919, the larger for the Navy and the two smaller ones for the United States Shipping Board Emergency Fleet Corporation.

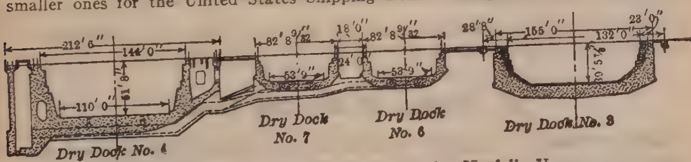

Fig. 47*b*. Transverse Section of Docks, Norfolk, Va.

Details of all four dry docks as to dimensions and cost can be found in the tabulation in Art. 30. One pumping plant consisting of three 54-in. vertical volute pumps serves all three of these docks. Dry Dock 4 is provided with an intermediate caisson gate seat so that the inner end of the dry dock can be used for smaller vessels on long-time repair work and the outer portion continue available for docking larger vessels. This arrangement practically provides two docks in one. A similar arrangement is provided in the Philadelphia Navy Yard Dry Dock and in the Commonwealth Dry Dock at Boston, Mass. These arrangements entail the additional cost of the interior seat, two dry dock caisson gates and independent pumping for the two sections of the dock. The older dry dock of the group, No. 3, as will be noted in Fig. 47*b*, is lined with granite ashlar masonry, but the three new docks are of concrete throughout without other facing or lining. A section of Dock 4 shown in Fig. 47*b* is at the pump well. The half-section to the right of the center line is so designed that the dock could be constructed on the natural stable slope of the excavation which was made by drag line in the dry. The floor invert is 20 ft. in thickness. The floor of the two smaller docks is 10-1/2 ft. thick. Excavation for these docks was also made in the dry. Water was kept out of the excavation site by a cofferdam of steel sheet piling, wooden sheet piling and earth embankment. Dry Dock 4, the large dock, was completed in about 2 years, Dry Docks 6 and 7 in 1 year, indicating that this type of dry dock can, under favorable conditions, be constructed as expeditiously as floating docks of similar size.

Fig. 47*c* is a half typical section of a graving dock constructed at the Philadelphia Navy Yard, and is similar in dimensions to that at the Norfolk Navy Yard. The

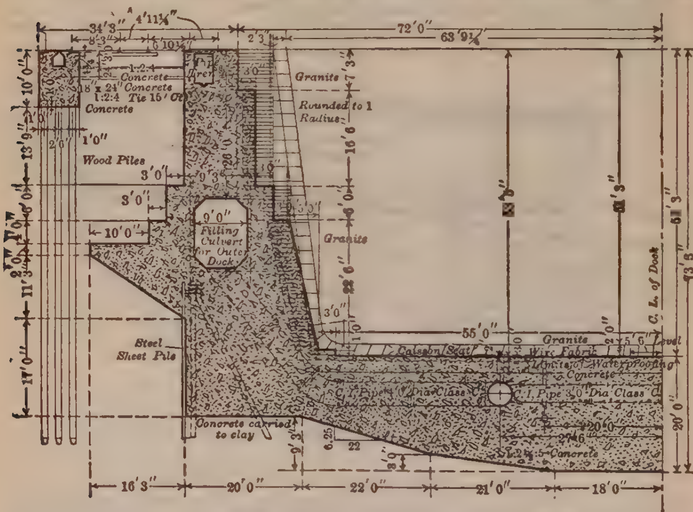

Fig. 47*c*. Half Section Graving Dock, Philadelphia, Pa.

steel sheet piling shown surrounds the entire site at the bottom and was placed to cut off the flow of water in the sand and gravel above the clay subsoil.

27. Design of Graving Docks

Data on Design. A graving dock should be designed having in mind the three conditions enumerated in the paragraph above, and consideration should also be given to the possible fourth condition. The necessary information having been obtained as to the character of the soil, its probable submerged weight and angle of repose and allowance made for the safe weight of masonry per cubic foot, stress diagrams should be drawn for all conditions. Fig. 48 is such a diagram for condition (a). In this case the hydrostatic pressure is just counterbalanced by the weight of masonry. The line of pressure does not pass through the middle-third at the base of the side-wall or in the center. If on analysis the maximum unit pressure in the virtual arch is not too high, the masonry at the center above the virtual arch may be considered inert, although it may be desirable to employ reinforcing metal to avoid unsightly longitudinal center line cracks.

Under these conditions the vertical components of the downward forces would be in excess of the vertical components of the upward forces of hydrostatic pressure, this excess being counterbalanced by the soil pressure or passive resistance and would appear as a vertical closure in the polygon of forces

(Fig. 48). In analyzing the floor arch thrust in the same way it may be necessary to consider not only the active earth and water forces on the rear of the retaining wall but also the soil pressure or passive resistance that would be afforded to this wall acting as an abutment for the inverted floor arch thrust, from which it will be seen that it is entirely probable in the preparation of the design and in the analysis of the structure and in the making of the stress diagram to insert exterior soil resistance or passive pressure forces.

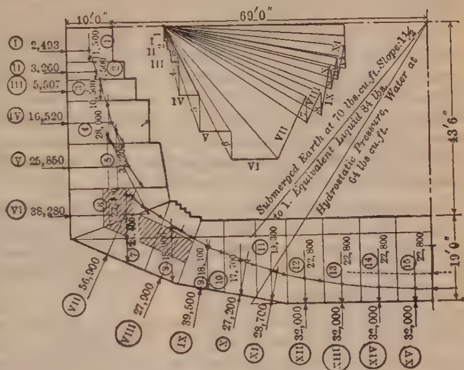

Fig. 48. Stress Diagram

When the weight of the section is in excess of the hydrostatic pressure, the diagram would have to take into consideration the bearing of the structure on the foundation, or soil pressure, which could be considered as equally distributed over the entire area of the foundation. However, in a case such as that shown where the line of pressure was outside of the middle-third at the center, in order to develop longitudinal cracks on the tension side, the floor at the center would have to lift slightly, relieving the soil directly beneath it of pressure and transferring the entire soil pressure to the sides, resulting in raising the line of pressure to within the middle-third as indicated by the dotted line.

Masonry Graving Docks on Rock Foundations. The same considerations govern the design, excepting that provision can probably be made for relieving hydrostatic pressure in whole or part; under the most ideal conditions the rock can be excavated out to the rough dimensions of the graving dock, and then lined with masonry, with or without relieving drains. A graving dock built at Hunter's Point, San Francisco, Calif., was built in this way, the excavation being made in impervious serpentine rock, and lined with a comparatively thin layer of concrete. No provision was made for draining. In graving docks founded on ledge rock, the necessary stress diagram should be made for all conditions. Fig. 49 shows a half transverse section of a graving dock on rock foundation.

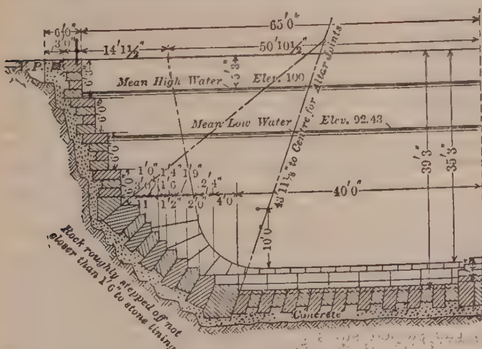

Fig. 49. Half Section Graving Dock, Rock Foundation

Altars are provided in the side-walls at convenient heights, the first at elevation of about mean high tide and additional altars at intervals below this. They consist of steps or platforms 2 to 3 ft. wide, and are used for the placing of shores to hold upright the vessel being docked, and as a means of access from and to plank stages or working platforms placed alongside the hull.

Stairways and Timber Slides. Stairways are provided for going into and coming out of the graving dock, two sets on either side of the entrance and at or on either side of the head with intermediate stairways to suit convenience. These are built directly into the altars or through the side-walls. Timber slides are used for letting down and hauling up material and are placed at convenient intervals in the side-walls on both sides of the structure. In order to simplify design and construction, portable stairways may be provided, leaving the altars clear and continuous.

Drainage. The floor is drained by means of either open gutters at the sides or in the center of the floor, or by drainage culverts with drain connections, located at intervals. Where gutters or drains are used the floor must be graded transversely to these, the gutters or drains being given gradients to insure self-cleaning.

Head. The inshore end of the graving dock is known as the Head, as distinguished from the outshore end, or Entrance. Heads are built rectangular, trapezoidal or circular or elliptical, correspondingly, the walls are designed and figured as retaining walls, or are built as simple or compound, circular or elliptical arches.

Timber Graving Docks have in the past been extensively employed in American practice, when vessels of smaller size with less draft and of different hull section were constructed for the merchant and naval service. They had the advantage of lower first cost and more expeditious construction and were especially suited for location in stable water-bearing subsoils. The principle of design and construction is different from that obtaining with respect to masonry graving docks and is based upon the partial, or entire, reduction of hydrostatic pressure on the bottom by drainage and the building of the side-walls at a slope approximating the natural slope of the soil, relieving this portion of the structure from the earth thrust. The flow of ground or tide water through these walls is cut off by a continuous and enclosing wall of sheet piling driven at the coping or some distance back from it, the timber altars of the side-wall being laid on inclined stringers supported on piles, a sloped wall of puddled clay being laid between the soil and the timber altars. The flow of water onto the floor is cut off or reduced by a continuous enclosure of sheet piling driven at the foot or toe of the wall or slope and 1 to 3 rows of timber sheet piling are driven across the entrance, the floor itself consisting of heavy timber planking, fastened to dimensioned caps bolted to the foundation piling, with which the bottom is studded at 3 to 4-ft. intervals, additional piles being driven in the center, where necessary, under the keel blocks, and under the probable position of bilge blocks. Three to 5 ft. of concrete is placed under the timber floor in between timber caps and piling. In this type of structure a certain amount of leakage or self-draining is expected and allowed for. Among the advantages claimed are that the sloped sides give better light and ventilation. Although this argument, undoubtedly, is of importance as applied to the older types of vessels, it loses its force when steel vessels of rectangular amidship sections, with practically flat bottoms, are considered, as, in both masonry and timber graving docks, artificial light must be employed, under such hulls. The disadvantage of this character of construction is that in order to secure necessary width of graving dock at the height of the blocks, the width at the coping line becomes excessive. Thus, with a vessel of 100-ft. beam, and 30-ft.

draft, with allowance for clearance, the width of the timber graving dock at the coping line would have to be nearly 200 ft. as against 140 ft. for a masonry graving dock, entailing the requirement of a considerably larger area of land, and difficulty in handling materials for building or repair by side-wall cranes. Timber graving docks have a further disadvantage of not being a permanent structure and requiring continuous and expensive repair and replacement. The surface of the ground around the structure is in a continuous process of settlement due to the percolation of water through it and to the washing out by this water of the finer particles of soil. On account of the difficulty of obtaining complete and intact sheet-pile water cutoff walls, frequently extensive washouts and undermining occur in this character of structure.

Blocking, Shores, and Fittings. Keel blocks are provided on the center line of the floor and consist of heavy dimensioned hardwood timbers. They should be so laid out as to afford sufficient bearing to avoid undue crushing under the maximum weight likely to be brought upon them. In American practice they usually consist of three or more tiers, placed transversely of the dock on 4 to 2 ft. centers longitudinally. Heights of blocks above floor should not be less than 3-1/2 to 4-1/2 ft. to give clearance for working under a ship.

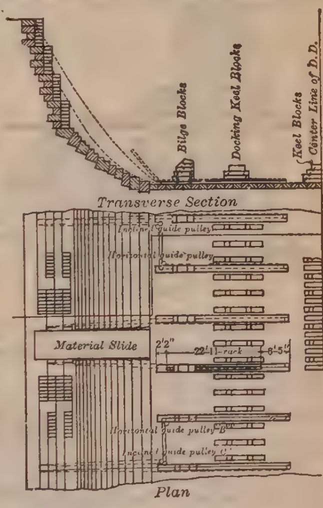

Fig. 50. Arrangement of Blocking

In European practice the lower blocks are often of cast iron, sometimes wedge-shaped, to permit ready removal. The lower course is fastened to the floor by anchor bolts, and the upper course, if of timber, by iron dogs. In addition to these blocks, bilge blocks are provided on both sides of the keel blocks, but placed at longer intervals apart. Some of the larger modern ships, especially in the naval service, are provided with four docking keels, two on either side of the center line, so that in being docked the ship will come to a horizontal bearing on central keel and side docking keel blocks, avoiding the expense and delay of holding the graving dock while blocking is being rearranged to fit the hull of the particular ship to be docked. When docking, keel blocks are not employed. bilge blocks are used, consisting of several tiers of blocks, the upper one slightly inclined or hinged to the block below and provided with a wedge. These blocks slide on bilge block bearers placed transversely of the dock. They can be drawn in under the ship and against the bilge by means of hauling chains, cast-iron racking being placed on the bearers and adjustable automatic pawls attached to the lower bilge block, holding the block in place when it has been drawn under the ship. These pawls are lifted and the block released when the hauling-back chain is employed. The docking keel and bilge-block bearers are sometimes made of reinforced-concrete, or entirely done away with, the cast-iron racking being fastened directly to the floor of the structure. Fig. 50 shows a half cross-section and floor plan giving position and arrangement of blocking.

Shores are used with, or to replace bilge blocks, to hold a vessel upright when the graving dock is unwatered. They bear against the vessel's side at frames and are wedged against the walls, rest on the altars, or are suspended from the coping by lines, for which purpose small cleats are placed at convenient distances. In order to assist in bringing and holding the vessel to alignment in position over the blocking, brest lines are employed, final adjustment often being made by block and tackle, for which small hand winches are installed at convenient intervals along the top of the dock wall.

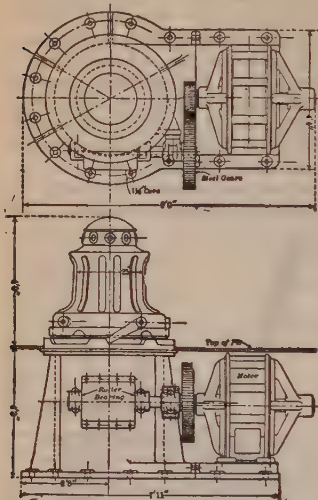

Fig. 51. Electric Capstan

Capstans and Bollards. As it is impracticable to place ships in graving docks under their main engine power or by tugs, power capstans are very often provided for this purpose. In smaller docks hand capstans are employed, assisted by windlasses on the ship being docked. On large graving docks, power capstans should be provided at the head end of the dock on either side of the entrance and in long structures midway of the length. These should have two speeds, the maximum for slow hauling from 15 000 to 35 000 lb. at the capstan barrel, the minimum is used for overhauling lines so as not to permit too much slack and possible snarling. Bollards or mooring posts are placed on both sides at intervals of about 50 ft.

Figs. 51 and 51*a* show an electric-motor-driven capstan of the latest type. Fig. 51*a* is designed with barrel height so as to permit the passage over it of the heavy dry dock traveling cranes.

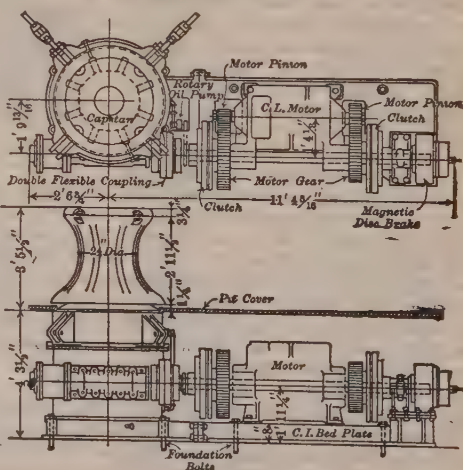

Fig. 51*a*. Electric Capstan

28. Construction of Graving Docks

As graving docks are always located on the foreshore of harbors, the problem of construction has an important influence on design. With the increase in draft of vessels and the necessity for providing for overdraft in case of accident, the clearance depth over entrance sills of graving docks has increased greatly and with it the head of ground or sea water to be taken care of during the construction period.

In certain locations it becomes impossible or impracticable, within the range of ready execution, to construct graving docks by any method involving the unwatering of the site. When such cases occur, recourse must be had to a method of construction that will make the unwatering of the site unnecessary. As the method of construction is an important item in graving dock design, it is well worth while to illustrate various methods that have from time to time been employed.

The usual course followed in the construction of timber graving docks is illustrated in Fig. 52 where (*a*) indicates the original conditions of the site. The entire site is surrounded by a wall of sheet piling, a portion of the round piling being driven previous to excavation; (*b*) shows the excavation, in part completed; (*c*) illustrates the driving of the round piling on the side slopes and in the bottom, and of the bottom enclosing sheet piling; and (*d*) shows the work completed. This method was generally followed in the construction of two timber dry docks built in the New York Navy Yard, and two similar structures built in South Brooklyn, N. Y.

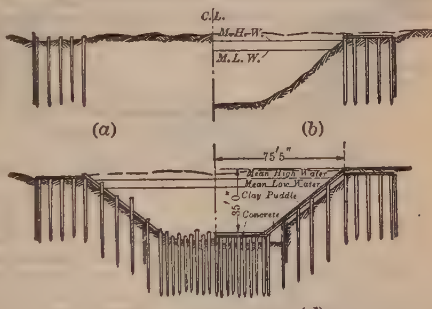

Fig. 52. Timber Graving Dock

Dry dock for Port of Boston: The method of construction for this dock is illustrated in Fig. 53. The structure is located on ledge rock, covered with a blanket of soil under water. On either side and around the head of the dock double timber bulkheads were placed, filled in with excavated material. The steps of construction (*a*), (*b*), (*c*), (*d*), are shown, (*b*) with the space between bulkheads filled and excavation made to ledgerock; (*c*) excavation in ledge rock; (*d*) completed structure backfilled. In this design the side-walls are retaining walls, the floor or bottom is shallow, and is underdrained, so that the underside of the floor is not subjected to hydrostatic pressure.

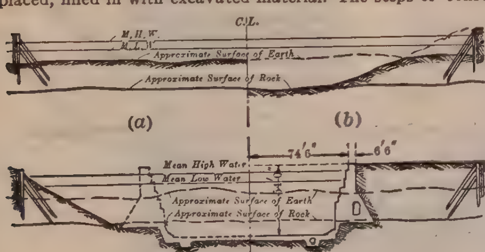

Fig. 53. Graving Dock, Boston, Mass.

Naval Dry Dock at Charleston, S. C., was located on a salt marsh, with underlying marl foundation. The entire site was surrounded with heavy sheet piling, held in place by timber trestle work, brace piles, and shoring, as illustrated in Fig. 54. The final excavation into the marl is shown in (*c*), and completed structure in (*d*). The method employed in making the excavation for the structure was: the first 10 ft. were taken out by hydraulic dredging, the remainder of the excavation in the marl being taken out by clamshell buckets operated by cableways and by pick and shovel and blasting. Cofferdam around the entrance to the work is illustrated in (*e*).

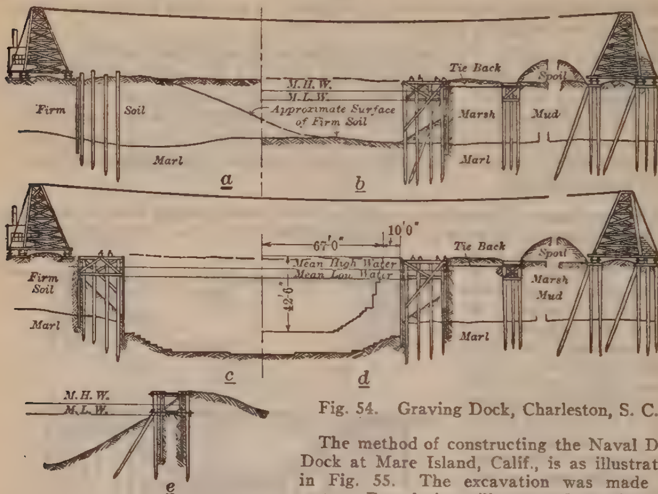

Fig. 54. Graving Dock, Charleston, S. C.

The method of constructing the Naval Dry Dock at Mare Island, Calif., is as illustrated in Fig. 55. The excavation was made in water. Foundation piling was then driven in the bottom and the timber crib of the general dimensions of the structure, built up on the surface of the water, loaded, and lowered until it rested on certain of the foundation piling, as shown in (*b*). Timber sheet piling was then driven around the

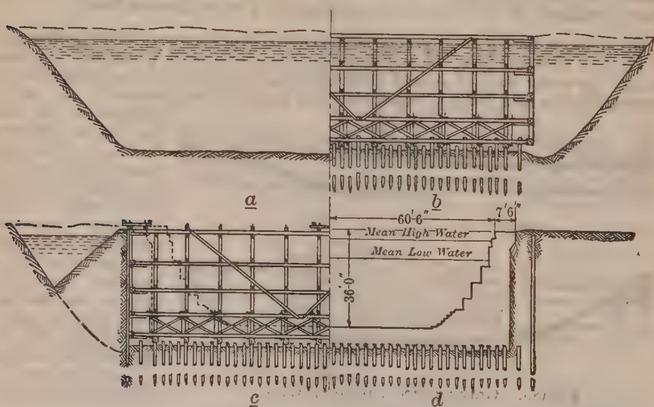

Fig. 55. Graving Dock, Mare Island, Calif.

crib work and then backed up with earth, as shown in (*c*). The interior of the crib was then pumped dry and the structure completed as illustrated in (*d*).

The side-wall, or English plan, is illustrated in Fig. 56. This method has been used with success, in the construction of some European graving docks, (*a*) illustrating the preliminary step of driving sheathing and excavating a trench for the side-walls; (*b*) completion of this trench and driving of the side-wall foundation piles; (*c*) the completion of the side-wall and the excavation of the interior or "dumpling," and the driving of the interior foundation piles; (*d*) completion of the work. In this method of construction there is a tendency for the side-walls to be thrust or move inward when the interior of the "dumpling" is removed. The floor work should be constructed in sections, or heavy bracing placed between the wall work pending completion of the bottom. A modification of this method was employed in the preliminary attempts at construction of Dry Dock 4, Navy Yard, New York, but failed, the uncompleted side-walls being thrust in.

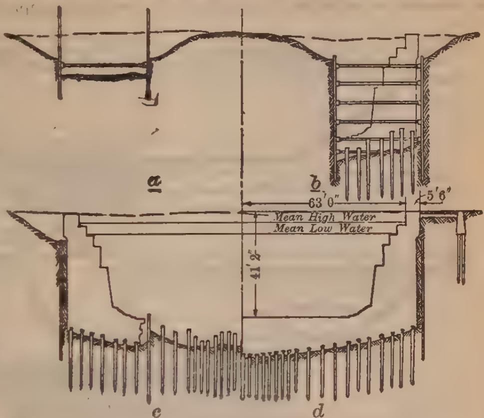

Fig. 56. Graving Dock Construction, English Trench Method

The dry dock at the New York Navy Yard was constructed by the method illustrated in Fig. 57. This dry dock was located in water-bearing quicksand soils. Open excava-

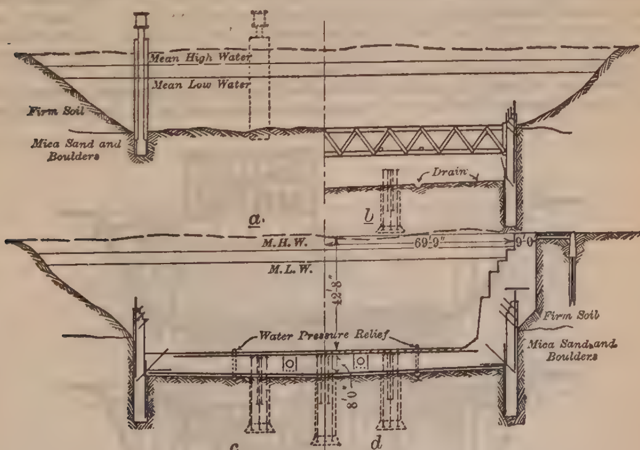

Fig. 57. Graving Dock, New York

tion was made by steam shovel to the quicksand. The entire site was then surrounded by a reinforced-concrete cutoff wall, placed by pneumatic process. The excavation of the interior was then made, bracing being placed between cutoff walls, as illustrated in (*b*). Interior rectangular piers or anchors were placed by pneumatic process. The floor was then built in 20-ft. sections, entirely across the structure, as shown in (c). Side-walls were then built up and the structure backfilled.

At Kobe, Japan, the character of the site was such that after an unsuccessful attempt to construct in cofferdam in the dry, it was decided to employ a method not requiring

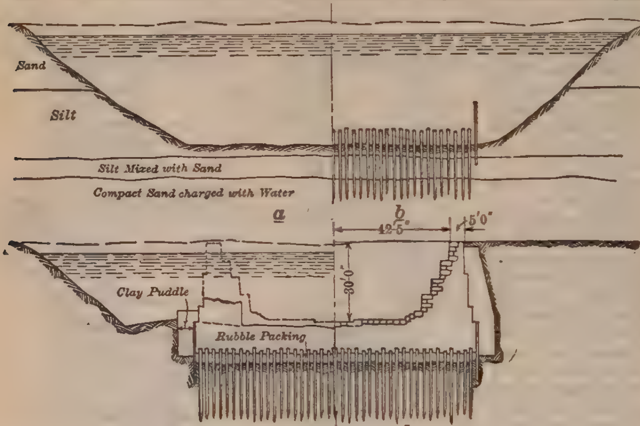

Fig. 58. Graving Dock, Kobe, Japan

the unwatering of the site. The plan followed is illustrated in Fig. 58. Excavation was made in water, as shown in (a), and piling then driven as shown in (b). Concrete was then deposited by skips and buckets under water, as illustrated in (c). Upon completion of placing of the underwater concrete up and above elevation of high water, the structure was pumped out and interior lining placed, as shown in (d).

A somewhat different method of construction proposed in connection with another dry dock is illustrated in Fig. 59. Excavation made under water, foundation piling

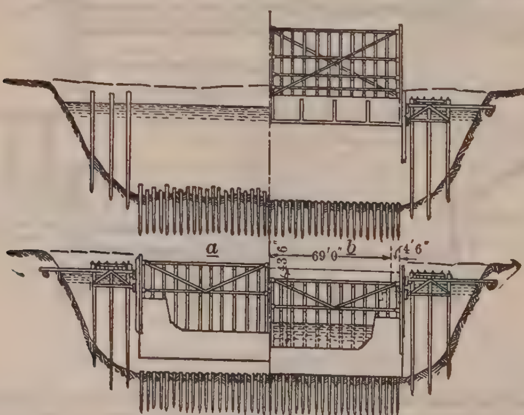

Fig. 59. Construction Employing Floating Caissons

driven as shown in (*a*), the foundation piling then cut off under water to grade, and the graving dock structure built in sections by means of caissons lowered to place, as illustrated in (*c*) and (*d*), in a somewhat similar manner to the method employed for breakwater and quay wall construction. See Arts. 3 and 15.

The above method was proposed for the construction of the Pearl Harbor, Hawaii, Navy dry dock. In the construction of this dock the general principle was used, but the 16 sections were constructed on a floating dock, and then by lowering the floating dock a steel tank cofferdam was floated over a section and bolted to it. The floating dock was then lowered and the whole section floated to place, the tank cofferdam flooded and the section lowered, the side-walls and bottom of the section built complete in the cofferdam, the tank cofferdam then floated by removing water from the tank, and then floated away and placed on the next section and so on. Space between sections was closed by concrete deposited in tremie.

Tremie Concrete. In view of the difficulty, at times, encountered in unwatering to permit construction in the dry, it is sometimes desirable to place concrete under water. This may be accomplished by the use of bottom-dump buckets or tremies; care must be exercised that the cement is not washed away from the fine and coarse aggregate. This is best accomplished by confining the concrete within forms and depositing it within the form in one continuous operation. In tremies, 12-in. pipes are found satisfactory. The operation is started by inserting a plug (usually a sack of straw) inside the tremie pipe and filling the tremie hopper above with concrete, the lower end of the tremie pipe resting on the bottom, being raised slowly as the concrete flows out. Care must be taken to exclude the outside water from entering or breaking through the flowing concrete. More than one pipe may be used in placing, but they should not be spaced more than 20 ft. apart, allowing a 10-ft. radius for the flow of the concrete. See Sect. 11, Arts. 9 and 10.

29. Gates and Pumping Plant

Caissons or Gates. Graving dock gates are, in many respects, similar to lock gates, description of which will be found in Sect. 15, Art. 19. In American practice caissons are more often employed for closing entrance to graving docks, and are usually box- or ship-shaped structures which are flooded and sunk in place at the seat, the removal of water from the interior of the dock

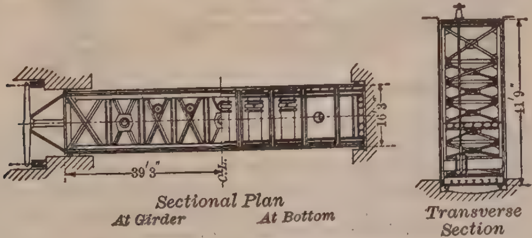

Fig. 60. Entrance Caisson, Sliding Type

drawing them up against the seat. When to be removed after the graving dock has been flooded, they are pumped out and hauled or towed to one side. The sliding types of caisson for which in connection with the dry dock structure a recess is provided at the entrance, is moved across the entrance by a hauling device, and returned to its recess in a similar manner, an illustration of which is shown in Fig. 60. This is the favorite type in English graving dock practice and it is employed for the entrance of the Quebec graving dock. The removable type of caisson is rectangular or ship-shaped, as shown in Fig. 61, or hydrometer-shaped, as shown in Fig. 62, the second type having a contracted

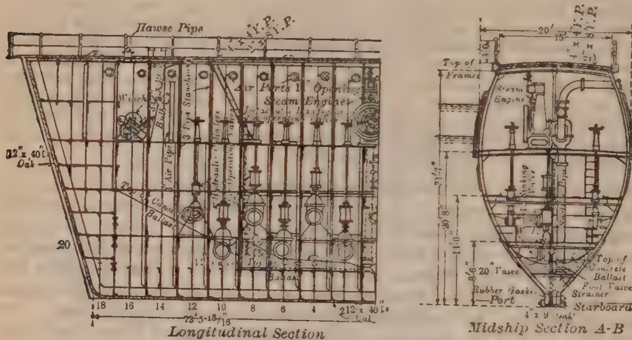

Fig. 61. Ship-Shape Caisson Gate

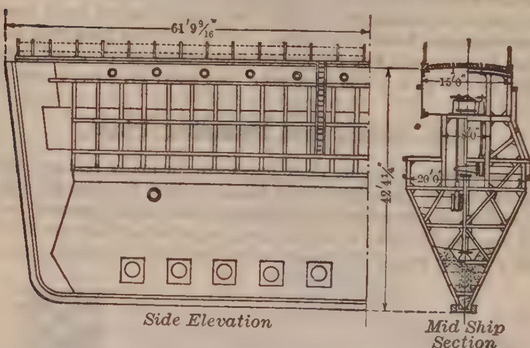

Fig. 62. Hydrometer-shape Caisson Gate

section for a depth of 6 to 12 ft. at the water line, to permit more rapid raising and lowering when being pumped out or flooded. Or the caisson may be of the rectangular or fin keel type. Where the caisson bears on the sill, water is excluded by either depending on the close fit of a timber meeting piece, or on rubber or hemp gaskets. To resist water pressure the caissons are built and designed with a series of interior horizontal girders or a main horizontal girder at about low water elevation, with the frames acting as a vertical beam. When one of the types of ship-shaped caissons is in place and the graving dock pumped out, the lifting effect of the exterior water is only active on the surface of the caisson in contact with water, so that the buoyancy at such time is somewhat over half of that of the caisson when floating. However, in nearly all cases the dead weight without the water ballast is not sufficient to hold the caisson in place under these conditions. Where the proportion of the net uplift or buoyancy to the total horizontal water pressure on the gate does not exceed 20%, the gate will not need special anchors. Hand- or power-driven capstans are usually installed on the caisson, at both ends, besides the pumping plant for raising the caisson. Caissons of this type being floating structures, care must be taken in the design to assure proper stability under all conditions, and for that purpose it is necessary to make the calculations and curves transverse and longitudinal showing displacement, center of gravity, center of buoyancy, contained water, and metacentric heights under various conditions, especial attention being given to the effect of the contained free water during flooding and lowering. On completion of the caisson these calculations should be checked by inclining experiments.

Modern practice in building caisson gates is departing somewhat from orthodox ship construction and is instead more and more following bridge practice. This tends toward economy, inasmuch as the trusses within the caisson are made to withstand primarily the water pressure, when the gate is in position, and the dry dock empty, whereas the stresses encountered in the ship construction become secondary in the case of the caisson gate, as its seaworthiness is a secondary consideration. Rivets in the shell plating need not be countersunk except on the outside to facilitate calking, and ordinary bridge practice of button heads is followed.

Fig. 62*a* shows a caisson gate of rectangular box type.

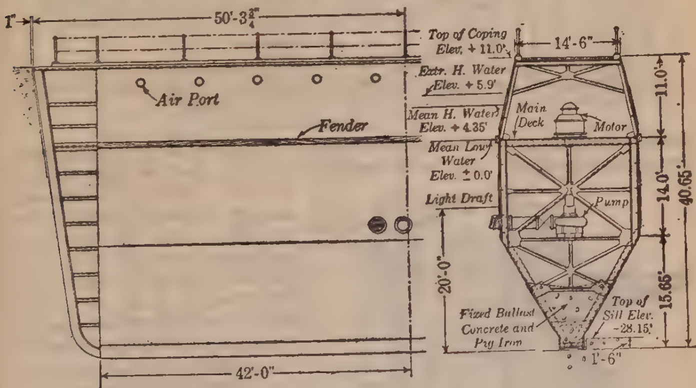

Fig. 62*a*

Pumping Plant. A graving dock is freed of water by a power pumping plant, electricity or steam being generally used, the selection depending upon the special conditions obtaining in the locality. The plant should be divided into two or more units, so that in case of a breakdown it would be still possible to operate the graving dock. The units employed have usually been vertical or horizontal centrifugal pumps and should be of such combined capacity and design that the dock without a ship in it will be unwatered by the entire pumping plant in from 1-1/2 to 2-1/2 hours. More recent practice in dry dock pump design, has employed pumps of screw or spiral type. The water head at the beginning of the pumping will be zero, the power being used up in friction and in velocity head, so that the pumping plant must be designed for the especial conditions in order to obtain overall efficiencies of over 50%. It is usually impossible to remove the last 2 ft. of water over the floor by these main pumps, the blocking and block bearers holding back the water so as to result in a surging effect in the drainage forebay. Where possible, main pumps should be

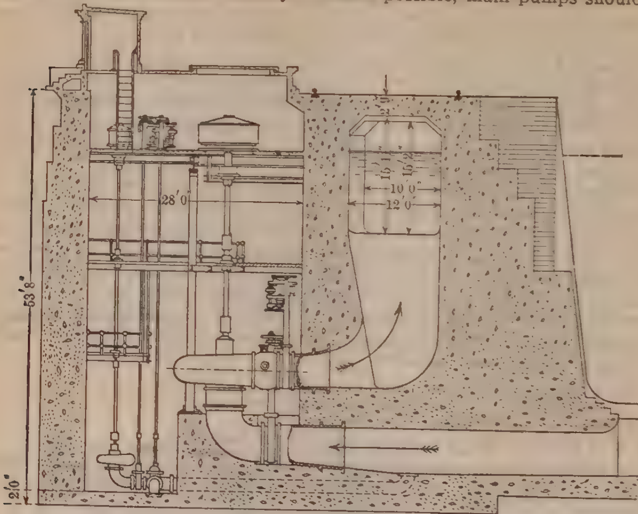

Fig. 63. Pumping Plant

placed low enough and with intakes so arranged as to postpone as long as possible this surging effect. For finally freeing the graving dock of water and for regular drainage purposes, smaller drainage pumps are provided. Fig. 63 shows a sectional elevation of the graving dock pumping plant for Dry Dock 4, at the New York Navy Yard; there are 3 main pumps and 2 drainage pumps.

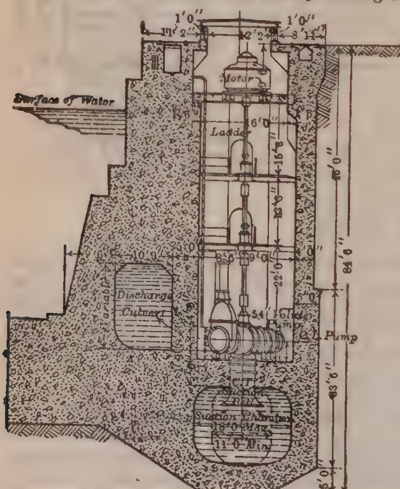

Fig. 63*a*. Cross-section of Pumping Plant, Philadelphia, Pa., and Norfolk, Va.

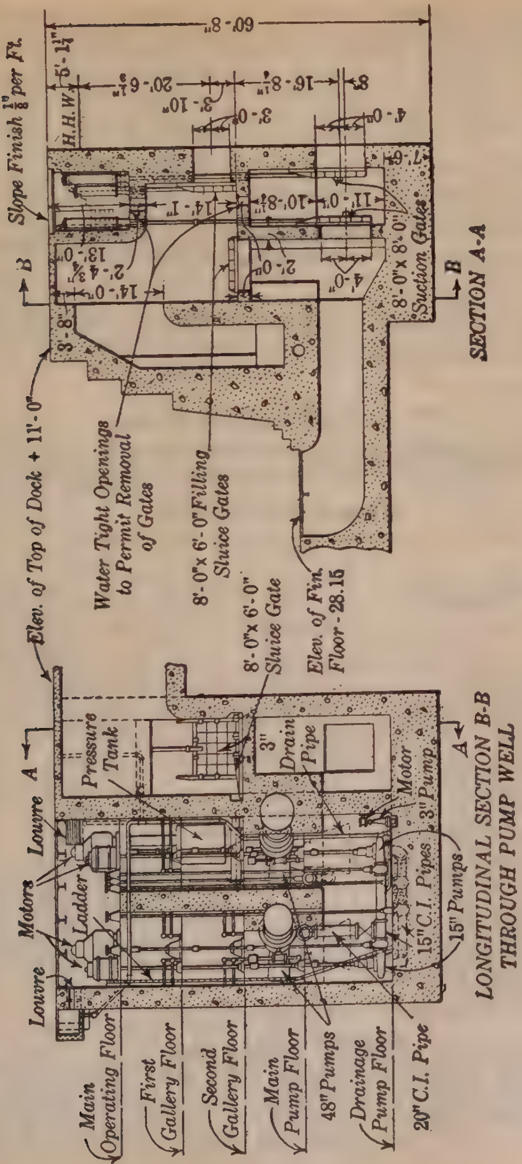
Fig. 63*a* shows a sectional view of the graving dock pumping plant for the dry dock at the Navy Yard, Philadelphia, Pa. There are three 54-in. electric-motor-driven pumps. The same general type of pumping plant is employed at the Navy Dry Dock in the Navy Yard, Norfolk, at the State Dry Dock at Boston, Mass., and the Balboa Dry Dock at Panama.

Fig. 63*b* shows a transverse and longitudinal cross-section of a pump well and plant. The well was built and placed as an open caisson. The main pumps are screw or spiral in type.

In the design of the main pumping machinery, the work to



SECTION A-A

LONGITUDINAL SECTION B-B THROUGH PUMP WELL

Fig. 63b

be done by the entire plant is obtained by the total volume and weight of water contained in the graving dock at high tide; the product of this weight by the distance between its center of gravity and the elevation of water surface at high tide will give the work done. The required capacity of the pumping plant may then be obtained by dividing the product by the number of minutes in length of time allowed for pumping out the dock, and in the same way the required motor horsepower obtained by assuming a 50% efficiency. It is customary to employ constant-speed motors.

Flooding of the structure is usually accomplished by flooding valves installed in the entrance caisson or by sluiceways and gates making connection with the sea or by both. These should be designed so that the structure can be flooded within 1 hour. On account of the location of the flooding gates in the lower part of gate caissons, frequently under certain conditions considerable sediment is carried into the dock by this method of flooding, so that sluiceways and gates, connecting to tide water at a higher elevation, are often more desirable. When of large area, they also make more rapid the final leveling of water in the interior and exterior of the graving dock, and make possible a more expeditious removal of the entrance caissons.

30. Cost of Graving Docks

The Cost of Graving Docks varies between wide limits, depending, as it does, upon the character of foundation, dimensions of the graving dock, partic-

Masonry Graving Docks

No.	Location	Built		Length, ft.	Cost		
		Begun	Finished		Total	Per running foot	Per ton, max. ship docked
1	Boston, Mass., N. Y. # 2	1899	1905	748	$1 100 000	$1470	$28.80
2	Charleston, S. C., N. Y. # 1	1902	1908	575	1 250 000	2170	36.80

ularly the usable depth and the kind of material employed in its construction. In masonry dry docks the lining of the structure with stonework, particularly granite, will add considerably to the cost. Excluding land value, timber graving docks have cost between $700 and $1200 per running foot of dock, and masonry graving docks between $1500 and $7000 per running foot of dock.

The cost per ton of maximum size ship that can be docked was obtained by taking the product in feet of the usable length, allowing 5-ft. clearance; the width of entrance at 1 ft. above blocks, less 2-ft. clearance; and the depth to top of blocks or 6 in. over sill at high water, dividing this by 35 to obtain long tons and taking 0.7 of this as a probable block coefficient. The following numbers refer to the table just given:

(1) Founded on blue clay and gravel and is built of concrete lined with granite.

(2) Founded on stiff marl, is of concrete lined with granite.

(3) Founded on piles driven in soft clay. Built of concrete with granite sills and entrance.

(4) Founded on reinforced-concrete surrounding walls and interior pedestals placed by pneumatic caissons in fine running mica sand and built of reinforced concrete lined with vitrified brick, granite sills and entrance.

(5) Founded on piles in clay and marl. Built of concrete, granite lined. This dock, after completion, was extended in length.

(6) Founded on piles driven in sand and gravel. Built of concrete, granite sills and entrance.

(7) Founded on ledge rock, concrete lined with granite.

(8) Founded on sand, gravel, clay; concrete and granite.

(9) Founded on ledge rock, concrete, granite, entrance sills, coping and steps, intermediate seat dividing dock into two sections when desirable, side-walls lined with granite. Actual cost in excess of that given by perhaps $500 000 on account of war conditions.

(10) Founded on rock, concrete with granite altars and entrance, sills, sliding caissons at entrance.

(11), (12), (13) These docks founded on so-called marl containing much shell detritus at entrance and blue clay. Concrete laid directly on marl and clay except at entrance to Docks 6 and 7, founded on timber piling.

(15) Cost and delay due to collapse of earlier work and fact structure was built in 16 sections as floating caissons. Foundation, coral rock, mud lava.

(16) Cost due in part to war construction, and also heavy water flow through open gravel on which the structure rested.

(17) Replaced older dock on same site. Cut out of soft serpentine rock by hydraulic dredge and rock lined with concrete.

The cost of graving dock appurtenances, although independent of foundation conditions, bears some relation to the character and size of the structure. Electric power capstans, including foundations, depending upon size, have varied from $7000 to $9000 each, and the pumping plant from $40 to $70 per motor or engine horsepower. Caisson gate costs will be a function of the width and depth of the entrance and, in general, will vary as the product of the square of the width and the square of the depth.

The upkeep and maintenance cost of the body of masonry graving docks is small and should not exceed 0.25% per annum. The upkeep cost of graving dock appurtenances varies with the character of the same, the cost of repair and replacing of blocking being high and, to some extent, dependent upon the frequency of use, and may be taken at from 10 to 15% of first cost, per annum. The upkeep cost of caisson gates is, in general, similar to that of the hulls of steel vessels and may be taken at from 3 to 5% per annum.

31. Floating Dry Docks

Definition. A floating dry dock is a structure of wood, wood and steel, steel, or reinforced concrete, capable of being submerged by the admission of water to its interior compartments, at which stage, if desired, a ship is floated into position; the structure is then raised by the removal of water from its interior compartments by pumping, or other means.

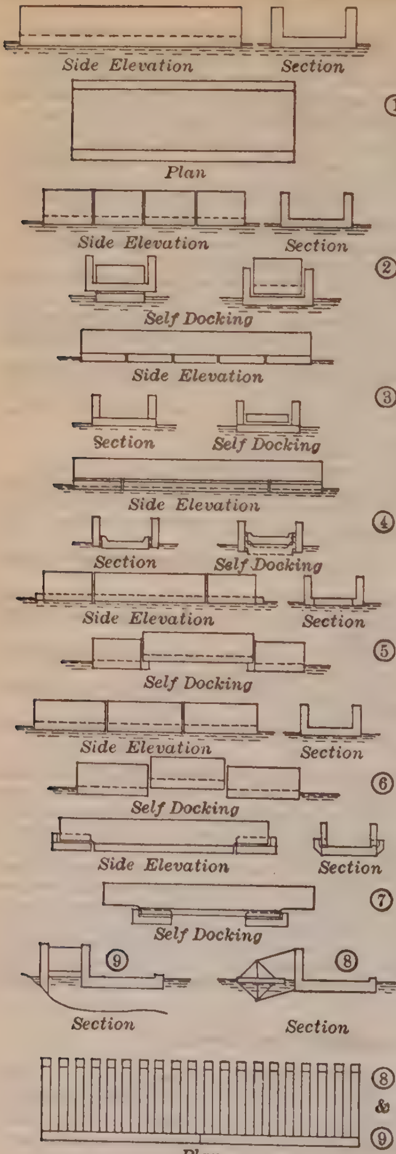

Fig. 64. Types of Floating Docks

Relative Advantages. Lower first cost, less time to complete, less operating expense in pumping, and the fact that it is a movable property, are claimed as advantages for floating docks as compared to graving docks.

The comparative first cost is entirely dependent upon the type of the floating dock and the location of the site available for the graving dock. Under the most favorable conditions for graving dock construction, the time consumed in the construction of a floating dock is somewhat less than would be the case with a graving dock. A graving dock has the advantage of permanence, more rigidity, less danger of accident, less expensive maintenance and repair, and less annual charges on account of its greater length of life. The selection of the type of structure is entirely dependent upon local conditions and requirements.

Types of Floating Docks are shown in Fig. 64: (1) The simplest type of floating dock is the solid trough type of timber or steel. It has the advantage of simplicity, of longitudinal rigidity, with the disadvantage that it must be built in its entirety intact, and can not be self-docked for repairing, cleaning, and painting.

(2) Sectional docks consist of a number of solid trough sections or slices of Type (1), and are constructed of such length that any one section can be docked, as shown, by one or two other sections. The sections are connected together by locking logs which hold them in alinement, but are not intended to furnish longitudinal rigidity for the entire structure. The operation of the dock usually requires skill and care in order that each section may take the load directly above it, the buoyancy of sec-

tions being adjusted by the amount of water pumped from them. This adjustment of weights, however, is not always necessary. With ocean-going vessels, the vessel itself is designed with sufficient longitudinal girder strength to distribute inequalities of load, unless the hull structure has been seriously injured, in which case the vessel should not be docked on a sectional type of floating dock. This type of structure is a favorite type in timber, especially for commercial use; on account of its low first cost and its flexibility, additional sections can be added, increasing the length of the dock.

(3) The Rennie type consists of continuous side-walls forming girders for longitudinal rigidity. These side walls rest on, and are fastened to, a series of pontoons of such dimensions that one or more pontoons may be removed from under the side-walls and lifted for repair by the remaining structure. Docks of this character are built with steel walls and timber pontoons, or entirely of steel.

(4) In the Clark and Stanfield type the side-walls are continuous and extend to practically the full depth of the structure, the pontoons being fastened between the side-walls, the fastening consisting of fish-plates and bolts. Pontoons can be self-docked; repair, cleaning and painting of side-walls being performed by careening of the entire structure. The side-walls being deeper than in the Rennie type, more rigidity is secured. Disconnection of pontoons for self-docking and repair is complicated. This type of dry dock is usually constructed of steel. The Havana dock now in commercial use in New York harbor, and the Naval dock at Algiers, La., are constructed on this principle.

(5) The Pola type is a sectional dock consisting of three sections each a solid trough. The central section is of about the same size as the two end sections together. The sections are connected together for longitudinal rigidity, which connection, however, is complicated. The central section is locked by the two end sections by means of a projection on each. The end sections are docked by the center section.

(6) The Cunningham Sectional type of dock is, in many respects, similar to Type (1) Sectional dock, but consists of larger sections, provision being made for joining the sections together by fish-plates and bolts. Self-docking is accomplished by raising one section with two other sections.

(7) The Maryland Steel Company type consists of a main pontoon of solid trough section with side-walls extending beyond its length and carried on two shorter end pontoons having low independent side-walls for stability in self-docking operations. In self-docking the two end pontoons raise the central section and the two end pontoons are in turn raised by the center section. This type is constructed in steel. The Naval dock "Dewey" at Olongapo, P. I., is of this type.

(8) The Single Side Wall type consists of one rectangular side-wall and pontoon or a series of sectional pontoons. On the other side of the wall is provided a shallow pontoon with vertical members and series of two parallel members pin-connected to the vertical members and to the side-wall of the dock. The purpose of this pontoon is to afford stability and hold the structure upright when raising or lowering.

(9) The Off-Shore type is similar to the Single Side Wall dock, but the vertical member is fixed directly on shore, the pontoon being done away with.

Types (8) and (9) can both be constructed with openings between pontoons so that the vessel after being lifted can be deposited on a separate floating structure or fixed platform, so that while the ship is undergoing repair the dock is ready to lift another vessel and is then known as a Depositing Dock. Neither of these types is in extensive use.

In the Burgess sectional dock the side-walls are replaced by an open framework in which slide ballast pontoons, which always remain on the surface and give stability to the structure. A structure of this character was built of timber in New York Harbor, but is not now in use.

The Camel type, as shown in Fig. 64*a*, consists of a one-piece rigid trough, closed at one end and having a gate similar to lock gates at the other end. The ship enters the dock, is partially lifted by removing the interior water, the gates are then closed, and the water inside the trough removed by pumping. This dock has the advantage of longitudinal rigidity, but it cannot be self-docked for repairing, cleaning and painting.

Location. Floating docks require considerable depth of water for their operation, this depth being fixed by the draft of the maximum ship to be docked, height of blocks, clearance of blocks to keel of ship, depth of floating dock pontoons, and the allowance under the dock for clearance and for filling up. The requisite depth must often be secured by dredging and the expense of dredging operations at such great depth is considerable. In many harbors, the excavation for deep floating docks will rapidly fill up. Provision must also be made for mooring the structure, which is usually done by placing it alongside a pier built for that purpose. When this is not done, approach piers to the floating dock must be constructed. A pier or quay is also necessary outside of the entrance to the floating dock to moor vessels while awaiting docking, or to assist in guiding the vessel into the floating dock. Such a structure is also necessary in connection with the use of graving docks. Sheltered locations are desirable for floating docks, this being more necessary on account of the difficulty of handling the dock in a high wind.

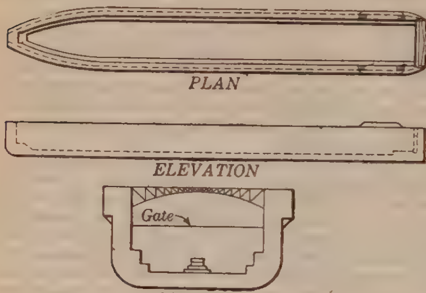

Fig. 64a

Data on Design. A floating dock must have sufficient transverse strength so that the excess buoyancy of the side-walls and the pontoons at the sides will be enabled to carry the concentrated weight of that portion of the ship supported on the central keel and side bilge-blocking, and also when floated light to carry the excess weight at the sides of the side-walls and the pumping machinery. The floating dry dock, when fully sunk, ready to receive a ship, is usually flooded with water to within a small distance from the position of the outside water. Especially with timber floating docks is this done. To guard against accidental over-flooding in the sinking of the dock, safety decks are often provided in the side-walls, above which the dock can not be flooded. When a ship has been placed in the dock and the operation of raising is commenced, the contained water is, as a rule, first removed from the side-walls. As the displacement of these side-walls per foot of lift is from necessity considerably less than the weight per foot of lift of the maximum-sized ship to be docked, the water is entirely removed from the side-walls when the ship has been lifted only a few feet; thus the maximum water pressure due to difference between external and internal water head occurs at the period when the side-walls have been emptied of contained water. The exterior sheathing or plating of the structure, beams, frames, and trussing must be analyzed for this condition of external pressure, which is illustrated in Fig. 65. In most floating dry docks this will not exceed 20 ft. of water head. This condition may be avoided by pumping from compartments of the pontoon directly under the ship, before removing all the water contained in the wing walls. It is to be borne in mind, however, that with a floating dry dock it is possible to raise partially out of the water a ship of greater displacement than could be lifted clear of the water, and for this reason it is often advisable to design the structure to withstand water pressure equivalent to the maximum submersion of the pontoon deck. In timber structures, as the timber is more or less constantly immersed, a reduction should be made in the allowable strength in tension, compression, and bearing. In steel floating docks, the practice of structural steel and steel ship design should be followed, the plating being considered as a continuous beam and not a catenary.

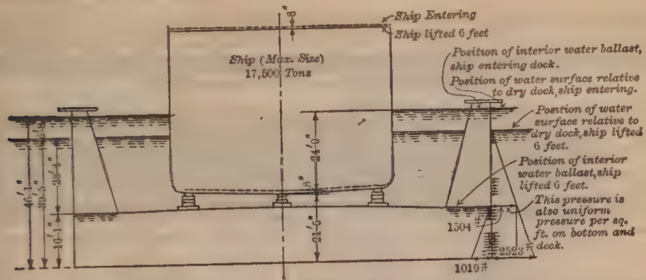

Fig. 65. Maximum Water Pressure on Dock

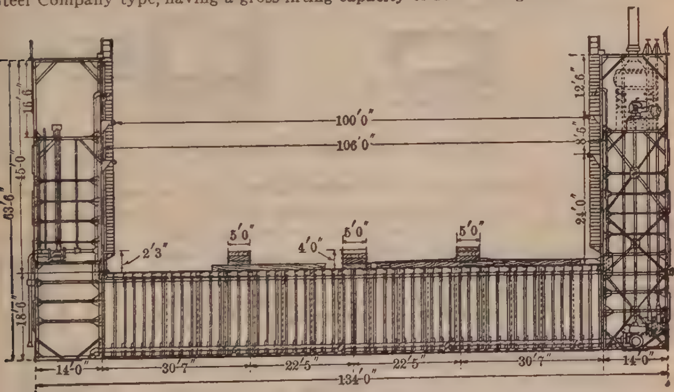
Fig. 66 shows a typical cross-section of a self-docking steel floating dock, Maryland Steel Company type, having a gross lifting capacity of 18 000 long tons.



Transverse Section

Fig. 66. Steel Floating Dock

Fig. 66*a* gives a plan, longitudinal section and cross-section, side and end elevation of a 45 000-ton steel floating dock of the bolted, three-section trough type (Cunningham) designed but not built.

Fig. 67 shows a half cross-section through one of the sections of a sectional timber dry dock, a type favored in commercial use on account of its flexibility, that is, the possibility of increasing its length and sizes by adding additional sections. The floating dock in question consists of 6 sections, each 80 ft. long, having a combined maximum lifting capacity of 18 000 long tons.

Fig. 67*a* gives a plan, longitudinal and cross-section and half end elevation of a 12 000-ton timber sectional dry dock.

Loading. The loading conditions to which a floating dry dock is subjected are dependent upon the method employed in removing the contained water from the structure. It is desirable, to some extent, to pump water from the various compartments so that the buoyancy or lifting effect will bear some relation to the load or weight of that part of the vessel directly above this

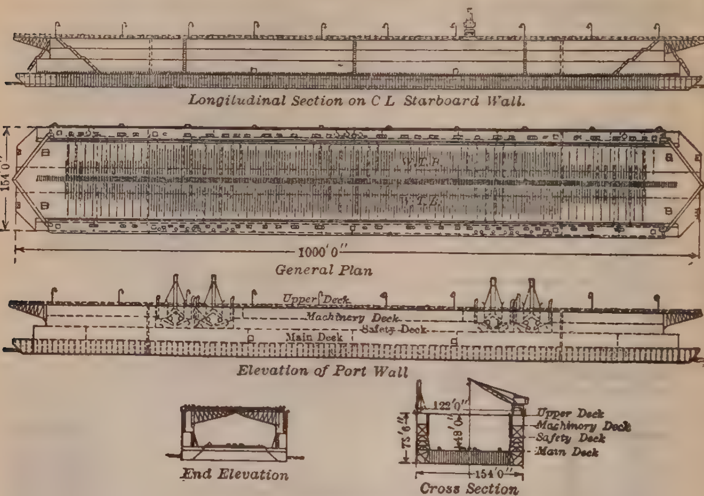


Fig. 66a. Cunningham 45 000-ton Dock

section of the floating dry dock. In order to obtain the maximum lifting effect of a floating dry dock, it is necessary to remove all of the contained water from the structure, with the result that the bending strain must be taken by the dock structure or the ship being docked. Consequently the manner of regulating the pumping and lifting dock and ship is of greatest importance, as it might readily be so operated as seriously to strain both ship and dock.

The Bending Moment produced in the ship and dock is shown graphically by Fig. 68: (a) showing the effect when lifting a long ship, (b) when lifting a short heavy ship, and (c) the method employed to decrease the bending moment by removing only a portion of the water from the end compartments. Fig. 69 illustrates the transverse loads to which a section of a floating timber dry dock is subjected.

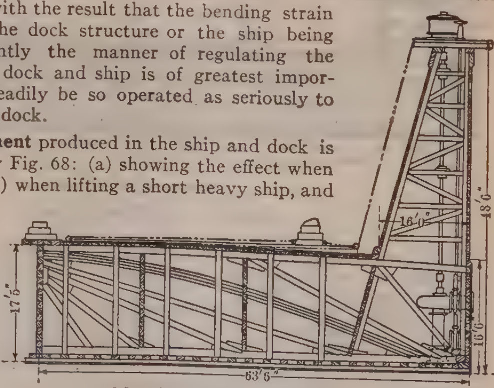

Fig. 67. Timber Floating Dock

Effective Capacity. The effective lifting capacity of a properly designed floating dry dock, whether of timber or steel, or a combination of them, will vary between 60 and 70% of the displacement of the pontoons. In general, it may be taken that one-third of this displacement will represent the dead-weight of the structure and the contained water that can not be re-

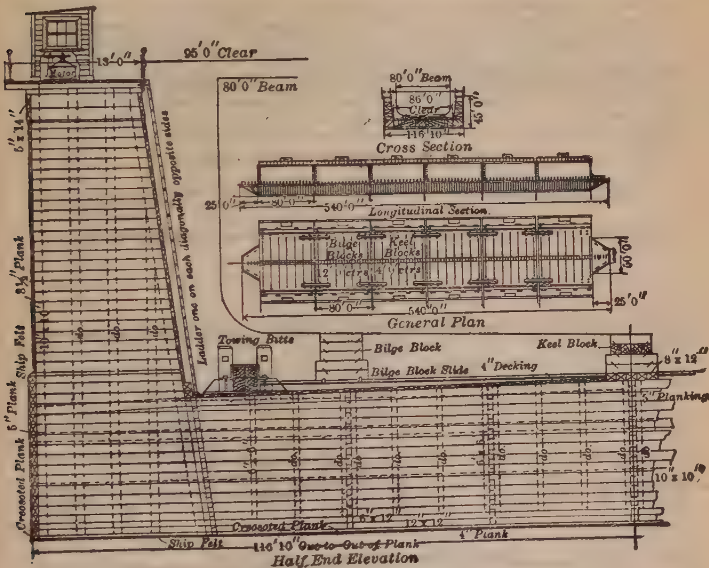

Fig. 67a. 12 000-ton Timber Dock

moved, and two-thirds will represent the effective maximum lifting capacity. In timber floating dry docks the buoyancy effect of the timber must be coun-

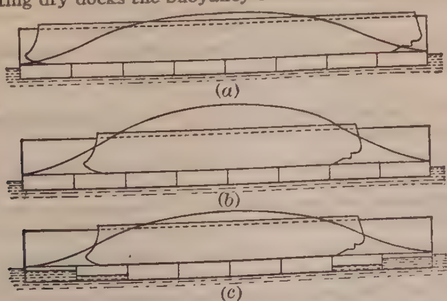

Fig. 68. Longitudinal Bending Moment

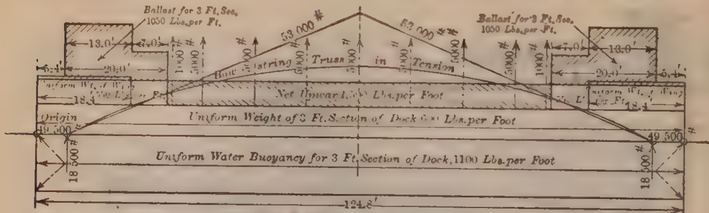
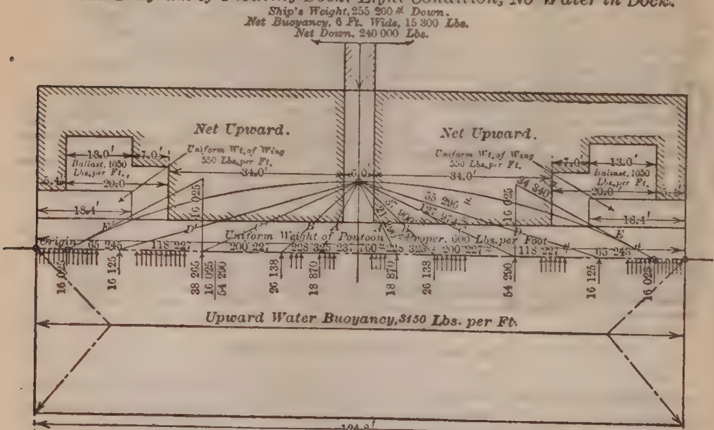
teracted by ballast, in which case proper allowance must be made for the reduction in weight of this ballast by reason of its submersion. Ballast is not needed in steel floating dry docks and usually is not necessary in floating dry docks of steel and timber.

Costs of Floating Dry Docks of different types can be given only approximately, as these are influenced by the varying costs of materials, size of struc-



Load on 3 Ft. Section. (One Frame)
Load Diagram of Floating Dock, Light Condition, No Water in Dock.



Load on 3 Ft. Section. (One Frame)
Load Diagram of Floating Dock, Full Load, Ship on Dock.

Fig. 69. Transverse Loads

ture, and location in which it is to be built. Such approximate relative costs may be taken as follows:

Timber solid trough type....................	$50 to $75 per lift long ton
Timber sectional type.	$48 to $70 per lift long ton
Timber pontoons, steel wing walls.........	$60 to $80 per lift long ton
Steel, sectional or solid trough..............	$70 to $100 per lift long ton

These costs are for the floating dry dock complete, but take no account of the cost of the necessary work required in connection with the operation of the structure, such as piers, approaches, dredging and other work. The variation given allows for differences in size and details and for location at which the floating dry dock is built, the higher figures for the steel structures being based on costs on the Pacific Coast of the United States.

The upkeep and maintenance costs of floating dry docks depend on the location and the materials employed. All timber floating dry docks have been in continuous use for 60 years, with only slight repair to them. In waters in which marine borers are prevalent, the exterior of timber pontoons must be protected by yellow metal, copper, tar felt covered with creosoted sheathing plank; or all planking must be creosoted. The interior of compartments will not require protection. The annual charge for upkeep of nine steel docks, as given by L. E. Clark, was 1.12% of first cost. Experience with such docks in warm climates indicates that annual upkeep cost will, in instances, exceed 3% of first cost. Steel structures in sea water require periodic painting to prevent undue corrosion.

32. Stability of Floating Docks

Stability. In order to secure the requisite stability against overturning when light or when lifting a ship, provision must be made for longitudinal and transverse watertight compartments. In a rectangular floating structure the general stability varies directly as the square of the number of watertight divisions. In timber floating dry docks, in most cases, the structure is divided into two transverse watertight compartments, additional longitudinal timber bulkheads being provided on either side of the central watertight bulkhead, but these bulkheads merely act as strengthening and swash bulkheads and do not materially affect the transverse stability. In steel floating dry docks four to six transverse watertight divisions are usually provided. The metacentric height is represented by

$$\mathbf{GM} = \frac{\mathbf{I - G\,B \times V - \Sigma i}}{\mathbf{V}}$$

in which I is the moment of inertia of the water-plane of flotation, $G\ B$ the distance between center of buoyancy and center of gravity, V the volume of displacement in cubic feet, and $\Sigma\ i$ is the summation of moment of inertias of interior contained water surfaces. Or the stability moment is

$$\mathbf{M_1} = \frac{\sin\theta}{35}(\mathbf{I - GB \times V - \Sigma i})$$

This calculation should be made for both transverse and longitudinal conditions, and it should be remembered that with a ship on the dry dock the stability of the ship must be taken into consideration, I, G, B, V and $\Sigma\ i$ of the formulas being the combined expressions for ship and floating dock.

In order to apply the necessary formula, diagrams, or curves should be available showing the characteristics of the floating dry dock under various conditions.

Fig. 70 gives an example which shows the curves of displacement, center of buoyancy, center of gravity, weight of contained water, and moment of inertia of exterior and interior water planes. Employing this and information as to similar characteristics of the maximum sized ship to be dry docked, curves can be drawn showing the metacentric heights at various drafts of ship and dock as is shown in Fig. 71, which is a typical case for a 12 000 long ton capacity Timber Sectional Floating Dock.

Imprisoned Air. When sinking a floating dry dock it is necessary to afford means for the escape of the imprisoned air. This is done by providing piping for air escape with connections at the upper parts of compartments, or in timber dry docks by providing air escapes directly through the deck.

Wind Effect. Sufficient stability should be provided so that with a maximum sized ship on the dry dock there will be no undue heeling of the structure due to wind action. The angle or heel of inclination θ is obtained from

$$\cot \theta = \frac{D \times G\,M}{A \times C\,L}$$

in which A is total pressure of wind in pounds, D is the displacement in pounds,

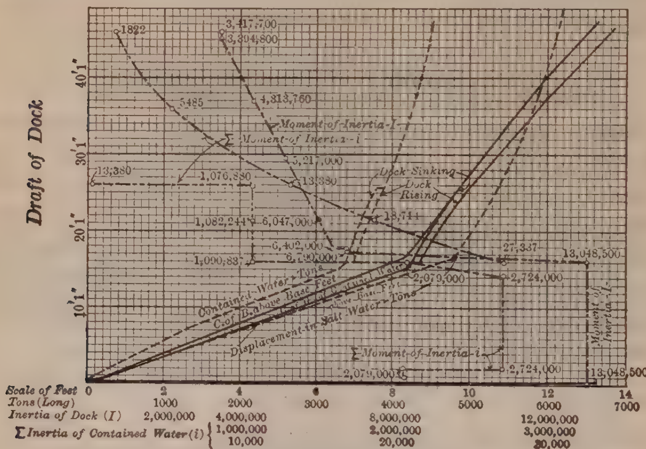


Fig. 70. Displacement and Other Curves

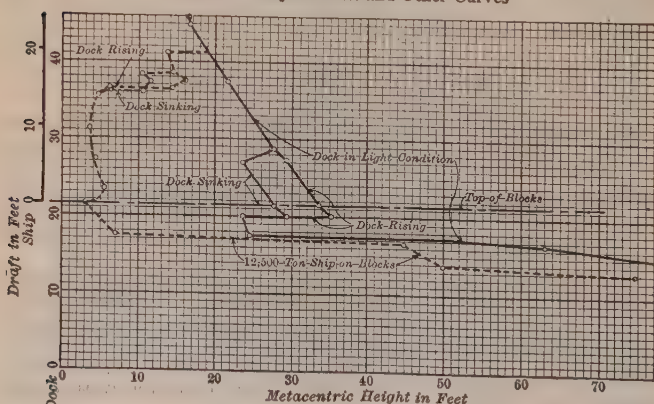

Fig. 71. Transverse Stability Curves

$G\,M$ is the metacentric height, and $C\,L$ is the distance between center of pressure and center of lateral resistance. A list in excess of 10 degrees is dangerous.

Pumping and Flooding Plant is so arranged that each watertight compartment can be controlled in pumping or flooding, independently of other compartments. In a solid trough dock, one or two main pumping plants are usually provided, on one or both sides of the dock, and connected to a pumping main, having a lateral connection to each compartment. Fig. 72 shows the general arrangement of such a pumping plant. Each section connection is controlled by direct-acting wedge-shaped valves, the valve rod being brought to one station by a system of bell crank levers, the dockmaster located at this station controlling the entire pumping of the dock. In sectional floating dry docks it is necessary to provide a separate pumping plant in each section. These may be driven individually or by means of continuous sectional shafting connected between sections by universal couplings, the operating power being either steam or electric. The most satisfactory system at present in use is electrically operated vertical shaft centrifugal pumps. In sectional docks, with two pumps in each section, one on each side of the structure, a cross-connection is often provided so that in case one pump should break down the section could still be operated by the other pump. This involves a longer time for pumping out and also serves to decrease the stability of the entire structure by decreasing the stability of one of its sections. The sinking by flooding is carried out by flooding valves or gates, leading to the various compartments, the dockmaster controlling this entire operation to insure even settlement without undue straining of dock or ship. Floating docks are often fitted with an indicator system to show in a central control station the depth of water in all compartments. An entirely satisfactory system has not as yet been successfully applied.

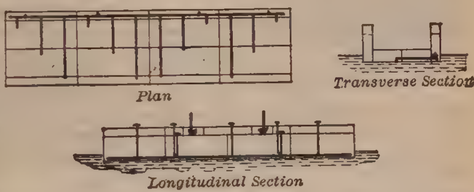

Fig. 72. Arrangement of Pumping Plant

It has been proposed to raise floating docks by compressed air, by removing the water from compartments by forcing air into them, and in a somewhat similar manner sinking by allowing this air to escape. While this has been tried experimentally on a small scale, it has not been successfully used in practice. The general idea has had some success when applied to raising sunken vessels by pumping air into the hull by forcing it into submerged cylindrical pontoons, made fast to the hull by chains or wire cables.

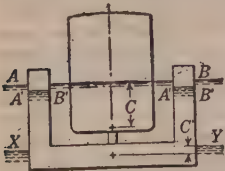

Fig. 73

Power Required in Operating Floating Dry Dock. The work done in raising a floating dry dock with a ship is directly proportional to the weight of the dock light and weight or displacement of the ship:

$$E = D \times c - D' \times c'$$

in which, as shown in Fig. 73, D is the displacement in pounds of ship and floating dock ready to lift, c in depth in ft. below surface of water of center of buoyancy of D, D' is displacement in pounds of dock or ship and dock wholly or partially raised, c' is depth in feet below surface of water of center of buoyancy of D', and E is the work in foot-pounds performed in raising the dock from position as shown by water line at $A - B$ with respect to dock to position as shown by water line at $X - Y$ with respect to the dock.

The necessary data for application of the formulas can be obtained from curves showing displacement and position of center of buoyancy of the ship and displacement of dock, weight of contained water and positions of center of gravity and center of buoyancy. The characteristics of the pumping plant can then be obtained by fixing on the time in which it is desired to raise the floating dry dock with a ship of maximum weight, usually taken at from 1 to 1-1/2 hours. The overall efficiency of an electrically driven centrifugal pump of the type herein described should be between 50 and 60%.

Fig. 74. Blocking

Blocking. The arrangement of blocking on a floating dock is in many respects similar to that employed in graving docks, and is shown in Fig. 74.

FERRIES AND SPECIAL WORKS

33. Ferry Racks

Ferry Racks. The landings or terminals for ferries consist of a slip with piles and fenders on each side called racks, transfer bridge, platform, and ferry shed. The racks are usually built diverging outshore, the inshore ends closely fitting the guard rails of ferry-boats. The racks consist of one or more rows or banks of piles with upper, lower, and one or more intermediate string pieces or wales on which are fastened vertical fender planking of oak, yellow pine, or some other hard wood. Where the ferry-boats are small or light, and the traffic infrequent, a single row of piles is used, the piles being spaced about 3 ft. on centers. The rack is stiffened at the inshore end by additional piles or clusters of piles, as this portion of the rack receives the principal wear and shock. The height of the rack is dependent upon the range of tide, as it is evident that the fender system must be of sufficient height, or depth, so that the guard rail of the ferry-boat, when loaded or unloaded, will never be below or above the rack. The wales are made up of several thicknesses of heavy planking or dimensioned timber, so as to be readily fitted to the required curve and are bolted to the round piles. The vertical fender planking is fastened to the wales by drift bolts or dock spikes at the upper and lower extremity. Ribbon pieces are fastened to the wales and through the vertical fenders by countersunk-head screw bolts. The upper ends of fender planking are sawed off at a bevel to shed water, and the tops of piles are rounded for the same purpose and often covered with canvas or zinc for protection against the entry of water and consequent rot. Frequently the fenders at the inner end of ferry racks are coated with heavy oil, or grease. In heavy ferry rack construction, two, three, or four rows of piles are employed, the piles in the rear rows being staggered, and the tops of rear rows are cut off at a lower elevation. In two-bank racks two or more wales are fastened to the back of the front high row and one or two heavy wales to the front of the second pile row, so as to transmit the shock of the incoming ferry-boat to the second row of piles, and if three rows of piles are used, the third row is also provided with wales of this type. The outshore ends or entrances of racks are usually constructed with a cluster of piles, driven a slight distance apart, and drawn together at the top, and lashed with wire cable fastened with staples, these dolphins or clusters frequently receiving the first impact of the entering ferry-boat, guiding the ferry-boat into the slip. Fig. 75 shows general arrangement of various types.

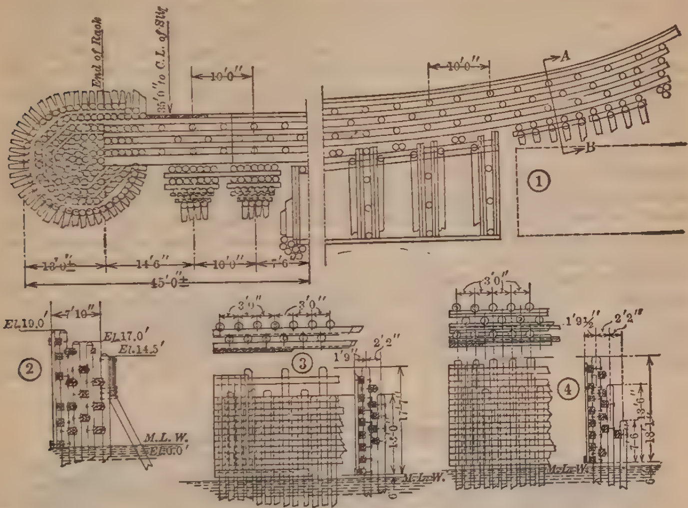

Fig. 75. Ferry Racks

(1) Plan of three- and four-bank rack for Municipal Ferry, New York City, 39th Street, Brooklyn.

(2) Typical section of (1). Front wales, two 6 × 12-in. Rear wales, three 4 × 12-in. Fenders, 5 × 12-in. white oak.

(3) Typical elevation, section, and plan of two-bank rack, D., L. & W. R. R. Passenger service.

(4) Elevation, section, and plan of three-bank rack, D., L. & W. R. R.

The work can be laid out by securing plans of the guard rails of various ferry-boats that are to use the slip, and from these making a plan showing maximum dimensions. Lay out the slip with racks fitting this plan and measure ordinates from and perpendicular to the center line to pile locations. Construct a light temporary platform along the slip and on this locate points on which batten ranges can be fastened, giving the transverse range of piles, the piles being located and driven by measuring out the proper distance on this range. All piles need not be so located, but piles every 10 or 12 ft. having been accurately located, intermediate piles can be driven in general conformity with the desired curve. The work can be laid out from a temporary platform or existing adjoining pier or structure alongside of the site of the ferry slip. A ferry-boat can be moored in place and governing dimensions obtained by driving piles at intervals against the guard rail or the templet used.

34. Transfer Bridges

Ferry Transfer Bridges should be of such length that at extreme tides, with maximum and minimum loading of ferry-boat, the gradient will be possible for traffic, the range being from low tide with heavily loaded boat having little freeboard to high tide with light load and greater freeboard. The outshore end of the bridge, when light, is usually carried by a pontoon, so that it will, at all times, float to about the elevation of the ferry-boat deck. For this adjustment of height the buoyancy of the pontoon is employed, sometimes with the assistance of counterweights fastened to the bridge by wire or chain cables, and carried up over sheaves mounted on an overhead frame. The final adjustment of height is made by hand or power-operated windlass fastened to the end of the bridge. The outshore end of the bridge is usually curved to fit the bow or stern of the ferry-boat, and is provided with heavy hardwood or iron toggles which can be moved out to rest on the deck of the ferry-boat, so that when the weight of traffic leaves the ferry-boat and moves on to the bridge, this weight, in excess of the buoyancy effect of the pontoon, is carried by the ferry-boat and not by the overhead gear. The inshore end of the bridge is supported on rollers, in roller chocks, supported on the platform, or is carried on heavy hinges on a rolling or sliding bearing fitted with car springs or rubber buffers to assist in taking up the shock of the incoming boat. The ferry-boat is secured to the bridge by means of two lines made fast to eyes or chocks on the deck of the ferry-boat, the slack in the lines being taken up by windlasses. The bridge itself usually consists of a platform suspended from two or four structural steel or timber trusses, a timber bowstring truss being frequently used. The overhead gear with counterweight should be of sufficient strength to support the outshore end of the bridge when unloaded, so that the pontoon may be removed when necessary for calking and repair. Fig. 76 shows a ferry

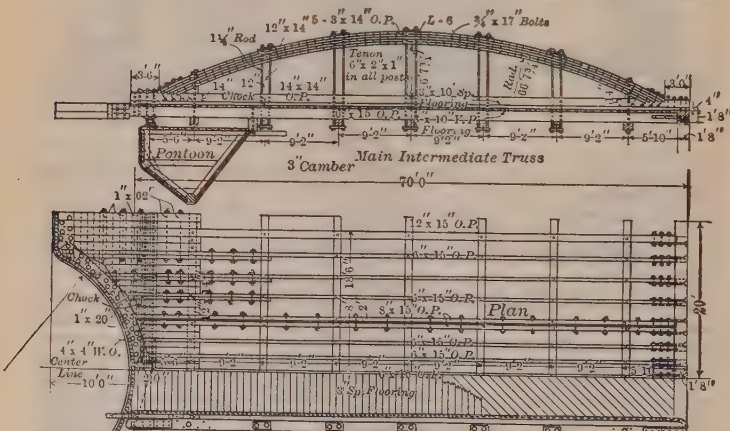

Fig 76. General Traffic Transfer Bridge

bridge and pontoon and is typical of this character of structure in general use. Where double-deck ferry-boats are employed, elevated adjustable gangways or bridges are provided for the upper-deck traffic.

Ferry Houses or terminal sheds are, as regards materials employed and details, similar to pier sheds, structural steel framing with metal siding and sheathing being largely employed. The shed is carried out over the transfer bridge and often projects out a distance over the slip to afford protection against the weather.

Railroad Car Transfer slips are more rectangular than ferry slips for general traffic, and the racks are consequently built straighter or no rack used.

Fig. 77 is a section of a typical three-bank rack; the fender planking is horizontal, and this appears to be standard practice for car transfer racks. The transfer bridges must be of sufficient length to insure a reasonably flat slope for variations in tide and freeboard of the car float. Where possible grades should not exceed 5%. It is not desirable to run locomotives on the float, and the transfer of cars is effected by using two or more pushers or empties to couple up with. When operating on a steep grade the locomotive remains on the level platform. The outer end of the bridge is supported on a pontoon or by means of a counterweight.

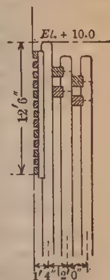

Fig. 77

Fig. 78 shows a transfer bridge with pontoon and overhead gear. The adjustment of the height of track is made by removing water from the compartments of the pontoon by means of a small power pump, or by filling it, the final adjustment being made by the overhead gear with hand-operated winches.

Fig. 79 is a two-track transfer bridge, employed by the N. Y. Central R. R. in Weehawken, N. J. In this the supporting pontoon is replaced by two counterweights, each weighing 46 short tons, the adjustment of height being made by a power-operated vertical screw shaft. In this type the weight of cars is almost entirely carried by the overhead gear. The estimated weight of structural steel for one transfer is 740 000 lb.

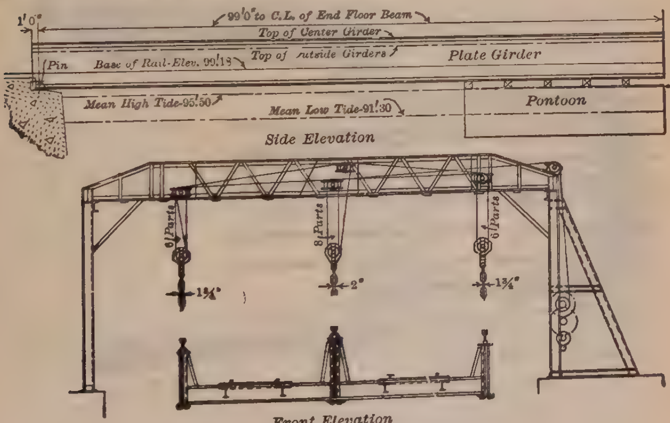

Fig. 78. Railroad Car Transfer Bridge

The general type of railroad and car transfer in use often consists of a bridge made up of two or more timber Howe trusses hinged, or supported, on a rolling log inshore, with the outshore extremity resting on a float or pontoon. Directly over the outer end, and supported on pile foundations, on either side, an overhead or gallows frame is provided; the bridge is connected to this by chain or wire cable tackle, and the final adjustment of height made by this means.

River Car Transfers are employed in connection with ferrying railroad cars across rivers. When the range of tide is not very great, such transfers are similar to those used in harbors. However, when the elevation of tide fluctuates to a considerable extent, as in the great interior rivers of the United States, it is customary to use a method of transfer similar to that shown in Fig. 80.

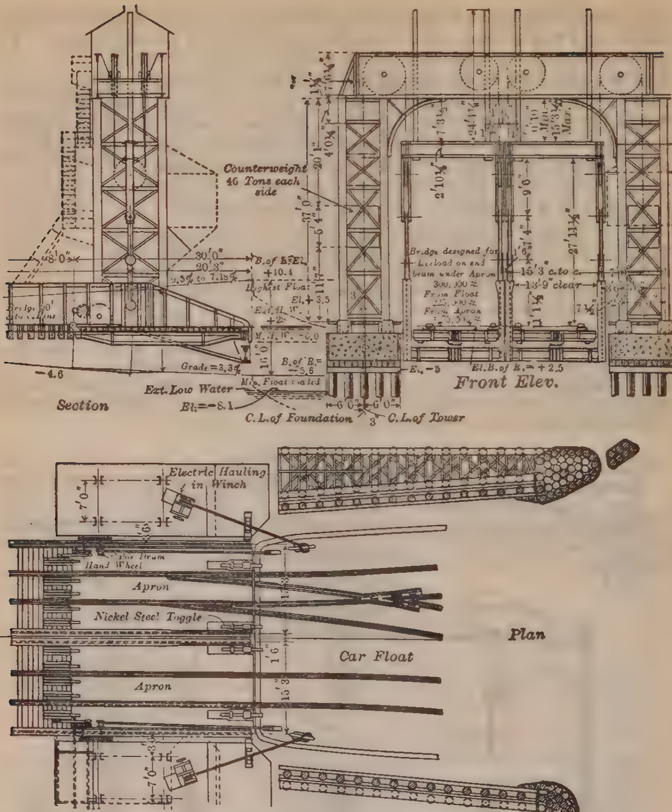

Fig. 79. Transfer Bridge, N. Y. C. & H. R. R. R.

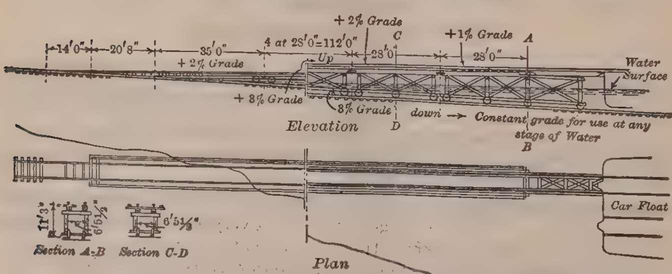

Fig. 80. Cradle, Illinois Central R. R., Mississippi River

This system has been in successful use for many years for transferring railroad cars from or to tracks from car floats. The arrangement is known as a "cradle." Standard-gage railroad track is laid on an incline, usually diagonally, along the bank or river levee slope. The cradle running on this track is hauled up and down the incline according to the stage of tide. Fig. 80 shows a cradle in use at Harahan and Baton Rouge by the Ill. Cent. R. R. for transferring cars across the Mississippi River.

35. Coal, Ore, and Grain Plants

Coal Handling Plants are usually of two general types: (a) The wharf storage type, in which the coal is received by rail or otherwise from shore, by ship or barge from the water, and stored on the wharf itself for distribution and use; (b) the type where the coal is received by ship or barge cargo, and transferred to, and stored on, shore, for shore consumption, or to be again distributed for ships' use; or delivered to the pier from the shore by rail or otherwise, and distributed directly to ships or barges. The last-mentioned type is often provided with some pier storage as an auxiliary feature.

Type (a) is, manifestly, somewhat limited in capacity, depending on the dimensions of the pier and the consequent storage-bin area, as it is inadvisable to store coal in bins to a greater depth than 20 ft., on account of the possibility of spontaneous combustion, and the consequent necessity for re-handling coal. The bins are usually given a bottom slope to permit ready self-discharging, with a minimum of man-handling, the discharging being effected by portable chutes, collapsible or fixed, for discharge into ships' or barges' holds, or for discharge on shore under the bins into carts or railroad cars, the loading of hoppers being effected by fixed hoists with collapsible cantilever arms, on which the bucket or unloading device travels transversely on trolleys or carriages, the distribution in the length of the bin being performed by bucket or belt distribution; or the entire loading device may travel longitudinally of bins for the purpose of distribution. Fig. 81 shows such a plant built in 1901, at the Navy Yard, New York.

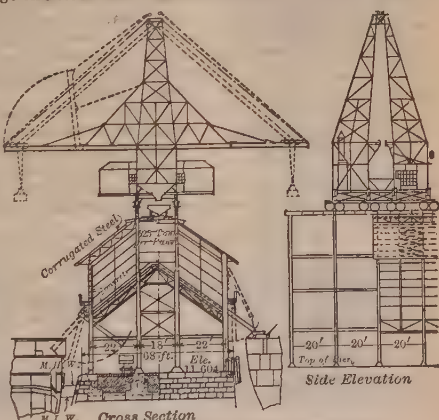

Fig. 81. Coaling Plant, New York

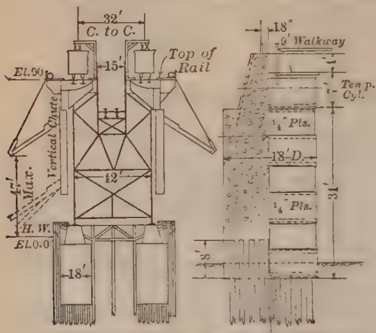
The arrangement of coal handling plants of Type (b) is multitudinous in character, and no attempt will be made to cover this feature in this section, other than to state that for small plants the stationary or movable coal tipple is employed with great economy. In larger plants, a very satisfactory method appears to be a loading apparatus, cable-operated railroad dump cars, discharging to shore storage bins or piles. When coal is required for ship or barge cargo, cars are run out on the pier and discharged into smaller bins or hopper chutes convenient to ship or barge hatchways, cars being discharged directly over the bins by bottom or side-dump cars, or, in some cases, by tipping the car.

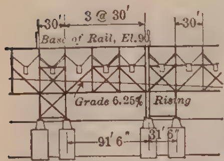
Fig. 82 shows a recent coal pier and plant of Norfolk & Western R. R., Lambert's Point, Va. The method of operation is: Coal from mine arrives at yard and travels by gravity over automatic weighers, and is hauled up incline to pier by power hauling cable to tipping platform, where the car is inverted and contents of car dumped, the capacity being 30 cars per hour. Empty car, on being righted, returns to yard by gravity. Special electric trolley pier cars are raised to the top of the pier by elevators, discharging coal through hoppers and chutes. Empty pier cars are returned for new load. Capacity of this coal pier ranges between 3000 and 5400 tons per hour.



Trans. Section   Detail of Cylinders

Fig. 83 shows the layout of a somewhat similar plant in use by the D., L. & W. R. R., Jersey City, N. J.

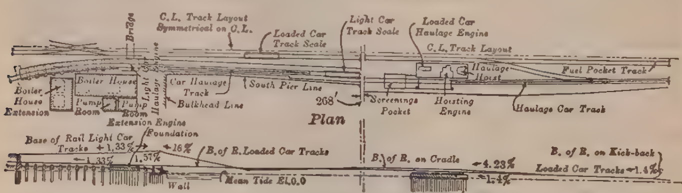
Where a considerable amount of coal is to be stored, it may be placed in piles on shore in close proximity to the coaling pier by being dumped by cars from overhead tracks or trestles, or directly from grabs or buckets operating on travelers. When required, coal is re-loaded by means of grabs or buckets operated by travelers or locomotive cranes and placed in cars. Vessels are loaded with coal from coal barges placed alongside by manhandling in bags, and hoisting by ship's gear and winches. This method of loading is often found most economical, as the ship's crew is employed in the operation, and has other advantages where coal bunkers are small, widely distributed, and access to them is difficult, such conditions especially applying to naval vessels. Floating mechanical coal conveyors are also employed for loading coal on steam vessels.



Side Elevation

Fig. 82. Coaling Plant, Lambert's Point, Va.

Coal is sometimes stored under water in compartments or enclosures for that purpose, as there is no deterioration due to atmospheric action, no losses due to dust blowing away, and the possibility of spontaneous combustion and consequent expensive rehandling is avoided. Coal stored under water 14 years shows a deterioration of only 1-1/2 %.



Elevation

Fig. 83. Coaling Plant, Jersey City, N. J.

Ore Handling Devices for loading and unloading are generally similar in layout to Type (b) Coal Handling Plants, except that the material is seldom moved back and forth, but is usually moved in one direction either from the source to be loaded or from the ship to be unloaded. An important feature in the design is the considerably greater weight per cubic foot of the ore.

Fig. 84 is a section showing an ore trough and pier at Cleveland, Ohio. Ore can be delivered from the vessels directly to freight cars, to stock piles, or placed in the ore trough to be picked up for distribution by conveyors. The ore pier is provided with loading and unloading traveler operating longitudinally of the pier. Fig. 85 shows an ore pier at Two Harbors, Minn.

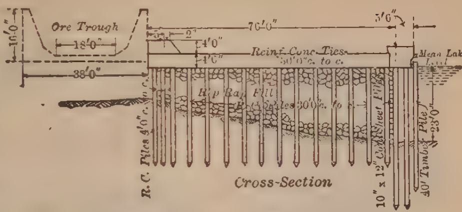


Fig. 84. Ore Pier, Cleveland, Ohio

Grain Handling Plants. When cargoes of grain are to be handled in bulk, the grain is usually loaded and unloaded by means of grain elevators, the material being stored in bins. Grain elevators may be portable, mounted on barges, or constructed on piers or quays. The material is handled by endless belts, by a succession of buckets on a continuous chain, by pneumatic power, or in lesser bulk by buckets or grabs. The pneumatic system of unloading has the advantage of extreme flexibility and can be applied in any position, saving the cost of hand trimming. Grain unloading plants for handling large cargoes are found on the Great Lakes, but not in other American ports where the plants are solely for loading into vessels. For unloading, floating equipment is most often employed, unloading the cargo of the vessel and loading barges for distribution and trans-shipment in the same operation.

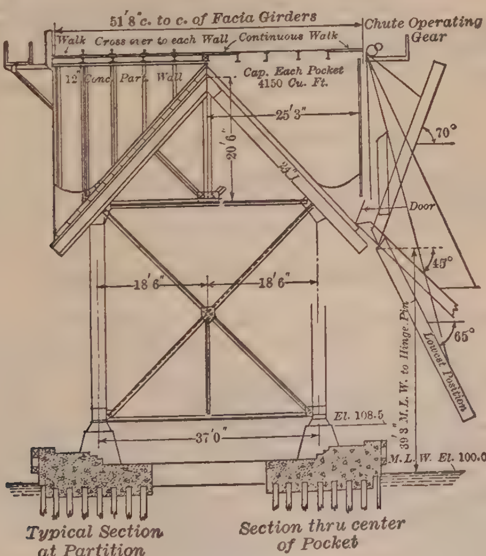

Fig. 85. Ore Pier, Two Harbors, Minn.

Fig. 86 shows the latest type of grain elevator constructed at Girard Point, Philadelphia, Pa., Pennsylvania R. R., having a total capacity of over 1 000 000 bushels.

Grain comes in on cars on a descending grade, and is hauled to and from the unloading shed by cable. Unloading is performed by power shovels into receiving hoppers, discharging therefrom on receiving belts, and is raised to receiving garners and weighed,

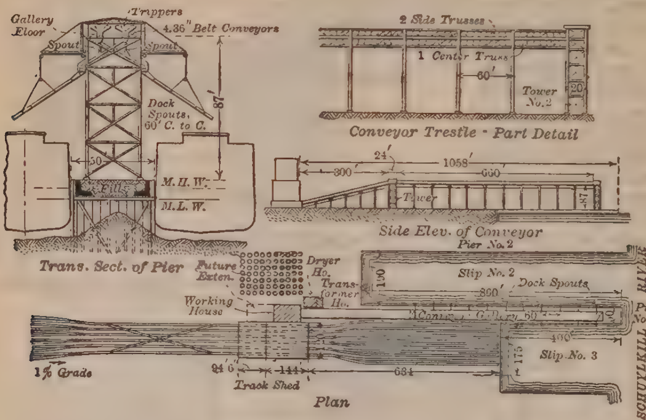

Fig. 86. Grain-handling Pier, Philadelphia

and thence by means of spouts distributed to the storage bins or to the pier shipping conveyor consisting of four 36-in. belts, from whence it is distributed by trippers through side pier spouts.

36. Dumps and Landing Stages

Dumps are constructed and set aside for the handling of refuse material. On account of securing and retaining ample depth for the purpose of navigation, in most ports it is against the law to dump material within the navigable water area, whether the material is of such character as to sink to the bottom or float on the surface of the water and interfere with navigation or be unsanitary or obnoxious. In some of the larger cities public dumps are provided where excavated ma-

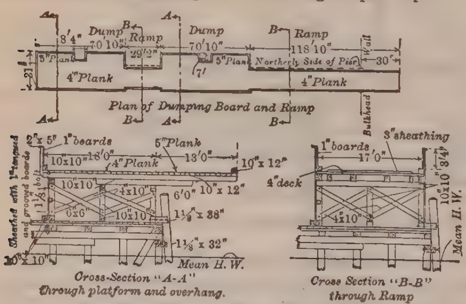

Fig. 87. City Dump

terial or refuse may be dumped into barges for transhipment for local filling, or disposal at sea. Fig. 87 shows a dumping board at Pier 33, New York City. Fig. 88 is a typical example of a dumping board for distribution of excavated material.

Floating Landing Stages are provided where there is considerable range of tide and it is not desirable to incur the expense for the construction of a wet dock, or where, for a similar reason, it is inadvisable to construct a fixed pier or quay with two or more platforms to be used at various stages of tide. Floating landing stages on a small scale are employed for small boat landings and consist of a float or pontoon with a gangway from the pontoon to the pier or quay platform. When constructed, the deck is supported by its own buoyancy or on hollow pontoons, the buoyancy of which must be sufficient to carry the weight of passengers or cargo. The pontoon must be divided into two or more longitudinal and two or more transverse watertight compartments in order to insure stability against overturning when the compartments are partially full of water. The formula to be applied is given in Art. 32 under Stability of Floating Docks.

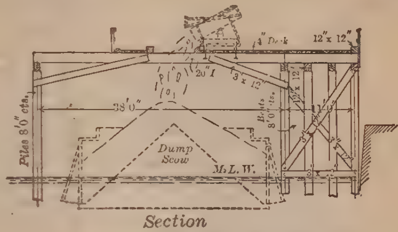

Fig. 88. Railroad Car Dump

The floating landing stage at Liverpool, England, consists of a deck supported on pontoons, and is 2500 ft. long by 80 ft. wide, and has eight gangways or bridges connecting it with the shore. The maximum range of tide at this port is 30 ft.

On many of the interior rivers of the United States, there is considerable freight and passenger traffic, loading and unloading taking place at various places along the bank where no regular landings are provided, the light-draft, stern-wheel steamboats employed running close to the bank and transferring traffic by platforms or gangways. At many of the more important ports where the elevation of the river varies greatly, and ordinary wharves are not available or advantageous, floats are employed. Figs. 89 and 89*a* show how the problem is solved at Memphis, Tenn.

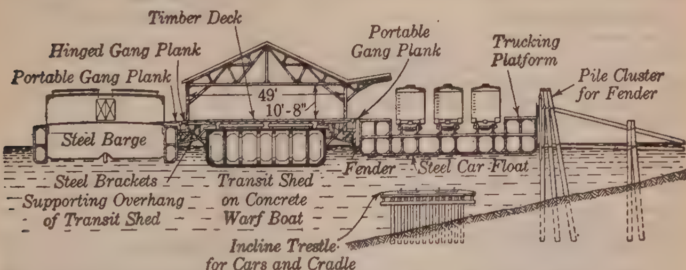

Fig. 89. Freight Transfer between Cars and River Barges, Memphis, Tenn.

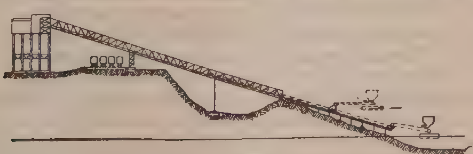

Fig. 89*a*. Coal Handling Equipment, Memphis, Tenn.

Where the river bank is steep, and bulky cargo is to be handled, landing stages or floats are employed in connection with inclines, as shown in Fig. 90. This type of incline is usually double-tracked, with a platform on each track, the two platforms being connected together by a cable running over a drum of a hoisting engine which operates the mechanism. This particular type is in use on the Tennessee, Mississippi, and Ohio Rivers, used in connection with the handling of iron and steel products, coal, and cotton. The telferage systems are also extensively employed for river landings, a typical example of which is shown in Fig. 90*a*, employed by the Illinois Central R. R., South Memphis, Tenn.

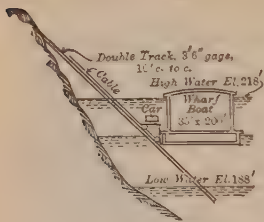

Fig. 90. Car Handling

37. Shipbuilding Ways

Although the construction and launching of ships come within the province of the naval architect, the design and construction of the platform or ways on which the vessel is built is a question of foundation design and one that will be dealt with briefly here.

Shipbuilding Ways are in many respects similar to marine railways, and are, primarily, inclined slips on which a vessel is built, and which project far enough out into and under the water so that when the vessel is ready to be launched it may pass down from the land to the water. As with marine railways, building ways may be of the lengthwise or broadside type. The broadside type is resorted to where the basin or stream into which the vessel is launched is narrow and does not afford the requisite width for lengthwise launching. Broadside ways are common on the Clyde River. Building ways consist of the fixed ways, which is the incline or platform fastened to the foundation, and the cradle or sliding ways. The vessel itself is built on the fixed ways or on blocking, and the fixed ways are frequently not placed until shortly before the vessel is ready for launching. Then the weight of the vessel is transferred to the cradle or sliding ways and in turn to the fixed ways by means of wedges. A lubricant is placed between the sliding and the fixed ways, usually a mixture of tallow and soap, and at the proper time, the vessel is released by sawing or by a trigger device. The gradient or inclination of the ways is fixed dependent on the type and launching weight of the vessel so that with the release, by whatever method secured, the sliding ways and vessel will move down to the water and

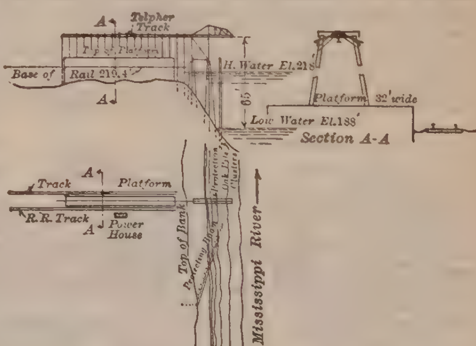

Fig. 90*a*. Telferage Landing

be launched into it. It is customary as a matter of precaution to place horizontal jacks to give the sliding ways and vessel a push or "kick."

The fixed ways consists of two longitudinal strakes, one on each side of the center line of keel, and of sufficient width to carry the maximum moving load of the vessel and sliding ways, the safe bearing capacity of the timber used across the grain being considered.

Inclination of Ways. Inclination or the gradient of the ways is dependent upon the length, type and probable launching weight of the ship to be built and is seldom greater than 7/8 in. to the foot run. Ways for moderate sized steel vessels with a launching weight of from 2000 to 4000 tons have a gradient of 5/8 to 3/4 in.; on larger heavier vessels 5/8 to 1/2 in. is used, and on very large vessels of great length such as the largest transatlantic liners and battle cruisers 1/2 or 7/16 in. is employed. For the last two classes of ships the ways are often built with a varying gradient, that is, with a very flat circular profile, so that the ship when launched and moving down the ways moves on the arc of a great circle. This arrangement has the advantage of bringing less strain on the trigger or launching device, and the vessel once released and moving down the ways receives an increasing acceleration. With a vessel of considerable length this has the further advantage of decreasing the required length of the outboard or under-water portion of the ways; that is, the requisite depth of water at the end can be obtained in a shorter run.

Foundations. The foundations of the blocking, or fixed ways, must, of course, be designed to carry the maximum weight of that section of the vessel built directly above it, and the lower or outboard portion must be designed with a view to the fact that as the vessel is launched the maximum weight section will move down, superimposing its load over the entire lower ways as it passes over it.

As the vessel reaches the water and becomes submerged therein it is immediately in part water-borne, and the foundation directly under the stern becomes relieved in increments of the superimposed weight, while the load under the bow or upper end of the vessel is increased by the upward force of the outboard vertical buoyancy effect. This change in condition continues until the stern or outboard end of the vessel is entirely water-borne, and about to be lifted from the ways when a pivoting action about the upper end of the bow occurs, and that portion of the weight of the vessel representing the upper end reaction is concentrated at the bow or upper end. This pivoting pressure is the maximum pressure brought to bear upon the ways foundation and has a decreasing effect continuing down the ways from the initial point of pivot until the vessel leaves the ways entirely. With larger vessels a pivot cradle is constructed under the bows detached from the sliding ways or cradle, the hull of the vessel at the bow end resting in a trunnion saddle (a) which sets in the pivoting cradle (b), all shown in Fig. 91. In designing ways it is imperative that all of the load and maximum weight pressure conditions be obtained. Fig. 91*a* shows the buoyancy pivoting hogging curves and maximum way pressure curves for a 3500-ton dead weight cargo coal barge. The ways must be extended outboard sufficiently so that the depth of water at the end will be approximately the draft of the vessel at the bow, where the sliding ways leave the fixed ways when the vessel is launched; otherwise the vessel would drop through a vertical distance represented by the excess in draft at this point. In practice, it is quite usual to launch expecting and providing for some drop,

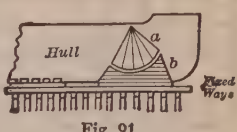

Fig. 91

the opening between the fixed ways at the outboard end being cleared sufficiently so that the hull of the vessel at the bow will not strike any obstruction and cause damage to the hull or the ways.

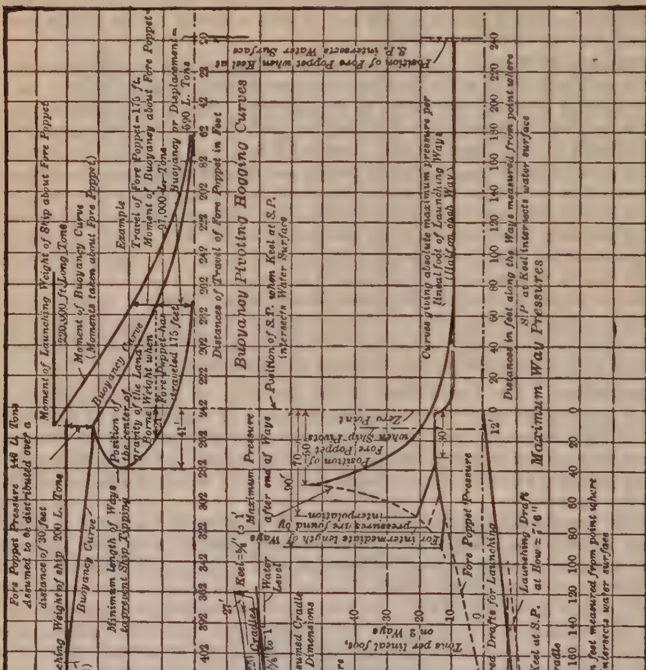

Fig. 91a. Hogging Curves and Way Pressures

The type of foundation required is dependent entirely upon the location and can be treated similarly to other foundation conditions. However, due to the necessary restrictions of being located on some foreshore, timber or concrete piling is the general rule. When timber piling is employed it is, of course, subject to rot and decay above the wet line. Sometimes to avoid the necessity of constantly repairing this portion of the ways, the piling is cut off at mean tide or wet line and concrete or masonry cross-walls or concrete piles are built on the timber piles, or the necessity of such construction is avoided by the use of reinforced-concrete piles of the precast or cast-in-place type, the relative advantage of the two types of construction being, as in other foundations, a question of the particular conditions and restrictions involved. It is impossible to lay down a rule as to the relative desirability or permanency in ways foundations as it so frequently happens that for reasons of development and change in ship dimensions and design or for other reasons it becomes necessary to change materially the carrying capacity of a ways if it is utilized during the life of that particular shipbuilding plant. Experience has rather demonstrated that changes in the foundation, usually with a view to increasing its carrying capacity, are called for whenever a new ship is to be laid down.

The outboard end of the ways, as with the marine railway, must be constructed below water level, and must be heavily braced longitudinally and transversely. A portion of the ways can be built by sawing off the foundation piles by an under-water saw arbor, or by employing divers, or the entire site can be enclosed by a cofferdam and the water then removed and the ways constructed in the dry. The last method is frequently resorted to in new ways, but as the under-water part of the ways is so subject to damage in the course of launching or damage by passing vessels, or floating objects, it is customary before launching to have divers carefully inspect this portion of the ways and to rebuild it also when needed by this method. Fig. 91*b* shows the plan and elevation of a typical building and launching ways for a 9000-ton dead weight cargo ship, the launching weight of which is assumed at 2850 tons. Attention is invited to the piling plan necessary at the outboard end where the foundation at *CC* and *DD* is greatly reinforced. This is to take care of the pivotal pressure hereinbefore referred to.

In construction of merchant vessels frequently the launching weight is always the weight or displacement of the bare or light ship, the boilers, machinery and most of the accessories having been placed while the vessel is on the ways under construction. It is often desirable either for the purpose of rapidly clearing the ways and getting it ready for another ship, or by reason of the fact that the particular plant does not construct and install the machinery and other ship's gear, to launch the hull and place the machinery, etc., afterward, in which case the launching weight is to that extent so much less. In the construction of naval vessels, especially battleships and cruisers having heavy armor and armament, the exterior armor, turret armor and often turrets, together with much of the machinery and all of the guns, are placed after the vessel is launched, so that the launching weight is usually only 30% to 40% of the full load displacement.

Types of Building Ways. The ways shown in Fig. 91*b* is of the simplest type, and that most generally used, and has the advantage of economy of first cost. As previously stated, a more permanent foundation is obtained by the use of concrete cross-walls or pillars. Ways of this character have the disadvantage that the outboard end is under water, not subject to visual inspection, and when preparing to launch there is, of course, some difficulty in providing the proper lubricants under water. Such ways must always be extended some distance out to insure a depth for clearance.

A twin set of ways was constructed by the Newport News Shipbuilding Co., a plan, section and side elevation of which are shown in Fig. 91*d*. In these ways the water is excluded from the lower end by means of floating caisson gates. These ways have the advantage of permanency, shorter length and less height required for overhead crane runway structure. They undoubtedly involve the element of a much higher first cost and entail drainage of the lower portion of the site during the process of building.

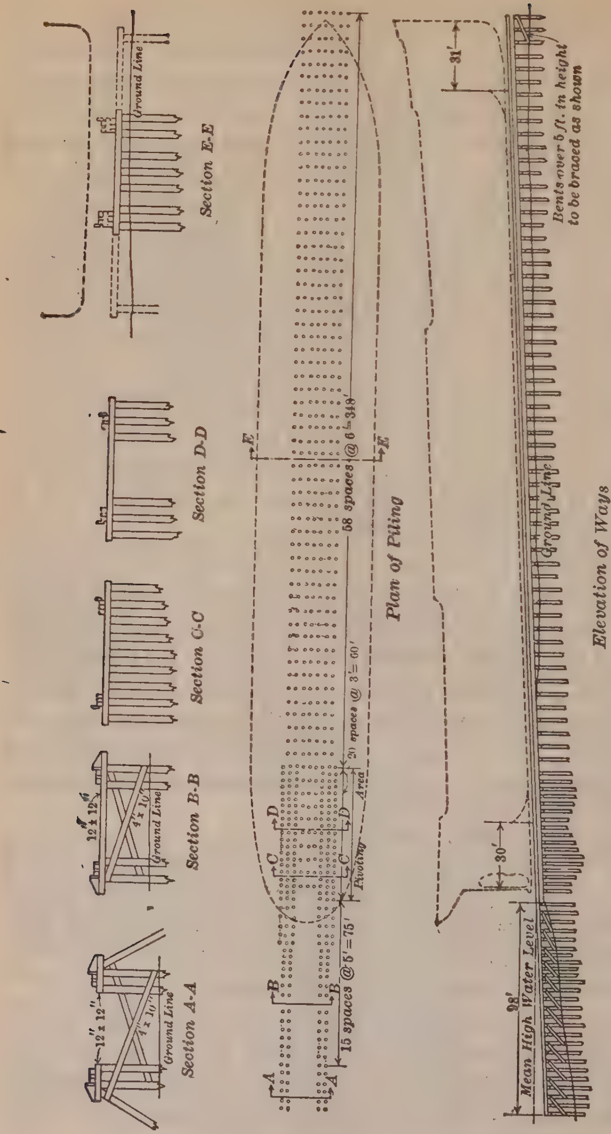

Fig. 91b. Cross-section Showing Transverse Bracing

Description of these types of ways naturally lead to the consideration of the use of a shallow graving dock for shipbuilding purposes. Ships have in the past been built in a basin or graving dock, which results, of course, in tying up this important part of the repair plant and preventing its use for ship docking and repair work; such use would not be resorted to in ordinary circumstances unless there was assurance that the dock could not be profitably used for ordinary docking purposes. A shallow dock has been built at the Puget Sound Navy Yard especially for shipbuilding purposes. A shipbuilding ways of this type is particularly adaptable to this location on account of the extreme range of tide, nearly 20 ft., which would have made the length and cost of an ordinary building ways and the maintenance of the under-water portion very expensive as compared to other locations.

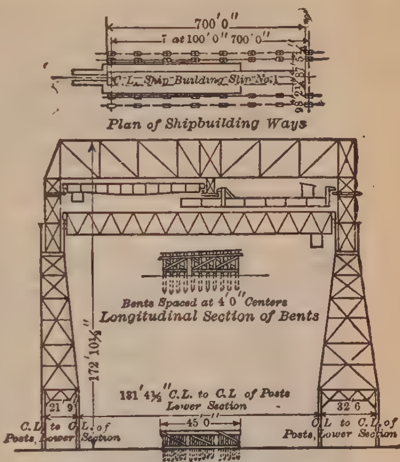

Fig. 91*c*. Timber Building Ways

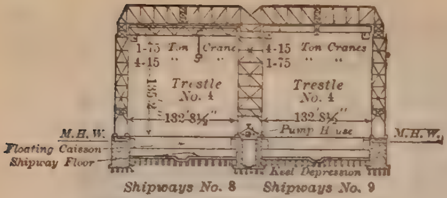
Shipbuilding Cranes. Because this matter begins to come within the scope of the shipbuilding plant layout and design, it will be very briefly dealt with as a matter of general information. A simple and very effective method of handling the frames, shapes, plates, built-up bulkheads, etc., for a ship is the employment of two or more aerial cable ways, usually arranged longitudinally, picking up material at the head of the slip and moving it longitudinally and transversely to the desired location. Such handling has been effectually employed in merchant shipbuilding, and is especially adaptable to certain types of work.

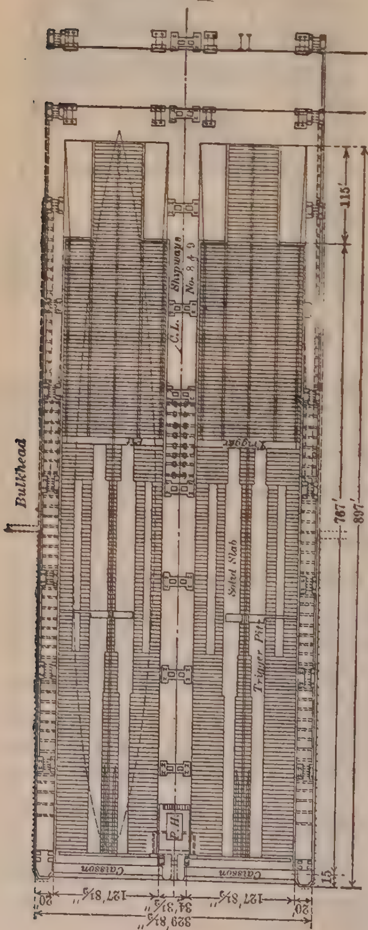
An effective type of crane is the light, fixed-hammer-head tower crane. This usually has a lifting capacity of 5 to 15 tons, and must be so arranged as to cover the entire area of the vessel and be able to handle material from storage and assembly spaces alongside of the ways. The cranes are usually grouped on either side of the ways, three, five or seven being employed. The arms must be put at varying elevations in order to avoid interference and give the requisite clearance for the depth of hull, etc.

A similar type crane is sometimes employed, on one or both, sides of the ways, but instead of being fixed travels on a standard-gage or special-gage track parallel with the ways and at one side, or cranes of this character may be of the jib or luffing type.

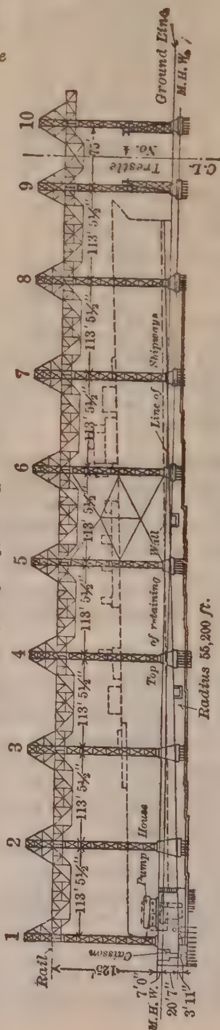
When a large complicated passenger vessel such as the transatlantic liners or a battleship or battle cruiser is to be built it has often been considered desirable to resort to more complete and extensive weight-handling devices than can be afforded by the fixed or movable tower crane service. The building ways of several of the important shipbuilding plants are served by longitudinally traveling cranes; it will be noted in Fig. 91*d* that the twin ways of the New-



Transverse Section Looking Outshore



Plan View of Shipways No. 8 & 9



Longitudinal Section Looking North Showing Battle Cruiser on Ways

Fig. 91d. Timber Ways

port News Shipbuilding Co. are each served with one 75-ton and four 15-ton longitudinal cranes, which pick up material from the assembly and storage space at the head of the ways. Fig. 91*c* is a plan and cross-section of typical building ways and overhead crane structure employed by the Navy for the shipbuilding ways at the New York, Philadelphia and Norfolk yards. The upper cranes each span one-half of the width of the ways, are of 15 tons capac-

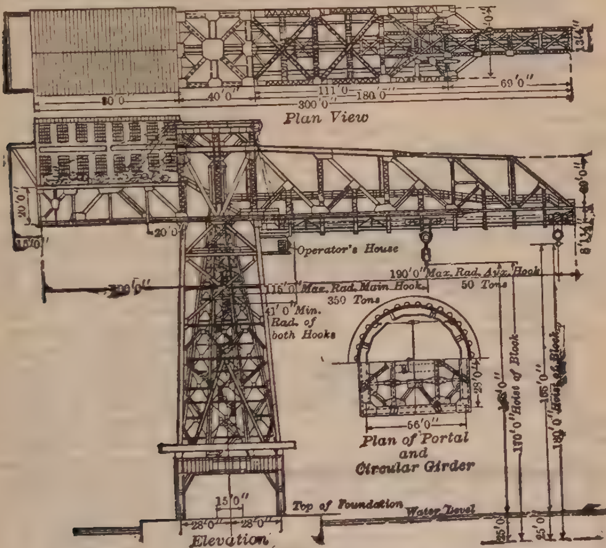


Fig. 91*e*. **350-ton Fitting-out Crane**

ity; the lower, larger crane is of 40 tons capacity. They handle material from the head of the ways and also are so arranged as to pick up material from cars running parallel with the ways. Fig. 91*e* is a side elevation and plan of a 350-ton fixed-hammer-head crane which is to be employed for placing of heavy weights on vessels after they are launched. It is designed to be placed on a special fitting-out pier and vessels are brought to the pier and traversed longitudinally along its side so as to come within the reach of this appliance.

38. Cargo Handling Cranes

Cargo Handling Devices and Appliances are utilized dependent upon the character of merchandise and the special conditions affecting availability of ships' gear and crew. Cargo ships are provided with masts, cargo booms, winches, etc. Modern freighters are usually provided with two to eight cargo booms per hatch. To facilitate or replace such ship gear, piers or quays are provided with various apparatus, cargo hoists, cranes of various types—gantry or portal or semi-portal cranes. elevators, conveyors, revolving cranes, straight line roof cranes, telfers. Besides this, various crawler types of cranes, electric motor trucks, sectional elevators or conveyors.

Numbers in the following examples refer to Fig. 92.

(1) and (2) Antwerp, Belgium, on the Scheldt. Quay wall runs entire length of the city. Principal wharfage capacity is derived from interior wet docks. Range of tide is 16 ft. Open sheds constructed some distance from quay wall. Portable crane spans outside railroad track; cranes handle cargo from the ship to cars, or to the face of the shed, in which it is handled by hand trucks for storage or transfer to cars in the rear for re-shipment. Shed is for transfer or temporary storage. Warehouses for permanent storage are usually found with railroad connections close by.

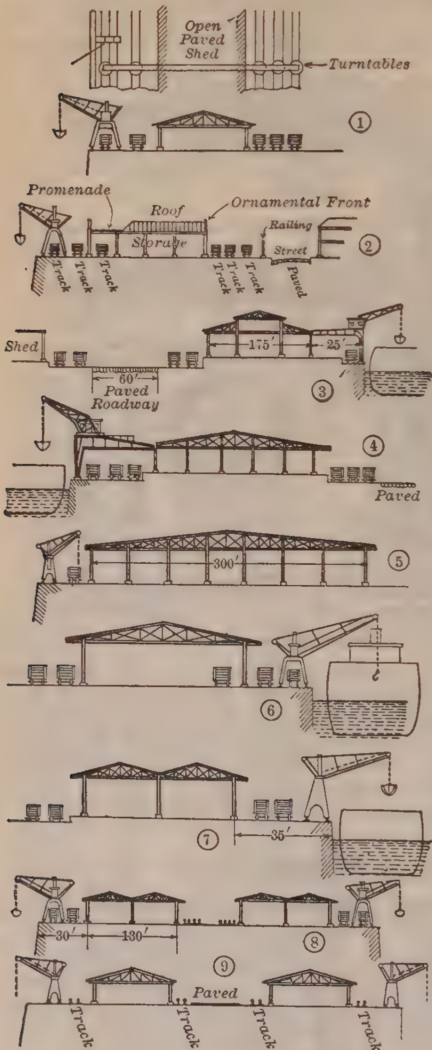

Fig. 92. Cargo Handling Methods

(3) Hamburg, Germany, on the River Elbe. A greater amount of wharfage room is secured by interior basins. The plant of the Hamburg-American Line is the one illustrated. The sheds are about 2500 ft. long and 175 ft. wide, and are from 30 to 35 ft. from the face of the quay wall. In this space are operated electric cranes which span an outside railroad track which handles the cargo from steamer to railroad track or to side of ship. In interior of shed cargo is handled by hand trucks through the shed for local storage or to carts or railroad tracks in the rear for direct delivery, or delivery to warehouses.

(4) Bremerhaven, mouth of the Weser on the North Sea. Tide has range of 8 ft., but on account of insufficient depth of water wet docks are employed. Shows typical section of the North German Lloyd terminal. Sheds are about 200 ft. wide, of corrugated iron siding, with wooden roof trusses, tar and gravel roofs. Electric cranes are provided for loading and unloading; cranes operate by picking up cargo from the holds of steamers by circular movement, swinging onto railroad cars on three lines of track, or to the sides of the shed. Loading and

unloading are accomplished by this system on the shore side, and by barges and ship's boom and tackle on the waterside.

(5) Havre, France, at the mouth of the Seine. Range of tide 25 ft. Wet docks employed. Coffee and cotton landings. Sheds are 300 ft. wide and 2600 ft. long. The sides are continuous rolling doors, roof of tar and gravel, with glass skylights. Cargo is handled by crane from ship to side of shed or to railroad track.

(6) Southampton, England, American Line terminal.

(7) London, England, shows system of handling at Albert Dock. Sheds are of light corrugated iron construction and run entire length of quays.

(8) London, England, Tilbury docks.

(9) Glasgow, Scotland. Typical arrangement of cargo handling.

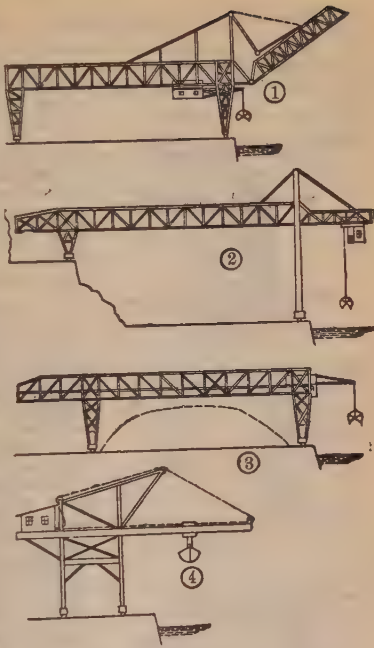

Fig. 93. Cargo Handling Travelers

Movable Shore Cranes for miscellaneous cargo handling, though not generally employed in American practice, are usually employed in connection with handling of homogeneous cargo in bulk, various types of standard-gage locomotive cranes being used for that purpose. Special cranes or traveling transporters are extensively used, the following types being shown in Fig. 93.

(1) One of four loading and unloading bridges at Rotterdam, Holland, 8 long tons capacity.

(2) One of two transporters, 10 long tons capacity.

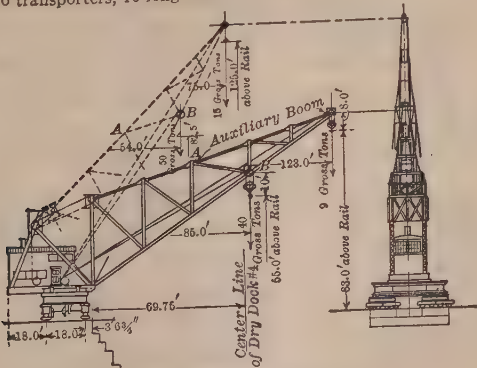

Fig. 94. Traveling Dry Dock Crane

(3) Coal loading and unloading bridge. (4) Loading appliances.

Fig. 94 shows type of heavy locomotive crane employed in connection with ship repair and dry dock work. The crane is of 50 long tons capacity at 68-ft. radius, of lesser capacities at greater reach and of 15 long tons capacity at 123-ft. reach, and travels 120 ft. per minute, with a maximum load. Cranes of this type are in extensive use in various U. S. Navy Yards.

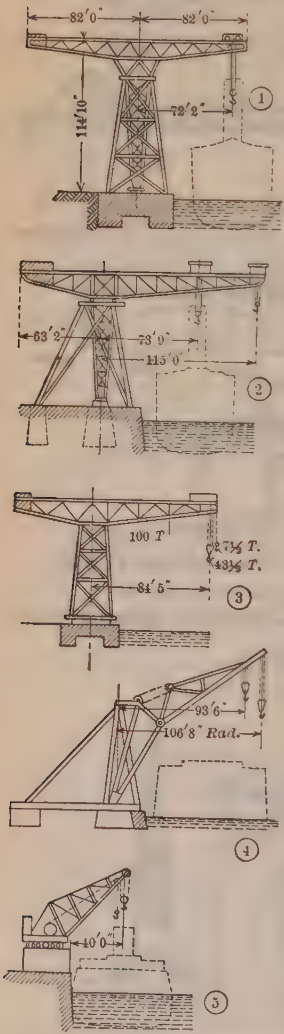

Fig. 95. Heavy Fixed Cranes

Stationary Cranes. Fig. 95 shows types of fixed shore cranes for heavy lifting and for building or repair purposes.

(1) 150-ton hammer-head crane at Bremen, Germany. Interior spindle is supported on base step bearing, the crane revolving in the 4-leg tower.

(2) 150-ton revolving crane at Kiel, Germany. Crane of the hammer-head revolving type. Interior spindle, stepped at the base, operating within the 3-leg support.

(3) Bremen, Germany, capacity 100 tons, hammer-head type, revolving on circular track at the base.

(4) Hamburg, Germany, 100 tons, stiffleg derrick type of crane.

(5) Barrow-in-Furness, England, 120-ton jib crane, revolving on pedestal base.

Cranes of the hammer-head type have been constructed of 250 long tons lifting capacity. Fig. 96 illustrates English practice, and shows a crane at Portsmouth Dock Yard.

Fig. 97 illustrates German practice, and shows a 250-long ton capacity crane constructed for Blohm and Voss at Hamburg, Germany, in 1912. The crane is supported at a bearing on the top of the fixed spindle or tower; the enclosing structure revolves with the crane and bears against a track at the base.

Sheer legs are often used for heavy lifting, Fig. 98 showing a 100-long ton sheer leg with luffing jib device, the reach of the sheer leg being regulated by power-operated horizontal screw, connected to the foot of the rear inclined member. This horizontal screw is sometimes replaced by a vertical quadrant with worm screw drive or pinion and racking. Sheer legs are also used for floating cranes.

Floating Cranes are employed in connection with shipbuilding and repair, for loading and unloading heavy weights, handling lock gates, and for wrecking purposes. Fig. 99 shows the A-frame boom type in extensive use in American practice. The A-frame may be held in position by back stays of structural material or by wire cables; or in smaller derricks the A-frame may be replaced by a mast. Cranes of this kind from 10 tons to 250 tons capacity are in use, the larger capacity being obtained in one crane by a lift directly over the bow, employing water ballast at the other end.

Fig. 100 shows a revolving tower floating crane of 75 long tons capacity. A crane of this type is employed in New York by the Department of Docks and Ferries, for placing quay wall concrete blocks. A similar crane is in use at the Navy Yard, Boston. The load moment is taken care of by fixed ballast, water ballast, and the stability of the structure.

The bridge type of floating crane is shown in Fig. 101, the bridge or trolley running through the uprights so that the load may be transported from shore or vessel to the deck of the crane, or through the crane to be handled on barge or shore at the other end. This crane was constructed in 1901, and rebuilt in 1910, and is at the Navy Yard, New York. A similar crane is at the Navy Yard at Bremerton, Wash. Two bridge cranes of 150 tons capacity at the Navy Yards, Boston, and Pearl Harbor in Hawaii, are similar. The load moment is counterbalanced by power, automatically operated counterweights or by water ballast.

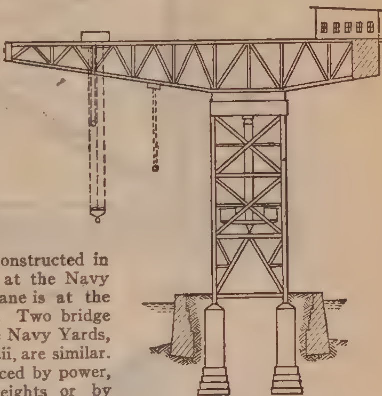

Fig. 96. 250-ton Crane, Portsmouth, England

An Incline Bridge Crane is illustrated in Fig. 102, and is in use by Schneider & Company, Chalons, France, built in 1911, of 25 tons capacity. The revolving jib type crane is shown in Fig. 103. One of 250 long tons capacity is self-propelling and is in use at Wilhelmshaven, Germany. Two similar cranes of the same capacity, with less reach, are in use in the Isthmian Canal Zone, where they are to be employed for removing and placing lock gates, and for other purposes. These cranes can lift 672 000 lbs. The pontoons are 150 ft. long, 88 ft. wide, and 15 ft. 9 in. deep.

39. Design of Cranes

The Design of cranes involves the field of mechanical, electrical, and civil engineering, and for floating cranes, also naval architecture. For stationary or movable shore cranes, the structural features are analyzed and designed in accordance with prevailing structural steel practice, the operating machinery in accordance with electrical and mechanical machine design. Having decided on the required lifting capacity and the speed of lift, in order to obtain the horsepower of the power unit, allowance must be made for the loss in friction in hoisting blocks, gearing, bearings, and operating mechanism. Three to five per cent loss in friction should be allowed for each block sheave. The diameter of sheaves should preferably be 50 times the diameter of the wire cable and should not be less than 30 diameters. Steam power is generally used, although on larger stationary or floating cranes electric motor operation has come into general use, generated by central plants or by isolated plants installed on the crane.

With the application of the maximum load moment, structural steel work must be designed to carry this and also the wind load, taken at 30 lb. per square foot of exposed surface, or without load, 40 lb. per sq. ft. For floating cranes the longitudinal and transverse stability is obtained, applying the formulas.

$$\mathrm{G\,M} = \frac{\mathrm{I - B\,GV - \Sigma i}}{\mathrm{V}} = \text{Metacentric Height}$$

$$\mathrm{R\,M} = \frac{\sin\theta}{35}\,(\mathrm{I - B\,GV - \Sigma i}) = \text{Righting Moment}$$

for which purpose the position of the center of gravity for the entire structure is secured. This calculation is made for the crane when light and when lifting the maximum load at maximum reach. The point of application of the lifted load will be at the center of the sheave pin on the jib or boom of the main structure. The overturning moment due to the lifting of this load is the product of the load by the horizontal distance from the center of the load to the center of the float or pontoon, and the change of trim due to the application of such load may be obtained in approximate terms by dividing this overturning moment by the moment due to inch change of trim.

$$\text{Moment due to change of trim of 1 in.} = \frac{\mathrm{D \times G\,M}}{Wl}$$

where GM = metacentric height in feet;
I = moment of inertia in feet of water plane of flotation;
BG = vertical distance in feet from center of buoyancy to center of gravity;
V = volume of displacement in cubic feet;
D = displacement in tons or pounds;
Σi = summation of moment of inertia in feet of interior water planes;
Wl = length of waterline in inches.

Half of the total change of trim will represent the reduction in freeboard at one end of a rectangular pontoon and the increase in freeboard at the other end. The heel or inclination due to wind pressure is given by

$$\cot\theta = \frac{\mathrm{D \times G\,M}}{\mathrm{A \times CL}}$$

in which A = total wind pressure in tons or pounds; and
CL = distance in feet from center of pressure to center of lateral resistance.

40. Port Development

A port was mentioned in Art. 1 as one definition of a **harbor.** In the commercial sense a port is a harbor, improved or developed for commerce. Many improvements necessary for this purpose have been discussed in this and other sections. Breakwaters, channels, anchorages, buoys, lights, moorings, slips, basins, docks, wharves, piers, coal- and oil-burning plants, lighters, derricks and derrick barges, railroads, roads, transit or wharf sheds, warehouses for long-time storage, ship repair plants, inclusive of dry dock, cranes and trucks all have their place in the equipment of ports for water-borne cargo-carrying vessels. These are physical attributes of the port involving engineering design and construction. There are other necessary requirements of the first-class port.

A port affords the means of interchange between land-borne and water-borne commerce. Ships are useful only in transporting the freight and passengers between ports. On an average only one-half of their total life is spent in transit and in performing this useful purpose. The other half is spent in ports, loading and discharging cargo, repairing and fitting. It is therefore important that all of these port facilities shall be arranged to reduce the stay of the ship in port and consequently increase the time the ship is at sea performing her useful functions. This consideration is the all-important one to civil engineers in charge of port development and operation, and of equal importance to the naval architect whose profession is concerned with the design, construction and operation of ships. Too frequently this is ignored and these two separate branches of the engineering profession work independently. In port development there should be more cooperation between these branches.

Port Planning requires information other than physical characteristics of the harbor. Not only does the first-class port imply a neighboring city and the facilities above named but to plan and design successfully the engineer must first ascertain the nature and quantities of the commodities to be handled, which, in turn, involve the matters of bulk or package, nature and size of packages, etc. The seasonal movements should also have consideration.

Port Hinterland. To design the port, the territory back of the port city must be studied as to production of goods for export and absorption of imported commodities. This in turn requires consideration of railroad and road access.

Port Details. Given the above-mentioned details, the port engineer is prepared to design the commercial port. Sea access must be provided for the deepest draft ships likely to use the port. No port today can be considered first-class which will not accommodate ships drawing 30 ft. of water and some cargo vessels, notably oil tankers and ore carriers, have a draft approaching 35 ft. Some Atlantic liners draw over 40 ft. There must be several feet greater depth of channel and berth for safe ship operation, but when there is a considerable tidal variation this may be utilized to cheapen channels, though access at high tide only is a handicap to a port.

Wharves and Piers may be narrow and of a temporary nature for the successful handling of certain commodities such as oil in bulk, which requires only a series of pile dolphins 50 ft. on centers for securing the ship, backed by a trestle or runway, only wide enough to support the oil pipes and furnish a footing for handling lines; or they may be of permanent construction and wide enough to handle and classify miscellaneous cargo from a large ocean vessel. Where practicable, the design should fit the commodity. An ore " dock " at the head of the Great Lakes has filled a 12 000 ton Lake carrier in sixteen minutes. The time of the ship is the most important element. One extra day in port may cost the ship operator from $1000 to $3000, when direct and indirect charges are considered.

For Miscellaneous Cargo, the modern wharf, except for special instances, should have an apron wide enough to accommodate a standing railroad track and a running track in front of the transit shed, and the latter should be wide enough for the **transit storage** of the ship's cargo in the space opposite to the ship for classification and storage as to marks of destination. This, for large ships, requires wide sheds. The width can be figured mathematically for a ship of given capacity and size. The Dock Commission of New Orleans, La., builds its sheds 200 ft. wider for ships berths on one side only. Manchester, England, has a quay warehouse 134 ft. wide and five stories high, with two railroad tracks on the apron and two at the rear, all served by traveling cranes. This is for transit business only and was built after experience with its

Dock 9, which is lined with quay warehouses 110 ft. wide and four stories high. The normal movement of miscellaneous cargo requiring classification is from the ship, into the shed, through the shed to car or truck at the rear. A standing track and a running track at the rear platform are thus required. The platform should be the height of the car floor.

Coordination of the water carrier with the land carrier is a prime object of proper terminal construction and for miscellaneous package, freight in particular, is best attained through parallelism, the transit shed serving for classification and temporary storage, the time limit being fixed generally by port regulations to clear the sheds for a new set-up for the next ship. Whether by ship's gear exclusively, by a combination of ship and shore hoisting equipment or by means of cranes, fixed or traveling upon the apron, miscellaneous cargo can be lifted in and out of the ship much faster than it can be broken down in the hold for removal or stored therein for shipment. Rate of break-down or storage of miscellaneous freight naturally varies between wide limits, due not alone to the skill of the particular gang of stevedores but also to the uniformity or the lack of uniformity of the packages. A fair average figure is 20 tons per hatch per hour.

Necessary Berths. Even the small ports expecting to do a miscellaneous business should have berths for several ships, with sheds and equipment for loading and discharging them. Wharf front of 450 ft. should be provided for each 10 000-ton ship. In the absence of better data upon which to plan, 120 tons of miscellaneous cargo may be figured per lineal foot of wharf front per annum, but capacity should be figured for the individual case and for the commodities of the particular port.

Belt Lines. Port cities of the United States are in general served by several different railroad trunk lines. Proper service and proper coordination demand that every wharf shall be accessible to every trunk line. This is best accomplished through local terminal belt line railroads which intersect all of the trunk lines, take the freights of each at a terminal yard outside the congested district of the port and serve the water front and all industries. In populous port districts, there may be an inner belt line serving the industries and shipping berths and an outer belt for general interchange between railways. For the port district of New York an inner belt, an intermediate belt and an outer belt are contemplated. At present the lighterage system of the port constitutes the inner belt. It is expensive as it involves an extra handling of goods for each operation or shipment.

Business of the Port will, for the first-class port, comprise **exports** and **imports,** but in planning a water terminal all classes of freight interchange must be studied. Coastwise business forms the largest percentage of the total of some of the most important communities. Others have a large river and intraport traffic. The individual community must be studied as to river, rail, highway, and ocean possibilities and probabilities, and the terminal must be made convenient and capacious for the coordination of these agencies of transfer.

Mechanical Applicances of standard or adapted design may be had for handling either bulk or package cargo. They should be provided whenever an engineering study indicates they can be used with economy.

The Free Port has not been resorted to in American port policy. The nearest approach is in the bonded warehouse referred to in Art. 23. A free port is an area on the seacoast or on navigable water within the boundaries of which imports or foreign cargoes may be brought, unloaded and stored without being required to pay the legal tax impost of the country in which a port is located. The advantages of a free port are that importers and foreign merchants can store and retain dutiable goods within the area without the additional investment of the duty involved, and can retain such goods within the area of the free port until it is brought inland, when duty is collected at the boundaries of the port, or it may be transhipped without being subjected to the collection of duty or expense other than that of handling and storage. Raw materials may be worked into manufactured articles within the confines of a free port, and such articles transhipped without payment of custom fees or if taken over the boundary of a free port are subject to the impost on these manufactured articles. The various advantages of the free port have greatly stimulated the growth of such ports, as is witnessed in the case of Hamburg, and this method of port legislation and regulation might with profit be followed in American port economics.

41. Shipping Terms

Tonnage. When displacement of a vessel or docking capacity of a dry dock is referred to the tons are always long tons of 2240 lb., and in all ship and dock computations 35 cu. ft. of sea water or 36 cu. ft. of fresh water are taken as weighing one ship ton.

The gross tonnage of a vessel is the measure of her cubic capacity in terms of 100 cu. ft. and is the volume in cubic feet of all enclosed spaces inside of frames divided by 100 cu. ft.

The net registered tonnage is in the same way the gross tonnage less the volume in 100 cu. ft. of certain machinery and other spaces not accessible to cargo, such as crew space, steering-gear house, chain lockers, stores, etc.

The term "registered," as applied to net tonnage, refers to the measurements for that particular vessel as measured and registered by one of the national registry agencies, such as British Lloyds, Bureau of Veritas of France, or the American Bureau of Shipping. The displacement of a vessel is the weight of the vessel or water displaced by the vessel under any particular conditions and varies with the draft of the vessel at any particular time.

The dead weight tonnage of a vessel is the gross carrying capacity in tons and is the displacement of the vessel fully loaded, full draft to the Plimsoll mark, less the displacement of the vessel light and bare without coal, crew and ship's or crews' supplies. The cargo-carrying capacity of a vessel in tons is something less than her dead weight tonnage, being this dead weight tonnage less the weight of bunker coal, crew, ship and crew supplies, etc.

The actual cargo-carrying capacity of any vessel is dependent on the spaces or cubage available for cargo loading and dead-weight tonnage exclusive of fuel. The ideal arrangements for which stevedores contend is to take advantage of full weight carrying capacity and completely fill volume of cargo-carrying holds. In general and for approximation purposes cargo-carrying steamers in the ocean trade will carry about two-thirds of the tons of freight represented by dead-weight tonnage or about the number of tons weight represented by the numerals in the term "gross tonnage." Forty cubic feet are generally considered as representing a cargo ton.

In the design and construction of dry docks the weight to be lifted or the draft considered is that of the vessel light with no cargo and little coal. Dockage and other tolls are usually based upon the registered gross tonnage; an entra charge is made for cargo or excess fuel, etc. The **Plimsoll Mark** is the mark made on the sides of the hull amidship to indicate the depth to which the vessel may be safely loaded.

The Block Coefficient is the ratio of the under-water volume of the ship to the volume of the circumscribing rectangular parallelopiped, namely, the rectangular solid of the same length as the load water line and with width equal to the beam of ship and depth equal to the ship's draft.

The Load Water Line Coefficient is the ratio of the area of the load water line to that of the circumscribing rectangle.

SECTION 20

HIGHWAY ENGINEERING

BY

JOHN S. CRANDELL

PROFESSOR OF HIGHWAY ENGINEERING, UNIVERSITY OF ILLINOIS

GENERAL DATA

1. Preliminary Investigations

Relocation of Existing Highways. A report should be made, accompanied by maps and plans, covering the following: Climate, topography, soil, location, population, census of nearby cities, past and present traffic census, local materials of construction, labor supply, local industries, and a forecast of probable future growth of both population and traffic in the territory.

Location of Proposed New Highways. A reconnaissance survey, similar to that for a railway, is necessary. In addition, the items above should be supplied insofar as is possible. All trustworthy information concerning stream flow, drainage and soil conditions must be furnished. The traffic forecast is a matter of uncertainty, and may be wholly a guess, but the guess should be toward a maximum rather than a minimum.

Alignment. Changes in alignment of existing streets in the built-up sections of cities and towns are costly. Except in extreme cases such changes are not attempted. Dangerous jogs at street intersections may often be improved or eliminated by suitable changes in the arrangement of the sidewalks without making any expensive changes in the abutting structures.

Sharp curves are usually not as dangerous as long tangents, if the curves are properly marked. Landscape architects should be restrained from making needless, and sometimes foolish, curves in suburban developments. These are always sources of danger. Curves that exist because of topographic conditions are generally satisfactory, and cause no trouble. However, long, sharp curves on steep grades should be avoided wherever possible, as frequently there is danger of cars and trucks getting out of control.

For highways it is not necessary to lay out curves with the long radii usual in railway location. Yet, with speeds on the highways of 50 m.p.h. and more, it is undoubtedly necessary to keep the curves as flat as is economically possible. Various state and county departments have adopted standards to which they try to adhere as far as may be. During 1928 the minimum radius usually allowed on federal-aid projects was about 500 ft.

The reprehensible practice of designing rural pavements with no superelevation of the outer edge of curves should be prohibited. In 1929, nearly all the new designs of roads called for superelevation. The formula for superelevation recommended by the American Association of State Highway Officials is:

$$\mathbf{E} = 0.067\,\frac{\mathbf{V}^2}{\mathbf{R}}$$

where $\mathbf{E}$ = maximum elevation in feet per foot of width;
$\mathbf{V}$ = velocity in m.p.h. (35 recommended);
$\mathbf{R}$ = radius of curve in feet.

Provision should be made wherever possible to give a line of sight at least 400 ft. ahead. This means that on sharp curves in cut, where buildings do not interfere, the embankment on the inside must be removed so as to give the needed vision. This is not always possible in mountainous country, but much can be done by simple relocation of the existing roadway. On new roads there is scant excuse for not providing sufficient sight ahead.

With the slower speeds of yesterday it was found that simple curves were sufficient, but with speeds of over 30 m.p.h., curves on first-class highways should be spiraled. This is specially necessary where the radius is less than

400 ft. Any method of figuring spirals for railway alignment will be satisfactory for highway curves. Reverse curves are dangerous and should be avoided. Even a very short tangent introduced between two curves will make the road safer than none at all. If spirals are used their ends may be brought together instead of introducing a tangent.

Grades. Horse-drawn traffic restricted grades to a greater extent than does motor traffic. The horse now may be eliminated from future consideration. The limiting factor is the heavy motor truck. Contrary to prevalent opinion, it is not possible for loaded 5- and 7-ton trucks to climb any and all grades. Many hills that may be fairly easy for a passenger car are all but impossible for the heavy truck. Existing steep grades should be investigated, not alone from the standpoint of theory, but also from the standpoint of the truckman who operates over such grades. It is not possible to keep trucks in perfect condition the year round; it is not possible to keep the highway itself in perfect condition continuously; and the weather is another changeable factor. Hence in location or relocation these facts must be kept in mind. Highway engineers will learn much that will be of benefit to the users of the highways if they will talk and drive with motor truckmen.

Arbitrary grade limits are unsatisfactory. A short steep grade occasionally may be preferable to a longer route over a light grade. The average truck, when not overloaded, has no difficulty with 12% grades if such hills are not too long. It must not be forgotten that these trucks and even passenger cars frequently encounter more difficulty in descending than in ascending. A long, steep grade must be avoided because of danger from runaways. Burned-out brake bands and stripped gears may result in disastrous accidents. If possible, a short up-grade should follow a long down-grade, so that runaways may have a chance to recover themselves. In spite of legislation to the contrary it is a matter of frequent occurrence to see motor trucks descending at 40 m.p.h. It is possible to so design a highway that even a coasting truck may not exceed some safe limit.

In general, the grade should be kept under 6%, not so much for economics as for safety. The grade established may determine the type of pavement to be selected. If a pavement is kept clean, then all types are reasonably safe on grades up to 7%. On steeper grades the following should be used: Stone block, hillside brick, concrete, bituminous macadam, or bituminous concrete with a cover of 3/4-in. stone chips rolled into the surface. Brick and the bituminous types may be unsafe on frosty mornings.

Widths. For city, town and village streets the following widths are recommended by Harland Bartholomew:

On country highways of the first class the width should never be less than 18 ft., increased an additional 2 ft. when approaching cities. This permits safe passing at high speeds. Traffic lanes should be at least 8 ft. wide on roads wider than 18 ft. Thus, three-lane traffic calls for a 24-ft. width, four-lane for 32-ft. and so on. These widths are minimum. A far better arrangement is the 10-ft. lane, which permits trucks to pass each other in safety.

Traffic lanes should be identified by painted lines upon the surface of the roadway.

On curves the width should be increased. The increase should be on the inside of the curve. Motor vehicles require a wider lane on curves than on tangents, but how to figure this amount exactly is a difficult problem. The longer the wheelbase the greater is the width required. If a transition curve is used the widening should begin at the point of curve of the spiral. If no

Fig. 1

spiral is used the pavement should begin to increase in width at a point not less than 30 ft. before the P. C.

The Extra Width. The extra width should be such that two motor buses may pass each other safely at a reasonable speed. The only way to ascertain the exact width required is actually to measure the path of moving motor vehicles of long wheelbase when rounding curves at high speed. In addition to extra width really needed to take care of the path of the car, there is an additional amount needed to make the road *apparently* safe. The average motorist finds it difficult to judge distances while driving on curves, so that an additional width must be supplied to aid him in his judgment.

The **width required,** irrespective of the psychological effect on the driver, may be figured from the following formula: $\mathbf{W} = l^2/2\,\mathbf{R}$, where **W** is the extra width in feet of the traffic lane, l is the length of the vehicle in feet, from the rear axle to the extreme front (usually the bumper), and **R** is the radius of the curve in feet. To this must be added whatever may be considered necessary in order to make the curve *appear* safe to the motorists who are either careless or not too sure of their driving abilities.

Local Materials. All sources of information concerning the location and possible use of suitable local materials should be tapped. The state geologist can frequently be of great help and should be consulted at the outset. Government reports, and other reliable data should be searched out and used. Contractors and engineers interested in such work should be interviewed, and in this way much time may be saved, while a more intelligent estimate may be prepared. A most important matter that is often overlooked is that of freight rates and local transportation charges. Local statutes and ordinances should be looked up. Labor rates and union rules must be carefully investigated. The Bureau of Public Roads, Washington, D. C., and most state highway departments will test road-making materials free of charge, and report upon their suitability for use. For the foundation of a road or pavement it is frequently possible to use local materials that might be wholly unsuited for use in the wearing course. The use of local materials often modifies the original scheme, and if intelligence is mixed with the materials a much cheaper form of construction may be possible.

Railroad Grade Crossing Eliminations. Railroad grade crossings may be eliminated by (1) relocating the highway, (2) relocating the railroad, (3) separating the grades. All are expensive. Where grades are separated extreme care must be taken in the design so that no new element of danger is introduced, such as sharp turns on cuts and fills, restriction of sight distance, columns, piers or bents in subways, poor drainage, too little headroom, narrow highway bridges, no sidewalks on highway bridges or through highway subways, and the like.

Headroom. For highway under railroad, allow 14-ft. minimum clearance. For highway over railroad, allow 22-ft. clearance unless railroad permits less. This is governed by law in some states. Highway grades on approach should not be greater than 6%, using 200-ft. vertical curves at changes of grade. The width of pavement should be the same as that of the highway itself and allowance must be made for ditches and sidewalks. Structures should be designed to take care of future traffic growth by subsequent additions as may be necessary.

2. Traffic Census

"The fundamental purpose of traffic or highway transportation research is to provide for the highway executive an accurate and reliable analysis of the demand for highway service. The demand for highway service can be measured only by an accurate and comprehensive study of present traffic, its volume and type, leading to an estimate of the future volume and character of traffic on the highway system and the individual routes."

Data may cover the following items: Count of passenger cars, motor trucks, buses, motor cycles, bicycles, horse-drawn vehicles, pedestrians, and parked vehicles. Detailed information may be obtained for each of these items, and may assist in forming a complete picture. Passenger car data should show state of registration, place of ownership, purpose of trip, origin, destination and number of passengers carried. Motor truck data should show weight on front and rear axles, tire equipment, weight of truck, load capacity of truck, state of registration, place of ownership, origin of trip, destination, commodity on board, probable return routing.

These data should be collected at such periods as will give the student of them a broad view of each case. In city districts data should be collected during 24-hour observation periods. This is true also of important through state routes which carry much night traffic. On the majority of roads, however, a 10-hour period is ample. Special observations must be taken to learn what hours this 10-hour period should cover, as in some localities heavy traffic begins at daybreak and is over early in the afternoon, whereas in others traffic may not begin until the middle of the morning. Observations must be made at different seasons, under various weather conditions, week days, Sundays, and holidays. The past history of the roads or streets should be looked up, and any pertinent facts recorded. United States census figures, school statistics, election returns, and any other available sources of information as to the contiguous population should be examined. A list of industries in nearby towns together with the number of employees should be compiled. All factors that make use of the highways should be studied.

In most cases it is possible to predict with a fair degree of accuracy what the traffic may be in five years on any particular route. Occasionally something upsets all calculations, but always it will be found that the calculation involved showed too small an increase. There is no decreased traffic. Prediction of future traffic is based primarily on prediction of future registration of motor vehicles, and this is fairly simple. The United States Bureau of Public Roads has prepared curves which agree well with actual figures. For full information see Report of a Study of Highway Traffic and the Highway System of Cook County, Illinois, Report of a Survey of Transportation of the State Highway System of Connecticut, and Report of a Survey of Transportation on the State Highway System of Ohio.

The writer suggests that the engineer or city official who undertakes to make a survey for the first time, unaided by any who have had experience, will look over the area carefully, and will make up several different types of forms on which to tabulate data. These forms may be tried out and the one that is easiest to follow should be selected. In city work it is possible to place only one man at each intersection where traffic does not exceed 4000 vehicles per 10-hour day. The information obtainable would include type of vehicle, approximate load, direction traveling (including turns), state of registration, hour, and weather. On such a busy intersection one man cannot count pedestrians. If traffic is greater than 4000 vehicles per 10-hour day it will be necessary to place two observers at such intersections on opposite sides of the street. The form as illustrated in Fig. 2, on next page, was found to work well in practice.

3. Finance

Money for road building is obtained by taxation. The forms of taxes are: **Direct taxes,** such as property taxes, poll tax, license fees, fuel tax, income taxes, special assessments, and tolls; and **indirect taxes,** such as import duties, excise taxes, and internal revenue. Direct taxation furnishes the revenues used by state and local units, whereas the federal government secures its funds largely from indirect taxes.

Motor vehicle license fees are usually levied on the horsepower of passenger cars, and on the weight capacities of trucks. The S. A. E. or the N. A. C. C. formula for

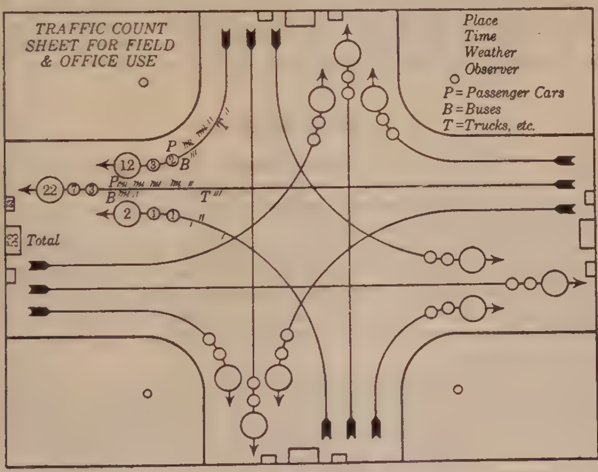

Fig. 2

the former is: **Hp. = 0.4 ND²,** where **N** = number of cylinders, and **D** = diameter of bore in inches. The minimum fees and taxes in 1928 for a touring car varied in the United States from $5 to $15.

A wheel tax is legal in some states. It is a license fee levied by a city.

A gas tax or a fuel tax was levied in 1929 in all states. The rate varied from 2 to 5 cents per gallon. Motor vehicle fees and gasoline revenues are divided between the construction and the maintenance of roads.

There are two methods of **financing** a highway construction program: The **pay-as-you-go** method, and the plan of capitalizing annual taxation by the **issuance of bonds.** The former inflicts no direct financial burden on posterity, and the program may be changed at will to meet current conditions. Bond issues require that a definite program must be followed. This method assures a speedily constructed system and should be used when the present system is small and incomplete. When the system approaches completion the pay-as-you-go method may be successfully adopted.

There are three types of bonds: Term, annuity, and serial. Of these the serial bond is the cheapest. Bonds should be sold in conformity with the progress of the construction program.

E. W. James points out that one detail is essential in determining a choice between the methods. The total cost of the same road varies according to the method of financing adopted. If the sum of $100 000 is to be spent in building 10 miles of highway, the cost is $10 000 per mile if the funds are produced from annual revenues. But the total cost of a $100 000 bond issue, serial type, may be $142 000, and the total cost of a mile of road paid for by this method would then be $14 200.

Local assessments are frequently necessary in financing municipal improvements. The assessments may be spread by: (a) Frontage Method, in which the assessment on any lot is found by multiplying its frontage by the rate per front foot; (b) Area Method, where each lot is assessed in proportion to its area; (c) Area-Distance Method, in which the assessment is made directly proportional to the area and inversely proportional to the distance from the improvement; (d) Zone-area Method, in which zones of uniform depth parallel to the street lines are laid out, and to each zone a rate of assessment is arbitrarily assigned, and (e) Benefit-factor Method, where the assessment decreases as the distance from the improvement increases.

4. Federal Aid

The policy of federal aid for highway construction was initiated with the Federal Aid Road Act of July 11, 1916; under the provisions of this act and subsequent amendments a total of $840,000,000 (through the fiscal year 1929) has been apportioned to the states.

All funds have been apportioned to the states in the following manner: One-third in the ratio which the area of each state bears to the area of all the states; one-third in the ratio which the population of each state bears to the total population of all the states; and one-third in the ratio which the mileage of rural delivery routes and star routes in each state bears to the total of such roads in all the states.

Since the passage of the Federal Highway Act of November 9, 1921, amending the original federal-aid act, federal-aid funds have been available for expenditure only on a system which has been selected and is known as the federal-aid highway system, consisting of approximately 187 000 miles of interstate and intercounty highways. Except in states where more than 5% of the area is unappropriated public land the amount of federal participation is limited to 50% of the cost. In those states having more than 5% of their area in unappropriated public land, the participation at present is limited as follows:

Arizona	72.34	Nevada	87.72	South Dakota	55.62
California	60.05	New Mexico	63.43	Utah	78.90
Colorado	56.08	Oklahoma	55.47	Washington	54.38
Idaho	59.75	Oregon	62.25	Wyoming	64.20
Montana	56.46				

Expenditures from appropriations of recent years have been limited to $15 000 per mile exclusive of bridges over 20 ft. in span, except in the public land states, where the amount is increased in the same proportion as the allowable federal participation.

In the construction of federal-aid roads, all plans and specifications are prepared by the state highway departments, subject to the approval of the Secretary of Agriculture, who acts through the Bureau of Public Roads. Each state is permitted to select designs suitable for the particular conditions existing, and it is required only that such designs shall be adequate for the conditions. A minimum width of 18 ft. is required unless particular conditions justify the approval of a lesser width. Contracts are let by the state highway departments and construction supervised by them. As a condition to receiving federal aid each state agrees to maintain the roads constructed with such funds and should a state fail to comply with this agreement the federal government is authorized to perform such maintenance, paying the cost from

States	Mileage in federal-aid highway system	Total federal-aid apportionment 1917-1929	Apportionment for fiscal year 1929

* These states have completed or provided for completion of the 7% system and additions in excess of 7% have been authorized.

funds due to the particular state, and to withhold further federal-aid funds from the state until reimbursement has been made for such payments. In the administration of federal aid, the federal government deals only with state highway departments.

In addition to the funds which have been provided for federal-aid road construction, a total of $77 000 000 has been provided for the construction of roads and trails in the national forests. This work is done either in cooperation with state or local authorities or independently by the federal government.

5. Soils

Classification. Soils are formed by the decomposition of mineral, animal, and vegetable matter. They may be designated as sedentary or transported. Sedentary soils are those which remain near their source of formation, while transported soils have been carried by some geological agency from the place where they were first formed to some other. Soil as far as its composition and properties are concerned is extremely variable. The principal constituents of any soil, however, whatever its source, are nearly always silica, with varying amounts of alumina, oxides of iron, lime, magnesia, and the alkalies. A small amount of organic matter is usually present also. Soils are generally classified as gravel, sand, clay, loam, marl, peat, and muck.

Gravel consists of small pieces of rock, worn smooth by abrasive action, mixed with sands and clays in varying proportions. Gravels occur throughout the United States and Canada in those districts which were at one time covered with the glacier. Gravel should contain enough binding material, mixed with the stone particles, to bind the whole into a solid mass. Clay is the most common form of binder found in gravel in its natural state. If present in too large quantities, however, it is detrimental. If gravel does not have sufficient binding material, this can be remedied by adding some cementing material such as clay, shale, marl, loam, or stone screenings. Some gravels contain so much earthy material that it is necessary to screen them before they are suitable for road-making purposes. An indication of the binding qualities for pit gravel may be obtained by noticing the gravel in the pit. If the bank faces are vertical and the gravel breaks off into chunks, good binding qualities may be expected. River gravel generally contains less clay and more silica than the pit gravel of the same locality. Soil classified as hardpan may mean either a very compact clay, or a gravel which is cemented with clay or an iron oxide.

Sand is largely the result of the breaking-down of sandstone rocks, and a sandy soil so-called probably contains over 80% of pure sand. A sandy soil is hard to compact, and possesses little binding power unless wet or mixed with some cementing material such as clay. Quicksand is sand saturated with water, and possesses no stability.

Clay results from the decomposition of feldspar, oligoclase, and micaceous rocks. A clayey soil might be termed such when containing at least 60% of clay. Clay when wet will swell and puddle with water, becoming very plastic. When mixed in the proper proportions with sand or gravel, it makes a very satisfactory road material in localities where stone is unobtainable. Clays used for fire clays in the manufacture of brick, besides being plastic, must possess certain refractory qualities which enable them to withstand long periods of heat at high temperatures without fusing. **Shales** have chemically the same composition as clays, but they have a laminated structure, and are similar in appearance to slates. Shales, however, will rapidly disintegrate on exposure to the atmosphere. In the southwestern states a clay of which mud bricks might be made is called " adobe."

Loams may be any soil between sand and clay. They contain more or less of each of these two materials. They may be classified as heavy clay loams, clay loams, sandy loams, and light sandy loams, depending upon the quantity of the sand or clay content. In the Middle West a black loam which contains so much clay as to be sticky when wet is known as " gumbo."

Marl is a term which applies to all calcareous clays containing as a minimum 15% of carbonate of lime, and as a maximum 75% of clay.

Peat and Muck are generally distinguished from other soils by the presence of humus or vegetable matter. They are formed by the decomposition of vegetable matter under water, and are undesirable materials for road building.

DRAINAGE AND FOUNDATIONS

6. Drainage

Subdrainage

Object. It is of the utmost importance that the natural foundation of a road should be kept dry in order to provide a firm and unyielding support. This can in certain instances be accomplished by subdrainage only. If the subdrainage system is correctly designed it may serve to lower the level of the ground-water and thus allow the ground to dry out; to remove water which is prevented from flowing off by an impervious stratum which underlies the road surface; to remove water which is always present in a road when the latter is thawing; to reduce the injurious action of frost by removing the moisture from the road; and to intercept water before it reaches the roadbed. Tile drains do not prevent nor remove capillary moisture. But capillary moisture itself may not be harmful unless it leads to saturation of the soil. Some soils do not respond to any method of drainage.

Methods in use for improvement of drainage conditions are: Placing a thick layer of sand, cinders, or similar materials on top of the soil and working this layer in by harrowing, or else leaving it in place without mixing. Tile drains, deep side ditches, and blind drains are advocated for certain conditions.

Porous Tile and Vitrified Pipe. The pipes are cylindrical in shape and are manufactured in 1-ft., 2-ft., or 2-1/2-ft. lengths with varying diameters. The porous tile pipe is made with plain ends, whereas the vitrified pipe is provided with a bell end. It is good practice not to use a size smaller than 4 or 5 in. in diameter. Where a large quantity of water is expected, if its amount is known, the size of pipe may be determined by one of the well-known formulas for flow of water through pipes.

The pipes should be laid in a properly constructed trench. The bottom of the trench should be covered with a layer of small-sized gravel or broken stone passing a 1/2-in. screen. The pipe is laid in the trench with open joints, or with the joints protected with small strips of burlap, and is then covered for a depth of about 1 ft. with a material of a size similar to that used in the bottom. The rest of the trench is then filled with large size broken stone. The filling should be carefully tamped around the pipe. Where a pipe with a bell end is used, the bell is placed toward the high end of the trench. On macadam roads it is customary to lay the side drains at a distance of from 1 to 2 ft. beyond the edge of the stone. The pipes are generally placed at a depth of from 2-1/2 to 4 ft. and are usually laid to the grade of the road, but with a minimum of 2 in. in 100 ft. The outlet end of the pipe should be protected by a small headwall of boulders to prevent the washing out of the pipe at this end. Whether a line of pipe is needed on one or both sides of the road is a matter of judgment. On side-hill work one line of pipe on the uphill side will generally serve. In constructing a road through broad, flat, wet places, one line of pipe at the side of the road may not be sufficient, and a line on each side of the road will be necessary. Through cuts, two lines are sometimes specified. In streets, tile drains should be laid under grass parkings, or, if such do not exist, under the gutters. For sizes of tile pipe under street pavements see Folwell's Sewerage, pp. 147–171.

Capacity of Tile Drains in Cubic Feet per Minute

From Spalding's Roads and Pavements, p. 36

Slope per 100 ft.		Diameter of pipe in inches				
Inches	Feet	4	6	8	10	12
2	0.17	4.0	12.0	27.0	49.5	81
4	0.33	5.5	16.5	38.0	70.0	114
6	0.50	6.5	21.0	46.5	86.5	143
9	0.75	8.0	25.5	57.5	106.5	176
12	1.00	9.5	29.5	66.0	122.5	204
24	2.00	13.5	41.5	92.5	173.0	288
36	3.00	16.5	51.0	114.0	212.0	353
48	4.00	19.0	59.0	132.0	245.0	408
60	5.00	21.0	66.0	148.0	275.0	456

Box Drains may be used in place of pipe in localities where stone is available. They should never be built of wood.

Blind Drains. Subdrainage is sometimes accomplished by digging trenches either across or alongside the road, afterward filling them with stone. The depth and distance apart of the trenches will depend upon the conditions encountered.

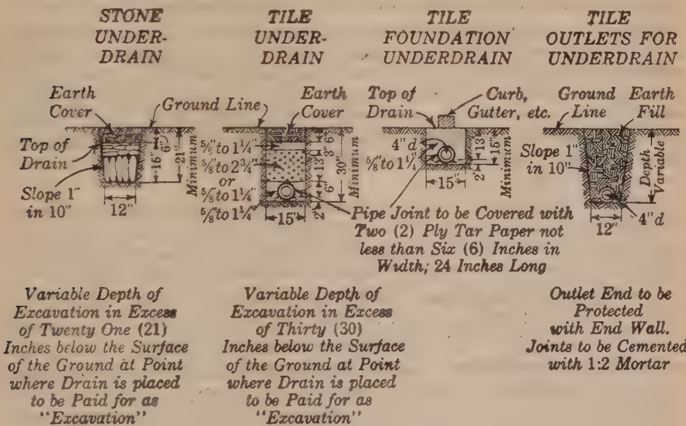
The V-Drain Foundation of the Massachusetts Highway Commission has given very good satisfaction on poor subsoils. It is built by excavating the full width of the surfaced roadway from 6 to 8 in. deeper at the sides and from 12 to 18 in. deeper at the center than usual, thus producing a flattened V-shaped trough. This trench is filled with stone varying in size from 1/2 in. to 12 in. in longest dimensions. The large stones are placed at the bottom of the trench. The grade of the trench is parallel to the finished grade of the road. The water follows the trench to the low points, where it is led to the sides of the road by a culvert across the road.

Soil Treatment. In places where the soil is very poor and is a hindrance to drainage, an improvement can be made by excavating the soil for a certain depth, depending upon conditions, and refilling with field stone, broken stone, or a good gravel.

Surface Drainage

Surface drainage is accomplished by giving the road or pavement surface a crown or transverse slope, which sheds the water to the side ditches or gutters. The ditches or gutters have a longitudinal grade which generally corresponds to the grade of the center of the road and the water is carried by them to the point where it is discharged. In this manner the flow of water is confined to a small area.

The Crown of the road or pavement is formed by the intersection of two planes or as a parabolic curve. At street intersections, the crown will have to be modified to fit the grades of the intersecting streets. On curves of main trunk highways the crown should consist of one plane sloping up from the inside edge of the curve. On streets that are bordered with curbs the elevations



UNDERDRAINS

Fig. 3

of which cannot be changed, a uniform slope both ways from the center of the road can be obtained in some cases by making one gutter deeper than the other. Frequently, however, it is necessary to use a different slope each side of the center.

Amount of Crown. The Special Committee on "Materials for Road Construction," Am. Soc. C. E., in 1918, recommended the following crowns:

Kind of roadway	Inch to the foot		Kind of roadway	Inch to the foot	
	Maximum	Minimum		Maximum	Minimum
Asphalt block	1/4	1/8	Cement-concrete	3/8	1/4
Bituminous surfaces	1/2	1/4	Gravel	1	1/2
Bituminous concrete	1/2	1/4	Sheet-asphalt	1/4	1/8
Bituminous macadam	1/2	1/4	Stone block	1/2	1/4
Brick	3/8	1/8	Wood block	1/4	1/8
Broken stone	3/4	1/2			

Crown Formulas. The following formulas, originated by Mr. Andrew Rosewater, M. Am. Soc. C. E., give the crown for brick, stone-block and sheet asphalt pavements. Let C = crown of pavement in feet, W = distance between curbs in feet, and f = grade of street in feet per 100. For brick, stone-block, wood-block, and compressed European rock-asphalt, $C = \frac{W(100 - 4f)}{6000}$.

For American sheet asphalt composed of sand and asphalt, or of compressed natural sand rock, $C = \frac{W(100 - 4f)}{5000}$. The formulas are based on the laws of the parabola, and the crown C is the total rise at the center above the pavement at the curb. The crown can be found for any other point by deducting from C an amount equal to C times the square of the distance, expressed as a fractional part of the half width, from the center to the point in question.

Ditches for country roads are made by either cutting out a trapezoidal-shaped section at the edge of the shoulder, or by a more gradual rounding off of the road at this point, giving a flatter and shallower ditch. The latter is preferable particularly if a road-scraper is used to any extent in the maintenance of the road. Ditches to be effective should be given a good bottom slope and should be kept clean. The slope of the ditch is made the same as the grade of the road surface, except in some cases where the grade of the road surface is very slight.

Gutters. Cobblestone, brick, concrete and stone-block gutters are laid on steep grades where water may wash out the sides of the road. Gutters are made from 1-1/2 to 6 ft. in width, and have the same slope as the road surface. It is better, however, to drop the center so as to form a trough section.

The Minimum Longitudinal Grade recommended by some engineers is 0.5%. If the road surface is kept in good repair and the water has a chance to run off at the sides. a flatter grade than 0.5% can be used.

Methods of Construction. During construction the shape of the surface may be obtained in four ways: by measuring from a string at grade which is stretched across and along the road at intervals; by blocks placed on the subgrade and each course; by using a board templet corresponding to the curvature of the cross-section; and by a series of stakes set at intervals across the roadway. Where the cross-section is composed of two planes the string method is rapid and accurate. Where the cross-section is a parabolic arc, the board templet or stakes are preferable.

Pipe Culverts

Capacity. The size of opening may be determined by formulas or an estimate of the runoff of water may be made and a size of pipe designed to take care of this amount. If the required area calls for a size of pipe that either is too large to be used, or cannot be obtained, two or three lines of smaller pipes may be substituted for it. It is, however, inadvisable to use a pipe less than 12 in. in diameter because a smaller pipe than this is liable to become choked.

Construction. Pipe culverts of all types should be laid on a firm bedding. If the soil furnishes a poor support, the pipes should be bedded in a layer of concrete or broken stone. This is more essential for culverts of vitrified pipe than for those made of the other materials. The trench should be excavated to the grade of the pipe. After the pipe is laid in the trench, good earth or small stone should be filled in around it and carefully tamped so that the pipe will be supported throughout its length. Concrete makes the best headwalls, since it is cheap, durable, and can be molded in any form desired. The headwalls for small culverts are generally built parallel to the center line of the road, with a thickness of at least 12 in. The bottom of the headwall should be 18 in. or more below the bottom of the pipe to prevent the water from flowing around the outside of the pipe and thus washing it out. The headwalls must be made long enough to keep the earth away from the pipe.

Vitrified Pipes used for culverts should be the best quality salt-glazed sewer pipe of the double strength type, with socket joints. This pipe is made in

2-1/2-ft. lengths with diameters from 12 to 36 in. The pipes are laid in the trench with the socket end toward the inlet, so as to have at least 15 in. of material over the top of the pipe. The joints are sometimes filled with cement. Under conditions ordinarily encountered in highway work vitrified pipe makes a very satisfactory as well as a cheap culvert.

Cast-Iron Water Pipe with bell and spigot joints has been used in culvert construction for a long time. It is manufactured in 6-ft. and 12-ft. lengths, and hence is not so easily adaptable for use. It is very strong and will last for many years. This kind of pipe can be placed within 6 in. of the road surface without danger of breaking. The principal objection to cast-iron pipe, outside of its cost, is its weight, which makes it expensive to handle. The weight per foot of heavy-weight pipe for some of the sizes from 12 to 72 in. in diameter is: 12-in., 85 lb.; 18-in., 200 lb.; 24-in., 300 lb.; 36-in. 500 lb.; 48-in., 850 lb.; 60-in., 1250 lb.; 72-in., 1750 lb.

Corrugated Metal Pipe is made in any length desired, ranging by multiples of 2 ft. up to 36 ft., or is made in nest sections that are later bolted together in the field. The pipe may be laid to within 6 in. of the road surface. Since it weighs about one-twentieth as much as cast-iron it is much more easily transported. The nest sections are of a particular advantage in this respect. Care should be taken to select pipes made of the proper kind of metal. Wrought iron is superior to steel as far as its non-corrosive properties are concerned, and hence pipes made of iron generally have a longer life. The non-uniformity of results obtained with metal culverts of different makes has been due almost entirely to the different kinds of material used in the manufacture.

Concrete Pipes may be cast and laid as any other form of pipe. The joints are made tapering, or with some form of socket. The pipes are built in lengths of from 2-1/2 to 8 ft., with thicknesses varying from 2 to 6 in., depending upon the diameter. Concrete pipes weigh more than cast-iron pipes, but may be constructed so as to cost about one-fourth as much. In the case of concrete pipes constructed in place, the use of reinforcement will not be economical until they exceed 4 ft. in diameter.

7. Foundations

The loads due to traffic are transmitted by the wearing surface to the foundation. If the foundation fails, the pavement or surface above it will fail. The kind of foundation and its thickness depend upon the amount of traffic and the nature of the underlying subsoil.

The Different Materials Used as a foundation are the subsoil encountered, gravel, broken stone, slag, broken brick, hydraulic cement concrete, bituminous macadam and bituminous concrete, and old pavements. When a poor subsoil is encountered, the poor material should be excavated for a depth of several inches and refilled with a good gravel. Sandy subsoils may be improved by the addition of clay, and clayey soils by the addition of sand.

Broken Stone. The lower course of a macadam road, when the latter is built in two courses, is the foundation for the upper or wearing course. Ordinarily this course is about 6 in. in depth after compaction. Where the subsoil is poor or the road is subjected to heavy traffic, or it is desired to aid the subdrainage of the road, the lower course should be increased in thickness, or an additional layer of broken stone should be used. This extra layer varies from 3 to 10 in. in thickness, and is composed of the larger-sized products of the crusher. Instead of this layer of broken stone, a telford base is sometimes constructed, which consists of placing by hand stones broken into sizes 6 to 8 in. deep, 3 to 8 wide, and 6 to 15 long. The stones are placed on edge with their longest dimensions at right angles to the axis of the road. The spaces between the stones are filled with spalls, after which the whole surface is thoroughly rolled. Large stones laid flat instead of on edge are sometimes substituted for telford. The cost of either a broken stone or a telford base depends upon the amount of stone used. Slag and brickbats, where available, can be used in place of broken stone. Gravel foundations are usually laid 6 to 8 in. in thickness.

Cement-Concrete foundations should ordinarily be used under all types of stone block, wood block, brick, sheet asphalt, and bituminous concrete pavements. The thickness of the concrete foundation varies from 4 to 11-in., 6 in. usually being employed. An 11-in. foundation is necessary when the traffic is exceptionally heavy. The usual proportions of the cement, fine aggregate and coarse aggregate vary from 1 : 2 : 5 to 1 : 3-1/2 : 7. Whenever a concrete foundation is constructed, traffic should be kept from it for 7 to 10 days in order to allow it to set up thoroughly. The processes of proportioning, mixing and placing are identical with those of the concrete pavement. Center joints are rarely used. Transverse joints are seldom necessary and are liable to cause difficulties with the wearing course.

Black Base. Bituminous-bound foundations are often termed "Black Bases." Many have been in use for a half century. The old black bases in Washington, D. C., were built of gravel bound with coal tar. Later, crushed stone was used instead of gravel, and either may be used. Either a mixed base or a penetration base may be laid. Coal tar or asphalt may be the binder; both have been successful. If the penetration method is used, the manner of construction is similar to that for the bituminous macadam except that the seal coat is omitted together with the cover. If a mixed base is desired then the method is that of bituminous concrete.

For details of construction and materials see Asphalt Base Pavements, Brochure No. 12, published by The Asphalt Association. Also, "Black Base," by Hugh W. Skidmore, published by The Asphalt Association.

New Tops for Old Pavements. Many old pavements are admirably suited for new tops, and such pavements should not be torn up until it is certain that they will not serve.

Slag. Crushed slag filled with granulated slag makes an excellent foundation. In the course of time such a base sets up like concrete. It should be about 8 in. thick, or more. It is a suitable base for bituminous tops, brick, and other block pavements.

MATERIALS

8. Non-Bituminous Materials: Stone, Brick, Wood

Rocks used for road-building purposes are trap, granite, limestone, sandstone, chert, slate, and field stones.

Diabases and Basalts, which are dark-colored igneous rocks, are commonly known as **trap.** Trap is extremely hard and tough, and its excellent wearing qualities have caused its widespread use throughout those sections of the country where it is found. When used in the construction of broken-stone roads subjected to a light traffic, the wear on the stones will not be sufficient to make enough binder to hold the stones together. To prevent the surface from raveling, more binder of a bituminous material must be applied.

Granite is made up chiefly of quartz and feldspar. In trade, gneiss, syenite and porphyry are commonly known as granite, although not so in a geological sense. If the structure is close, even and granular, these stones make excellent road material for broken-stone roads. If of a coarse structure, they are not so desirable. Granite and syenite are more largely employed for paving stones than other materials, the latter being one of the best materials for this purpose. Stone blocks made of porphyry have been found to wear slippery, and in Europe their use is being discontinued.

Limestone possesses excellent binding qualities, but much of it is neither hard nor tough, and such stone is therefore only suitable for roads taking a light traffic. Some limestones are as hard and tough as trap.

Sandstone, due to the fact that it easily breaks up under the action of traffic, and is lacking in binding qualities, is generally considered as only a fair material for broken-stone roads. Stone blocks, however, made of Medina, Potsdam, and Colorado sandstone have been used to a considerable extent with excellent results.

Quartzites, which are metamorphosed sandstones, give better results when used for broken-stone roads than sandstones, as they are harder.

Chert is a variety of quartz of a flinty structure. It occurs in certain parts of the country either as a solid mass or in a broken-up state, mixed with clay similar to gravel.

Field Stones are boulders which have been carried along by the glacier and are found mainly in those districts which were covered by the glacier. They are composed of a variety of different kinds of rocks, some of which make good road-building materials. Those stones which show signs of weathering and decomposition should not be used. Cobblestones used for paving gutters and streets are small boulders which have been selected from field stones.

Slate, an indurated or hardened clay, is of little value as a road-building stone on account of its fracture and low cementing value.

Chats is a term used to denote the tailings of lead mines. It is a dolomitic limestone, and considered good for use in road construction.

Tests for Broken Stone. By making petrographic and chemical analyses, a rock can be identified and its constituents ascertained. For the purpose of determining the value of a rock as a road-building material, several tests have been devised. The usual tests made of broken stone are for abrasion, toughness, absorption of water, specific gravity, hardness, and cementing power.

The Abrasion Test as adopted by the American Society for Testing Materials, is made by means of the Deval machine, and consists of placing 50 pieces of stone approximately the same size and having a total weight of 5000 g, $\pm$ 10, in one of the cylinders, the cylinder being rotated for 10 000 revolutions, at the rate of between 30 and 33 to the minute. The weight of the detritus that will pass a sieve of 1/16-in. mesh is determined, and the percentage of wear computed. The coefficient of wear, also known as the French coefficient, equals $400/W$, in which W is the weight in grams of the detritus passing the above sieve, obtained per kilogram of rock used. In interpreting results of this test a coefficient of wear below 8 is called low; from 8 to 12, medium; over 12, high. (See A. S. T. M. D2-26.)

The Test for Toughness, as adopted by the American Society for Testing Materials, is made on rock cylinders, 25 mm. in diameter by 25 mm. in height, which have been bored out of the rock by a diamond core drill. These cylinders are placed in an impact machine underneath a plunger 1 kg. in weight, and the latter is subjected to the blow of a 2-kg. hammer. The hammer falls 1 cm. for the first blow, and the fall is increased 1 cm. for each succeeding blow. The number of blows required to destroy the test piece is used to represent the toughness. The average of three specimens is used. Results of this test are interpreted so that rocks which run below 8 are called low; from 8 to 12, medium; and above 12, high.

Common Commercial Sizes of broken stone are screenings, 3/8-in chips, 1/2, 3/4, 1, 1-1/4, 1-1/2, 2, 2-1/4, 2-1/2, and 3 in. The size of the crushed stone depends upon the kind of stone, the crusher, and the screen, and the details of operation. The inclination of the screen and, if a rotary screen, the weather, the speed at which it is run, will make a variation in the separation of the sizes of the screened product.

Specifications for Stone Blocks (A. S. T. M. D59-26) should call for a close, medium-grained, homogeneous material, durable, sound and uniform, with no outcrop, soft, brittle or laminated stone. The stone is tested for crushing, abrasion, and toughness. Cobble should be sound, durable and uniform stone, 4 to 8 in. in diameter.

Clays for Making Vitrified Bricks are not often found in a natural state. A clay for this purpose should be fusible, plastic, and be able to be heated to a high temperature without losing its shape. Vitrification is obtained by subjecting the clay to heat, which changes the chemical properties of its constituents, making them coalesce with each other into a new and homogeneous solid. All clays are composed mainly of silica and alumina and certain impurities such as quartz, lime, magnesia, potash, and soda. The impurities, with the exception of quartz, act mainly as fluxes. An excess of silica will cause a weak and brittle specimen, and an excess of alumina will cause shrinkage, cracking, and warping. An excess of lime and magnesia hastens disintegration upon exposure. Shales are also used for the manufacture of paving-bricks. They produce a harder and more brittle brick than one of fire-clay. Paving-bricks are manufactured by crushing and screening the properly mixed clays or shales. This material is then mixed with water in a pug-mill to the right state of consistency, and is then pushed through a mold, the clay being fed to the mold by means of an augur. The bar of clay as it comes from the mold is cut by machines into the size of brick desired. Paving-bricks are made with plane faces and also with some projections on the faces so that, when laid, there will always be a space between the faces which will later be filled with the joint filler. Some machines are designed so as to cut the brick with lugs on one side and grooves on the other. Other bricks are repressed after being cut, and lugs or grooves, together with the curved edges, are formed by the die used in repressing. The raised letters on the brick serve this same purpose. After being cut or repressed, the bricks are dried and then burned for from seven to ten days at temperatures varying from 1500 to 2300 deg. F. The bricks are slowly cooled in the kiln after the fire is withdrawn, which serves to anneal and toughen them.

The recognized sizes and varieties of paving brick manufactured in 1928 are: Plain wire cut (no lugs), 2-1/2 × 4 × 8-1/2 in., 3 × 4 × 8-1/2 in., 3-1/2 × 4 × 8-1/2 in. Repressed lug, 3-1/2 × 4 × 8-1/2 in. Wire cut lug, 3-1/2 × 4 × 8-1/2 in.

Tests for Paving Brick (A. S. T. M., C7-15). Visual inspection may result in rejection of bricks for being broken, chipped, off size, misshapen, bent, twisted, or badly kiln marked; obviously too soft or too poorly vitrified to endure street wear; so badly off color as to give the pavement a mottled appearance. The rattler test shows the percentage of loss of weight due to abrasion and wear in the rattler. The following scale of average losses represents what may be expected:

	General average loss, per cent	Maximum permissible loss, per cent
For brick suitable for heavy traffic	22	24
For brick suitable for medium traffic	24	26
For brick suitable for light traffic	26	28

Which of these grades should be specified in any given district and for any given purpose is a matter wholly within the province of the buyer.

Wood Blocks that have not been treated by some preservative process have given unsatisfactory results. Rectangular-faced blocks of Southern long-leafed yellow pine, Norway pine, and tamarack are usually specified, only one kind of wood, however, to be used on any one contract. Black gum and short-leaf pine may be satisfactory under certain conditions, but require a different treatment than the woods first mentioned. The Australian hard woods, Jarri and Karrah, are slippery, and are considered too costly for use in this country.

The common method of preserving wood blocks is to treat them with some preservative fluid, the most common being a pure creosote oil or a water-gas or a coal-tar product. In the United States the yellow pine blocks are impregnated with the oil under a pressure of from 50 to 150 lb. per sq. in. The amount of oil absorbed by the wood varies from 10 to 22 lb. per cu. ft.

Timber (A. S. T. M., D52-20). The wood which shall be treated shall be Southern yellow pine, Douglas fir, tamarack, Norway pine, hemlock, or black gum. Only one kind of wood shall be used in any one contract. The blocks shall be sound, well manufactured, square butted, square edged, free from unsound, loose, or hollow knots, knot holes, worm holes, and other defects such as shakes, checks, etc., that would be detrimental to the blocks. No one block shall be accepted that contains less than 50% of heart wood.

It is recommended that blocks 4 in. in depth, shall be used for streets with very heavy traffic, and blocks 3-1/2 in. in depth for streets with moderate traffic. Wood blocks should not be used on light traffic streets.

9. Bituminous Materials

The Bituminous Materials used in the United States may be classified as follows: asphalts, asphaltic and semi-asphaltic oils, coke oven tars, coal-gas tars, water-gas tars, combinations of coal-gas and water-gas tars, combinations of asphaltic materials and tars, rock asphalts.

Nomenclature of Bituminous Materials and Their Uses. Definitions adopted by the Special Committee on "Materials for Road Construction" of Am. Soc. C. E. are noted thus, †; others adopted by the A. S. T. M. are designated thus, * and others proposed by the Committee on "Standard Tests for Road Materials" (Committee D-4) of the A. S. T. M. have been indicated thus, ‡.

Asphalt.†* Solid or semi-solid native bitumens, solid or semi-solid bitumens obtained by refining petroleum, or solid or semi-solid bitumens which are combinations of the bitumens mentioned with petroleums or derivatives thereof, which melt on the application of heat, and which consist of a mixture of hydrocarbons and their derivatives of complex structure, largely cyclic and bridge compounds.

Asphalt Block Pavement.† One having a wearing course of previously prepared blocks of asphaltic concrete.

Asphalt Cement.† A fluxed or unfluxed asphalt, especially prepared as to quality and consistency, for direct use in the manufacture of asphaltic pavements, and having a penetration at 25° C. under a load of 100 g. applied for 5 sec. of between 5 and 250.

Asphaltenes.†* The components of the bitumen in petroleum, petroleum products, malthas, asphalt cements and solid native bitumens, which are soluble in carbon disulphide, but insoluble in paraffin naphthas.

Bitumens.*† Mixtures of native or pyrogenous hydrocarbons and their non-metallic derivatives, which may be gases, liquids, viscous liquids, or solids, and which are soluble in carbon disulphide.

Bituminous Concrete Pavement.† One composed of broken stone, broken slag, gravel, or shell, with or without sand, portland cement, fine inert material, or combinations thereof, and a bituminous cement incorporated together by a mixing method.

Bituminous Macadam Pavement.† One having a wearing course of macadam with the interstices filled by a penetration method with a bituminous binder.

Bituminous Material.† Material containing bitumen as an essential constituent.

Liquid Bituminous Material.† Bituminous material showing a penetration at 25° C. under a load of 50 g. applied for 1 sec. of more than 350.

Semi-solid Bituminous Material.† Bituminous material showing a penetration at 25° C. under a load of 100 g. applied for 5 sec. of more than 10, and under a load of 50 g. applied for 1 sec. of not more than 350.

Solid Bituminous Material.† Bituminous material showing a penetration at 25° C. under a load of 100 g. applied for 5 sec. of not more than 10.

Bituminous Pavement.† One composed of broken stone, broken slag, gravel, shell, sand or fine inert material, or combinations thereof, and bituminous cement incorporated together.

Bituminous Surface.† A superficial coat of bituminous material with or without the addition of stone or slag chips, gravel, sand, or material of similar character.

Blown Petroleums.* Semi-solid or solid products produced primarily by the action of air upon liquid native bitumen which are heated during the blowing process.

Carbenes.†* The components of the bitumen in petroleums, petroleum products, malthas, asphalt cements, and solid native bitumens, which are soluble in carbon disulphide, but insoluble in carbon tetrachloride.

Coal-tar.†* The mixture of hydrocarbon distillates, mostly unsaturated ring compounds, produced in the destructive distillation of coal.

Coke Oven Tar.†* Coal-tar produced in by-product coke ovens in the manufacture of coke from bituminous coal.

Consistency. The degree of solidity or fluidity of bituminous materials.

Cut-Back Products.* Petroleum, or tar residuums, which have been fluxed with distillates.

Dead Oils.†* Oils, with a density greater than water, which are distilled from tars.

Dehydrated Tars.†* Tars from which all water has been removed.

Emulsion.† A combination of water and oily material made miscible with water through the action of a saponifying or other agent.

Fixed Carbon.†* The organic matter of the residual coke obtained upon burning hydrocarbon products in a covered vessel in the absence of free oxygen.

Flux.†* Bitumens, generally liquid, used in combination with harder bitumens for the purpose of softening the latter.

Free Carbon.†* In tars, organic matter which is insoluble in carbon disulphide.

Gas-House Coal-Tar.†* Coal-tar produced in gas-house retorts in the manufacture of illuminating gas from bituminous coal.

Native Asphalt.†* Asphalt occurring as such in nature.

Normal Temperature.†‡ As applied to laboratory observations of the physical characteristics of bituminous materials, is 25° C. (77° F.).

Oil-Gas Tars.†* Tars produced by cracking oil vapors at high temperatures in the manufacture of oil-gas.

Penetration. See penetration test.

Petroleum.‡ Liquid bitumen occurring as such in nature.

Topped Petroleum. Petroleum deprived of its more volatile constituents.

Pitch.†* Solid residue produced in the evaporation or distillation of bitumens, the term being usually applied to residue obtained from tar.

Hard Pitch.† Pitch showing a penetration of not more than ten.

Soft Pitch.† Pitch showing a penetration of more than ten.

Refined Tar.†* A tar freed from water by evaporation or distillation which is continued until the residue is of desired consistency, or a product produced by fluxing tar residuum with tar distillate.

Rock Asphalt.†‡ Sandstone or limestone naturally impregnated with asphalt.

Rock Asphalt Pavement.† A wearing course composed of broken or pulverized rock asphalt with or without the addition of other bituminous materials.

Sheet Asphalt Pavement.† One having a wearing course composed of asphalt cement and sand of predetermined grading, with or without the addition of fine material, incorporated together by a mixing method.

Straight-Run Pitch.* A pitch run to the consistency desired, in the initial process of distillation, without subsequent fluxing.

Tar.†* Bitumen which yields pitch upon fractional distillation and which is produced as a distillate by the destructive distillation of bitumens, pyro-bitumens, or organic material.

Viscosity. The measure of the resistance to flow of a bituminous material, usually stated as the time of flow of a given amount of the material through a given orifice.

Water-Gas Tars.†* Tars produced by cracking oil vapors at high temperatures in the manufacture of carburetted water-gas.

Tests and Specifications for Physical and Chemical Properties. Various tests have been devised in order to determine the physical and chemical properties of bituminous materials. Tests are made for control of the manufacture of bituminous materials, to obtain a record of the properties of materials used, and are employed in specifications to secure the materials desired for use in the construction and maintenance of roads and pavements.

Asphalt Cements. Specific gravity at 25° C.; flash and fire points; solubility in CS_2; solubility of bitumen in CCl_4; solubility of bitumen in petroleum naphtha; penetration at 0° C., 200 g., 60 sec.; penetration at 25° C., 100 g., 5 sec.; penetration at 46° C., 50 g., 5 sec.; float test; melting point by ring and ball method; ductility at 25° C.; fixed carbon content; paraffin content; loss on evaporation at 163° C., 5 hours; penetration of residue (same as for asphalt cement); melting point of residue, by ring and ball method, float test on residue; ductility of residue at 4° C.; ductility of residue at 25° C.

Road Oils. Specific gravity; specific viscosity; total bitumen; proportion of total bitumen insoluble in paraffin naphtha; flash point; residue at 100 penetration.

Tar Cements. Water; specific gravity at 25° C.; solubility in CS_2; specific viscosity, Engler; melting point, by cube method; softening point, ring and ball; float test; distillation by weight and by volume; specific gravity of total distillate at 25° C.; softening point of residue by ring and ball method.

The tests used in a given specification depend upon the kind of bituminous material employed and the method used.

For the purposes of this section it is not necessary to describe tests of which the name itself gives an indication of the method of performing the test. Such tests include specific gravity, solubility in carbon disulphide, carbon tetrachloride, petroleum naphtha, evaporation, and distillation. For detailed descriptions of methods of conducting all of the tests for tars and asphaltic materials, see A. S. T. M. standards and tentative standards.

Flash and Fire Points (**open-cup**). The material is placed in a Cleveland open cup apparatus and the temperature is raised at approximately 10 deg. F. per minute. A test flame of 5/32-in. diameter is passed across the center of the cup as the temperature read on a thermometer inserted in the material reaches each successive 5° F. mark. The **flash point** is taken as the temperature read when a flash appears at any point on the surface of the oil. The **fire point** is taken as the temperature at which the oil ignites and continues to burn for at least 5 seconds.

Softening Point (**ring and ball**). The material is melted and run into a brass ring 5/8 in. in inside diameter and 1/4 in. deep. It is allowed to cool in the air, and is then suspended in a beaker of water maintained at 5° C. for 15 minutes. A 3/8-in. steel ball is immersed at the same time. The ball is then placed in the center of the upper surface of the bitumen in the ring and heat is applied in such manner that the temperature of the water is raised 5° C. each minute. The temperature of the water recorded at the instant that the material touches the bottom of the beaker is known as the **softening point.**

Consistency. The consistency of bituminous materials is determined by the Engler viscosimeter, the New York Testing Laboratory flat apparatus, or the penetrometer.

With the **Engler Viscosimeter** the viscosity of liquid bituminous materials is determined by noting the time which is required for a given amount of the material, having a given temperature, to flow through a very small orifice. The result of the test should be expressed as specific viscosity, which equals the ratio of the number of seconds required for the passage of 50 cc. of the bituminous material at the temperature used divided by the number of seconds required for the passage of the same volume of water at 25° C.

The New York Testing Laboratory Float Apparatus consists of an aluminum float and a brass collar. The collar is filled with bituminous material and screwed into the bottom of the aluminum float and the apparatus placed on the surface of a water bath. As the plug of bituminous material in the collar becomes warm and fluid, due to the heat from the water bath which is maintained at any temperature desired for the test, it is gradually forced upward and out of the collar until water gains entrance to the saucer and causes it to sink. The time in seconds between placing the apparatus on the water and when the water breaks through the material is taken as the measure of consistence.

The Penetration Test is made by measuring the distance a weighted standard needle will penetrate into the material at a given temperature in a given period of time. The temperatures, weights, and periods of time which are employed to a considerable extent are as follows: Penetration at 0° C. with a weight of 200 g. for 1 minute; penetration at 25° C. with a weight of 100 g. for 5 seconds; penetration at 46° C. with a weight of 50 g. for 5 seconds. When the penetration of a material is mentioned without reference to temperature, weight of the load, or time, it is understood that reference is made to the penetration at temperature of 25° C. with a weight of 100 g. for 5 seconds. The unit of penetration is 0.1 mm. In literature and specifications the penetration is referred to in terms of the above unit either as a penetration of 6.4 mm. or 64.

Ductility. In the ductility test a briquet of the material is formed in a standard briquet mold. The briquet with clips attached is placed in a ductility testing machine filled with water at a temperature of 4° C. or 25° C. The briquet is then pulled apart at a uniform rate and the distance in centimeters registered at the time of rupture of the thread of bituminous material is taken as the measure of ductility.

Fixed Carbon. Fixed carbon is the organic matter of the residual coke obtained upon burning hydrocarbon products in a covered vessel in the absence of free oxygen.

Paraffin. One hundred grams of the material is distilled rapidly in a retort to a dry coke. Five grams of the distillate is then thoroughly mixed in a 60-cc. flask with 25 cc. of Squibbs' absolute either. Then 25 cc. of Squibbs' absolute alcohol is added, and the flask packed closely in a freezing mixture of finely crushed ice and salt for at least 30 minutes. The precipitate is filtered out quickly with a suction pump, using a No. 575 C. S. and S. 9-cm. hardened filter paper. The flask and precipitate is then rinsed and washed with a mixture of equal parts of Squibbs' alcohol and either cooled to − 17° C. (1° F.) until free from oil. When sucked dry, the filter paper is removed and the waxy precipitate transferred to a small glass disk and evaporated on a steam bath. The residue (paraffin) remaining on the disk is weighed, and from this weight the percentage on the original 5-g. sample is calculated.

Extraction of Bitumen from Bituminous Aggregates. The aggregate is prepared for analysis by heating it in an enamel-ware pan on a hot plate until it is sufficiently soft to be thoroughly disintegrated by means of a large spoon. The disintegrated aggregate is then allowed to cool, after which a sufficient amount is taken to yield on extraction from 50 to 60 g. of bitumen. It is then placed in a mechanical extractor and carbon disulphide is poured into the receptacle containing the aggregate. After allowing the material to digest for a few minutes, the machine is started, slowly at first in order to permit the aggregate to distribute uniformly. The speed is then increased sufficiently to cause the dissolved bitumen to flow from the receptacle. When the first charge has drained, the machine is stopped and a fresh portion of disulphide is added. This operation is repeated from four to six times until the liquid flowing from the receptacle is clear. After the aggregate is thoroughly dried, it is weighed. The difference between this weight and the original weight taken shows the amount of bitumen extracted.

ROADS

10. Earth Roads

Since earth roads may be constructed out of any kind of soil it is difficult to compare their characteristics. Soils act differently under different conditions. A sand road is good in wet weather whereas one of clay is impassable. A clay road is good in dry weather whereas sand makes hard traveling. If these two materials can be so mixed that their good characteristics predominate, then a road good in any weather is possible. Earth roads are cheap to construct, and, if traffic is not unduly heavy, their maintenance cost is low.

Of the 3 000 000 miles of road in the United States (1928) 85% are unsurfaced, 10% are a low type surfacing such as sand-clay, gravel or untreated stone; 4% are an intermediate type, and less than 2% are high type. Hence the earth road for years to come must be the predominating type. With this in mind many experiments have been tried for the purpose of improving earth roads at low cost. Surface treatments with a number of different materials have been tried with varying degrees of success. On the whole the bituminous materials have been the most successful. C. N. Conner cites three general methods of treatment: (1) The skin surface treatment or penetration method, hot or cold; (2) the mixed-in-place treatment, cold; (3) the premixed method, hot or cold. Treatments (1) and (2) are discussed under "**Gravel Roads,**" p. 1925, and (3) is discussed under "**Asphalt,**" p. 1942.

One point of utmost importance is often lost sight of by those who are new to the practice of treating low type roads, and that is that each road, and even certain stretches of each road, may be a problem in itself. A material or a method that may be satisfactory on one stretch of road may be unsatisfactory on the next stretch. Soils may change in character within a few feet, and all materials are not equally suited for use on all soils. The man who wants to be successful must experiment for himself, and he must watch developments with an all-seeing eye. Failure to realize this has retarded the art in many localities. Tars, asphalts, and road oils are not identical materials. Maintenance men have wasted great sums because they have used incorrect methods and wrong materials.

Earth roads may be improved sometimes by the admixture of small amounts of such materials as pea-gravel, granulated slag, portland cement, stamp sand, lime, steam coal ashes, chats, and similar hard particles. A layer is usually spread over the earth road and then is harrowed into the surface; or traffic is supposed to work in the materials. As a rule a layer an inch thick is about as much as can be handled easily. Sometimes no harrowing should be attempted, and traffic will compact the surface. Again, it may be necessary to blade or drag the road, and some roads respond well to rolling, while others do not. If you have no experience you must experiment; if you have experience you *will* experiment. Experiments on earth roads in Iowa seemed for a while to indicate that admixtures of portland cement might be of great value; later, these roads so treated were not as good as untreated sections, and the cost was considerable. Yet it is possible that the same method might be eminently successful with some other earth road. A light tar may be useful with some soil roads, but if there is much clay present it will surely be a failure. In general, the maintenance engineer should buy two or three barrels each of several different bituminous materials and try them out on the same road where conditions and soil are the same. After a year's trial much should have been learned.

The bituminous materials suitable for earth road treatments are road oils, cut-back asphalt, water-gas tar, and coal tar. As a rule the road oils are cheaper than the tars, and the tars are cheaper than cut-back asphalt.

See specifications Road Oil, Illinois, and Pennsylvania specifications for cold application (cut back).

In some instances it has been found that earth roads should be given a prime coat of light tar (Pennsylvania Specification C2) followed by a seal coat of cut-back asphalt. A cover of pea-gravel, stone chips, or coarse sand often helps make a tougher surface that is capable of carrying more traffic.

A method of making soft earth roads passable is to spread three layers of ordinary 1-1/2-in. chicken wire for wheel tracks. Heavy trucks will not cut through a road so reinforced. Another device is a longitudinal section of a corrugated metal pipe laid across mud holes, the pipe thus forming a rut for the wheels. The device has been trade-marked under the name of "Metal-rut."

Construction of Earth Roads. Good drainage is an absolute necessity. Proper subdrainage and surface drainage must be provided. In providing for surface drainage the slopes from the center to the sides should not be made too steep; a slope of from 3/4 in. to 1 in. per foot is used, the latter being a maximum. The surface of the road may be made to conform to the arc of a circle or be made up of two planes meeting at the center and sloping to the ditches. Care should be taken in constructing the ditches to see that they have sufficient fall to carry the water away. In places where the country is flat and the work involved is simply that of giving a crown to the road, earth roads may be constructed most economically by means of road scrapers or graders. If the soil is not too compact, the use of the plow could be done away with in using the road grader. The latter is usually worked by beginning at the sides, going down one side and back the other, gradually approaching the center, the blade being so adjusted as to plow to the proper depth, and move the earth up from the sides toward the center. The material deposited by the grader is sometimes harrowed and then rolled; when rolling is not resorted to, the material is left to be packed down by traffic. Care must be taken to spread the material evenly and in layers usually recommended not to be over 6 in. deep. Where much grading is involved, the bulk of the work will have to be done by the common methods of earth excavation, the road grader being used to finish the road to the desired surface.

Sand-Clay Roads are constructed somewhat differently, depending upon whether the subsoil is of sand or of clay. The amount of clay necessary is that amount which will just fill the voids in the sand. It will also depend upon the character of both the sand and the clay. It may be approximately determined by finding the quantity of water which is contained in a known volume of sand, the amount of water representing the percentage of voids. Proper drainage must always be provided. The construction of a sand-clay road is a slow process, and the best results can be obtained only by giving the road constant attention for some time after it is first finished.

The Maintenance of Earth Roads consists principally in keeping the surface shaped up and the ditches cleaned out so that the water will not have any chance to stand either in the road or at the sides. Water, if it has a chance to soak into the road, soon softens it to such an extent that it is easily cut up by the action of traffic and is soon destroyed. Two of the most useful tools for the maintenance of earth roads are the road scraper and road drag. There are many different types of these machines. The road drag, which is the simplest, consists of two blades about 7 to 9 ft. long set parallel to each other about 30 in. apart. The blades may be made of steel, of plank, or of split logs. This device is so hitched to the team that it may be dragged along the road at an angle at about 45 degrees with the axis of the road. Work with the drag scraper is done in a similar manner as with the road scraper; namely, starting in at the side of the road, and working up toward the center. Dragging may be done at all seasons, but should be carried on only after a rain when the road is in a moist condition. If the road is properly drained it will be found that the surface can be kept in excellent condition by the use of the road drag or road scraper at frequent intervals.

Summary of Specifications for Road Oil of the Illinois Division of Highways

E1 is a light asphaltic oil.
E2 is a light semi-asphaltic oil.
E3 is a heavy semi-asphaltic oil.
E4 is an extra heavy semi-asphaltic oil.
E5 is a heavy asphaltic oil.

The road oil shall be homogeneous and shall contain not to exceed 1% by volume of water. It shall meet the following requirements:

	E1	E2	E3	E4	E5
Specific gravity 15.5°/15.5° C...	0.94–0.97	min. 0.91	min. 0.92	min. 0.93	0.95–0.98
Specific viscosity, 60° C.......	8–16	8–16	16–28	28–42	16–28
Total bitumen, per cent, minimum....................	99.5	99.5	99.5	99.5	99.5
Bitumen insoluble in 86° Bé. paraffin naphtha, per cent....	min. 11	max. 8	max. 9	max. 10	min. 12
Flash point, deg. C., minimum.	80	80	80	80	80

Asphalt Cut-Back. Asphalt for Cold Patching

Specification Pennsylvania Highway Department

This material shall be a cut-back asphalt prepared by compounding a suitable volatile naphtha with an asphalt meeting the requirements of the Department's Specifications for Penetration Asphalt.

Specific viscosity, 25° C.	80 to 120
Residue at 100 penetration, per cent by weight	65 min.
Loss at 163° C., 20 g., 5 hr., per cent	25 min.
Penetration of residue, 100 g., 25° C., 5 sec.	30 to 75
Ductility of residue, 25° C., cm.	30 min.
Bitumen insoluble in 86° Bé. paraffin naphtha, per cent	12 min.

11. Gravel Roads

Dust Palliatives, Surface Treatments

Gravel roads are easy to construct, repair and maintain, offer ease of traction and resilience, are cheap in first cost if the material is at hand, and maintenance charges may be kept at a figure less than the interest on investment in a high-class pavement. Many more miles of gravel roadway would be built if its worth were realized. Every state has gravel that is available for road use. Only a relatively small percentage of the highways of the country can ever be built with high cost roads. The gravel road is the happy mean between the earth road and the expensive pavement. When mileage in a district is large with small assessed valuation, gravel is the material to be used rather than the more expensive crushed stone. But freight rates are the same on gravel as on stone, therefore if the material must be brought from a distance it may be cheaper in the long run to pay more for stone, if it is of good quality.

Many roads carry scarcely any traffic except in summer. Such roads should be built and maintained cheaply. Usually an earth road is unsatisfactory in these cases, but a gravel road serves to advantage. Where traffic is local and is fairly heavy throughout the year, a more expensive form of construction should be used, or, if it can be satisfactorily done, the gravel road should be surface treated with a bitumen.

Gravel consists of small pebbles, stones, or fragments of stone intermixed with powdered rock, sand, loam, clay, marl, flints, iron oxide, silicon, etc., formed by the action of water upon disintegrated portions of rock.

Good results in road work will be obtained with a graded gravel that consists of 80% small pebbles or fragments of stone that pass a 1-1/2-in. ring and are retained on a 1/4-in. mesh sieve, and 20% of sand and clay (or similar materials) in such proportions that they act as a binder which does not become objectionably dusty when dry nor unduly muddy when wet. A gravel that will stand for some time with a vertical face in the pit or bank will ordinarily be satisfactory.

Angular pebbles are better than those that are round; the pebbles of seabeach and shore gravels are generally too round. By careful grading, a gravel may be produced of which the particles key well, thus reducing voids to a minimum, and the quantity of binder needed. Since the wearing surface depends on the hardness and toughness of the stone, the less binder necessary the better the surface will be, and the less mud and dust will be formed.

The best **binder** is that formed from the dust of rocks high in cementing value. Trap rock gravels are therefore better than granite gravels, since they possess both durability and fair cementing qualities. Limestone and sandstone gravels are not so durable. If the binder does not naturally possess enough cementing value, then clay must be added.

Bank-run, or pit gravel, is often too earthy, and should be screened. The larger pebbles may be crushed, or may be raked into the foundation course.

Construction

1. **Drainage.** Thoroughly drain the subgrade. Gravel free from excess binder may be used to advantage for filling draining ditches.

2. **Subgrade.** Shoulders on each side of the road may be constructed (a) as shown, and gravel deposited in the trench. (See Fig. 4).

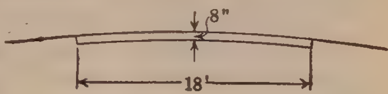

Fig. 4

(b) Or, on a flat subgrade the gravel is spread, deeper in the center than at the sides. (See Fig. 5.) The center takes most of the traffic and a gravel road always flattens under traffic. The depth of gravel may vary at the center from 8 to 15 in.

3. **Grading of Gravel.** Grade gravel so as to key well; it will then require less binder, and give a more durable wearing course. Where sea-beach or shore gravel is used it should be run through a crusher to give angularity to the pebbles; otherwise they do not key well and the road ravels.

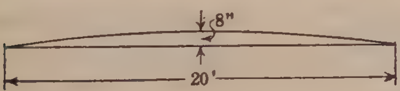

Fig. 5

4. **Bottom Course.** Deposit gravel, and any binder needed in excess, on dumping boards; mix, and rake into place. Rake large pebbles to form foundation of bottom course.

Character. Pebbles retained on 1/4-in. and passing 2-1/2-in. screens.

5. **Depth of Course.** Do not spread more than 4 in. deep for any one course at a time. Satisfactory rolling is impossible with greater thicknesses.

6. **Rolling.** Roll each course with a roller weighing at least 2 tons. A grooved roller is better than a smooth one as it gives more uniform compaction.

7. **Second Course.** Not more than 4 in. deep.

Character. Retained on a 1/4-in. and passing a 1-1/4-in. screen.

8. **Rolling.** Roll so as to obtain a crown of 3/4 in. to the foot, and until the road is thoroughly compacted. If water is to be obtained cheaply, the gravel should be moderately sprinkled while it is being rolled. Too much water will float off the binder. Inasmuch as a gravel road is built for the sake of economy, watering may be too expensive, and rain must be depended on to make the materials bind.

If no roller is available, then traffic must compact the gravel *after each course is put on*, in which event a patrolman should be retained to fill up the ruts for at least 30 days after the apparent completion of the road. He should shape up the road with a blader or a drag, and endeavor to keep traffic spread out over the entire graveled width.

Gravel roads are sometimes constructed in two courses, leaving off the topping of fine material.

Repairing

1. If badly rutted and worn, break up the surface to make the new material bond with the old, raking the large pebbles to the bottom.

2. Remove all vegetation from the roadbed.

3. If necessary, scarify and harrow the old surface. Then reshape with a grader and hand rakes. If a grader is not available use a log drag.

4. Apply sufficient graded gravel to make a good wearing course. A road in very bad condition may require up to 6 in. of new material. Apply new gravel in *thin layers*, adding a little clay, if necessary, to make the old and the new materials bond. Or, if the old road has an excess of sand and binder, use clean gravel free from fines.

5. If water is handy sprinkle moderately while rolling in dry weather.

6. Roll, always beginning at the side of the road and working toward the center.

7. Form a crown as in a new road of not more than 3/4 in to the foot. A higher crown will force vehicles to keep to the center of the road, soon forming ruts.

Maintenance

1. **Install a Patrol System,** and furnish the patrol man with a complete kit of tools.

2. Place piles of gravel at convenient intervals along the road. They should be at least as close as 1/8 of a mile.

3. Rake *new* gravel into the ruts, raking the large pebbles from the surface.

4. Use a grader, or a drag, or both, to keep the road in shape. Proper dragging helps preserve the crown.

Gravel Roads Treated with Bituminous Materials

All gravel roads are not susceptible to successful treatment with bituminous materials. In most cases, however, careful study of the materials at hand will indicate what method should be tried. Sometimes it is wise to try out more than one method on any given road or in a definite locality, and then select that one which promises the best results over a period of time. Some gravels will respond well to any of the usual treatments, whereas others require a particular method. It is sometimes impossible to tell from a laboratory examination of the gravel what the results will be, and in such cases only experiments with the gravel in place on the road will tell the story.

There are two general methods of treatment, but these may be modified to suit individual cases. These methods are (a) surface treatment by the superficial spraying of tar or asphaltic oil over the finished gravel road, and (b) the mulch method. In general, a well bound gravel road, that is free from loose particles, that does not contain over 20% of clay, and that presents a firm surface to traffic will take a surface treatment of bitumen satisfactorily. If the gravel in the road is loosely bound, is dusty, and does not tend to set up well after a rain, then the mulch method will probably be the better one to try.

Highway engineers and the general public must realize that a gravel road is a cheap type, and that although bituminous treatments may improve such roads to an almost unbelievable extent, still, a gravel road is a gravel road. Too much must not be expected of it. It will not carry an unlimited tonnage of heavy, fast truck traffic, although it will carry an endless procession of passenger cars with no apparent damage the year round unless such cars use chains in the winter months. A treated gravel road is rapidly destroyed by chains in a surprisingly brief time. Pot holes and long ruts are formed in such profusion that economical repairs are impossible.

Having determined upon the kind of treatment, it then becomes necessary to continue the maintenance of these roads by successive applications year after year. No gravel road should be treated unless provision is made certain to continue until such time as a better type of road is built. A treated gravel road that is allowed to deteriorate soon becomes almost impassable. It is far worse than an untreated surface, which, though it may become corrugated and full of holes, is still serviceable.

Maintenance of Gravel Roads with Tar or Asphaltic Oil

Method (a)

1. Put the surface of the road in good condition some time before the bitumen is to be applied, by blading, dragging, rolling, and thus thoroughly filling all ruts and depressions and removing " wash board."
2. Immediately before spraying sweep off all loose dust and dirt.
3. Do not treat a wet road.
4. Apply two coats of bitumen (cold application) of 1/4 gal. per square yard. Applications should be at least 24 hours apart.
5. Let first application sink into the road without applying cover. (If possible keep traffic off that section of the road.)
6. After the second application apply sufficient fine gravel or clean sand to prevent traffic from picking up the surface.
7. In case a thicker, heavier crust is desired omit the second coat of cold application and substitute a hot treatment (tar, p. 1929, or asphalt, p. 1928) at the rate of 1/4 to 1/3 gal. per square yard, and cover with 3/4-in. screened gravel, rolled in.

Note. There are many variations of the above outline, but this is the basis of them all.

Method (b)

The second method has been variously known as the mulch method, the Wisconsin method, the Minnesota method, and several others. It resembles the old Cape Cod method of treatment of sand roads, and under proper conditions it is highly successful. Though many twists and kinks are put in it, essentially it is as follows:

1. Clean off manure and other filth, but do not sweep the road.
2. Apply a cold surface treatment of tar or asphaltic oil over the entire road surface at the rate of 1/4 gal. per square yard.
3. With a heavy grader drawn by a tractor push the upper inch to inch and a half of treated gravel from one-half the width of the road onto the other half.
4. Apply 0.2 gal. per square yard to the fresh surface thus exposed.
5. With the grader push all the loose material from the other half of the road onto the freshly treated side, making a cut with the blade such that the second half resembles the first, after operation (3) above.
6. Apply 0.2 gal. per square yard to the fresh surface of the other half, identical with operation (4) above.
7. With the grader push one-half the loose material back onto the surface just treated. The whole road has now had two treatments, of which the original has been pushed back and forth so that the bitumen has intimately mixed with the gravel. The loose gravel on top is then ready for the next operation.

8. Work the road with bladers, scrapers or drags until a smooth, waveless, rippleless, non-corrugated surface is obtained.

9. When traffic has thoroughly compacted the road, apply from 0.15 to 0.2 gal. per square yard of bitumen.

10. After 2 hours apply a cover of fine gravel sufficient to take up any excess of bitumen. In some localities the cover is applied immediately after the distributor has applied the bitumen.

The tar to be used should conform to specification D-104 or D-105, 27-T. The asphalt should be a cut-back conforming to specification for cold surface treatment.

Note. Either tar or asphaltic oil may be used, but in this work tar has been more successful, on the whole, than asphaltic oil.

Maintenance

1. Clean out ruts and holes that may have formed.

2. Make up a batch of sand and gravel mixed with tar (for cold application) or asphalt cut-back in the proportion of 17 gal. of bitumen to one cubic yard of aggregate. The gravel used should contain no pebbles over 3/4 in. Sand should be free from earth.

3. Fill the ruts and holes with the mix.

4. Let traffic consolidate the patches. It is sometimes advantageous to spread the mix freely over the old surface and drag until the mix has set up in the low spots.

5. Apply cold application of bitumen, 1/4 gal. or less per square yard.

6. Sand the surface after 24 hours. Some states require sanding within two hours, but this does not allow sufficient time for the bitumen to penetrate. By treating only half the width at a time traffic will not be unduly inconvenienced.

A word of caution should be given here concerning **hot** surface treatments with either tar or asphalt. Experience has demonstrated that there is great danger of these causing rolls and waves in the road surface if they are persisted in year after year. The **cold** treatments are far less liable to wave. Some of the rolling can be avoided if the covering material is of large size, that is, over 1/2 in. and less than 1-1/4 in. If gravel of such sizes is used it must be rolled into the surface to prevent its being thrown off by traffic. Crushed stone is not so liable to be whisked out of place.

Sometimes, after repeated treatments, a gravel road presents a surface that resembles a huge washboard. When this is such that cars are disagreeably shaken, there is no way to make the road smooth again short of scarifying it, shaping, rolling and the application of a light surface treatment.

In some sections of the country the existing gravel roads break up badly in springtime. When this is the case it is usually cheaper to scarify the entire area that is broken up, let it dry out, and then retreat it as in the beginning.

It will be noted above that initial treatments consist of a total of 1/2 gal. per square yard. Subsequent treatments, for the most part, must be reduced to 1/4 gal. or less. It is a great mistake to continue to treat these roads with 1/2 gal. applications yearly, as a wavy surface is almost certain to form.

Cost of Treatments with Tar or Asphalt

Costs vary with location, labor rates, freight charges, and similar items. The initial cost for treating a gravel road that is in fair condition will be from \$1500 to \$2000 per mile of 18-ft. road or, 14 to 20 cents per square yard. Subsequent treatments including maintenance should not average more than

$1000 per mile per year, and with care may be somewhat less (1927 prices). Maintenance throughout the year is absolutely essential. By repairing small breaks promptly it is possible to keep the annual maintenance charges low.

Dust Palliatives

Many materials have been tried to alleviate the dust nuisance on gravel roads. Light asphaltic oils have been moderately successful in some localities and unsuccessful in others. On the whole, calcium chloride has proved to be a better dust layer than other materials. It is customary to make two applications per season, the first being at the rate of about 1-1/2 lb. per square yard, followed by 1/2 lb. to 1 lb. Spreading machines are used to insure uniform distribution.

Calcium chloride is not successful in climates where there is either too much or not enough moisture. As it is a hydroscopic and deliquescent salt it requires some moisture in the atmosphere, but an excess will make a muddy, dirty road that is more objectionable than a dusty gravel, whereas a deficiency will make it necessary to sprinkle the road occasionally.

Sea water has been tried where available, but the salt thrown upon the vehicles ruins the finish, and it injures horses' hoofs.

Roads in the Southwest

The attention of engineers and contractors unfamiliar with the arid area of the United States is drawn to the fact that it is cheaper in many instances to build a bituminous-bound road than one of the water-bound type. Water in Oklahoma, Arizona, New Mexico, and parts of Texas, southern California, Colorado, and Nevada, is more expensive to use than tar or asphalt. Hence certain types of bituminous-bound or treated roads are particularly suited to these localities.

Gravel, of one kind or another, is to be found in most of the inhabited portions of these states, and often rock of good quality as well. Adobe gravel and caliche are best built and maintained by a double bituminous treatment, as follows:

Adobe and Caliche. 1. Shape up, and roll to cross-section.

2. Spread 1/2 gal. of tar or asphaltic oil per square yard. (Spec. tar for cold application for surface treatment and oil for cold application.)

3. Let this dry in for 12 hours or more and follow with:

4. A seal coat of 1/2 gal. of tar applied hot (spec. for hot surface treatment), or a seal coat of 1/2 gal. of asphaltic oil (spec. for hot application).

5. Cover with stone chips, or pea gravel.

As a rule a tar priming coat is superior to one of asphalt. This priming coat alone will not suffice. It *must* be followed by the seal coat.

Maintenance must be most thorough, or the road will rapidly go to pieces. Six barrels of seal coat should be kept along each mile of road for patching purposes, and the road must be carefully watched for any breaks in the surface. Eternal vigilance will accomplish wonders with this simply constructed road. Many of the southwest gravels can be turned to good account by the following:

1. Spread gravel evenly 6 in. deep.
2. Apply 1-1/2 to 2 gal. of hot asphaltic oil in several applications, harrowing the road with a disc harrow after each application.
3. When the oil is thoroughly mixed with the gravel, shape up the road and roll it.
4. Apply a seal coat of 1/4 gal.

Eastern and northern contractors should remember that gasoline rollers and tractors must be used in this waterless country.

Asphaltic Surfacing Material for Gravel Roads

1. Free from water.
2. The gravity at a temperature of 60° F. shall be between 15 and 19° Baumé (0.94 to 0.966 specific).

3. The asphalt contents of 100 penetration using a No. 2 needle for 5 sec. at 77° F after evaporation in the open air at a temperature not exceeding 500° F. shall be not less than 55%.
4. Specific viscosity (Engler) at 50° C. for 50 cc. from 17 to 29.
5. 20 g. upon being maintained at uniform temperature of 325° F. for 5 hours in a cylindrical vessel 2-3/8 in. in diameter by 1 in. high shall lose not less than 15% by weight.
6. Soluble in CS_2 = 99.5%.
7. It shall not flash below 130° F. (Cleveland tester).

Specifications
Pennsylvania Department of Highways

Asphalts. A hot and a cold application asphalt are specified.

The cold application material must be prepared by fluxing an asphalt cement of 120 to 150 penetration (100 g., 5 sec., 25° C.) with naphtha. The naphtha used when distilled in accordance with the A.S.T.M. tentative method, D 86-24T, shall have an over point of not greater than 250° F. and the dry point shall not exceed 450° F., and the naphtha shall show a continuous distillate between these points.

The mixture must conform to the specification listed in the table below, in which the viscosity will be subject to variation within the limits designated.

The hot application must be the properly prepared residuum from an asphaltic base petroleum and must meet the requirements for it listed in the table below.

Summary Specification Requirements for Cold and Hot Application Asphalts for Surface Treatment

Specifications of Pennsylvania Highway Department

	Cl Cold Application	Hl Hot Application
1. Specific viscosity, 40° C.	34–50	......
2. Float test, 50° C., sec., minimum	......	125
3. Residue at 100 penetration, per cent	68 min.	88–95
4. Ductility of residue, 25° C., cm.	30 min.	25 min.
5. Evaporation loss, per cent:		
(a) 20 g., 5 hr., 100° C.	22 min.	......
(b) 20 g., 5 hr., 163° C.	25 min.	5 max.
6. Penetration of residue (5b) 100 gr., 5 sec., 25° C., per cent	60–100	......
7. Total bitumen, per cent, minimum	99	99

The following notes refer to the table on page 1929.

[1] All tests shall be made on the sample as received including distillation test, and the results reported on a dry basis.

[2] Within the viscosity limits designated, a material should be chosen to meet local conditions of temperature, road conditions and climate. It is recommended that materials be called for under the following range and headings: Light 8-13, medium 13-18, heavy 18-25, extra heavy 25-35.

[3] It is recommended that materials be called for under the following range and headings: Light 35-60, heavy 60-80. The heavy material may require heating before use and care should be taken to avoid foaming on account of the possible water content.

[4] The specification range for total bitumen covers a wide variety of materials. If products from vertical retort or low carbon coke-oven tars are desired, a range 88-95% should be specified. If high-carbon coke-oven or mixtures of coke-oven and gas-house tars are desired, a range of 78 to 88% should be specified.

[5] If desired, a float test may be substituted for the softening point test, in which case the requirements shall be as follows: Float test at 50° C. (122° F.) 100 to 220 sec.

Specifications for Various Kinds of Tars

American Society for Testing Materials[1]

The Tar shall conform to the following requirements:

	Cold application				Hot application		Tar cement for bituminous macadam		Coal tar pitch, stone block filler	Test specifications

Softening point residue cube in water, maximum	....	....	....	....	....	....	....	....	75 C.	D 61
Ductility at 50-100 penetration at 25° C., maximum	....	....	....	....	....	....	....	....	50 min.	D 113-22T

The specification range for softening point, within the above limits, should be 5° C. for any given locality, for example, 30 to 35° C. for cold climates, equivalent to a float test at 50° C. of 100 to 160 sec.; 35 to 40° C. for warm climates, equivalent to a float test at 50° C. of 160 to 220 sec.

6 The softening point (cube-in-water method) specified should have a range of not over 10° F. within the above limits. The range, within the limits of 115 to 135° F., should vary with the use of the material, for example, if used in a mixture with sand, in a northern locality or a southern locality. The softening point range, within the above limits, should also vary according to the character of the paving.

Refined Tar for Use in Repair Work Cold-Patch

General Requirements. The refined tar shall be homogeneous.

Properties. The refined tar shall meet the following requirements:

1. Specific gravity at 25° C. (77° F.) 1.140 to 1.190.
2. Specific viscosity, Engler, 50 cc. at 40° C. (104° F.) 35.0 to 60.0.
3. Total distillate, per cent by weight,

    To 170° C. (338° F.) 2.0 to 8.0.
    To 235° C. (455° F.) 10.0 to 18.0.
    To 270° C. (518° F.) not more than 26.0.
    To 300° C. (572° F.) not more than 30.0.

(a) Softening point of residue (ring and ball), not more than 65° C. (149° F.).

4. Bitumen (soluble in carbon disulphide), per cent by weight, 80.0 to 88.0.
5. Water, per cent by volume, not more than 2.0.

Methods of Testing. Tests of the properties of the refined tar shall be made in accordance with the following methods:

1. Specific gravity: A. S. T. M. Tentative Method D 70–26 T; Proc. A. S. T. M., 1926, Part I, p. 869.
2. Specific viscosity: U. S. Department of Agriculture Bulletin 1216, p. 59.
3. Distillation test: A. S. T. M. Tentative Method D 20–26 T; Proc. A. S. T. M., 1926, Part I, p. 881.
   (a) Softening point: A. S. T. M. Standard Method D 36–26; A. S. T. M. Standards adopted in 1926, p. 93.

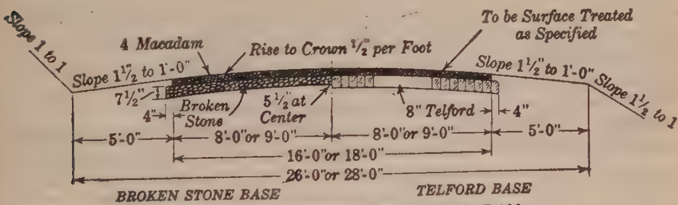
12. Broken Stone Roads

Characteristics. An ordinary macadam road, if properly built of the right kind of stone, is a very economical and satisfactory surface for light traffic. It affords an excellent foothold, is noiseless, does not offer much resistance to traffic, and is comfortable to use. In dry weather, however, a macadam surface is extremely dusty unless the surface is treated with a palliative or coated with bituminous material.



BITUMINOUS SURFACE TREATED MACADAM

Fig. 6

Foundation and Subgrade. The lower or foundation course of a macadam road may be strengthened by a telford base, a V-drain foundation, or by increasing its thickness. The construction of telford and V-drain foundations has been described in Art. 7. When traffic and soil conditions are favorable, however, it is customary to build the foundation course directly upon the subgrade. The subgrade is a shallow trench composed of two or more planes or a curved surface sloping from the center to the sides of the road. The trench is the same width as the broken stone surface. The sides of the trench are formed by the earth shoulders, generally 3 to 5 ft. wide. The subgrade should be brought to true line and grade and be thoroughly compacted with a steam roller. Any low spots which appear during compaction should be brought up to grade with good material and rerolled.

Size of Stone. Broken stone roads are ordinarily built in three courses. The sizes of stone and the materials used vary in different specifications. For the first or foundation course the size of the stone is often from 1 to 3 in. in longest dimensions, while sometimes it is specified as from 1-1/4 to 2-1/2 in. Gravel and slag are sometimes substituted for broken stone in the foundation course. The second course is composed of stone ranging from 1 to 2 in., or from 1/2 to 1-1/4 in. in longest dimensions. The top course consists of screenings varying from 1/2 in. down to dust. Since nearly all of the broken stone used for road construction is screened through a rotary screen, it should be noted that the speed at which the screen is revolved, the pitch, the length and the size of holes in the screen all influence the grading of the stone into different sizes.

Sizes of Crushed Stone for Water-Bound Macadam

	Stone for base	Top course	Screenings (large)	Screenings (small)
Product of soft rock...	2-1/2–3/1/2 in.	1-1/4–2-1/2 in.	0–3/4 in.	0–1/4 in.
Product of hard rock..	1-1/4–2-1/2 in.	1-1/4–2-1/2 in.	....	0–1/4 in.

Laying the Stone. Some engineers advocate laying the larger stone on top of the smaller in cases where the stone is low in hardness and toughness and is liable to be crushed during rolling. Large stones in the surface wear longer than smaller ones, but more rolling is required to secure a smooth surface. To gage the thickness of a layer, wood cubes of a depth equal to the thickness of the layer are sometimes placed at intervals in the roadway and the stone is filled in to the tops of them. Another method of obtaining the same result is to set longitudinal strings at the proper elevation at the sides and center of the roadway. Stone for the foundation course, if brought in bottom-dump wagons, may be dumped directly upon the subgrade and spread with stone forks or with a stone spreading machine. Stone brought to the work for the second course should be dumped on boards and shoveled from there to the road to prevent the segregation of sizes which might occur if the stone was dumped directly upon the road from the wagons.

Rolling. The first and second courses are each laid to the required thickness and separately rolled, being sprinkled with water to aid compaction if necessary before the next course is placed. The roller used in compacting this material should be at least 10 short tons in weight. The process of rolling should be to begin at one edge of the roadway, roll longitudinally, and work toward the center. After reaching the middle of the road, the roller should pass to the other side, again roll longitudinally, and work toward the center This manner of rolling keeps the road in shape and prevents either pushing the crown out of line or flattening it. Careful rolling is absolutely necessary in order to obtain a good shape to the road surface. Steam or gasoline rollers always should be used as horse-driven rollers are not sufficiently heavy to properly compact broken stone. Usually 12 to 18-ton rollers should be used for hard, tough rock, and 10 to 12-ton rollers for soft stone.

Applying Screenings. Having finished and rolled the second course as above described, the surface is covered with a layer of stone screenings and thoroughly sprinkled with water in order to fill the voids in the stone with the screenings. More screenings are added as desired and rolling is continued, the surface being sprinkled in front of the roller. When the proper amount of water and screenings have been used, a wave of grout will be pushed along in front of the roller A coating of screenings should be left over the entire surface, no more being used than is necessary to cover the stone. The stone screenings resulting from the crushing of the rock with which the first two courses are built are generally used for the binder. When this material is unsuitable for this purpose, clay, loam, sand, or screenings of a different rock are substituted for it.

The Thickness of the Courses varies in different specifications, and is governed by the amount of traffic which the road is to receive and the condition of the subgrade. Common values are 4, 6, and 8 in the total thickness after rolling, where the subgrade furnishes a good support. The upper course is from 2 to 3 in. in thickness after rolling. In some states the stone surfacing is the same thickness throughout the width, while in others the thickness is reduced at the sides from 1 to 2 in.

Maintenance. Water, if allowed to stand on a macadam surface, will soften the macadam and cause it to wear out rapidly. Also when the frost is coming out of the ground the surface will be in a soft condition and require attention. Thorough surface and under drainage is just as essential as it is in the case of an earth cr gravel surface.

Slag Roads. Blast furnace slags are produced in the manufacture of iron and steel, and, in some cases, are very similar in appearance to close-grained igneous rocks. In some cases, blast furnace slag may be excavated from slag banks by means of a steam shovel, which serves to break of the material sufficiently so that it may be screened. The slag from the open-hearth process is generally run into molds. Usually it is broken up in a rock crusher into sizes suitable for road work. The methods used in building slag roads are similar to those described for the construction of broken stone roads.

Shell Roads. The state of Maryland has built many miles of oyster shell roads along the eastern shore of Chesapeake Bay.

Maryland State Roads Commission Specifications stipulate that the subgrade shall be firm and well rolled. The depth of the first course of shells is either 5 in. or 5 in. at the center and 3 in. at the sides. The depth of the second course is either 3 in., or 5 in. at the center and 3 in. at the sides. The shells are spread upon the roadbed with shovels from piles along the road or from a dumping board. They are rolled with an 8-ton roller and are sprinkled with water or bound with sand during the process of rolling until the surface is firmly compacted. The third course is composed of clean, sharp sand, spread just thick enough to cover the second course after the latter has been thoroughly compacted.

Surface Treatments

A macadam properly built of good materials and well maintained with bituminous surface treatments will last indefinitely under medium traffic, and the cost of maintenance is far less than the interest at 6% on a pavement of the first class. It may be safely said that a bituminous treated macadam will stand up for many years under unlimited pleasure car traffic. Heavy truck traffic causes internal wear.

Surface treatments may be divided into: (a) cold surface, and (b) hot surface treatments. On the whole the former have been the more successful. Hot treatments have resulted all too frequently in wavy or "wash-board" surfaces. Once such surfaces form it is almost impossible to eradicate them short of scarifying the entire road. Cold treatments rarely wave unless too much bitumen is applied. Hot treatments suit the traveling public better than cold treatments because as soon as the bitumen is cool it sets up, whereas the cold treatments splash traffic until the bitumens harden, often taking nearly a week. Asphaltic oils and tars are used. Location of the job, materials of construction, weather conditions, and price are factors to be considered. Materials with high viscosity are used in hot weather or in the southern states, and the lighter materials are used in cool weather or in the northern states and Canada. As a rule the asphaltic oils are cheaper than the tars. In general tars have been more successful for cold surface treatments, and asphaltic oils have been successful for hot treatments. Asphalt cut-backs have been the

Bituminous Materials for Cold and Hot Surface Applications Suggested by the U. S. Bureau of Public Roads

Material	Specific gravity 25°/25° C.	Flash point	Specific viscosity	Float test
Asphaltic road oil for cold application	0.935 to 0.970....	Not more than 50° C.	At 25° C., 80 to 120	....
Oil for hot application	Not less than 0.980	Not less than 80° C.	Not more than 60 at 100° C.	At 32° C., not less than 60 sec.
Tar for cold application	1.10 to 1.14......	....	At 40° C., 25 to 35	....
Tar for hot application	Not less than 1.13	....	....	At 32° C., 60 to 150

Material	Loss at 163° C. in 5 hours	Float test of residue	Total bitumen soluble in CS_2	Per cent of bitumen insoluble in 85° B naphtha
Asphaltic road oil for cold application	Not more than 30%	Not less than 90 sec. at 50° C.	Not less than 99.5%	Not less than 6%
Oil for hot application	Not more than 15%	Not less than 110 sec. at 50° C.	Not less than 99.5%	Not less than 6%
Tar for cold application	....	....	95 to 100%...	....
Tar for hot application	....	....	Not less than 85%	....

Material	Total distillate by weight	Temperature when applied	Quantity per sq. yd.	Cover per sq. yd. in lb.
Asphaltic road oil for cold application	....	Air..........	1/3 to 1/2 gal.	28 to 35
Oil for hot application	....	200° F. to 250° F.	1/3 to 1/2 gal.	30 to 40
Tar for cold application	Not more than To 170° C.—2% 270° C.—25% 300° C.—35%	At least 50° F.	1/3 gal.......	25 to 30
Tar for hot application	To 170° C.—1% 270° C.—15% 300° C.—25%	200° F. to 250° F.	1/3 to 1/2 gal.	30 to 40

most successful asphaltic materials used for cold applications. They set up quickly but their cost is greater than for the road oils.

If it is desired to lay the dust only, and not to form a wearing surface, then a cheap road oil may be spread which will waterproof the surface for a season. Initial treatments will approximate 1/2 gal. per square yard. Such oil can be bought for about 6 cents per gallon delivered at siding. No cover is put on such treatments, but the oil is permitted to penetrate the surface. It is a mistake to waste money on oils which merely lay the dust.

Method for Surface Treatment

1. Sweep macadam thoroughly, removing all loose material, and make sure that manure and other filth are wholly removed.

2. Patch holes, using either hot-patches or cold-patches. Be sure that no dust pockets are left. If at this time it is observed that the old macadam is rough and will not be helped much by patching, then it must be scarified and rolled. In this case use new stone where necessary.

3. When macadam is dry apply bitumen. For an initial treatment with cold material use about 1/2 gal. per square yard. Puddles of bitumen must be broomed out or fat spots will result. If the road has been treated before, a treatment of from 0.1 to 0.3 gal. is all that is required. As a rule, if as much as 1/2 gal. is necessary it will be best to spread it in two applications of 1/4 gal. each.

4. Two hours or more after the last application cover the bitumen with pea-gravel, clean stone chips, or slag chips. It is a mistake to use sand for a cover. With tars the amount of cover for initial treatment will be about 25 lb. per square yard. With asphaltic oils use about 35 lb. Use less cover on subsequent treatments. If a hot treatment is given the bitumen may be immediately covered.

On hills it will be found advisable to use 3/4-in. stone for cover, rolling the stone into the treatment. This will prevent skidding, and will also keep the treatment from pushing or waving.

If holes form no time should be lost in repairing them. Chains on motor cars form ruts during the winter. These must be repaired at the first opportunity.

The important point to remember is that in all surface treatment work on whatever type of road or pavement the amount of bitumen used must be kept at a minimum. Too much is worse than none at all.

For specifications see A. S. T. M. specifications for tars and asphalts and U. S. B. P. R. specifications for cold and hot applications.

13. Retread

There are many milesof old roads that are not satisfactory for modern traffic and yet are too good to tear up and replace with something else. Such roads are old gravel, shale, badly worn macadam, shell, caliche, and similar types. A method known as **Retread** has been devised to salvage these roads and to make them into good roads at low cost. The method is also called **mixing-in-place.** The operations necessary are extremely simple; the machinery actually called for is only a blade grader, although a roller is desirable; the cost is very low; the method seems to be wrong in principle, but the results are surprisingly good. Any road other than an earth road may be retreaded. Materials used are clean 3/4 in. crushed stone, and either tar or asphalt of the proper consistency. To date (1929) the tars have been more successful for this type of work.

* Trade mark registered, The Barrett Co.

Construction

1. Prepare old road by filling up ruts, removing bumps, and making the surface smooth and firm. This work can all be done with the blader, letting traffic compact the old road. It is essential that waves and depressions shall be taken out before the new top is put on. It is sometimes wise to wait a week or so to see if a smooth riding surface has been produced by the grading operations.
2. Spread clean 3/4-in. stone over the road to a depth of about 2 in. Blade it.
3. Apply tar (spec. "**Retread**") at the rate of 3/4 gal. per square yard.
4. Use road grader, blading until the tarred stones show a tendency to ball up under the grader. This may take three to four days. Ruts and waves must be bladed out before the tar sets up.
5. If a roller is available, roll until solid.
6. When road has set up, apply 1/4 gal. per square yard of the same grade of tar.
7. Cover with stone chips or pea gravel. Roll.

Traffic is not kept off during construction. In fact, if no roller is to be had, traffic will satisfactorily compact this type of road.

Maintenance

A retreaded road is maintained either by surface treatments, usually annually, or by an additional retread top which, of course, will add additional depth and strength to the road. For surface treatments the amount of bituminous material applied will vary from 0.2 to 0.5 gal. per square yard. These treatments should be covered with pea-gravel or stone chips, although it is a wise plan to let the bitumen soak into the road for a few hours to liven up the old material. Then apply the cover.

Refined Tar for Retread

General Requirements. The refined tar shall be homogeneous.

Properties. The refined tar shall meet the following requirements:

1. Specific gravity at 25° C. (77° F.), not less than 1.120.
2. Specific viscosity, Engler, 50 cc. at 40° C. (104° F.), 25.0 to 40.0.
3. Total distillate, per cent by weight:

   To 170° C. (338° F.), not more than 3.0.
   To 270° C. (518° F.), not more than 30.0.
   To 300° C. (572° F.), not more than 40.0.

   (a) Softening point of residue (ring and ball), not more than 60° C. (140° F.).

4. Bitumen (soluble in carbon disulphide), per cent by weight, 88.0 to 97.0.
5. Water, per cent by volume, not more than 3.0.

PAVEMENTS

14. Bituminous Macadam Pavements

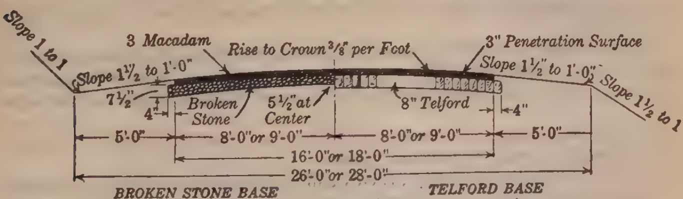
A bituminous macadam differs from other types of bituminous pavements in that the bitumen is added to the aggregate after the latter is in place on the road. All the materials for sheet asphalt, asphaltic concrete, tar concrete, and asphalt block are mixed in a central plant or roadside plant. But a bituminous macadam is constructed in place by placing a layer of aggregate on the foundation and, after rolling, pouring or spraying binder over it. This is often called the "penetration method."

When built with the same care and attention to detail that is accorded higher types of construction the penetration pavement is an excellent one, and it will stand up under all but the heaviest truck traffic. Failures of this type can always be traced to one or more of the following: insufficient foundation, poor aggregate, carelessness in construction and inspection, and bad weather at the time of construction.

The equipment required by the contractor is less than that for any other bituminous type except asphalt block. Ordinary day labor is sufficient for the most part. Yardage possible per day is large. Cost is low. Results are good. Usually the cost should be about 20% lower than bituminous concrete.

A number of variations from the general method of construction have been devised. It is doubtful if any of these show any real points of superiority whereas every one of them increases the cost. These will be briefly commented on after the general method has been explained.

Foundations. It is assumed that the subgrade has been drained and shaped to correct cross-section, and that ditches and shoulders have been built. Time for the subgrade to settle must elapse before the foundation is placed. Satisfactory types of foundation are concrete, black base, broken stone or slag, and



BITUMINOUS PENETRATION SURFACE COURSE

Fig. 7

gravel. Broken stone bases should be at least 6 in. deep, and may be 12 in. where heavy traffic is expected or the character of the soil demands such a depth. Gravel should be at least 9 in. deep.

Existing macadam or gravel roads make good bases for new tops if they are really thick enough. There is but one way to determine this and that is to dig test holes here and there, indiscriminately, and thus learn exactly how much stone is in the road. If less than 6-in. is found more stone must be added or the old road must be rebuilt as a foundation for the new top. One item of the utmost importance is: All holes, waves and irregularities in the old road must be removed before the new top is built, otherwise these will show up in time in the top.

[illegible], unprotected [illegible] are frequently used [illegible]. These must be [illegible] will [illegible] through the surface.

The [illegible] as follows: Base, wearing course, [illegible] course, cover. The stone must be clean, hard, tough, and durable.

Construction

Wearing Course. 1. On the prepared base lay wearing course stone at [illegible]. This stone [illegible] should pass a [illegible] ring and be retained on a [illegible] ring.

2. Remove all fines [illegible] dirty stone, and replace with clean stone.

3. Roll with a [illegible] roller until stone is keyed in place. [illegible] being rolled to prevent [illegible] of the stone. Roll enough to [illegible] but do not [illegible] voids.

4. Spray or pour binder over the [illegible] stone. As a rule use [illegible] gal. per square yard [illegible]. The binder may be asphalt or tar for [illegible]. [illegible] of binder may be mechanical or by hand from [illegible]. [illegible] uniform distribution.

5. Immediately spread a layer of [illegible] stone chips (choking course) in [illegible] the [illegible] of the wearing course.

6. Roll with [illegible] roller. Continue rolling until the surface is perfect [illegible]. [illegible] it may be necessary [illegible] and wait until the sun is off the pavement. [illegible] to develop waves in the pavement [illegible] it is almost impossible to roll them out. Diagonal rolling is advantageous.

7. Sweep off all loose material that is not held by the binder.

8. Apply a second or seal coat of binder at the rate of from 1/2 to 3/4 gal. per square yard.

9. Immediately spread the cover. This may be stone chips, pea gravel, or coarse sand. There should be an excess over that which will be held by the seal coat. This excess tends to find its way into voids and helps make a tight [illegible].

10. Roll [illegible]. A tandem roller may be used here, but roll slowly. Fast rolling is certain to develop waves.

11. If [illegible] within 60 days a second seal coat should be applied using about [illegible] gal. per square yard. Use a cold application tar.

Repairs

1. Dig out area [illegible] and examine base carefully for failure. If base has failed it must be rebuilt with good materials.

2. On repaired base build up the macadam patch in identically the same way as in original construction.

Maintenance

From time to time penetration pavements require surface treatments with some bituminous material. There is no rule for determining this. The only guide is the condition of the pavement. If the mosaic surface of the aggregate is plainly visible then it is time to treat without delay. As a rule tar [illegible] require treatment sooner and more frequently than where asphalt is used. There are numerous instances of asphalt macadams that have not needed treatment over a period of 8 to 10 years. The essential thing is to watch the pavement and treat it before it begins to go to pieces.

Treatments may be either hot or cold. The hot treatments have the advantage of drying immediately so that they do not cause traffic to be spattered with bitumen, although they have the disadvantage of sometimes causing waves to form. This disagreeable feature can be largely overcome by covering the treatment with 3/4-in. stone chips which are rolled into the road surface. A sand cover should never be used with a hot treatment because waves are almost certain.

Cold treatments take longer to dry, but they have the decided advantage of finding the tiny cracks and filling them, thus waterproofing the pavement far better than the hot treatments. They rarely cause pushing or waving of the wearing course. The cover for the cold treatments should be either chips or washed pea gravel, rolled in.

Do not form a thick mat. Keep the amount of surface treating material to the minimum, otherwise a bump will form, followed by other bumps, and soon the entire surface will be a succession of bumps or waves. These may sometimes be removed by cutting them off with a hot shovel.

It is possible to treat an asphalt macadam satisfactorily with a tar surface treatment, and vice versa. Some engineers prefer to surface treat tar macadam with a hot asphalt, and it is probably true that such a treatment lasts longer than a like application of tar.

So long as maintenance is continued and truck traffic does not become too intense, there is no reason why a bituminous macadam, properly built, should not last indefinitely.

Maintenance Methods

1. After repairs have been made, thoroughly sweep and clean the pavement. If a fire hose or a water sprinkler wagon is available the pavement may be scrubbed.

2. Apply a treatment of asphalt (specifications for hot application, surface treatment, or cut-back), or tar (specifications for cold surface treatment, or hot surface treatment) at the rate of from 0.1 to 0.5 gal. per square yard, depending on the condition of the surface.

3. (a) If hot application or cut-back asphalt is used, cover immediately with 1/2-in. stone chips or pea-gravel, using from 20% to 60 lb. per square yard, depending on amount of bitumen used. Tars require 35% less cover than asphalts.

   (b) If cold surface treatment of tar is used allow at least two hours to elapse before cover is applied. In some cases, where the pavement shows signs of being brittle it is best to close the road, applying no cover, and let the old surface absorb the fresh tar.

4. Roll the cover into the surface.

One of the most successful variations of the method outlined above is that known as "pitch grouting," or "asphalt grouting." It is similar in most respects to the usual method except that, instead of using asphalt cement or tar binder alone, these materials, in either case, are mixed with an equal volume of hot sand, and the resulting mastic is flushed over the stone. Results have been excellent, but the cost is about that of asphaltic concrete.

Another successful variation is to lay a mastic course directly on the base and spread the wearing course stone therein. This forms a waterproof bed and securely binds the wearing course stone in place, and it also prevents the escape to the base of any binder from the wearing course.

Another scheme is to spray the base with binder, spread a layer of stone and roll it into the binder; then spray more binder and cover with stone, and roll; and so on until the desired depth is obtained. This is an inverted type. A number of other variations have been tried with some success. Some have been patented.

Specification for Asphalt

Suitable for asphaltic macadam

The bituminous material, which shall be oil asphalt, or fluxed Bermudez asphalt, shall meet the following requirements:

	Oil asphalt	Bermudez
1. Specific gravity at 25° C., not less than..........	1.000	1.040
2. Flash point, not less than........................	175° C.	175° C.
3. Penetration at 25° C., 100 g., 5 sec..............	100 to 120	100 to 120
4. Ductility at 25° C., not less than................	30	30
5. Per cent of total bitumen soluble in carbon tetrachloride, not less than........................	99	99
6. Per cent loss at 163° C., 50 g., 5 hr., not more than.	1	3
Penetration of residue at 25° C., 100 g., 5 sec., as per cent of original penetration, not less than...	60	50
7. Total bitumen percentage, soluble in carbon disulfide, not less than..........................	99.5	94

Specification for Refined Tar for Tar Macadam

General Requirements. The refined tar shall be homogeneous and free from water.

Properties. The refined tar shall meet the following requirements:

1. Specific gravity 25° C. (77° F.), 1.220 to 1.280.
2. Float test at 50° C. (122° F.), seconds, 130 to 190.
3. Total distillate, per cent by weight:
   To 170° C. (338° F.), not more than 1.0.
   To 270° C. (518° F.), not more than 10.0.
   To 300° C. (572° F.), not more than 20.0.
   (a) Softening point of residue (ring and ball), not more than 65° C. (149° F.)
4. Bitumen (soluble in carbon disulphide) per cent by weight, 75.0 to 85.0.

15. Bituminous Concrete Pavements

A bituminous concrete pavement is one composed of broken stone, broken slag, gravel, or shell, with or without sand, portland cement, fine inert material, or combinations thereof, and a bituminous cement incorporated together by a mixing method. The reader's attention is called here to the difference between bituminous concrete and bituminous macadam pavements. In the former the ingredients are combined in a mixing plant from which they are then taken and spread on the foundation. In the latter the aggregate is spread over the foundation to the required depth and it is then coated in place with bitumen which is either poured or sprayed. Bituminous concrete is frequently spoken of as a "mixed job," while bituminous macadam is known as a "penetration job."

Bituminous concrete pavements occupy a place between sheet asphalt and bituminous macadam. Materials that may be unsuitable for either of these types may often be used to advantage. Thus, a sand which would not produce a good sheet asphalt pavement might be incorporated with other aggregate to form a good concrete. It is possible to use gravel and obtain satisfactory results. The combinations that are possible are numerous. Some of these have been patented, but the basic patent for the best of these combinations, namely Warren Brothers' Bitulithic pavement, has expired. The basic patents of Amiestite pavement have expired.

The fundamental idea of all concrete mixtures is that of stability. If, therefore, a mix can be made of which the particles are so formed and the percentages of each size so proportioned that a minimum of cement is required to bind the whole into a solid, the result will be good concrete. Following this reasoning it will be seen that stability will be arrived at if the individual pieces of aggregate interlock. And those bituminous concretes which are made of a graded aggregate such that the percentage of voids is a minimum while the stability, due to interlocking, is greatest, are the best.

Due to the fact that it is not always possible to secure ideal materials several types of bituminous concrete have been developed. Under careful supervision these have proved themselves to be satisfactory. In general, asphaltic concrete is a very serviceable pavement. Tar concrete, as a rule, is not as good, although the early Bitulithic pavements were for the most part built with tar binder and many of them are in excellent condition at the present date (1929).

The Asphalt Association's Brochure 10 divides asphaltic concrete into three classes: Class 1 — Mixtures in which practically all of the mineral aggregate is retained on the 10-mesh sieve. Class 2 — Mixtures containing substantial quantities of both coarse and fine aggregate with a preponderance of particles retained on the 10-mesh sieve. Class 3 — Mixtures containing substantial quantities of both coarse and fine aggregate with a preponderance of particles passing the 10-mesh sieve.

The advantages of asphalticconcrete are: Resistance to impact and abrasion of traffic, low tractive resistance, freedom from producing dust, easy cleaning, the fact that it may be opened to traffic as soon as it has cooled after final rolling, maintenance cost low, easy repair, and the fact that local materials possibly unsuitable for other types may be used. The disadvantages are that: A mixing plant is required, experienced inspectors are necessary, the utmost care must be used in proportioning and mixing to secure uniformity, frequent tests must be run on the materials and the mix, the pavement sometimes becomes more slippery than other types after use, and the surface may become unduly wavy until it resembles a washboard if the proportions of aggregate and consistency of the asphaltic concrete are not correct.

Foundations. For all classes of bituminous concrete pavements, foundations of gravel, broken stone, slag, old macadam, bituminous concrete, bituminous macadam, concrete, old brick, and stone block pavements have been used. The foundation must be strong enough to carry the traffic to which the pavement is to be subjected. Weak foundations mean failure.

Mixing Plants. There are three types: Permanent, railway, and portable or semiportable. A permanent plant is economical only in cities whose paving programs call for considerable amounts of asphaltic concrete over a period of years. The other types are suitable for occasional city work and for rural road work. For detailed description of paving plants and their operation see Brochure 13 of The Asphalt Association, and booklets of the various manufacturers.

Mixtures. *Class* 1 — Broken stone, or slag, or crushed gravel may be used. The aggregate should be hard, tough, and clean. All fragments should pass a 1-1/4-in. screen, and at least 85% should be retained on a 1/4-in.

screen. Stone should have a percentage of wear of not less than 5, and a toughness of not less than 8. Usually this class is referred to as one-size stone asphaltic cement. Since there is practically nothing passing the 10-mesh sieve the resulting mix will be full of voids. It has been found in practice that from 5 to 7% of asphaltic cement produces a good mix. It sometimes happens that an inexperienced inspector, noting the open character of the mix, endeavors to fill the voids by adding asphaltic cement. This will insure failure, as the pavement will be so " fat " that it will shove and become wavy. If too soft an asphaltic cement is used the same effect is produced. If too hard, the pavement cracks and disintegrates. The surface voids are sealed against moisture by the application of a seal coat and cover. The proper penetration limits of asphaltic cement for Class 1 mixtures are tabulated herewith.

Traffic	Temperature		
	Low	Moderate	High
Light	100–120	100–120	60–70
Moderate	85–100	85–100	60–70
Heavy	85–100	60–70	60–70

Class 2. If to the aggregate of Class 1 is added enough fine aggregate and filler to make a dense, almost voidless mix when the proper amount of asphaltic cement is introduced, the resulting mixture is Class 2. It frequently happens that crusher run makes an ideal mix. The fine aggregate, if not the product of the crusher, should be a clean, hard sand. Not too much attention need be paid to the grading. As a matter of fact it will be found that a combination of coarse and fine aggregates that is satisfactory for the production of a portland cement concrete will be satisfactory for asphaltic concrete. What is of prime importance is that the aggregate shall be of such size, shape, and proportion that perfect interlocking takes place during the rolling of the pavement. When this is attained and a suitable grade of asphalt cement is added in sufficient quantity to bind all particles together then an excellent pavement is certain. The penetration limits of asphaltic cement for Class 2 mixtures are

Traffic	Temperature		
	Low	Moderate	High
Light	50–60	50–60	40–50
Moderate	50–60	50–60	40–50
Heavy	40–50	40–50	30–40

Grading of Aggregate for Class 2

	Per cent
Passing 1/4-in. screen	0– 15
Passing 1/2-in. screen	25– 75
Passing 3/4-in. screen	95–100

A seal coat is advocated. It should be applied after the final rolling.

Class 3. " Topeka " is the representative of this class. As this mix was evolved to evade the Bitulithic patent, and as this patent has now expired there is no good reason why anyone should lay Topeka. It is an inferior mix. The grading of the aggregate and penetration limits for asphaltic cement are:

Traffic	Temperature		
	Low	Moderate	High
Light	50–60	50–60	40–50
Moderate	50–60	50–60	40–50
Heavy	40–50	40–50	30–40

	Per cent
Mineral aggregate passing 200-mesh screen	5–11
Mineral aggregate passing 40-mesh screen	18–30
Mineral aggregate passing 10-mesh screen	25–55
Mineral aggregate passing 4-mesh screen	8–22
Mineral aggregate passing 2-mesh screen	less than 10
Bitumen	7–11

The tendency of this mix is to roll, push and form waves. In order to give stability to such a mix there should be added a quantity of crushed stone that will pass a 1-1/4-in. ring and be retained on a 3/4-in. ring. The exact amount should be determined by laboratory experiment.

Analysis of a Coarse Graded Aggregate for Bituminous Concrete

	Per cent
Coarse Aggregate	
Passing 1-in. screen, not less than	95
Total passing 3/4-in. screen	25
Retained on 1/4-in. screen, not less than	85
Chips for Seal Coat	
Passing 1/2-in. screen, not less than	95
Retained on 1/4-in. screen, not less than	85
Fine Aggregate	
Passing 1/4-in. screen	100
Total passing 40-mesh sieve	30–70
Retained on 200-mesh sieve, not less than	90
Penetration of Bituminous Material	60–80
Composition of the Mixture	
Coarse aggregate	45–60
Fine aggregate	25–40
Mineral filler	3– 5
Asphaltic cement	6– 8

Analysis of Typical Bitulithic Pavement

Aggregate	
Passing 1-1/4-in. retained on 1/2-in. screen	30–60
Passing 1/4-in. retained on 4-mesh screen	15–25
Passing 4-mesh, retained on 10-mesh screen	5–15
Passing 10-mesh	20–35
Analysis of that part passing the 10-mesh sieve:	
Passing 10-mesh, retained on 40-mesh sieve	15–40
Passing 40-mesh, retained on 80-mesh sieve	22–53
Passing 80-mesh, retained on 200-mesh sieve	15–40
Passing 200 mesh	10–15
Asphaltic Cement	8–12

Hot Mix, Laid Cold. There is a large field for a bituminous concrete that can be laid cold. Several have been developed; to date Amiesite and Tarvialithic are most representative. The methods of manufacture in all are similar. Briefly, the aggregate is cleaned, heated and dried. It is mixed with a suitable bitumen, loaded into cars or trucks and shipped to its destination. Some trouble has been experienced in unloading these mixes from railroad cars, but if a clamshell bucket is used it is fairly easy. In both of these pavements two mixes are used, a coarse mix for the lower course of the pavement and a fine mix for the top. The coarse mix is laid about 2 in., or more, thick and spread uniformly and rolled with a 10 to 12-ton roller. The top is then spread from 1/2 in. to 1 in. thick, and rolled until a smooth pavement results. In cold weather it is customary with Amiesite to follow with spreading a thin layer of sand which has been treated with asphaltic oil and to roll this into the pavement, thus sealing it. In hot weather these pavements seal themselves, but in the late fall they are liable to remain unsealed unless some such method is employed. When carefully made and laid either of these pavements will carry heavy trunk line traffic.

The hot-mix-laid-cold type is specially suited to the small town which has no asphalt plant, and where an occasional bituminous job is indicated. This type has been successfully laid over old, worn-out pavements such as brick, concrete, water-bound macadam, stone block, and even wood block. There are a few tricks to be learned by the novice who has never laid this type but who may have had experience with hot mixes. He should consult the manufacturers before he attempts to lay his first job.

It is a mistake to attempt to lay one of these pavements with a total thickness of less than 2 in.

Analysis of Amiesite

Coarse Aggregate in Lower Course	Per cent
Passing 1/4-in. sieve	0– 5
Passing 5/8-in. screen	0– 25
Passing 1-1/2-in. screen	75– 95
Passing 2-in. screen	100

The top course contains coarse aggregate and filler. The filler consists of clean rock screenings, all passing a 1/8-in. screen. The coarse aggregate for the top is:

	Per cent
Passing 1/4-in. screen	0– 20
Passing 5/8-in. screen	95–100

Lime is added after the asphaltic cement has been mixed with the aggregate. The percentage of the materials used is:

	Lower course	Top course
Mineral aggregate	86 –90	85 –89
Filler	4 – 6	5 – 8
Asphaltic content	4 – 6	5 – 7
Lime	.5– 1	.5– 1

The aggregate is supposed to be washed, before mixing, with petroleum naphtha.

The Amiesite aggregate is mixed with asphaltic cement. The Tarvialithic aggregate is mixed with a special grade of Tarvia.

16. Asphalt

Sheet Asphalt

Characteristics. Sheet asphalt pavements are those in which the wearing course is composed of a mechanical mixture of asphalt cement with a carefully graded sand, passing a 10-mesh sieve, and mineral filler. A sheet asphalt pavement is waterproof, smooth, noiseless, easily cleaned, and non-productive of dust. It is *not* slippery when wet unless it is dirty, and that is not the fault of the pavement. Repairs and maintenance are simple and inexpensive, with no inconvenience to the traveling public. It wears away uniformly. It will carry the heaviest traffic of the largest cities, and yet it is well suited to residential districts. As it is a black pavement it absorbs heat. Unless carefully constructed of proper materials it may become wavy or rutted in hot

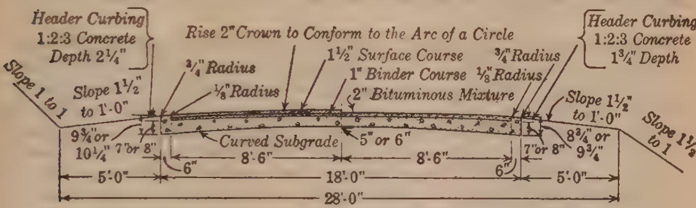


Fig. 8

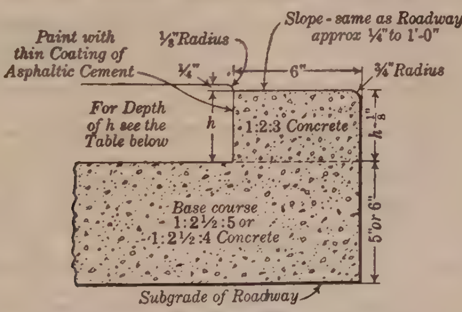
summer weather. Gas leaks may ruin it. Lubricating oil dropped from motor cars tends to cut back, or soften, the asphalt cement.

The wearing course mixture is usually laid over a binder course which is laid directly on the foundation.

Foundations. Sheet asphalt pavements have been successfully laid and maintained over the following foundations: cement concrete, black base;



h	*TYPE OF PAVEMENT SURFACE*
1¾"	*Bituminous Pavement Spec. D-E*
2¼"	*Bituminous Pavement Spec. A*
3¾"	*3" Vitrified Brick or Wood Block*
4¼"	*3½" Wood Block Pavement*
4¾"	*4" Vitrified Brick or Wood Block*
6¼"	*5" Stone Block Pavement - Sand Bed*
6"	*5" Stone Block Pavement - Cem. Sand Bed*

HEADER CURBING

Fig. 9

old brick, stone block and concrete pavements; old macadam; and gravel roads. If an old pavement is to be used, run a heavy roller over it to ascertain the weak spots. Repair such areas. Loose blocks will roll even after the sheet pavement has been laid, and this will cause a failure at such a point.

Depressions in the old pavements must first be filled with some binder course material and the entire surface of the old pavement should be made fairly true. If the old road is widened, then sufficient time must be allowed to let the new stone or gravel consolidate and pack. Six to eight weeks is not too much.

Binder Course. The binder is an intermediate course between the foundation and the wearing course. It is composed of a mixture of asphalt cement, or coal tar binder, with broken stone, slag, or crushed gravel. Whatever the material it should be strong and tough. A soft stone will cause a failure of the wearing course. Binder stone should all pass a 1 in. to 1-1/2 in. ring, depending on the depth of the binder stone. There are two classes of binder course: open binder, and close binder. Open binder consists of stone or slag aggregate from 1/4 in. to 1-1/2 in. in size, with practically no fine material. There should be enough variation in sizes between these limits that the mixture will interlock under rolling. No attempt is made to fill the voids as the sheet mixture serves this purpose. Close binder is really an asphaltic concrete the aggregate of which consists of broken stone and sand. The grading of these materials is as follows:

Total Mineral Aggregate	Per cent
Passing largest screen specified and retained on 1/2-in. screen....	15–65
Passing 1/2-in. screen and retained on 10-mesh sieve...........	20–50
Passing 10-mesh sieve...................................	15–35

Of asphalt cement 4.5% to 6% is added, the exact percentage being found by trial. Each particle should be thoroughly and uniformly coated with asphaltic cement. Too much asphaltic cement causes fat spots to develop in the wearing course. Too little makes for a brittle binder course. The mix should be delivered on the job at between 200° F. and 350° F., and if it is between these limits it should crawl when dumped from the truck.

Wearing Course. The aggregate consists of a hard, durable, finely graded sand and a fine filler, such as limestone dust, slate dust, or portland cement. The amount of asphaltic cement varies from 9% to 13%. These materials are mixed in a central plant and brought to the job in trucks. The temperature of the mix should be between 250° F. and 350° F. Stiff mixes require the higher range. Also, when hauling long distances the higher temperatures are necessary, and the truck load should be covered to keep in the heat. When the mix is dumped, it is raked over the binder course to a depth (loose measurement) of about an inch greater than that desired for the finished depth. The rakes are hot, the men work rapidly, and the greatest care must be exercised to see that the spreading is done uniformly, so that no high or low spots may develop under rolling. Absolute uniformity of mix is essential. Variations that are noticed should be reported immediately.

Sand for the wearing course should be hard, tough, clean, and fairly sharp. The Asphalt Association recommends the gradings shown in table at top of next page.

The mineral filler aids in filling voids, and it also seems to increase the stability of the mix. The most satisfactory materials have been found to be limestone dust and portland cement. Both of these are very finely ground and yet they do not tend to make the mix ball up. Other materials are sometimes used. The amount of filler varies from 10% to 20% of the total mineral aggregate.

Asphalt Cement. Satisfactory asphalt cements, as shown by service tests, have been made from California, Mexican and Texas asphaltic oils, gilsonite and asphaltic oil, and "Bermudez" and "Trinidad" refined asphalts.

Standard Sand Gradings

Sieves	Heavy traffic, per cent		Light traffic, per cent	
Passing 10-mesh, retained on 20-mesh	5	23	10	35
Passing 20-mesh, retained on 30-mesh	8		10	
Passing 30-mesh, retained on 40-mesh	10		15	
Passing 40-mesh, retained on 50-mesh	13	43	15	45
Passing 50-mesh, retained on 80-mesh	30		30	
Passing 80-mesh, retained on 100-mesh	17	34	10	20
Passing 100-mesh, retained on 200-mesh	17		10	
Passing 200-mesh	0		0	
	100		100	

The following is from Brochure 9 of the Asphalt Association:

The most desirable consistency of asphalt cement for sheet asphalt construction will be governed largely by climatic and traffic conditions. Stability of the topping mix in particular depends to a considerable extent upon the consistency of the asphalt which binds the sand grains together, as the most carefully graded and compacted sand exhibits but little resistance to displacement by itself. A very soft asphalt cement will not hold the sand grains together in their original position with sufficient tenacity and its use will therefore result in undue deformation of the surface under traffic. On the other hand, too hard an asphalt cement will produce a brittle mixture in cold weather which is not sufficiently malleable to prevent the formation of contraction cracks in the pavement. The following table will serve as a general guide in selecting suitable ranges of penetration for asphalt cements to be used under various climatic and traffic conditions:

Penetration Limits of Asphalt Cement

Traffic	Temperatures		
	Low	Moderate	High
Light	50–60	50–60	40–50
Moderate	50–60	50–60	40–50
Heavy	40–50	40–50	30–40

Inspection of Sheet Asphalt. Competent inspection of both plant operation and street work are very necessary to successful sheet asphalt construction. This will ordinarily necessitate the services of two inspectors who have acquired sufficient experience to suggest modifications in proportions or methods of manipulation, within specification limits, which from time to time may be desirable. These plant and street inspectors should work in harmony and keep in close touch with one another. The former should occasionally visit the street in order to observe how the mixtures behave during laying.

The plant inspector should carefully observe all details of plant operation, particularly in connection with the heating of individual constituents, their measuring and proportioning, the period of mixing, and the condition of the mix upon leaving the plant. He should keep a record of the temperatures to which the asphalt, sand and stone are heated prior to mixing and the temperature of the finished mixture when discharged. He should also record the number of loads sent out. He should test and record the consistency of the asphalt cement particularly if fluxing is carried on at the plant, in which case he should see that the proper proportions of refined asphalt and flux are used and that a uniform product is obtained. He should make grading tests of the mineral aggregate constituents and see that at all times proper proportions of asphalt cement and aggregate are used. He should check measurements from time to time and should make occasional pat tests of the surface mix as it is being prepared. He should be provided with the necessary equipment for plant testing and a room in which such tests may be made. In addition to his own tests he should, however, forward to a testing laboratory samples of the various constituents and of the mix itself for check and control tests. The testing equipment of the plant inspector will ordinarily include the following:

An armored thermometer of suitable range for recording temperatures of the hot aggregates and mixes.

A set of standard screens and sieves, as may be called for in specification requirements.

A stiff brush for cleaning sieves.

A large balance of 10 lb. pan capacity and a set of decimal weights for broken stone weighings.

A small sand balance with pan capacity of 200 g. for weighing sand.

A complete penetration test outfit for determining the consistency of asphalt cement.

A pat test outfit.

A supply of report forms.

The room assigned to plant testing should contain a short workbench for testing apparatus, shelves for samples, a chair and a table. For sampling, the inspector should be provided with suitable cans, gum labels, pans and a long-handled metal dipper.

The street inspector should carefully observe all details of the laying of the pavement. He should take and record the temperature of the various loads of hot mix received on the work and for this purpose should be provided with an armored thermometer. He should see that the loads are so distributed as to give the specified thickness of pavement and that they are properly raked and compacted. He should take occasional check samples of the mix as received and should forward these to the testing laboratory and in some cases it may be advisable for him to take samples of the finished pavement for laboratory analysis and density determinations.

Construction

(a) **Binder Course.** 1. Thoroughly clean base. Remove any standing water. Let base dry.

2. Deliver binder at a temperature of at least 225° F. and not more than 350° F.

3. Dump binder outside area where it is to be spread, although it may be dumped on the base in advance of the actual spreading area.

4. Use hot rakes and spread binder course in a uniform layer of such depth that when compressed it will be of correct thickness.

5. Roll. Use a roller of at least 10 tons weight. Roll longitudinally, beginning at sides and rolling gradually toward center. *Roll slowly.*

6. Do not stop the roller except at the beginning and end of area to be rolled. Once the roller starts let it continue until the end is reached.

7. Use hot tamper at places that the roller cannot reach.

8. If fat spots develop, cut them out and fill in with fresh, hot binder.

9. Do not roll over the unprotected end of the binder course unless no more is to be laid for the present. In that event the rolled-out ends are trimmed off when new binder is placed.

(b) **Wearing Course.** 1. Be certain that the binder course is clean.

2. Deliver wearing course at a temperature of at least 250° F. and not over 350° F. Do not attempt to work when the air temperature is below 45° F.

3. Dump mix outside of area on which it is to be spread. Spread with hot shovels, and rake with hot rakes. Rake to uniform depth such that after compression the wearing course will be of correct thickness.

4. Paint contact surfaces of gutters, manholes, and curbing with a thin coat of hot asphaltic concrete or cut-back asphaltic concrete.

5. Work rapidly, and have no delays of any kind. Keep moving.

6. Roll. Use a tandem roller 10 tons or more in weight. Do not use a light roller for the initial rolling. A 15- to 18-ton roller is best. Always start rolling along the sides and gradually work to the center. Then roll diagonally. On wide streets roll perpendicular to first rolling. Keep on rolling until certain that no more compression is possible. If mix sticks to roller wheels moisten them with water or oil.

7. Correct for high or low spots before final rolling by raking or addition of fresh mix. Test surface with 10-ft. straight-edge.

8. Do not let roller man reverse except at ends of fresh mix when rolling longitudinally on initial compression. Waves are almost certain to be formed if he does.

9. Use hot tampers where roller cannot compact the mix.

10. Before roller finishes, spread a light coating of limestone dust or portland cement over the surface of the fresh mix, sweeping it and then rolling it. A light tandem roller can be used for finishing.

11. The roller should stop just before it reaches the unprotected end of the fresh mix. On the end where the fresh mix joins that part of the wearing course that has already been rolled the roller should continue onto the compacted area. If there is a delay or work is stopped for the day the roller may run over the unprotected end, but that portion must be cut away and the edge trimmed up vertical and painted with hot asphaltic concrete before the next load of mix is spread.

12. Keep traffic off until pavement has cooled to air temperature. A minimum of six hours is desirable; 24 hours is better.

Repairs

1. Cut out damaged area, making sides of cut vertical.
2. Examine base thoroughly to see if it has failed. If a gas leak is suspected, use your nose. If that fails, a lighted match may reveal the leak.
3. If base is at fault cut out the poor section and replace with new material. If it is a concrete base and traffic on the street is heavy the substitution of black base for the concrete will speed up repairs.
4. On the base, spread binder course; tamp or roll it thoroughly.
5. Paint the vertical edges of the old pavement with hot asphaltic concrete.
6. Spread wearing course and proceed as under "Construction."

Maintenance

The essential item needed to keep a correctly designed sheet asphalt pavement in first-class condition (assuming it has been properly mixed and laid) is: traffic. All bituminous pavements need traffic to "iron them out" and keep them fresh and lively. If the sheet pavement is right in the first place then the more traffic it gets the better it is. And traffic is its best source of maintenance.

Failures

There have been numerous failures of sheep asphalt, but these are attributable to faulty materials, poor construction methods, poor design, weak bases, underground gas leaks, and so on, and they are not attributable to the type of pavement itself.

Heavy motor truck traffic has caused the failure of many old sheet pavements which were built long before such traffic was anticipated. Similar failures are to be found for every type of pavement. There will be no failures of the wearing course if asphaltic cement of the proper penetration is used and if sand of the standard grading only is permitted.

A sheet asphalt pavement is a high-class pavement; it requires high-class workmanship and expert supervision, together with first-class materials. Sloppy, careless work will positively show up later. If those responsible for a pavement achieve a failure the fault is theirs, and not the pavement's.

South American oils are replacing to some extent the oils from the Mexican field. The asphalts obtained from these South American oils may differ from those which have been used, and it is possible that considerable experimentation must be carried on to insure satisfactory results.

A start has been made toward producing mechanical spreaders and rakes. Since sheet asphalt pavements are usually laid in city areas, it seems unlikely that machines similar to concrete finishing machines will be used to any great extent, since such machines are seldom used within city limits for finishing concrete pavements.

A Typical Sheet Asphalt

	Per cent
Binder Course:	
Passing 1-in. and retained on 1/2-in. screen	15–65
Passing 1/2-in. and retained on 10-mesh screen	20–50
Passing 10-mesh sieve	15–35
Sand for Wearing Course	
Total passing 10-mesh sieve	100
Total passing 10-mesh sieve and retained on 40-mesh	12–50
Passing 10-mesh, retained on 20-mesh	2–15

Note. When less than 99% of asphalt cement is soluble tetrachloride, the percentage of bitumen (solubility in carbon disulfide) shall be separated.

Asphalt Block Pavement

"An asphalt block pavement is one having a wearing surface composed of a properly proportioned mixture of asphalt cement, crushed rock and inorganic dust, heated to a proper temperature and molded into uniform blocks under heavy pressure." Blocks are made in the following sizes:

Length, in.	Width, in.	Depth, in.	Weight, lb.
12	5	2	11*
12	5	2-1/2	13-1/2
12	5	3	16
8	4	1-1/4	3-1/2†

* This size is commonly used.
† For special work requiring light weight.

Penetration limits for the asphalt cement are as follows:

Traffic	Temperature		
	Low	Moderate	High
Light	15–45	15–45	10–35
Moderate	15–45	15–40	10–30
Heavy	10–35	10–35	10–25

A large yardage of this type of pavement has been laid in and around some of the large cities. Some of these pavements have been very successful; others have been disappointing. Undoubtedly the failures can be traced to inferior blocks. If the asphaltic concrete is too soft the blocks get out of shape, causing the pavement to wave. If too hard, then the blocks break off at the edges and a rough surface develops. On grades of over 3% considerable trouble has been experienced from the blocks dragging under traffic. The cost of an asphalt block pavement is almost always higher than that of a sheet asphalt pavement in those localities where there is a sheet plant or where there is enough business to warrant setting up a portable plant. The logical place for asphalt block pavements is in those towns where a yardage is laid that does not attract a contractor who owns a sheet asphalt plant. If the blocks are honestly made, of the proper materials, and well laid, the resulting pavement is excellent and will carry very heavy city traffic. Cuts in such a pavement are easily made and repair accomplished. Maintenance consists in surface treating the blocks with a hot asphaltic oil, and covering with coarse sand. Screenings passing a 3/8-in. mesh are sometimes used for cover, but if they are of limestone the pavement is liable to become dusty for a while.

Foundations. Best results are obtained where a new cement concrete foundation is laid. It is not economy to use old macadam, brick, or other old roads, as this pavement is expensive and a good base is required. In Florida the natural sand base has been used with varying degrees of success. Using a concrete base the blocks are laid in a mortar cushion or bedding course about an inch or less thick. Since a variation in depth of block is allowed of from 1/8 in. to 1/4 in. it is not possible to lay them directly on a smoothly finished foundation as is done with wood block. The mortar bed is made of sand and cement in the proportion of one part cement to four parts sand, and enough water to make a workable mortar. Care must be taken to strike this bedding course to a true and even surface, otherwise unevenness in the resulting pavement will be most apparent. As in brick and stone block construction, the pavers stand on the blocks already laid and must not step into the bedding. Joints are broken, and the blocks are laid at right angles with the curb.

It is customary in most cases to sweep sand into the joints. A far better method would be to give the blocks a surface treatment with a hot asphaltic oil which will fill every joint. A waterproof pavement is then secured immediately. A sand cover should be applied over the surface treatment.

Rock Asphalt

Rock asphalt is sandstone or limestone naturally impregnated with asphalt.

There are a number of deposits throughout the world. In the United States rock asphalt is found in Kentucky, Alabama, Missouri, Oklahoma, Texas, California, and in unimportant deposits elsewhere. The materials found in the various deposits vary greatly in character, and but few of them, as found, are suitable for road work. There is no uniformity of asphalt content. In 1928 most specifications required that there be about 6-1/2% of asphalt present. This was based on the assumption that because the Kentucky rock asphalts that had given good service contained approximately that amount, therefore all rock asphalts should contain a similar amount. It is reasonable, however, to suppose that the size of sand particles will have much to do with the amount of asphalt necessary. Investigation of this was begun in 1928.

Rock asphalt is mined, loaded into cars and shipped by rail to a convenient unloading point. Difficulty is frequently experienced in unloading, especially if the rail haul has been far and long, and if the weather is cold when unloading is attempted. Sometimes it has been necessary to use dynamite to loosen the material. Steam pipes are sometimes introduced into the mass to liven it. The cost of unloading may be a serious item and must be included in all estimates. While pick and shovel unloading is customary, it is sometimes possible to use a clamshell shovel. In this case the men in the car may have to hang onto the bucket to give enough weight to force it into the rock asphalt.

Under favorable conditions the material is fairly easy to handle. It is unloaded from the car and loaded into trucks and taken to the job where it is spread cold on the foundation, which may be a concrete base, or an old pavement. It is spread to such depth that when finished the rock asphalt will be 2 in. thick, minimum. It is a great mistake to try to skimp.

Rolling is very essential. Best results are obtained with a corrugated roller, but a regular roller will do. Much of the European work is hand-rolled.

If the material is of uniform consistency, is carefully spread and well rolled, the resulting pavement is good. Most failures have been due to non-uniform asphalt content, resulting in fat spots and lean spots, poor foundations, and faulty rolling.

The cost will vary with the length of haul, and the difficulty experienced in unloading. Cost at the mines in Kentucky is about $6.50 per ton, f.o.b. cars.

Rock asphalt has been successfully used as a cold patching material in other types of pavement. It is also a good material to use at highway-railway crossings. It may be laid in the rain.

It has been found advantageous to give the foundations a prime coat of asphaltic oil about 24 hours before the rock asphalt is laid. Some of the rock asphalts work better when heated, notably those from Texas and Alabama.

17. Concrete Pavements

Characteristics. A portland cement concrete pavement furnishes a smooth surface, is easy to clean, and produces practically no dust. The resistance to traffic is low. When clean it is not slippery. The white glare is tiring on the eyes. Under horse-drawn traffic concrete paving is noisy. Grades of 8 to 10% are common in a number of instances from 15 to 18% grades have been used. Cracks can be easily repaired, but depressions and disintegrated spots are difficult to repair satisfactorily without cutting away the old concrete. Worn-out concrete pavements are often topped with bituminous wearing course or, occasionally, with new concrete or brick. With well built and carefully designed pavements there is almost no cost for repairs for the first five years. After that the costs may become somewhat heavy.

Subgrade. A concrete pavement should be laid on a well compacted and well drained subgrade. If the subgrade is of clay or other heavy soil, it should be replaced with clinker, broken stone, cinders, gravel, or some other suitable material. Although this is desirable it is not always possible. The general practice is to require that the subgrade be of uniform density. Rolling should be reduced to a minimum on heavy soils. Prior to placing the concrete the subgrade should be thoroughly wet, otherwise the subgrade will absorb water from the concrete. It should not be so wet as to be muddy.

Ingredients and Proportioning. The materials used for the fine aggregate of a cement concrete pavement are generally sand or stone screenings, and for the coarse aggregate either broken stone or gravel. The broken stone employed should be obtained by crushing hard, tough rock. Preferably the stone should be composed of naturally graded sizes and free from dust or dirt. What has been said relative to broken stone applies as well to gravel. The sand used should be clean, sharp and coarse, free from loam, clay, and vegetable or organic matter. The cement should be a first-class portland cement that will meet the standard specifications of the A. S. T. M. Care should be taken to use clean water. The proportions which are used in connection with the construction of concrete foundations are not rich enough in either cement or mortar to make satisfactory concrete which is to be subjected to the abrasive and impact forces of highway and street traffic. The proportions used for the best class of one-course concrete pavements are about 1 : 1-1/2 : 2. For two-course pavements the base may be 1 : 2-1/2 : 4, and the top, 1 : 1 : 1-1/2.

Materials may be proportioned either by volume measurement or by weighing. When volume measurement is used it is important to use devices

that will give fairly accurate results. Measurement by shovels or wheelbarrows is poor practice. In volume measurement compensation should be made for the bulking of the aggregate due to moisture. Proportioning by weight is probably the most satisfactory method. It automatically compensates for aggregate bulking, and in addition furnishes a close check on the quantity of materials used.

Design. In 1929 there were as many designs for concrete highways as there were states; and the cities and towns within the individual states had, in many cases, designs of their own which differed from the state designs. Fig. 11 shows the 1927 cross-sections for the several states noted. There was no uniformity of opinion of highway engineers as to standard cross-sections, transverse joints, longitudinal joints, joint fillers, methods of curing, reinforcement, crown, proportioning the mix, materials, nor waterproofing. In general the slab with the thickened edge was more popular than the slab of uniform thickness. For theory of plain and reinforced concrete see Sect. 11.

Reinforced Pavements. Reinforcing is usually placed about 2 in. below the surface of the pavement. The concrete is first struck off to the approximate depth, the reinforcing is placed, and then the top 2 in. of concrete is placed and finished as in unreinforced construction. The materials and their proportions in the base are usually the same as in the top. The top course should be placed as soon as possible after the base course is laid to secure a monolithic slab. The reinforcement usually consists of woven wire or expanded metal, although a mesh work of small round bars is sometimes used. The economic value of reinforcing has not been definitely determined. It is valuable from an esthetic standpoint, since it reduces cracking.*

Construction. Mixers should be equipped with timing and locking devices so that the mixing time is accurately controlled. The length of time for proper mixing should not be less than one minute after all of the materials including the water are in the drum. Concrete should be delivered from the mixer to the subgrade by a boom and bucket rather than by a chute. The amount of water used in the mix should be reduced to the minimum consistent with workability. The tendency is always to use too much water, which results in loss of strength, more work to get a smooth surface, and sometimes in a weak wearing surface. Scaling of the surface is probably due in part to excess water.

Concrete is deposited in one or two layers. The finished thickness varies from 5 in. to 10 in. The usual crown for highways is 1/4 in. per foot. The use of templets to strike the surface of the concrete, and of bridges which span it, thus enabling the laborers to work over the surface without standing on it, should be insisted upon.

Finishing the pavement is most important. When a finishing machine is used, proper methods will produce a smooth surface. The following is recommended by the Portland Cement Association:

1. Strike off and compact the newly placed concrete with a mechanical finisher. Under ordinary conditions three times over the surface will suffice.
2. Belt the surface. The belt should be applied by working it backward and forward transversely and at the same time pulling it forward longitudinally.
3. Straight-edge the surface for high and low places. Use a 10-ft. straight-edge. All such places should be removed by adding or taking away concrete. Use a wooden float on all such disturbed places.
4. Allow the concrete to stand for an appreciable time to let the excess water come to the surface. (10 to 20 minutes). With a wooden float or a wooden straight-edge remove the excess water, laitance, or inert matter by lightly scraping the surface. These tools should have a working edge of from 6 ft. to 10 ft., and long handles.
5. Again test the surface for irregularities and remove them with the float as in operation 3.
6. After the surface water has evaporated the final belt is applied. Apply it at such time and in such manner as to produce a coarse, gritty surface texture.

It should be noted that finishing machines are adapted to pavements of constant widths, and are not suitable for many locations in city work.

* The Portland Cement Association says: " Reinforcement is put in concrete pavements for one purpose only — to hold together any cracks that form."

When hand finishing methods are used the procedure is precisely the same as in the machine method, except that a heavy hand templet should be used to strike off the concrete to the proper contour. It should then be tamped, using a heavy tool resting on the forms. The tamping face should be about 4 in. wide. After tamping, the entire surface should be floated with a wooden float. From this point on the procedure is the same as given in operations 2 to 6 above.

Joints. Longitudinal joints should be used when the width of pavement is greater than 14 in. This central joint should be of the tongue and groove type. Tie bars should be used to prevent the adjoining parts of the pavement from separating one from the other, thus destroying the ability of the joint to transmit loads. In city construction only one joint will usually be necessary up to widths of 40 ft. For greater widths two or more joints will be necessary. In rural roads the number of joints will depend on the method of construction, the total width of the pavement, and the relation of pavement width to traffic lanes. In general, the width between any two joints or any joint and the edges of the pavement should not be less than 9 ft., nor more than 20 ft. Each longitudinal joint should be built to coincide with a traffic lane marker.

Transverse joints always should be provided. There will be more or less contraction and expansion of the concrete due to changes of temperature, variation in the moisture content of concrete, and variation in the condition and character of the subgrade. If expansion joints are not present, when the concrete contracts, the tensile strength will be exceeded and the pavement will crack; when it expands it will tend to crush, spall or bulge. The edges of the joints will need protection from the abrasive action of traffic; a bituminous filler should be used. The width of the transverse joints depends on the distance between them. This distance varied in 1928 specifications from 15 ft. to 202 ft., with 30 ft. as an average.

Curing. Cement concrete pavements must be cured. If the water present at the time of placing the concrete can be retained in it, then that amount is sufficient to produce maximum strength. Therefore it is possible to cure concrete pavements in one of several ways and secure satisfactory results. All of the following methods are in use:

Earth Cover. As soon as the concrete has attained its final set it is covered with earth to a thickness of about 2 in. This earth is immediately sprinkled and must be kept moist until curing is effected, usually from 14 to 28 days. The earth is removed before traffic is admitted. Instead of earth, straw or hay may be used. In cold weather manure is sometimes used.

Ponding. On level roads the slabs may be kept wet by throwing up earth dams or dikes along the edges and across the pavement at suitable intervals, and keeping the areas so formed covered with water. This is rather expensive, especially if water is scarce.

Burlap. As soon as possible after the concrete has set it is sprinkled and covered with two layers of burlap which is then kept wet by frequent sprinklings. After 14 days it may be removed.

Calcium Chloride. Soon after the final set of the pavement $CaCl_2$ is scattered over the surface at the rate of 1-1/2 to 2-1/2 lb. per square yard. This method has been satisfactory, and it has the advantage over those preceding that there is no cleaning up to be done. After the curing period traffic may be admitted.

Water Glass. Sodium silicate may be sprinkled over the pavement as soon as the initial or the final set has taken place.

Bitumens. Tars and asphalts are used. To be effective they must be applied immediately after the final set. Cold or hot application materials have been satisfactory, applied at the rate of from 1/4 to 1/2 gal. per square yard. They may be applied successfully on any grade, and are especially useful in hot, dry climates.

Water. Contractor and engineer alike must make certain that the water supply is adequate. Water supplies that fail in midsummer may cause contractors to fail in the fall. Inquiry should be made locally as to the certainty of supply. If ponding is attempted in hot weather then large gallonage is necessary.

Early Strength. It is often inconvenient to keep traffic off a finished road for from 14 to 28 days. Numerous schemes have been tried, other than using special cements, to attain a strength at 3 days equal to that normally produced at 28 days. The Universal Portland Cement Co. suggests the following:

1. Decrease the amount of mixing water.
2. Increase the mixing time up to 5 minutes.
3. Increase the amount of cement.
4. Place the concrete at a temperature of at least 70° F.
5. Keep concrete at 70° F. for at least 3 days.
6. Keep concrete damp for 3 days.
7. Use $CaCl_2$ where tests show it increases strength. (**Note:** Some cements do not show increased strength when $CaCl_2$ is added.)

The temperature of materials and of the weather plays a very important part in attaining strength. Pavements built in hot July and August weather of 1 : 1-1/2 : 3 mix, standard cement, properly cured, should be of such strength as to be usable after three or four days.

The amount of $CaCl_2$ is 2 lb. per sack of cement. It is customary to mix 100 lb. of it with 50 gal. of water, and then substitute 1 gal. of the solution for 1 gal. of mixing water.

Early Strength Cements. There are a number of such materials on the market. Some are excellent and some are simply standard cement with $CaCl_2$ mixed in them. Lumnite cement attains normal 28-day strength in 24 hours or less. Its manipulation is different from portland cement, and the user is cautioned to observe most carefully the directions for its use. Such brands as Incor and Velow are used in the ordinary manner and attain 28-day strength, or better, in about 3 days.

Hydrated lime, infusorial earth, and similar materials are sometimes used to insure a more workable mix. Their value is as yet undetermined.

Waterproofing. Changes in moisture content cause serious deformation, and stresses that lead to disintegration. Experiments are under way in which the endeavor has been made to waterproof concrete road slabs on all sides. The subgrade has been covered with roofing paper which is then mopped with coal tar pitch. The slab is cast thereon. Tar is sprayed over the top surface, and along the edges, immediately after the final set. Experiments which the author has conducted lead him to believe that if the concrete is cured with water, is then allowed to dry for a week, and is then treated to refusal with a very light water-gas tar, such slabs will be made waterproof on the upper surface, and that abrasion and wear will be greatly reduced. Rattler tests showed 9.2% wear on treated cubes of concrete, and 14.4% on untreated. The bottom of the slabs must be waterproofed by some such means as is noted above. The same grade of water-gas tar saves concrete from the disintegrating effect of seawater, alkali water, and water containing other deleterious substances.

Reinforcement. Reinforcement consists of steel mesh or steel bars. Mesh and light bars probably do not add to the strength of the concrete, but if cracks appear then such reinforcement holds the slab together and prevents the cracks from opening. Bar reinforcement, when properly placed, and if the bars are 1/2 in. or more in thickness, will increase the load capacity. The cost of a concrete pavement is measurably increased when steel is introduced. There is a wide variation of ideas on the subject. For weights and areas of steel bars see the table on page 680. For gages of iron wire and sheets see the tables on pages 688 and 699.

Reinforcement in city street pavements is very undesirable if there is reason to believe that there will be many service cuts made. It is extremely costly to cut through heavy steel, and much damage to the contiguous concrete may result. It is much better in such locations to add an inch depth of concrete and leave out the reinforcement.

Doweling. In order to prevent slabs from rising or sinking to elevations different from their neighbors, recourse has been made to steel dowels which are so inserted that they extend from one slab into the next. This method is apparently efficacious in some cases and disastrous in others. Experience shows that the steel must be of such size that bending is eliminated, and that the ends of the dowels must be free. Since the slabs will expand and contract there must be room in the dowel hole to take care of this. Various forms of caps and tubes have been tried. One simple method is to insert the dowel in a length of gas pipe about 2 in. longer than the dowel, and grease the dowel. Tin, paper and cardboard tubes have been tried. There is no standard.

If the dowels are 3/4-in. bars, or larger, and the spacing is 3 ft. or less, it is probable that part of the moving load will be carried across the joint to the adjoining slab. But if the dowel is placed in a large dowel hole this is not true.

Blow-ups. Doweling may help to prevent blow-ups. But, if the blow-up does occur and is bad, the dowels may help shatter the ends of the slabs.

Warping. There is often a great difference in temperature between the top and the bottom of a slab. This causes the slab to change shape. With a cool subgrade and a hot sun the slab will arch along the center line. At night the opposite effect will be observed. Therefore, at times the edges are supporting the load, whereas at other times the edges are clear of the subgrade. Corners of the slab are sometimes unsupported; corner breaks are commonest. In order to compute the thickness necessary for a concrete road slab, Clifford Older assumed that a load is applied at an unsupported corner, and that rupture takes place in a plane at right angles to the bisector of the corner.

Let S = unit stress in tension in pounds per square inch, which should not exceed one-half of the modulus of rupture of the concrete.

W = load.

t = thickness of slab at edge in inches.

Then $t = \sqrt{3\ W/S}$.

Let t_c = thickness of slab at center $= 0.7t = 0.7\sqrt{3\ W/S} = \sqrt{1.5\ W/S}$.

If a continuous dowel is used, then half the load is carried across the joint, and $t_2 = \sqrt{1.5\ W/S}$.

If four corners carry the load, then $t_3 = \sqrt{0.75\ W/S}$.

Scaling. Scaling is caused by too much rolling, tamping, belting, or other manipulation which brings the fines to the surface. Frost may also cause scaling. This layer of material seems to have, frequently, no real bond with the aggregate below it, and in time a peeling or scaling begins which sometimes continues until from 1/4 in. to 3/4 in. of the surface has peeled off. The large size aggregate is then exposed to the elements and to traffic, and unless a bituminous surface treatment is applied to seal the surface there may be serious disintegration. A bituminous surface treatment should not be attemped until the pavement has stopped scaling, as the treatment will peel off with the scale.

Joint Filler. Numerous fillers are on the market. There are two classes, premolded and poured. The former is made of roofing felt impregnated with asphalt. It is easy to handle, is made in convenient lengths, and of various thicknesses. The 1/2-in. thickness is common. At transverse joints the practice is to let the material extend 1/2 in. above the concrete, and it must extend through the slab to the subgrade. If a poured filler is used the form is removed at the joint, the joint is cleaned and the filler is poured so as to fil the joint completely. A bitumen which will positively adhere to the concrete should be used. A new form of filler is applied from a pressure gun, similar to grease guns for automobile lubrication.

Repair

Corner breaks, shattered edges, and blow-ups are the most frequent causes of trouble. If the broken corner or edge seems to have settled firmly into the subgrade it is often possible to make a satisfactory bituminous patch that sets up quickly and lasts as long as the pavement itself. But if the broken portions have no firm foundation they must be removed and fresh concrete patches must be built. For this purpose an early strength cement is imperative. Curing must be effected by $CaCl_2$, bituminous cover, or water glass. Barricades must be put around the patches and must be lighted at night. If the original slab was reinforced then it is well to cut away the old concrete in the broken area, leaving the reinforcement in place in the new patch.

Trenches and service cuts should have the edges of the old concrete beveled so that the patch will be supported if the backfill settles. It is well to place extra steel reinforcement in such areas. It is fairly easy to introduce heavy steel reinforcement across such cuts.

Maintenance

Cracks form in the best built concrete pavements. The most satisfactory material yet found (1929) for filling them, to keep out water and dirt, is coal tar (specification D-110–27-T).

1. Clean cut crack with an iron hook or poker.
2. Sweep out dirt.
3. Be sure the crack is *dry*.
4. Fill it with coal tar which has not been overheated.
5. Wait for tar to settle and shrink.
6. Repour joint until it is full to overflowing. It is not desirable nor is it economical to smear the concrete surrounding the crack.

The pavement should be examined twice a year at least, and all cracks should be poured. If wide cracks are to be filled a mastic of sand and tar is better than tar alone.

Concrete pavements that show signs of disintegration can often be saved by surface treatments with bituminous materials. Both tars and asphalts are suitable. Frequently it will be found that the material applied does not adhere well to the concrete. In such cases a priming coat of water-gas tar applied at the rate of 1/6 gal. per square yard will tooth into the concrete and the surface treating material will then adhere firmly. On the whole, hot surface treatments are superior to cold. Emulsions of asphalt have been satisfactory, but are somewhat more expensive. It is most necessary to clean the concrete thoroughly before treatment. A cool day is preferable to hot weather as the hot treatment will then chill and remain in place on the concrete. Too heavy a treatment must be avoided, or a wavy surface will be produced. Tar (specification D-108 or D-109), or asphalt (specification Pennsylvania H1), are suitable.

1. Thoroughly clean the concrete with push brooms and water.
2. Let pavement dry thoroughly.
3. Apply tar or asphalt at the rate of 0.3 to 0.5 gal. per square yard.
4. Immediately cover with clean 3/4-in. stone chips, or washed pea-gravel.
5. Roll the cover into the bitumen with a light roller.
6. Touch up any spots that failed to be covered.

Some engineers claim that they find that such a treatment fills all cracks and that it is unnecessary to pour open cracks before treatment. A treatment should last for about two years under ordinary traffic. The subsequent treatments should be lighter. As little as 1/8 gal. per square yard has been satisfactory for second treatments.

In the autumn all holes should be patched with coal tar.

From time to time specialties in concrete pavement design and construction have appeared. The most successful have been Hassam, and Vibrolithic. Hassam is, in reality, what may be termed a penetration type. Crushed stone is laid on the prepared subgrade, shaped and lightly rolled or brought to crown by any suitable means. Cement grout is then poured over the stone, and the pavement is then finished as a regular concrete pavement except that it is rolled.

Vibrolithic is a concrete pavement that has been pounded or vibrated with a machine which consists of a gasoline engine whose flywheel is slightly off center. After the concrete has been poured and struck, a layer of hard, tough, dense, clean stone is spread, and then platforms are placed over it and the machine is run back and forth over the platforms. The pounding effect pushes the new stone into the mix and tends to make the concrete denser. The platforms are removed and the surface is belted or floated as usual. If care is used in the selection of the top layer of stone so that only excellent material is allowed, then the resulting pavement is superior in wearing qualities to ordinary concrete. This method practically assures a drier mix, and a denser and more durable pavement. The only question is whether or not the extra expense is justified. On rural highways it probably is not; on city streets it probably is justified.

18. Brick Pavements

Vitrified bricks are used for pavements. They are made in a few sizes only. There are two styles: wire-cut, and repressed. Both styles may or may not be furnished with lugs, according to the preference of the buyer. Wire-cut, either plain or with lugs, have largely supplanted repressed, though the latter are used for special forms. "Vertical fiber brick" are plain wire-cut brick. They are no better than other wire-cut brick.

A brick pavement is durable, easy to clean, offers slight resistance to traction, is not slippery, does not create dust, is expensive in first cost but may be cheap over a term of years, and properly laid it will carry the heaviest modern traffic successfully.

Paving bricks must be hard, tough, evenly burned, thoroughly annealed, and uniform in texture. They are made uniformly 8-1/2 in. long; their permissible variation from this may not exceed 1/2 in. Transverse dimensions vary, but are usually 2-1/2 × 4 in., or 3 × 4 in., or 3-1/2 × 4 in. A brick 2 in. in depth has been tried but it has not sufficient strength to stand up under heavy truck traffic. Brick are sold as No. 1 pavers, No. 2 pavers, and culls.

Foundations. If the character of the soil is sandy and firm, and the traffic that is expected on the road is not excessively heavy, it may be possible to lay a good pavement directly on such soil. Many brick pavements of this kind have been laid in Florida and elsewhere where similar conditions exist. Such pavements last for years with little maintenance cost. The soil, in any case, ultimately carries the load, and if the soil is firm and well drained there is no reason why a brick pavement should not be laid directly on it, provided that heavy truck traffic, such as is met with close to large cities, is not encountered. In all cases where the soil is the foundation it is necessary to provide a curb flush with the top of the pavement. This should be of either stone or concrete. The old method of using a wooden form or curb is worthless now, if it is expected that such a form will hold the brick in place.

If the soil does not drain rapidly and thoroughly, then some other form of foundation must be used.

Rolled Stone Base. A brick pavement laid on a firm macadam base with a 1-in. bedding course is a good form of construction where drainage is good and the soil is firm. The macadam should be at least 6-in. deep, but a greater depth is desirable. Such a base is usually much cheaper than one of concrete.

Black Base. This type of foundation has been used but little, although it has many points of excellence.

Slag Base. A crushed air-cooled blast furnace slag foundation is good. The particles of slag should all pass a 2-1/2-in. ring and be retained on a 1/4-in. screen. The filler should be granulated slag. If water is used, as in macadam construction, it will be found that these slag bases set up in a few months so that they resemble concrete. A slag base should be at least 6 in. in depth, and somewhat thicker if very heavy truck traffic is expected. Vitrified slag does *not* set up, and this material does not make a first-class base.

Cement Concrete Base. This is at once the most popular and the most expensive foundation for brick. It has been used so extensively that many people are not aware that a brick pavement may be laid on any other type. It has one distinct advantage over other forms of base which is that it bridges over soft spots in a poorly drained subsoil. Another merit is that its greater supporting strength, inch for inch of depth, makes it possible to construct a thinner concrete foundation than any other type with consequent saving in materials and excavations. Concrete bases should be mesh reinforced, since it is imperative to keep at their minimum width such cracks as may form in it. Cracks in a base permit a sand bedding course to find its way into them with consequent damage to the brick top. Further, every crack in a concrete base sooner of later tends to show up in the brick. Hence the necessity for reducing the possible number of cracks, and keeping those that form at their least width. Old concrete pavements are sometimes resurfaced with brick.

Bedding Course, or Cushion. No matter what type of foundation is used it is necessary to overlay it with a bedding course on which to lay the brick. The bedding course, or cushion, as it is often called, takes up any inequalities in the surface of the foundation. Many materials have been used, but the most successful have been sand, granulated slag, sand-tar, sand-asphalt and sand-cement. Of these sand is the poorest and sand-tar the best.

Sand. Sand has the property of bulking when moist, and therefore, if moisture finds its way to the bedding course, the sand may tend to push out of place. When dry, sand will run, so that if there is a crack in the foundation the sand cushion may run through the crack and thus leave an empty space under the brick. Sand may shift its position and so may cause a similar shift to take place in the brick surface above it. Yet, in the tests of U. S. Bureau of Public Roads at Arlington, Va., those sections of brick pavement that were laid on a sand bedding course withstood the tests better than those on sand-cement.

Granulated Slag. This material has been very satisfactory. In the course of time it sets up; this may take a number of months, but in the interim between laying the brick and the setting of the cushion the former have had ample opportunity to find a perfect bed which thereafter does not change. It is good practice to sprinkle the slag before the brick are laid in order to assist slightly the setting up tendency. The depth of the bedding course when laid is usually 3/4 in. to 1 in.

Sand-Cement. This has not been uniformly successful. The idea of using these two materials, mixed in the proportion of 1 part cement to 4 parts sand, is that the mix will overcome the deficiencies of plain sand. Usually the materials are mixed dry in a concrete mixer and spread just ahead of the pavers. Unfortunately there is a tendency to skimp on the quantity of cement, and to mix the materials inadequately. In theory this bedding course should set up, but in practice there are numerous instances where it never does so. In such cases it is no better than sand.

Bitumen-Sand. The best type of bedding course is one composed of sand mixed with either tar or asphalt. Light tar, or a cut-back asphalt, is mixed cold with clean sand in the proportion of about 7% of bitumen to 93% of sand, by weight. This mix is spread in advance of the pavers and struck true to cross-section and grade. The brick thus are embedded in a waterproof cushion that will not shift. If, then, an asphalt filler is used the pavement will be quiet, easy riding, and repairs are simple.

If an old pavement is used as the base for a new brick top it will be found expedient to use a bitumen-sand bedding course.

Fillers. A filler is used in block pavements (1) to prevent movement of the blocks, (2) to waterproof the joints, (3) to facilitate easy cleaning of the pavement, (4) to prevent entrance of filth into the joints.

Sand, as a filler, fulfils none of these functions.

Cement Grout Filler. This is a mixture of 1 part cement and 1 part sand, and enough water to make a paint-like consistency. Grout fulfils all of the requirements, and in addition it protects the edges of the bricks from spalling, provided it is well made grout and properly applied. A curb is not necessary when grout is the filler except to hold the cushion in place. A 1 : 1 grout is liable to cause cracks to form; experience has shown that a 1 : 4 grout preserves the pavement better, although there is difficulty in making such a mix because segregation tends to take place. The disadvantages of using grout are: (1) The pavement may not be used until the filler has set sufficiently, usually 10 days to 2 weeks; (2) the pavement may not be cut to gain access to pipes and underground wires without breaking the bricks so badly that they cannot be used again; (3) after the pavement has been cut and repaired, time must be given for the grout to set in the patched area, thus shutting off the patch to traffic; (4) if the brick are not of uniform quality, or the grouting is not good, the surface of the brick is liable to shatter, the shattered areas later becoming holes and ruts; (5) unless extreme care is used longitudinal and transverse cracks will be formed; (6) arching of the pavement occurs in hot weather and the pavement becomes noisy; (7) power sprinklers will wash out poor grout, thus opening the joints; and, (8) under extremely hot weather conditions grouted pavements may buckle, heave, or blow up. When this occurs the shattered bricks should be removed and replaced with new ones of the same make and size and color. In cutting out the shattered areas care should be taken to tooth out the old bricks, leaving only whole bricks in place, so that there will be an adequate bonding area for the new ones. Pneumatic chisels for this work greatly reduce labor costs.

Blow-ups usually are caused by the grout having been so poorly distributed that only the top portions of the joints are filled. Hot weather causes expansion, and as the bottom of the joints is partially or wholly empty, the pavement bulges upward. If a sufficient number of joints are in this condition, and the expansion is great enough, there is an explosion. Sometimes the bricks are thrown a considerable distance. If only a few joints are poorly filled a shattering or spalling of the contiguous bricks may result.

Asphalt Filler. A suitable asphalt filler fulfils all of the requirements, and has none of the disadvantages of grout. The National Paving Brick Manufacturers Association advocates its use in preference to any other. For successful work the brick must be clean, dry and warm, and the application of the filler should be made on a warm day if possible. Care must be taken not to overheat the asphalt before application. A suitable asphalt for filler purposes is given under specification **"Oil Asphalt Filler — Squeegee Method."**

Coal Tar Paving Pitch. Many of the most successful brick pavements ever laid were filled with coal tar pitch. This material is easier to use than asphalt, but its drawbacks are that it is liable to run in summer and be brittle in winter. Asphalt has largely supplanted it.

Protection of Edges. Truck traffic is liable to damage the edges of brick pavements unless they are protected by curbs. In an endeavor to reduce costs, engineers often omit curbs, but this, in the end, is an expensive omission. On rural highways the curb should be set flush with the surface of the brick, and it should preferably be of hard, tough stone. If concrete is used it should be heavily reinforced. A concrete curb may well be built integral with the base, making the curb of a somewhat richer mix than the base, to resist wear.

Shoulders. Gravel, stone, or slag shoulders should be built along the edges or curbs. These may be water-bound, but preferably should be bituminous-bound, using either hot or cold binder.

Construction: On Natural Base

1. Prepare base by removing all objectionable material.
2. Drain.
3. Set curbs.
4. Grade to proper line and cross-section.
5. Roll soil with three-wheel roller until thoroughly compacted. Water may be used on some soils to assist compaction. Don't over-compact clay soils.
6. Test line and cross-section with straight-edge and templet. Fill in low

spots and trim off high spots. Roll again. The natural base should be the depth of the brick below curbs and headers.

7. Lay brick with better face uppermost. Lugs, if any, must be turned in one direction only. Begin alternate courses with a half brick. Bricklayers must stay on the brick already laid, and in no case step onto the prepared base.

8. Inspect for culls and remove them from the work.

9. Roll brick with a light tandem roller (3 tons maximum), beginning at edges and working to center. Then roll diagonally.

10. Test surface with straight-edge and templet. Correct depressions of over 1/4 in. by removing bricks and adding sand to the cushion. Replace bricks and re-roll.

11. Apply filler. If bituminous filler is used on a very cold day the surface of the bricks should be heated first with a blow torch.

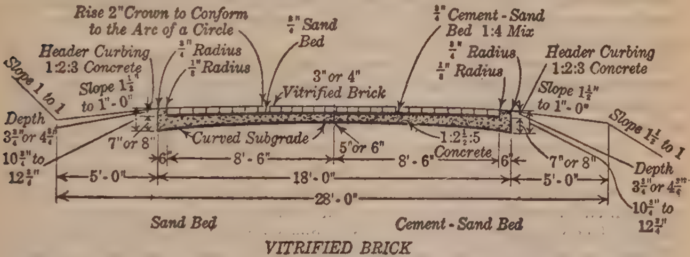

Fig. 11. Pennsylvania Highway Department Standard Brick Pavement

Construction on Old Concrete Base or Pavement

1. Replace shattered areas of concrete with new concrete.
2. Clean out cracks and fill with tar or tar mastic (specification D112-27T).
3. Spread bedding course 1 in. thick.
4. Roll with light tandem roller.
5. Test rolled bedding course with templet and straight-edge. Add enough cushion to level up any depressions. Roll again, and test again. Then repeat these operations until the bedding course is true to line and cross-section.
6. Lay brick as noted in the following section.

Construction on New Base

1. On the prepared base spread a 1-in. layer of bedding course, and spread to line and cross-section. Bedding course should not be spread too far in advance of paving.

2. Roll bedding course with a light tandem roller, and test frequently with straight-edge and templet, adding extra material where necessary.

3. On the bedding course lay the brick with the better face or wire-cut side upward. Lugs must be kept in one direction. Begin alternate courses with a half brick, turning fractured end inward. Joints across the course should be broken by at least 3 in. Each course is laid at right angles to traffic, except that it is possible to lay the brick longitudinally on curves that are not too sharp. Brick layers must keep on the brick, and must not step on the bedding course.

4. Inspect the brick laid, and cull defective ones, substituting good bricks.

5. Roll with a light tandem roller. Begin rolling at edges and work toward center. Then roll diagonally.

6. Test surface with straight-edge and templet. Correct depressions of over 1/4 in. in 10 ft. by removing bricks and adding extra bedding course. Replace bricks and re-roll. Test and retest until a smooth surface is assured.

7. Apply filler: (a) cement grout, (b) asphalt, (c) coal tar paving pitch.

(a) Mix 1 part portland cement with 1 part of sand, and then add enough water to make a thin mortar, about the consistency of paint. Do not mix too much at one time. Of the mix 2 cu. ft. will be enough. Mix the ingredients very thoroughly. When the water has been added, sweep the grout into the joints until they are full. A settling soon takes place, after which make a second application of grout, this time using a thicker paste. Push grout into joints with rubber-edged squeegees. On hot, dry days it is advantageous to sprinkle the surface of the bricks before beginning grouting. After the grout has been applied close the pavement to traffic for at least 10 days. Keep wet and cure like concrete.

(b) Use an asphalt filler which meets specification for Oil Asphalt Filler. Heat the asphalt in a suitable kettle, preferably of over 2 bbl. capacity. Do not heat over 400° F., nor try to apply it at less than 350° F. While asphalt is heating, clean surface of brick. Do not apply filler to a wet or damp pavement. Do not attempt to apply filler if temperature of brick and air is less than 55° F., as will not penetrate the joints. Quickly pour hot filler onto the surface of the brick and push it into the joints with squeegees. Best results are obtained by pushing always in the same direction and at an angle with the courses. Keep applying filler and using squeegee until certain that the joints will hold no more. A thin asphalt surface now covers the brick. Cover this with a light application of sand, pea-gravel, granulated slag, or fine stone chips. Roll with a light roller. The street may be immediately thrown open to traffic.

(c) Use a coal tar pitch which meets specification D-112. The method is identical with (b) above, except that the pitch must not be heated more than 300° F., nor less than 225° F.

Repair

1. Cut out and remove all defective, shattered, or soft bricks, removing each damaged brick completely.

2. Add enough bedding course to assure correct bedding of new brick.

3. Lay new brick as above; fill joints.

If an area of a grouted pavement has shattered it will be best to use an asphalt filler for the new bricks, as an expansion joint will thereby be placed about each individual brick.

Maintenance

Clean out thoroughly every crack and fill them when they are *dry* and *warm* with either asphalt or tar pitch.

If the pavement is badly cobbled, with numerous rough spots, it may sometimes be maintained in a reasonable state of repair by bituminous surface treatments given at yearly or bi-yearly intervals. The method is as follows:

1. Thoroughly clean the old pavement by flushing and scrubbing. All dirt must be removed, as bituminous materials will not stick to the bricks unless they are absolutely clean.

2. Patch all depressions. Hot patch is best for this work.

3. When patches have set up and the bricks are dry apply a hot surface treatment of tar II, or asphalt at the rate of 1/3 to 1/2 gal. per square yard.

4. Cover immediately with a heavy application of 1/4 in. to 3/4 in. hard, tough stone chips. Use about 60 lb. per square yard.

5. Roll with a light tandem roller.

6. Keep a close watch on these treatments and if a break appears it must be patched immediately. A uniform surface is then assured.

Specification

Oil Asphalt Filler — Squeegee Method

Description: Asphalt filler shall be homogeneous, free from water, and shall not foam when heated to 200° C. (392° F.). It shall meet the following requirements:

(a) Flash point: Not less than 200° C. (392° F.).

(b) Melting point: Ring and ball. 65° C. (149° F.) to 110° C. (230° F.).

(c) Penetration: At 0° C. (32° F.) 200 gms., 1 min., not less than 10.
At 25° C. (77° F.) 100 gms., 5 sec., 30 to 50.
At 46° C. (115° F.) 50 gms., 5 sec., not more than 110.

(d) Loss on evaporation: 163° C. (325° F.) 5 hr., less than 1.0%.

(e) Ductility: Not less than 3.

(f) Total bitumen: (Soluble in carbon disulphide) not less than 99%.

(g) Per cent of total bitumen: (Soluble in carbon tetrachloride) not less than 99%.

(h) Reduction in penetration: At 25° C. (77° F.), due to heating specified under Loss on Evaporation, not more than 50%.

19. Stone Block Pavements

In the United States, stone block for pavements usually are made from granites and sandstones. Limestone and trap blocks are used to a limited extent. Durax, a special type of stone pavement developed in Europe, was first used in America in 1913. Square blocks and rectangular blocks of a smaller size than is common in this country are also used in some parts of Europe.

Characteristics. The chief advantage of a stone block pavement is its durability. Motor traffic on rubber tires has eliminated the noise, and the granite block manufacturers are cutting improved blocks, such as the "Manhattan," so that the modern granite block pavement is no longer rough. It is adaptable to use on grades up to 15% if the joints are filled with bituminous materials, and on grades up to 10% if cement grouted joints are used. Some blocks become slippery from wear. Unless properly constructed and maintained, a block pavement is unsanitary.

Belgian Block pavements were constructed with blocks approximately 6 in. square on the upper face, with a bottom face smaller than the top, and of variable depths. Confusion as to the meaning of the name Belgian block is caused by the fact that many rectangular block pavements constructed with trap rock are now so named. A square yard of pavement required about 27 blocks.

Size of Blocks. Pavements are built usually of blocks having rectangular faces. From 1910 to 1918, the depth was reduced from 8 to 5 in. in many localities, thus saving in the cost of the blocks. The blocks should be dressed so as to be rectangular on the faces, having parallel sides and ends, with right-angle corners. Some specifications do not allow bunches or depressions on a face exceeding 1/4 in. If the faces are not free from bulges and hollows, it is impossible to get close and even joints in laying the blocks. Blocks are from 4-3/4 to 5-1/4 in. deep, 3-1/2 to 4-1/2 in. or 4-1/2 to 5-1/2 in. wide, and from

8 to 12 in. long. The blocks shall be so dressed that the joints shall not exceed 1/2 in. in width at the top and for 1 in. downward and not more than 1 in. in width at any other part of the joint.

Physical properties:

	For heavy traffic	For moderately heavy traffic
Percentage of wear, not more than	3.6	5.0
French coefficient of wear, not less than	11.0	8.0
Toughness, not less than	9.0	7.0

Laying the Blocks. The subgrade should be rolled hard with a 10-ton roller, and should be shaped with the same crown as the finished surface. The concrete foundation is then laid as described in Art. 17. The thickness of the foundation is variable, depending upon the traffic conditions, 6 in. being an average value. After the concrete has set, it is covered with a layer of sand 2 to 2-1/2 in. deep, which forms a cushion for the blocks to rest on and allows for any variation in the depths of the blocks. The blocks are placed by hand as closely together as possible, usually in straight parallel courses with the long dimensions perpendicular to the curbs. The blocks in one row should break joints with the blocks in another row by at least 3 in. At street intersections, in order to prevent the traffic of the cross streets from traveling parallel to the long joints and thus forming grooves, the blocks are laid with their long dimensions parallel to one or both of the diagonals of the square formed by the intersecting streets. The work of laying the blocks is started from the curb lines at either side and progresses toward the center of the street. The crown of a stone block pavement is usually parabolic in shape, and the amount of crown can be obtained by formula. The blocks may be laid to the desired crown by the use of strings, cross-section stakes or a board templet. After placing the blocks to the proper lines, they are thoroughly tamped with a tamper weighing from 60 to 70 lb. until no further settlement occurs. The blocks should all lie perpendicular to the sand bed. If any blocks settle more than others, they should be taken out and relaid. The joints should be filled with a suitable material.

Tar-Gravel Filler. The gravel should be of such a size that it will all pass a sieve of 1/2-in. mesh and be retained on a 1/4-in. mesh. A 3/4-in. joint is necessary for this type of filler. The gravel should be heated and swept into the joints until they are filled to within 3 in. of the top. Enough bituminous material is poured to fill the joints to the top of the gravel. The joints are then filled to the top with gravel and poured again with the bituminous material until entirely filled.

Specifications for Asphalt Filler for Stone Block Pavements

(To be applied as grout when mixed with sand)

General

The asphalt filler shall be homogeneous, free from water and shall not foam when heated in 175° C. (347° F.). It shall meet the following requirements:

Physical and Chemical Properties

1. Specific gravity 25°/25° C. (77°/77° F.).........not less than......... 1.000
2. Flash point.........not less than 175° C. (347° F.).
3. Penetration at 25° C. (77° F.), 100 g., 5 sec......*......to......*......

4. Ductility at 25° C. (77° F.) not less than.........30.
5. Loss at 163° C. (325° F.), 5 hours, not more than.........3%.

Penetration of residue at 25° C. (77° F.) 100 g., 5 sec. as per cent of original penetration, not less than.........50%.

6. Per cent of total bitumen soluble in carbon tetrachloride.........not less than ....99%.

* **Note.** The exact penetration limits should be inserted by the engineer with a 20-point limit. It is suggested that for low temperature conditions a penetration of from 70 to 100 be specified and for high temperature conditions a penetration of from 50 to 70 be specified.

Methods of Testing

Tests of the physical and chemical characteristics of the asphalt filler shall be made in accordance with the following methods:

1. Specific gravity, U. S. Dept. of Agriculture Bulletin 314, p. 5.
2. Flash point (open cup), U. S. Dept. of Agriculture Bulletin 314, p. 17.
3. Penetration, A. S. T. M. Standard Test D-5-16.
4. Ductility, Trans. A. S. C. E., Vol. LXXXII, 1918, p. 1460.
5. Volatilization Test, U. S. Dept. of Agriculture Bulletin 314, p. 19 using 50 gram sample.
6. Bitumen soluble in carbon tetrachloride, U. S. Dept. of Agriculture Bulletin 314, p. 30.

The asphalt grout or mastic is prepared by mixing the melted asphalt filler with as much of the hot dry sand as it will carry without making a mixture that is too stiff to flow into the joints. In no case, however, should the volume of sand exceed that of the asphalt and in general volume proportions approaching 3 parts of asphalt to 2 parts of sand will be found most satisfactory. Both asphalt and sand should be heated to between 300° F. and 400° F. but the latter temperature should never be exceeded for fear of injuring the asphalt. Portable kettles and sand heaters are used for this purpose and the mixture is usually made in large steel wheelbarrows or concrete carrier push carts. A measured quantity of the hot asphalt should first be run into the mixing receptacle and a measured quantity of hot sand then added. The contents should be thoroughly mixed with a rake or hoe and immediately flooded over the surface and pushed or squeegeed into the joints. Once the proper proportions are fixed they should be rigidly adhered to throughout the work.

It is very important that the asphalt grout be worked into the joints as fast as possible after the mixture has been made. A second application is almost always required over a considerable proportion of the area flooded by each batch in order to fill the joints flush with the surface. Bringing the joints flush by the addition of sand or other material is very bad practice and will ultimately result in a surface which is rough and cobbly in places.

Approximately 2.5 gal. of asphalt is required for filling each square yard of standard 5-in. granite block pavement, this amount being, of course, subject to variation with the width of joints.

Cement Grout composed of one part of portland cement and one part of clean sand is also used as a filler. The blocks are laid with thin joints and poured with grout. Traffic should be kept off the pavement for a period of 7 days, or until the cement has set up. This type of filler makes a smooth and durable pavement. The surface, however, will be more slippery than where the other types of fillers are used. Repair work will also be more costly, since in removing the blocks more will be broken due to the bond furnished by the cement.

The Maintenance of a stone block pavement, if properly constructed, is practically nothing for the first few years. The life of a granite block pavement constructed on a concrete foundation and with joints well maintained is almost limitless.

The Number of Blocks used per square yard will depend upon the size of the block and the width of the joints. Using the ordinary-sized blocks laid with 1/2-in. joints, the number per square yard will vary from 25 to 32.

Durax

A form of stone block pavement called Durax, or Kleinplfaster, has been laid to considerable extent in Europe, and to lesser extent in the Americas. Small cubes of granite cut by hand or machine, are laid on a dry mortar bed over a concrete base. The joints are filled with grout, or an asphalt filler. The cubes may be laid in straight courses or in concentric interlocking segments, with close joints. The dimensions of the blocks are 3 to 4 in. for length, width and depth. Owing to their small size these blocks should make for a cheaper pavement in first cost than that laid with regular granite blocks. Durax is suitable for medium-traffic streets. When grout filled it is noisy. A straight coal tar pitch is unsuitable as a filler. An asphaltic filler suitable for brick gives good results. A bituminous mastic has been satisfactory. In an 8-hour day a man can lay from 25 to 30 sq. yd.

20. Wood Block Pavement

There are three types of wood blocks in general use: the plain rectangular, the lug, and the hexagonal. By far the greatest yardage has been laid with the plain block. The lug block, being a patented product, has had a more limited sale, although it possesses several advantages over the plain block.

Long ago it was recognized that one of the causes of the bleeding of blocks was the pressure on them due to expansion. This pressure forces the preservative out of the blocks and onto the surface. If lugs take up the pressure, instead of the body of the block, then there will be less bleeding. The lug also forms a space around the blocks so that the filler which is applied readily finds its way to the bottom of the joints. A strip of corrugated cardboard inserted between the rows of blocks accomplishes all that lugs do.

Hexagonal blocks are cut from small trees, and the center of the tree is the center of the block. The blocks are not truly hexagonal and hence, when laid in a pavement, they do not fit close to each other, thus permitting space around the sides for the filler.

In 1928 there was but little wood block pavement laid in highway work as compared with factory floor construction.

Construction: Method A

For all types of blocks

1. Prepare, drain, and roll the subgrade.
2. Lay a concrete base, not leaner than 1 : 3 : 6, minimum thickness of 6 in.
3. Bring concrete to true and fairly smooth, even surface.
4. Let concrete cure for at least 7 days.
5. Spread a dry mortar cushion 1 in. thick on the base; 1 : 2.
6. Just before laying the blocks, sprinkle the cushion with water from a watering can. Do not use a hose. Do not soak, but just dampen the cushion.
7. Lay the blocks on the mortar cushion as soon as possible, being sure the joints are broken, and permitting no one to step on the cushion. Keep all workmen on the paved area.
8. Roll, with light tandem roller.

9. Cull inferior blocks.
10. Apply filler.
11. If sand or bituminous fillers are used the street may be immediately opened to traffic.

Method B

For plain rectangular blocks

1. As above.
2. As above.
3. Finish the concrete carefully, giving it a very smooth, true surface, free from any irregularities, depressions, or protuberances.
4. Let concrete cure for at least 7 days.
5. Spread a mop coat of coal tar pitch on the base using about 10 lb. of 150° F. melting point (cube in water) coal tar pitch per square yard. Spread this directly in advance of paving. Pitch may be sprayed on.
6. Dip one end and one side of each block in hot paving pitch and lay them on the pitch coated base. No defective blocks should be laid, as it is difficult to remove culls.
7. Fill any unfilled joints by pouring paving pitch into them.
8. Cover pavement with sand.
9. Open street to traffic.

Just as good results may be obtained by laying the blocks at right angles with the curb as at any other angle, and at far less trouble and expense.

Fillers

The question of fillers for creosoted wood blocks is a troublesome one. Cresote softens pitch, and ultimately destroys asphalt. It is for this reason that a hard pitch should always be specified, since a pitch of 150° F. melting point is softened in a year's time to 125°, or less. The cutting-back action of the creosote after this time is slight. Asphalt, under like conditions, often becomes a greasy mass that cleaves from the blocks and may be swept up by the street cleaners. Asphalt frequently does not waterproof the joints. It is undoubtedly true that pitch-filled wood block pavements sometimes give trouble and annoyance by bleeding through two summer seasons, yet if sand is strewn on the surface at the first sign of bleeding most of the annoyance will be avoided.

Cement grout has been used as a filler to some extent, but it is not recommended. Better results for far less money may be obtained with clean sand.

Application of Filler. The proper procedure for Method A is to flush pitch onto the blocks and force it into the joints with squeegees. A coating of pitch remains on top, and if the work is done in the summer it becomes a nuisance for the rest of the season. Plenty of sand should be used to take up this excess of pitch. If the joints are poured instead of flushed, the nuisance will be just as great and the expense of pouring will be much in excess of the flushing, while the joints will not be so well filled. If the paving is done in the late fall no trouble from this source will be experienced as the pitch on the surface will chip off during cold weather.

Method of Application of Pitch Filler

1. Heat pitch to not more than 300° F.
2. Pour or flush on the pavement only as much as the squeegee men can push into the joints with a minimum on the surface.
3. Use squeegees made of two pieces of wood about 5/8 in. thick, 4 in. wide,

and 16 in. long, fastened together with screws, and with a piece of old belting between them and projecting about 3/4 in. from the lower edge. Do not use **rubber as the hot pitch will destroy it.**

4. Work rapidly with small quantities.
5. Spread hot sand immediately over the tarred surface.
6. If the work is done in the late fall or the early spring when the weather and the blocks are cold, fill the joints only three-quarters full. Expansion will bring pitch to top of blocks.
7. If lug blocks are being used it is advisable to brush a little sand into the joints before applying pitch. This forms a dam around the bottom of the blocks and prevents the pitch from running underneath them in hot weather. If the blocks seem to have a tendency to float this should always be done.

Dried Out Old Pavements

Often trouble is experienced with old pavements that swell badly after rainy or damp weather. It will be found that the oil in the blocks has evaporated, leaving the pores open. Treat the pavement with a cold application of light tar, using from 1/4 to 1/2 gal. per square yard. After the pavement has absorbed all of the tar that it will, cover it with sand. The tar seals the pores and is absorbed by the wood. Of course this should be undertaken only after a long hot, dry spell when the pavement is in condition to receive the tar.

Bridge Floors

On bridges of the lift type wood block floors have been successfully used, though some means must be employed to keep the blocks in place. On some bridges this has been accomplished by placing metal fasteners every few rows. Probably the best method is to use the hexagonal block, and spike each block down with a heavy nail driven through the center. On other types of bridges the plain or the lug block has given excellent service. Care must be taken, however, to provide adequate expansion joints longitudinally.

Street Car Track Area

Much trouble has been experienced with wood blocks laid in the car track area. This has been due almost entirely to the faulty methods of laying the blocks. Often the blocks are laid as close as possible, so that if they swell they press unduly against the rails. Either the rails must spread, or the blocks must give. In modern track construction there is little chance for the rails to spread, so the blocks bulge or arch over the foundation. Under heavy truck traffic the arch is soon broken down, the blocks splintering off where the break occurs, and the area has to be relaid. It is very important that the blocks be suitably treated and that the joints be filled with coal tar pitch so that they may be made as nearly waterproof as possible.

1. Lay the blocks with sufficient space on all sides to permit expansion. Lug blocks, or plain blocks with corrugated cardboard spacer should be used.
2. Thoroughly fill all joints, especially along the rail, with pitch.

Factory Floors

Wood block makes the ideal factory floor. But common sense must be used to obtain good results. Pitch or asphalt on top of blocks in a factory is objectionable. A sand filler is unsatisfactory in many factories because the floors are cleaned by flushing with water, and the sand is washed out. Where edged tools are being made or used, or where painting is being done, sand is objectionable. Pitch is useless where heat is high and continuous, as in paint-drying and finishing rooms. If untreated or kyanized blocks are used, a low penetration asphalt may be successfully applied for the filler. If cement grout is used the blocks are certain to shrink, leaving a thin partition of grout between each block, which soon breaks down into sand and cement, and the joints are not as well filled as if sand had been used in the first place. The author suggests that responsible representatives of wood block manufacturing companies be consulted in every case before the plans and specifications are approved.

Space should be left around columns, walls, and fixtures so that if the blocks swell from moisture such swelling will not damage the structure. Such space should be filled with pitch or asphalt filler.

21. Sidewalks, Curbs and Gutters

Sidewalks in business districts usually extend from property line to curb but in residential districts it is common to find a grass plat and a row of trees placed between the walk and the curb. The widths of the walk vary from 4 to 6 ft. in residential sections, 8 to 20 ft. in business districts. The usual width for each walk is from one-fifth to one-sixth of the total width between property lines. The business district sidewalk is built with a slope toward the curb of from 1/8 to 1/2 in. per foot, depending on the material of which the sidewalk is made. The residential district walk is sometimes built with a crown, like that of the roadway. This is objectionable if a driveway to a garage is built across the walk. Sidewalks are built of planks, cinders, gravel, crushed stone, brick, flagstones, tar concrete, asphaltic concrete, and portland cement. Where the grade is over 15 to 20% it is advisable to substitute steps with 7-in. risers and at least 5 ft. wide. Short sections of walk may be introduced between the steps. On steep grades the pavement should be made somewhat rough to afford good foothold. At intersections the streets' names may be stamped into concrete walks, or tile or metal letters may be inserted They should be placed so as to be easily read by the pedestrian as he approaches the curb before he crosses the street. Names may be similarly placed on the curbs.

Concrete Sidewalks may be laid directly on the soil, if it is not continually wet. If it is, then a 6-in. layer of cinders, gravel, broken stone or slag must be used for a foundation. In this event a tile drain must be used as well in order to lead away any water that would ordinarily be retained in such foundation. The total thickness of the concrete is usually 5 in. in residential districts (with an extra inch or two at driveways) and 6 to 8 in. in business districts. If the walk extends to the curb, a 1-1/2 to 2-in. expansion joint must be left to be filled with bitumen, so that neither the sidewalk nor the curb may be damaged. Transverse joints which are filled with bitumen must be placed about 50 ft. apart; these may be 1 to 1-1/2 in. wide, and must extend downward through the concrete to the base.

Either a one-course or a two-course pavement may be laid. The one-course costs no more, and, if it is laid with care, is better than and just as attractive looking as the two-course. The one-course mix is 1 : 2 : 3. The two-course walk consists of the lower course 4-1/4 in. thick, of 1 : 2-1/2 : 5 mix, topped with a 3/4-in. course of 1 : 2 mortar. Coarse aggregate for the one-course walk may have a maximum size of 1 in.; for the two-course up to 1-1/2 in. The joints that mark off the slabs should extend through the concrete, otherwise unsightly cracks may develop. The wearing surface is finished by troweling or with a wood float.

Brick Sidewalks are laid either on a concrete base or on a bedding course of sand or gravel over the soil. The joints are usually filled with sand, which later gives vegetation a chance to grow therein. It would be better to fill the joints with cement grout or with a bituminous filler. But few brick pavements are now laid except where the decorative scheme calls for them.

Flags of Blue Sandstone or Granite are laid on a 3-in. to 4-in. foundation of sand or other suitable material. The joints are filled with cement mortar. Granite walks wear smooth and become dangerous due to their slipperiness. Limestone walks are not as good as sandstone.

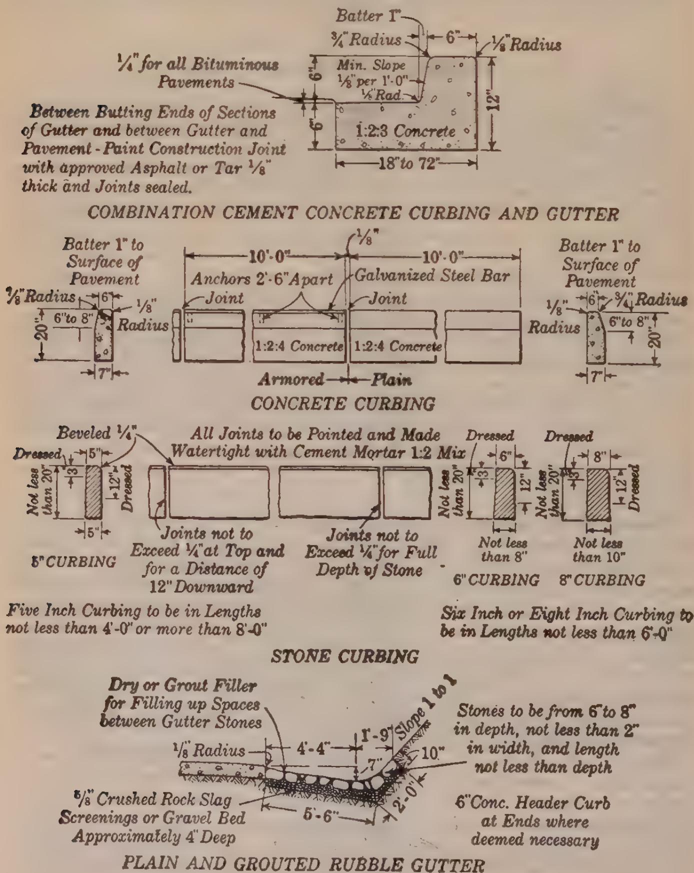

Fig. 12

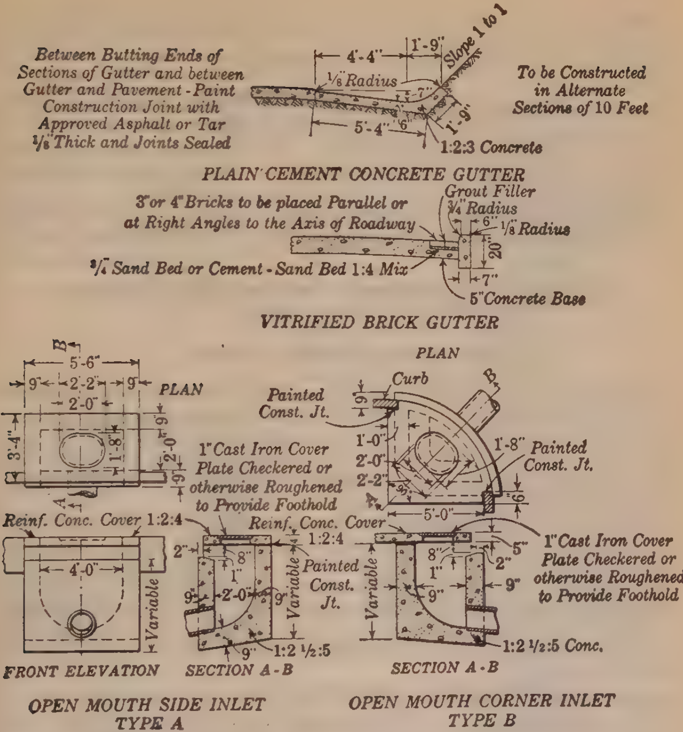

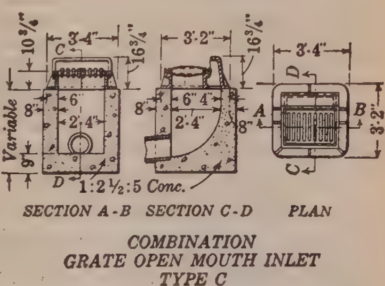

Fig. 12—Continued

Cinders are laid 6 in. deep and are then flooded and tamped or rolled.

Tar Concrete Walks are built on a coarse gravel foundation. Sometimes this is sprayed with hot coal tar before the binder course is laid. The binder course is composed of gravel, the pebbles of which will pass a 1-in. ring, and hot coal tar, in the proportion of 1 gal. of tar to 1 cu. ft. of gravel. These are mixed before the course is laid. This is laid to a depth of about 2 in. and thoroughly rolled. A topping or wearing course composed of 25% of coal tar and 75% of coarse sand is then spread and rolled, so that a total thickness of the wearing course is about 3/4 in. Coarse sand is then strewn over the entire walk.

Some very successful walks have been laid in parks, cemeteries, playgrounds, and similar localities, composed of either tar cut-back, or asphalt cut-back and 3/4-in. stone chips. Such walks are easy to build, and their cost is extremely low.

Curbs and Gutters. Stone curbs are usually composed of granite, bluestone, limestone or sandstone. Plain concrete curbs are of a 1 : 2 : 3 or 1 : 2 : 3-1/2 mix with a 1 : 2 mortar face. In size curbstones are 4 to 12 in. wide, 16 to 24 in. deep, and 4 to 12 ft. long. Concrete curbs should have expansion joints corresponding with those of the pavement.

The stone and the plain concrete curbs are usually known as separate curbs. There are two other types: integral, and combined curb and gutter.

SIGNALS, MARKING, PLANTING, SNOW REMOVAL, ETC.

22. Street Traffic Control

Accidents. Nearly 27 000 people were killed in automobile accidents in 1928 in the United States. This means that one out of four accidental deaths was caused by the automobile. The accompanying charts indicate clearly the types of accidents, direction of vehicle, action of driver, action of pedestrian, condition of vehicle, and condition of pedestrian at the time of the accident. (From Accident Facts, 1928.)

An analysis of fatalities at railroad and highway grade crossings shows that in 1926 31% occurred in urban areas, and 69% in rural areas. Also, rural grade crossings were responsible for 16% of all rural highway fatalities. Pedestrians are hit by automobiles at street intersections more frequently than at other locations. And collisions of cars occur more often at intersections than elsewhere. Unfavorable weather and light conditions do not play a very important part, since 75% of all accidents occurred on dry roads in clear weather.

Intersections. Control of traffic at intersections has been attempted by installing at such points: (a) STOP signs, (b) traffic officers, (c) signals. The Boulevard STOP sign is very useful, works well, and causes little annoyance to the driving public. It is installed on the cross streets where they intersect a Through or Boulevard route. Cross street traffic stops before entering the Through street or Boulevard. But little policing is necessary as drivers readily obey the sign.

At rush hours it is often wisest to place traffic officers at the busiest corners to direct traffic. This method is often far better than that of installing traffic lights, as in most cities under 100 000 population traffic can take care of itself very well without signals or policemen save at rush hours.

The Committee on Street Traffic Signs, Signals and Markings, of the American Engineering Council, says in its 1929 report that the reason " why signals to control street traffic should be installed are: (a) To increase the safety of pedestrians and vehicles at congested intersections; (b) to facilitate the movement of traffic with a minimum of delay at congested intersections; (c) to provide for the continuous movement of traffic throughout a heavy route; (d) to interrupt a heavy traffic stream at intervals so as to afford an opportunity for cross traffic to move."

A Signal is defined as comprising all signal lights that are operated together to control traffic at an intersection, whether the signal is mounted in one unit or in more. Traffic control systems are classified according to the character

Fig. 13

of the traffic movement resulting from the system. The types of systems are: (a) Independent; the operation of the signal is not related to the operation of any other. (b) Synchronized; all signals show the same color in the same direction simultaneously. (c) Limited progressive; the signals are grouped, the alternate groups showing opposite colors in a given direction and all signals changing simultaneously. (d) Flexible Progressive; a form of progressive system in which the operation of each signal is determined by the traffic requirements of the intersection and which, in addition, provides for the continuous movement of traffic.

Use of Colors. Three colors are recommended in the Model Municipal Traffic Ordinance, but many cities use only two. If three colors are used the order in which they should be displayed is *red, green, yellow*. Yellow is not recommended to be used to govern the turning of vehicles nor the movement of pedestrians. If a two-color system is used the colors are red and green, and the red is displayed simultaneously in all directions for the change period.

Experience shows that, in general, right and left turns should be made only while *green* is shown, although some of the large cities permit right turns on red and green.

Signals should not be operated at times when the volume of traffic is too light to justify their operation.

Cycle Lengths. The length of time that one color should be shown must be determined by trial. Usually this lies between 40 to 80 seconds. At certain periods of the day it may be necessary to change the length of cycle to meet the demands of traffic.

Guard Fences may be stone walls, timber fences, concrete fences, wire cables, or wire fabric. Cables and fabric have been the most satisfactory types. The visibility of these should be increased by suitable painting of them. In snow country they should be painted yellow, with black spots for contrast. The posts may be wood or reinforced concrete. The steel-wire fabric type is most in favor in many parts of the country.

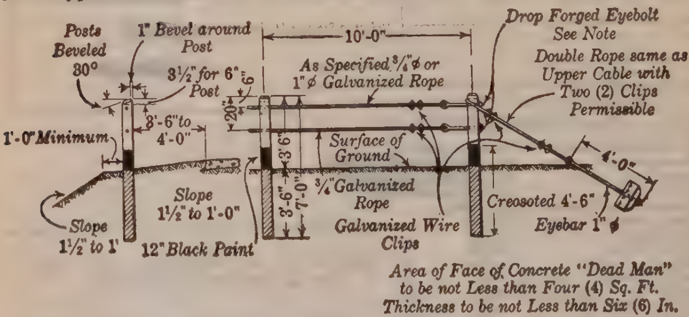

Fig. 14. Pennsylvania State Highway Type

Parking of vehicles in municipalities is controlled by local ordinances.

Vehicles may be parked parallel with the curb, or at angles of 30, 45 and 90 degrees. A lane at least 7 ft. wide must be provided for parallel parking, but motor cars parked at an angle require a lane at least 14 ft. and often 18 ft. wide. Theoretically the number of cars that may be conveniently parked on a block 250 ft. long on each side of the street is: parallel, 14; 30 deg., 17;

45 deg., 24; 90 deg., 32. Practically, however, this is impossible, due to location of hydrants, alley intersections, and "no parking" areas. It must be noted that whereas 32 cars may be parked at 90 deg. in the same curb length that 14 cars may be parked parallel, yet a lane 18 ft. wide is required for the former as against a 7-ft. lane for the latter. In general only parallel parking should be allowed, except on very wide streets.

Parking areas supplied by the municipality are gaining in favor.

23. Road Markers and Signs

The American Association of State Highway Officials adopted a system of standardized signs and markers which was developed by the Bureau of Public Roads. This set of designs is based on definite principles calculated to produce uniformity of significance in the signs, and make familiarity with them easy to acquire on the part of the most casual driver.

Shape. The **octagonal** sign is used to indicate STOP. The **diamond** signs indicate SLOW and CAUTION. The **circular** sign is used as an advance warning at railroad grade crossings only. The **square** signs are used to indicate any condition requiring **caution** that is not inherent in the road itself, but which is due to contiguous or adjacent conditions which also are often intermittent. **Rectangular** shaped signs of various dimensions are used to carry directions, information and restrictions of use or benefit to the driver. The **arrow** direction sign may be substituted for the rectangular direction sign. **Route markers** are of various distinctive designs.

Color. All signs of a precautionary character, including the circular railroad sign, the octagonal STOP, the diamond SLOW, and the square caution signs have black designs on a yellow background. All **direction, information** and **restriction** signs are black on a white background, except that the Rest Station sign is white on a green background.

Erection and Display of Markers and Signs

The standard markers are erected to direct traffic over a specified route. They should be so located as to be conspicuously visible day and night. They should be set facing and on the right-hand side of approaching traffic. Care should be taken to avoid placing them on the inside of curves, in sags and behind objects.

Type of Support. Markers should be mounted on standardized posts. Bolt holes in signs are punched on a multiple of 6 in. If posts are punched or bored similarly there will be no need for drilling in the field. Wooden, metal, and concrete posts are used. Leather or fiber washers should be used against the face and back of all metal signs. Where signs are described as being set at right angles to traffic, the angle should not be exact, but in order to avoid glare reflected back to the driver the sign should be turned away slightly from the road.

Height of Markers. Under ordinary conditions the center of the marker should be placed approximately 3-1/2 ft. above the crown of the pavement or traveled way. On ascending or descending grades this may be varied so that the rays from the headlights may properly illuminate the marker. On city streets where the standard marker is used and where street lights furnish adequate illumination, markers should be placed with the lower edge not less than 7 ft. above the gutter grade in order to clear parked cars.

Lateral Distance. Markers should be erected not less than 5 ft. nor more than 7 ft. from the edge of surfacing on improved roads, except that where a raised curb exists they may be set as close as 3 ft. to the edge of the curb. On unimproved roads there is no rule.

Location. At important cross roads and side roads, markers should be set from 50 to 125 ft. beyond or around the intersection in order to "pull" traffic past the intersection. At intersections or forks where the marked route turns, the marker should be erected 200 to 300 ft. in advance of the fork or turn with proper directional letter "R" or "L" immediately under the marker.

Overlapping Routes. Where two or more routes follow the same road, markers for all routes should generally be erected and carried on the same support. Two or more Route Markers should not be carried on the same post immediately in advance of a turn when only one route turns. If two or more overlapping routes turn at the same intersection, each individual marker should be accompanied by its own directional letters just beneath it.

Markers in Cities. Through towns and cities markers should be erected or placed at relatively short intervals so that one or more will be in view at all times. Where a stenciled marker is used on poles, a white band 20 in. high should first be painted around the pole at the required height from the ground. If a marker and a directional letter are to be stenciled the white band should be 30 in. high.

Standard Detour Marking. A detour should be made fool proof, therefore it is advisable to erect markers at *EVERY* intersecting road. Advance warning of a detour should be provided. Similarly, as the end of the detour, and consequently the main route, is approached the traveler should be warned.

Caution, Slow and Warning Signs

The color scheme for these signs is yellow background with a black design. The yellow shade is known as Federal Yellow. Two signs for different purposes should not be placed closer than 100 ft. if possible. The warning sign should precede the marker.

Longitudinal Location

Stop Sign. This sign is for use at places on a highway where traffic is required to stop. The STOP sign should not be set back from the point of danger in an effort to save a SLOW sign, because the stop should be made at a point where the cause of danger is visible and the driver can see and understand the reason why he has been made to stop. A SLOW sign should be set about 350 ft. in advance of STOP if there is reason to believe that traffic should be warned, in order to slow down for the stop.

Railroad. The railroad crossing signs should be erected 350 to 450 ft. from the crossing. If a stop sign is required as well it should be placed from 25 to 50 ft. from the tracks.

Turn and Curve Signs. A TURN sign is used where the curve has a radius of less than 200 ft. A CURVE sign is used where the curve has a radius of between 200 and 600 ft. The DOUBLE TURN sign is used in advance of two turns less than 350 ft. apart.

HILL Sign. A HILL sign should ordinarily be used only on descending grades steeper than 7% and longer than 200 ft., and on 6% grades if longer than 300 ft. A HILL SHIFT GEAR sign should be used on descending grades under the following conditions:

On grade, per cent	Hill shift gear sign used if descending grade is more than
6	2000 ft. long
7	1000 ft. long
8	750 ft. long
9	500 ft. long
10	400 ft. long
13	300 ft. long
15	200 ft. long
16	Any length

This sign should be used where the per cent or length of grade is less than above indicated, if the grade is also on a sharp curve.

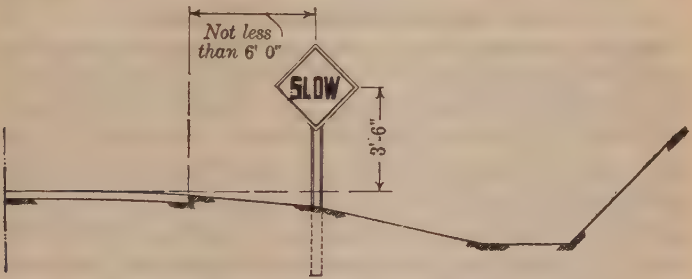

Fig. 15. Height and Location of Signs

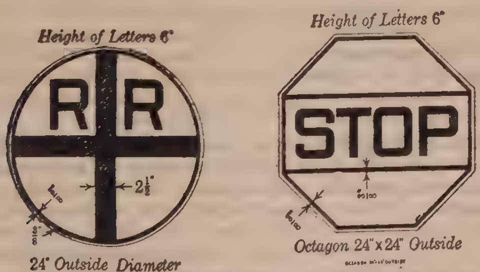

Fig. 16

SLOW Sign. The Slow sign should be used only where for safety, careful driving at a reduced speed is necessary. The use of the SLOW sign in conjunction with other signs is not recommended. It may be used as a prewarning for a STOP sign or to call attention to RAILROAD signs. The SLOW sign is a warning sign only; its use as an attempt to regulate the speed of traffic entering towns is not appropriate.

Direction and Information Signs

This series is intended to furnish the traveler with directional and general information, but involves nothing of a precautionary nature. The signs are generally rectangular, and the color scheme is black on a white background.

The list includes City and Village signs, Physical Feature, Camp Sites, Potable Water Signs.

Rest Station Signs. A REST STATION sign is provided for the use of garages, filling stations, merchants and others desiring them for appropriate display.

General Directional Signs. For indicating direction and distance to a place two types of signs are provided; a solid design and a slat design. A sign is clearer to read if not over four place names are on it. Directional signs should be placed at cross roads, forks and other points where signs of the numbering system are unavailable. They should be so placed that they may be read at night with the aid of headlights.

24. City and Roadside Planting

Shade Trees in Cities. Great care should be taken to select trees that will do well under the conditions in which they are expected to grow and thrive. The following points should be kept in mind in selecting the best trees for the prevailing conditions: (a) Form; (b) shade; (c) hardiness; (d) freedom from insect attack; (e) climate; (f) cleanliness; (g) ease of transplanting; (h) longevity. The following are recommended for northern cities in the United States: Elms, oaks, American and European lindens, Norway maples, black walnut, red gum, tulip (on wide streets only), oriental plane, and white ash (near smoky factories). The following are to be avoided: Poplars, willows, silver maples, birches, beeches, and American plane. The following are recommended for southern states: Pecan, laurel, magnolia, live oak, water oak, willow oak, laurel oak, camphor and palmetto trees.

Trees should be planted from 30 to 50 ft. apart. They should not be placed next the curb, but rather inside the sidewalk line and with turf or sod around them. When planted between the sidewalk and the curb they do not thrive as well, and they may also move the curb out of line. Trees should not be located within 25 ft. of a corner, and they should not be close to lamp-posts nor hydrants. Gas mains should be kept as far away as possible from rows of trees, as the leakage of gas will kill the trees in time.

Shade Trees on Rural Highways. Some trees that are undesirable in city streets may be permitted along country highways. The Lombardy poplar and the cottonwood are such. It is difficult, sometimes, to say where trees should be planted. If the pavement is 20 ft. wide, with two 8-ft. shoulders, and two ditches each of 8 ft. width, then, if the right-of-way is 66 ft., there would be a 7-ft. strip between the ditch line and the property line in which to plant roadside trees, but this may cause undue shade to be cast on the adjoining farm land. If the right-of-way is wider than 66 ft. no trouble from the farmers along the way should be experienced.

Erosion on cuts and fills may often be prevented by proper planting of shrubs and grass; see Bulletin 816, U. S. Department of Agriculture. Dorothy Perkins roses have done well in many localities on cuts and fills.

25. Snow Removal

Economical snow removal is dependent on prompt action. This is true alike of rural and urban districts. Action must start with the snowstorm and must continue without interruption, if the highways are to be kept open continuously. Experience has shown that fast moving trucks equipped with snow plows (stubble plow type) are, in general, better than tractors. The latter, either equipped with stubble plows, rotary plows, or blades, are necessary in deep drifts.

Snow Removal in Urban Districts. There are several methods: (1) Plow the snow to either the center or the sides of the street, after which it is loaded in trucks and hauled to a suitable dump. (2) Push the snow into sewer manholes. (3) Flush the snow into inlets and manholes, using fire hose and street flushing machines.

Snow Removal in Rural Districts. When the storm breaks the plows should be sent out. The equipment should consist of 3-ton or heavier trucks with the plows securely attached, and wing wideners to assist the plows. The trucks work best when equipped with pneumatic tires and very heavy tire chains. The chains should be as heavy as logging chains. If there is a very high wind blowing it is usually useless to begin to plow. Wait until the wind drops. The trucks should be able to travel at the rate of 25 miles per hour. There should be caterpillar tractors equipped with rotary plows to take care of heavy drifts. These may accompany the trucks. Trucks built specially for this work should have a differential lock so that one driving wheel will not spin while the other is stuck fast. A high speed truck equipped with a rotary plow is sometimes better than the caterpillar rotary as it can reach drifts more speedily.

It is important to widen cuts to accommodate snow of succeeding storms. The caterpillar rotary is frequently needed for this work. As much as possible the tractors should be kept off of bituminous pavements as the cleats are liable to cut into the surface and thus start disintegration.

Equipment. Powerful trucks in first-class condition are essential. Plows, blades and scrapers should be stocked to suit local conditions. As night work is common it is important that the trucks be equipped with special head-lights which can be turned, and it is well to also provide colored lights similar to those on a boat so that oncoming traffic will know that snow-fighting equipment is on the road and will not run into it. The tire chains should be examined frequently, and new ones substituted for old ones before trouble happens. In severe storms when the operators are working 24 or more hours at a stretch provision must be made for feeding them.

Costs. V-plow attachments complete cost about $2000. Rotary plows, complete for mounting, cost about $3000. Suitable 3-ton trucks cost $4000, whereas 5-ton trucks may cost as much as $6000. The cost of removing snow from rural highways is indeterminate. The average cost per mile in 1926-7 was $43.50 in the United States. No reliable data are to be found for cost per inch of snowfall, since much depends on the wind.

Snow Fences. The wooden fence of the collapsible type is satisfactory but it is too expensive. Lighter fences are on the market which are quite as effective and one-tenth as expensive. These light fences may be rolled into bundles and stored in convenient barns along the highways during the summer.

26. Distributors

A motor truck for distributing road oils, asphalts and tars must be substantially built of the best materials; it must have adequate power to propel the vehicle and work the pumps; it should be simple in operation and in construction, so that ordinary repairs can be readily made at any garage; it should have the gears arranged so that constant uniform speed may be maintained; its weight when loaded should not exceed the legal limits of the localities where it is to operate.

Trucks may be separated into two classes: those for hauling light loads for short distances over nearly level ground, and those for hauling heavy loads for long distances over hilly territory.

The type of bituminous material to be applied makes considerable difference in the equipment to be placed on the truck. For light oils and light tars to be applied cold, the truck needs simply a tank of suitable size connected to a pump or a compressed air supply which forces the material onto the road through a distributor, manifold, or spray bar equipped with suitable nozzles. For heavy oils and binders, applied hot, the tank should be lagged with a heat non-conductor, and fitted with an oil-burning heater which can rapidly raise the temperature of the material to the required degree.

Nozzles are made to throw sprays of different capacities. Many nozzles are made to throw a fish-tail spray. Two jets impinge and thus form the spray. The size of the holes that the jets emerge from determines the capacity of the nozzle. Nozzles are known by the size of these holes, which are regular standard steel drill sizes. The larger the size number, the smaller is the jet or spray.

Nozzles are liable to clog. When this occurs the truck must be stopped and the nozzle cleaned out before proceeding.

In place of the fish-tail nozzle a plain slotted nozzle may be used. Light materials have been distributed satisfactorily from a pipe having a slot sawed its entire length on the under side. The ends of the pipe are capped. Another type of nozzle throws a cone-shaped spray. This nozzle is very simple in construction and operation.

A motor truck usually spreads the material at some other speed than high. It is possible to control the speed closely and therefore the amount of material applied. Although the speed of the pump is supposed to vary with the speed of the truck this is not always so, and there is a limit to the capacity of the pump which cannot be exceeded. If the speed of the truck is known and the amount the pump delivers a minute, the amount spread per square yard may be found. In high, it is very difficult to control the speed of the truck, but most trucks are made to travel at a certain speed in each gear when the engine is running normally. No truck should spread binder at a greater speed than a good walk, or about 4 miles per hour. Good work of this class cannot be done at greater speed. Furthermore, if anything goes wrong with the nozzles it should be possible for the rear man who may be trailing the truck to be close enough to signal the chauffeur to stop.

On a grade the spreading should be done coming down the hill, thus giving sufficient power to the pumps by taking the load off the engine. *But the truck should never coast.* There are many trucks on the market that have not enough reserve power to operate and pump at the same time when going up hill. There are also trucks that cannot ascend a 10% grade when fully loaded. The prospective purchaser should study carefully the actual demonstrations of the trucks he may be interested in. Some trucks that give the best of service in some parts of the country are worthless in other localities where the topography is different, or the service demanded is dissimilar.

Some distributors are equipped with air pressure instead of pumps. Air pressure is handy, and has some advantages over pumps and some decided disadvantages. Of the latter, two are outstanding. First, it is necessary to have an extra engine on the truck to supply pressure, and this adds to the weight of the outfit, besides making just that much more machinery to keep in order. Second, since the air equipment is entirely independent of the truck's motor there is no definite control of the amount of material applied per square yard. Thus, a truck may run fast down a hill and labor slowly up hill, while

Data on Kinney Road Oil Spraying Trucks

Giving gallons per square yard at speed of 1 mile per hour. To get actual delivery divide by speed of truck spray 8 ft. wide × 5280 = 42 240 sq. ft. = 4683 sq. yd. per hour or 78.2 sq. yd. per minute.

the air pressure distributor is applying material at very different rates per square yard. The total amount distributed over a stretch of up-and-down hill road may be correct, while the actual amount applied per square yard may vary greatly, according to the speed of the truck. Air equipment is handy for blowing out pipe lines and for use in emptying tank cars. With experienced drivers it is equally as good as pumps.

There are but few makes of distributors on the market that are fully equipped. The smaller sized communities would do well to purchase one of

Heavy Application—Speed, Two Miles per Hour

Gallons per square yard	Amount for 2 miles	Nozzle required		Pressure, lb.	Temperature of test	Remarks Standard Oil No. 4
		Size	No.			
1/2	4 693	16	16	35	85°	Width of spray 8 ft.
3/4	7 046	16	16	53	85°	
1	9 386	12	32	25	85°	
1-1/3	12 516	12	32	37	85°	
1-1/2	14 080	12	32	42	85°	
2	18 774	1	32	45	85°	Above pump capacity at this speed.

these at the outset, and then, after a year or two a chassis may be bought and equipped to meet the particular needs of the purchaser. But to try to do this at the start means unwarranted expense, delays, and constant trouble. It is often advantageous to buy a chassis, and then purchase the tank and parts complete on skids. The chassis may be used then for other purposes during the year, while the distributor equipment may be slid onto the chassis in a few moments' time.

Purchasers should look carefully into the matter of total weight. Not only is it desirable to have a distributor that is within the legal weight limit, but it is often impossible to send very heavy distributors away from home because the bridges encountered will not support them safely. It may be a better bargain to buy a smaller outfit that can be used everywhere than to have a heavy machine on hand and not be able to use it except at home.

	Mile	11 734.	1955.6	2281.5	2607.4	2933.3

Proper rolling will reduce loose spread about 25%.
For 1000 ft. quantities multiply 100 ft. quantities by 10.
For road 5 ft. wide take half of 10 ft. quantities.
For road 6 ft. wide take half of 12 ft. quantities.
For road 8 ft. wide take half of 16 ft. quantities.
For road 22 ft. wide take 10 ft. plus 12 ft. quantities.
For road 24 ft. wide take twice 12 ft. quantities.
For road 26 ft. wide take 12 ft. plus 14 ft. quantities.
For road 28 ft. wide take twice 14 ft. quantities.
For road 30 ft. wide take twice 15 ft. quantities.

12	7 040	1760	2112	2464	2816	3168	3520	3872	4224
14	8 213	2053	2464	2874	3285	3696	4106	4517	4928
16	9 386	2346	2816	3285	3754	4224	4693	5162	5632
18	10 560	2640	3168	3696	4224	4752	5280	5808	6336

Width	Sq. yds.	65	70	75	80	85	90	95
8	4 693	3050	3285	3520	3754	3989	4224	4 458
10	5 867	3813	4106	4400	4693	4986	5280	5 573
12	7 040	4576	4928	5280	5632	5984	6336	6 688
14	8 213	5338	5749	6160	6570	6981	7392	7 802
16	9 386	6101	6570	7040	7509	7978	8448	8 917
18	10 560	6864	7392	7920	8448	8976	9504	10 032

To arrive at any price per yard higher than that given, add to price under cents column the sum or multiple of the sum in the yard column, i.e., 16 ft. at $1.65 would be 9386 + 6101 = 15 487.

Cubic Yards of Loose Gravel Required to Make One Mile of Road of Different Widths and Thicknesses

(From Report of Commissioner of Public Roads of New Jersey)

SECTION 21

STEAM RAILROADS

ASSOCIATE EDITOR

FRED ASA BARNES *

DIRECTOR OF SCHOOL OF ENGINEERING AND PROFESSOR OF RAILROAD ENGINEERING IN CORNELL UNIVERSITY

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

* Walter Loring Webb was the author of this section for the first edition and made the revisions for the second and third editions. He was asked to make the revisions for the fourth edition and commenced the work but service in the U. S. Army in France prevented, and the work was then taken up by Prof. Fred Asa Barnes.

STEAM RAILROAD ROADWAY

1. Right-of-Way

For single-track the usual width of right-of-way for the older eastern railroads is 4 rods or 66 ft., whereas western roads have generally taken a width of 100 ft. The necessary width on ground level transversely is: **w = b + 2 sd,** in which *b* is the width of roadbed, *s* the side slope (horizontal to vertical) and *d* the depth of fill, or cut. For ground sloping transversely the total width is greater and more land must be taken on the lower side than on the upper if the total is to be kept at a minimum. These are for minimum widths to accommodate the fills. In cuts, additional width is required for the side ditches, and possibly also an intercepting ditch at the top of the bank to keep surface water out of the cut; and some allowance should be made in all cases to give room for fencing, etc. For a Class A roadbed of the minimum width, 20 ft., a 25-ft. fill with side slopes of 1.5 to 1 requires a width of: $w = 20 + 2 \times 1.5 \times 25 = 95$ ft. Areas of land for different widths are given in the following table:

Area of Right-of-Way

Width in Feet	Acres per Mile	Acres per 100 Ft.	Width in Feet	Acres per Mile	Acres per 100 Ft.	Width in Feet	Acres per Mile	Acres per 100 Ft.
16.5 } 1 rod	2.00	0.038	27	3.27	0.062	40	4.85	0.092
			28	3.39	.064	41	4.97	.094
17	2.06	.039	29	3.52	.067	41.25 } 2.5 rods	5.00	.095
18	2.18	.041	30	3.64	.069			
19	2.30	.044	31	3.76	.071	42	5.09	.096
20	2.42	.046	32	3.88	.073	43	5.21	.099
21	2.55	.048	33 } 2 rods	4.00	.076	44	5.33	.101
22	2.67	.051				45	5.45	.103
23	2.79	.053	34	4.12	.078	46	5.58	.106
24	2.91	.055	35	4.24	.080	47	5.70	.108
24.75 } 1.5 rods	3.00	.057	36	4.36	.083	48	5.82	.110
			37	4.48	.085	49	5.94	.112
25	3.03	.057	38	4.61	.087	49.5 } 3 rods	6.00	.114
26	3.15	.060	39	4.73	.090			

For greater widths use sums or multiples; thus, for 87 ft. take the sum of the acres for 43 and 44 ft.

2. Cross-Sections of Railroads

For Railroad Roadbeds the specifications adopted by the American Railway Engineering Association call for flat subgrades having minimum widths of 20 ft., 16 ft., and 14 ft., Classes A, B, and C, respectively, see Art. 7. These are for depths of ballast shown in Fig. 14 for Classes B and C, Art. 9, and must be increased for the deeper ballast recommended for Class A as shown in Fig. 13. They apply to both cut and fill, but in cuts the total width of subgrade must be increased by the width of the two ditches.

Side Slopes of Excavations should ordinarily be 1.5 to 1. Firm earth will usually retain its slope permanently at 1 : 1. Loose rock will stand at 0.5 to 1, and solid rock at 0.25 to 1. Very soft earth, such as quicksand, may require a slope as flat as 4 to 1. Such earth as is proper to use for embankments will stand permanently when made with 1.5 to 1 slope. Loose-rock embankments will stand with 1 to 1 slopes.

Sodding the side slopes of embankments and excavations was formerly considered extravagant landscape gardening, but it is now realized that the protection from erosion makes the practice worth while. The shoulders and toes of embankments should be rounded off to circles of about 4-ft. radius rather than left with sharp edges, which are not easily maintained.

3. Clearing, Grubbing and Grading

Clearing is defined by the American Railway Engineering Association (Manual, 1929 Edition), as " Removing natural and artificial perishable obstructions to grading," and **Grubbing** as, " Removing the stumps and roots."

The specifications adopted by the association require the clearing of right-of-way and station grounds, except portions that may be reserved, and require that the clearing shall be kept at least 1000 ft. in advance of the grading. Grubbing is required wherever excavations occur, including borrow pits, etc., and also between slope stakes of all embankments that are to be less than 2-1/2 ft. high. It must be kept at least 300 ft. in advance of the grading.

On power shovel work it is more economical to allow the stumps to be undermined in the process of excavation, but they must not be placed in shallow fills and the specifications should require the tops of stumps under embankments to be at least 2-1/2 ft. below subgrade.

Grading includes all excavations and embankments for the formation of the roadbed, ditching, diversions of roads and streams, foundation pits and all similar works pertaining to the construction of the railway, its sidetracks and station grounds.

The specifications of the association require the *Classification* of all excavated material as " Solid Rock," " Loose Rock," " Common Excavation," and such other classes as may be established before the award of the contract.

Solid Rock is defined as rock in solid beds or masses in its original position which may best be removed by blasting, and boulders or detached rock measuring 1 cu. yd. or over.

Loose Rock comprises all detached masses of rock or stone of more than 1 cu. ft. and less than 1 cu. yd., and all other rock which can be properly removed by pick and bar and without blasting; although power shovel or blasting may be resorted to in order to facilitate the work.

Common Excavation includes all materials that do not come under the classifications " Solid Rock," " Loose Rock," or such other classes as may be established before the award of the contract.

For methods of clearing, grubbing, and grading and discussion of shrinkage and settlement, see Sect. 8

4. Fences

Wire Fences with wood, metal or concrete posts are recommended by the A.R.E.A. for right-of-way fences. The height is generally about 4 ft. 6 in., but it and other features must conform to the statutory requirements, if any. Four classes are provided, with the longitudinal wires spaced as follows:

Class A: *5 in. above ground, 4, 4-1/2, 5, 5-1/2, 6, 7, 8 and 9 in.
Class B: 7 in. above ground, 6-1/2, 7, 7-1/2, 8, 8-1/2 and 9 in.

* A barbed wire is stretched in the middle of the space to make a fence " hog-tight."

Class C: 2 in. above ground, 3, 3-1/2, 4, 4-1/2, 5, 5-1/2 for woven wire (25-1/2 in.) with 3 strands of barbed wire above spaced 4-1/2, 10 and 12 in.
Class D: 10 in. above ground, 10, 10, 12 and 12 in.

Smooth, round wire of No. 9 gage is specified for Classes A, B and the woven part of C, except that for the top and bottom strands of a Class A fence No. 7 wire is required. Ribbon, smooth, round or barbed wire may be used for Class D fences, the smooth wire being preferred, although barbed wire is still quite generally used, Vertical stay wires of No. 9 gage are specified for classes A, B and C, spaced 12 in. apart. These must be attached to the longitudinal wires with a mechanical lock or fastening which will prevent slipping either longitudinally or vertically, or they may be electrically welded. Woven wire fencing, giving the same effect or any combination of spacing, both longitidinal and vertical, or a combination of materials, is increasingly used. It is preferably fabricated in the shop if the ground is fairly level, but if desired may be woven in the field to fit rough ground better. In any case. all longitudinal wires should be provided with tension curves or " spring coiled " to take up expansion and contraction. Wires should be placed on the side of the post away from the track. Staples should be of No. 9 wire, 1 in. long for hardwood and 1-1/2 in. for soft wood. They should be set diagonally with the grain of the wood and driven home. The top wire should be double stapled.

Wire for fencing and staples should be steel galvanized with an even coating of zinc, and the fence should be so fabricated as not to remove the galvanizing or impair the tensile strength of the wire. The minimum ultimate tensile strength should be as follows: Line wire No. 7, 2200 lb.; line wire No. 9, 1500 lb.; stay wire No. 9, 1100 lb. If the fencing is electrically welded the galvanizing should be applied after fabrication. The galvanizing must stand one-minute immersion tests in a solution of commercial sulphate of copper crystals and water, the specific gravity of which is 1.185 and temperature between 60° and 70° F. The sample should be washed with water and wiped dry after each immersion, and if the zinc is removed or a copper-colored deposit formed after the fourth immersion, the lot from which the sample was taken is rejected.

Wooden Posts should be straight and free from splits, rot or other defects. They may be made of cedar, locust, chestnut, Bois d'Arc, white oak, mulberry, catalpa, or other durable wood native to the locality, or of treated timber. The dimensions of sawed or split posts should at least equal those given below for round ones. End, corner, anchor and gate posts should be at least 8 ft. long, 8 in. in diameter at small end, and set 3 ft. 4 in. in the ground; intermediate posts should be at least 7 ft. long, not less than 4 in. in diameter at small end, and set 2 ft. 4 in. in the ground. The posts should be set with the large end down. The spacing of posts should be not more than 20 ft. and the first line post from any corner, anchor or gate post should be only 10 ft. from it, center to center. Holes should be dug to full depth, even if blasting is necessary. To avoid blasting holes in solid rock, intermediate posts may be set on 6 by 6-in. sills, 4 ft. long, braced on both sides by 2 by 6-in. braces, 3 ft. long. Not more than two such posts should be placed consecutively. After the fence is erected, the tops of the posts should be sawed off on a one-fourth pitch, the high side being that on which the wire is fastened and 2 in. above it. Intermediate posts in hollows or sags should be anchored down by gaining and spiking two cleats near the bottom. End and corner posts should be anchored by cleats set one near the bottom and the other just below the ground surface, and also braced by braces to adjacent posts. The cleats should be made of 2 by 6-in. common lumber, 3 ft. long. The braces should be 4 by 4-in. common lumber. Wire braces made of a double strand of No. 9 wire should be used where bracing by tension is needed.

Concrete Posts are recommended as practical, economical, and a suitable substitute for wood. The cross-section is preferably a square or a circle, the latter having the most extended use, whereas square or nearly square sections are slightly more efficient in resisting the forces that ordinarily cause failure. This may be offset by greater resistance to deterioration and better methods of manufacture. Corners should be rounded off to a radius of not less than 5/8 in., and posts should taper from base to top. End, corner, anchor and gate posts should be at least 8 ft. long, 8 in. at base and 6 in. at top, set 3 ft. 4 in. in the ground and reinforced with four 3/8-in. rods. Intermediate posts should be at least 7 ft. long, 5 in. at base and 3-1/2 in. at top for round posts, and 4-1/2 in. at base and 3 in. at top for square ones.

Reinforcement must be held rigidly 5/8 in. from surface by at least four spacers per post, and consists of a No. 7 wire or 3/16-in. bar in each corner of the square posts and of six No. 8 wires or 3/16-in. bars, evenly spaced, for the round ones. Bars are preferably deformed, and all reinforcement should be of hard steel. Before being placed in the mold, it should be thoroughly cleaned of mill and rust scale, and of coatings that will destroy or reduce the bond. The proportions of cement, water and aggregate should be such as to produce a concrete having a compressive strength at 28 days of 2500 lb. per sq. in.; using a screen analysis as a guide in the proportioning of fine and coarse aggregates and the slump test to govern the consistency. The maximum slump should not exceed 5 in. The fine aggregate should consist of clean, hard sand, or stone screenings, or a mixture of the two, of which not less than 90% shall pass a No. 4 sieve nor more than 30% a No. 50 sieve, and not more than 3% by weight shall be removed by decantation. Sand should be tested for organic impurities and not used if it fails to meet the standard unless actual tests show that the concrete made with it is of the desired strength. The coarse aggregate should consist of crushed stone, or gravel, or a mixture of the two, ranging in size from fine to coarse within the following limits:

For line posts:

Passing 1/2-in. screen not less than 95%.
Passing No. 4 screen not more than 15%.
Passing No. 8 screen not more than 5%.

For corner and end posts:

Passing 3/4-in screen not less than 95%.
Passing No. 4 screen not more than 15%.
Passing No. 8 screen not more than 5%.

Clean, hard bank gravel, a natural mixture of fine and coarse aggregate, may be used if of suitable screen analysis, and if it meets the test for organic matter; or it may be modified by the addition of fine or coarse aggregate to produce the desired result. Concrete should be mixed in a batch mixer of approved type for at least 2 minutes, and no retempering of concrete should be permitted. Metal molds are preferred as more substantial and rigid than wooden ones, and all molds should be thoroughly cleaned and coated with a non-staining mineral oil or approved substitute just before being filled. Concrete should be thoroughly compacted into the molds and around the reinforcing, preferably by jogging or vibrating the molds during filling. Posts should remain in the molds at least 24 hours after being poured and should be carefully handled and protected from shock until thoroughly cured. They are preferably stacked in a vertical position where they are protected from direct sunlight. They should be kept thoroughly wet for 8 to 10 days and cured for 90 days before being shipped or set if cured naturally. Posts should not be cured out of doors during freezing weather.

Fencing may be attached to the posts by means of Western Union ties, molded holes through post, loops of galvanized wire projecting from the post, or other suitable device.

Steel Posts are increasingly used, the higher first cost being more than offset by the reduced labor costs since they may be driven, either by hand or the one-man post driver. Special types of fences from picket to solid board, sometimes surmounted by one or two strands of barbed wire, in wooden construction and from ornamental iron to woven wire on steel posts, also with barbed wire at the top, in metal construction, are used around yards and shops.

Farm Gates should be of all-metal construction and from 12 to 16 ft. wide, depending on the width of agricultural implements used in the vicinity or on legal requirements. The height should be at least 4 ft. 6 in. They should swing away from the track and, if hinged as is desirable, should shut by gravity and overlap the post so as not to swing toward track.

The First Cost of fencing depends on prices of material and labor and efficiency of the latter and should be estimated in each case from quotations on material and estimated output of labor. The **Annual Cost** involves also the estimated life and interest rate and should be used in making comparisons. Data collected in 1915 by a Committee of the A. R. E. A. showed the average life of wood posts to be as follows: Bois d'Arc, 26 years; catalpa, 12; cedar, 15; chestnut, 11; cypress, 11; locust, 17; oak, 9; and pine, 8. Pine posts treated with cresote are now widely used, having a life of 15 to 20 years and presenting a better appearance than many of the other kinds of wood. They are also much less subject to damage by fire.

A rough comparison of costs may be illustrated as follows, the quotations on materials and estimates of output of labor should be used for actual comparisons:

Material	Life, years	Cost, cents	Labor, cents	Total, cents	Annual costs		
					Interest	Amortization	Total
Oak	9	35	75	110	6.6	4.0	10.6
Pine (treated).	15	40	75	115	6.9	2.7	9.6
Steel.........	25	60	25	85	5.1	2.4	7.5
Concrete.....	50	55	85	140	8.4	1.3	9.7

Materials Required for Board Fences

Per Mile of Fence One Board High

Spacing of Posts	Number of Posts	Nails in pounds		Lumber in feet B. M.				
		8d	10d	1×4 in.	1×6 in.	1×8 in.	1×10 in.	1×12 in.
8 ft.	660	20.7	31.5	1760	2640	3520	4400	5280
10 ft.	528	22.0	33.5	1760	2640	3520	4400	5280
12 ft.	440	18.3	28.0	1760	2640	3520	4400	5280
14 ft.	378	15.7	24.0	1760	2640	3520	4400	5280
16 ft.	330	13.7	21.0	1760	2640	3530	4400	5280

The quantity of nails is figured on the basis of two nails to a board to each post and an allowance of 5% is made for loss. Where posts are 8 ft. apart it figured that 16-ft. boards will be used.

For Wire Fences the 16-1/2-ft. spacing, if used, will require 320 posts per mile. Barbed wire varies in weight with the type, but may be estimated roughly at 1 lb. per rod, or 320 lb. per mile, whereas No. 7 and No. 9 wire weigh 439 and 306 lb. per mile, respectively.

Materials, Except Posts, Required for Wire Fences. A.R.E.A. Standards

Per Mile of Fence

Class	Wire					Staples		Locks
	Longitudinals			Verticals No. 9	Total	1-in.	1-1/4-in.	
	No. 7	No. 9	Barbed					
	Lb.	Lb.	Lb.	Lb.	Lb.	Lb.	Lb.	No.
A	878	2142	....	1300	4320	31.1	46.4	47 500
B	....	2142	....	1236	3378	24.9	37.1	37 000
C	....	2142	960	700	2842	34.4	30.8	37 000
D	....	....	1600	....	1600	18.0	26.8	....

One inch extra was allowed at each end of vertical or stay wires and 5% was allowed for loss of staples. Nothing was allowed for loss of locks or ties, as, if fabricated in the field, some of the stay wires would be omitted at posts.

Staples are put up in 100-lb. kegs, the number per keg if of No. 9 wire being approximately as follows: 1-in., 10 800; 1-1/4-in., 8700; 1-1/2-in., 7200 and 2-in., 5800. For posts 20 ft. apart use 83% of weights given in table for staples. Locks are of various types, the weight may be estimated at 25 lb. per 1000.

Prices of both materials and labor are high (1929) and subject to wide variations in different sections of the country. Barbed wire costs from 5 to 7 cents per pound and smooth from 8 to 10. Staples cost about the same per pound as the wire and locks 50 to 75% more.

The Output of Labor is affected by topography of site, presence of trees or brush, and kind of soil as well as experience and efficiency of workmen. Assuming that one man will dig the holes and carry and set 35 posts per day, Camp estimates the labor per mile for various types of fences as follows:

Four-board fence, 16-ft. boards, posts 8 ft. apart, without battens......	29-1/2 days
Same, with battens..	36 days
Barbed wire fence, 4 strands, posts 16 ft. apart......................	13 days
Same, with posts 12 ft. apart..	16 days
Same, with top board and three wires, posts 12 ft. apart...............	17 days
Same, with top board and four wires, posts 12 ft. apart................	18 days

He allows about one day's labor, more or less, for each strand. Other data indicate that inexperienced men, particularly on short jobs, will take from 25 to 50% more time than stated above, and cost of foreman, whose time may be estimated at one-sixth that of men, and of clearing brush and distributing material must also be considered. Holes may be dug with an auger or digger at about half the cost with bar and shovel or 100 holes may be dug by one man in a day instead of about fifty.

Due to the shorter working day and the decreased efficiency of labor it is not likely that the outputs estimated by Camp could be duplicated at the present time; and the following estimates of labor in man-days per mile for the standard fences of the A.R.E.A. are based on more recent data. Values are based on a fence with posts 20 ft. apart.

Labor in Man-Days per Mile of Fence

Class	Wooden posts		Concrete posts		Steel posts Driven
	Auger	Bar and shovel	Auger	Bar and shovel	
A	42	48	44	50	31
B	35	41	37	43	28
C	40	46	42	48	30
D	26	28	28	34	21

Snow Fences. A snow fence is a structure erected for the purpose of accumulating drifting snow. Snow is carried by the wind close to the surface of the ground and is deposited in railway cuts on account of the eddies and diminution of wind velocities caused by these cuts. A snow fence is so placed that artificial eddies will form on the windward side of a cut at a sufficient distance to cause the snow to be deposited between the snow fence and the cut. A tight fence of sufficient height will cause snow to accumulate on its windward side. An open fence causes snow to accumulate principally on the leeward side. Frequently the best type of fence and its proper location may be determined only by experiment, therefore portable snow fences are used. When practicable a permanent snow fence located on the right-of-way line is the most economical. Where this line is 50 ft. or less from the center of the track, the boards should be close. For greater distances space may be left between the boards. When the distance is 100 ft. 50% of the fence should be open space. The height of the fence should not exceed 10 ft. Hedges of California privet, Armour Barberry, evergreens, spruce, and locust have been planted in recent years for this purpose. Their economical efficiency is still doubtful. Stone walls have been used effectually where field stone are plentiful.

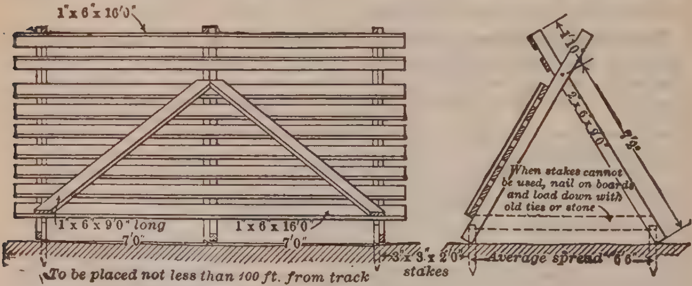

Fig. 1. Portable Snow Fence

A specification, quoted from Orrock's "Railroad Structures and Estimates," calls for cedar posts 8 in. in diameter, 12 ft. long set 3 ft. 6 in. in the ground and spaced 8 ft. on centers. The boards are 7/8 in. × 6 in. × 16 ft., and are nailed on with 6-in. clear spaces. This requires eight boards, four breaking joints at each post. A **portable fence** is made in panels 16 ft. long. Six boards 1 in. × 6 in. × 16 ft., spaced 6 in. clear, are fastened onto three pieces 2 in. × 6 in. × 9 ft., spaced 7 ft. apart. Two pieces 1 in. × 6 in. × 10 ft. act as stiffeners. Three other pieces, also 2 in × 6 in. × 9 ft., are bolted, using 1/2 in. × 4-3/4 in. carriage bolts, with plate washers, scissor-wise to the other three similar pieces. Two more boards are fastened to the tops of the second set of pieces. These sections may be folded up flat for storage. When in use, the scissors are opened until the lower ends are spread about 6 ft. 6 in. apart, and are fastened to stakes, 3 in. × 3 in. × 2 ft., driven into the ground. On hard, rocky ground a tie-board, 2 in. × 6 in × 7 ft., may be nailed to the lower ends of the scissors and weighted down with old ties, stones, etc. This construction is estimated to cost $22 per panel of 16 ft.

Another type of portable snow fence is made by weaving wooden laths 4 to 6 ft. long with five to seven double strands of smooth galvanized wire, making a sort of picket fence. By varying the widths of the lath and the number of turns of wire between them considerable difference in the percentage of area shut off may be obtained. This fence is made in rolls up to one

Fig. 2. Slide Fall, Northern Pacific Ry.

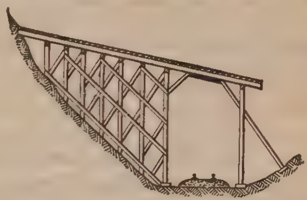

Fig. 3. Slide Fall, Northern Pacific Ry.

hundred feet long and is set up by fastening it at intervals to posts set or driven into the ground. By keeping the laths well painted and using wire heavily galvanized the fence may be made quite durable; and it is easier to handle than the other type.

Snowsheds are expensive to build and to maintain. Their probable necessity and the possibility of avoiding them should have its influence in deciding on the location of the road. There are two types of construction: (1) those to protect the track against slides, the track being on a side hill or at the base of a hill, and (2) those to prevent the filling of cuts or to protect the track from an excessive level fall. Although the detail varies somewhat with nearly every location, typical designs for timber sheds are shown in Figs. 2 to 5.

Sheds cut off the view considerably and are disagreeable to operate; hence a "summer track" is sometimes laid outside. To partially open up level fall sheds and to localize fires, movable sections 100 ft. long are provided which

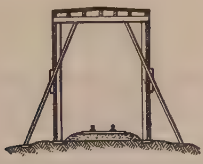

Fig. 4. Level Fall, Southern Pacific Ry.

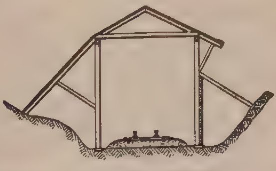

Fig. 5. Lower Fall, Canadian Pacific Ry.

are mounted on wheels and telescope into enlarged adjacent sections. The cost of maintaining the extremely heavy avalanche sheds, particularly those for double track, and the great fire risk have led some roads to build combination concrete and timber sheds and reinforced-concrete sheds. See Eng. News, Dec. 15, 1910.

Highway Grade Crossings. Three-inch planks, spiked to blocks on the ties on either side of each rail, the outer planks tight against the heads of the rails and the inner allowing a flangeway of 2-1/4* in., are commonly used for unimportant country roads and farm crossings. The space between the inside planks should be filled in flush with ballast. An old rail laid on its side with its head against the web of the track rail, or standing with separators between it and the track rail, is often used for the flangeway. The ends of such rails should be bent inward to give an opening of at least 4 in. On more important crossings the planking should entirely fill the space between the rails and the ends of the planking should be beveled both between and outside the rails to a thickness of 1 in., commencing at a point 10 in. from the end. On improved roads and paved streets the macadam or pavement is continued between the rails leaving flangeways as above. The width of the crossing should be not less than 18 ft. The width of a farm or private road crossing should not be less than 12 ft.

For specifications for bituminous grade crossings see Manual of American Railway Engineering Association, 1929 Edition.

5. Drainage and Waterway for Culverts

Longitudinal Drains are of three kinds: (a) intercepting ditches which protect the slopes of cuts, and intercepting ditches or tile drains which similarly protect embankments on saturated soil; (b) side ditches in cuts; (c) subsurface drains, which are usually made of 6-in. tile pipes and are located about 2 ft. underneath those of class (b). The **slope** must ordinarily conform to the natural slope of the ground for class (a) and of the roadbed for class (b) Since tile pipes will carry water on a flatter slope than mere earth ditches, drains of

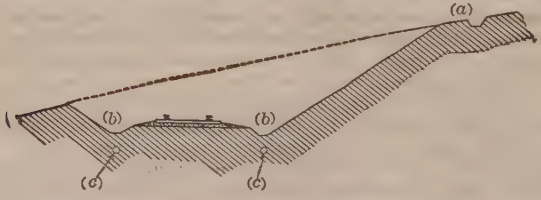

Fig. 6. Longitudinal Drains

type (c) are particularly necessary when the grade of the road is level or very flat, and especially if the soil is retentive and impermeable. Care should be taken that all such drains have a free and unobstructed outfall.

Cross Drains are used only when it is necessary, on account of the lack of a proper outfall, to conduct the water through the roadbed. When lumber is cheap, they may be made of boards so as to give an interior cross-section of 6 by 8 in. 6-in. cast-iron pipes are far better.

The Area of Waterway, or size of opening, of a culvert should be sufficient to care for the flow resulting from all ordinary floods but, unless the probability of loss of life or damages from interruption of traffic are very great, it is not considered necessary to provide for those phenomenal floods which occur at

* Increase to 2-1/2 in. on curves of 8 deg. and over.

very long intervals, because it is more economical to repair such damages once in fifty to seventy-five years than to tie up additional capital in construction for such long periods. It should be noted, however, that cost does not increase in proportion to capacity, this fact together with the impossibility of accurately determining required sizes and the advantages of standards in estimating and construction, have led most roads to adopt a few standard sizes for small openings rather than try to fit each case accurately.

The Maximum Rate of Flow or Runoff at a given point depends upon the following factors:

(a) Rate of rainfall, not necessarily the maximum, which is likely to be of such short duration as not to give time for the water to reach the culvert from any considerable portion of the area unless the watershed is very small.

(b) Area of the watershed.

(c) Permeability of surface and vegetation. Saturation by long continued rains makes most soils more or less impervious, also freezing. Vegetation retards flow.

(d) Shape and slope of the watershed, which affect the time required for the water to reach the culvert from different points. See (a).

The Form of Entrance Slope and Smoothness of a culvert affect somewhat its carrying capacity, although these factors are not usually considered in determining sizes but are simply made as favorable as local conditions and type of structure permit.

A Theoretical Determination of the proper area of waterway being impossible on account of the unknown influence of the factors affecting the runoff, recourse is had to observation and the use of empirical formulas. Consensus of opinion seems to favor "careful field observation and the use of intelligent judgment," particularly in settled country where other culverts and bridges exist over the same stream, thus giving opportunity for a study of their sufficiency at times of high water. In new country, high water marks, preferably at points where the stream has a well-defined channel, will furnish valuable evidence. Where there are no such guides the safest plan is to build a temporary trestle, which will not only provide an ample waterway for all floods during its life, but which will permit the construction of a culvert of proper dimensions under the trestle. The life of such a trestle should be sufficient to determine the area with all-sufficient accuracy.

Empirical Formulas are useful as a guide where only general information is available, but their use in other cases is warranted only to the extent that the formulas and the constants used therein are known, from long usage and observation of results, to fit local conditions. All of the above conditions should be considered in estimating the value of the constant to be used in a particular case in applying any empirical formula, of which some are quoted below. Let $\mathbf{a}$ = area of waterway in square feet and $\mathbf{A}$ = drainage area in acres.

E. T. D. Myer's formula, $\mathbf{a} = \mathbf{C}\sqrt{\mathbf{A}}$, in which $\mathbf{C}$ is a coefficient varying from 1 for flat country to 4 for mountainous country and rocky ground.

A. N. Talbot's formula, $\mathbf{a} = \mathbf{C}\sqrt[4]{\mathbf{A}^3}$. "For steep and rocky ground C varies from 2/3 to 1. For rolling agricultural country, subject to floods at times of melting snow, and with the length of the valley three or four times its width, C is about 1/3; and if the stream is longer in proportion to the area, decrease C. In districts not affected by accumulated snow, and where the length of the valley is several times the width, 1/5 or 1/6 or even less may be used. C should be increased for steep side slopes, especially if the upper part of the valley has a much greater fall than the channel at the culvert."

J. T. Fanning's formula, $\mathbf{a} = \mathbf{0.23}\sqrt[6]{\mathbf{A}^5}$, in which no allowance is made for variations in conditions which affect the flow.

R. McMath's formula, $\mathbf{a} = 0.5908 \sqrt[5]{A^4}$, which was designed primarily for application to sewers. Like Fanning's, it makes no allowance for variations in conditions.

C. B. & Q. formula, $\mathbf{a} = 0.46875\ A/(3 + 0.079 \sqrt{A})$.

Fanning's formula and the C. B. & Q. formula agree very closely, and also agree with Talbot's for a mean value of C. But Talbot's has the advantage

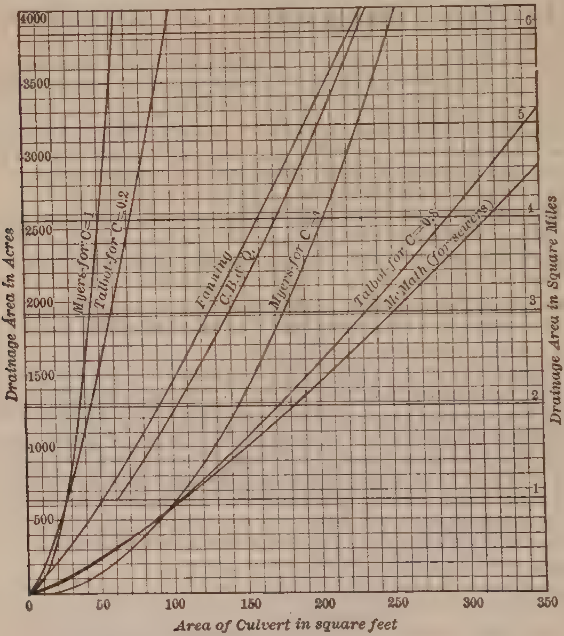

Fig. 7. Required Culvert Areas by Different Formulas

of flexibility. Curves for these formulas are plotted in Fig. 7, from which values of a may be readily found.

As a check on the waterway area found by the above methods, the rules for the proper size of a sewer to carry the storm flow of a watershed may be used. See Sect. 17, Art. 2.

The table on p. 2010 will be useful in selecting an arch culvert of the desired area.

Pipes of standard sizes are extensively used for small openings, and the following table, based on Talbot's formula, probably more used than any other given above, will be found convenient. For example, if the drainage area is 14 acres, a 16-in. pipe culvert might answer under the most favorable conditions, but the size should be increased, up to 36 in., according to the coefficient deemed proper for the locality.

Drainage Area in Acres Drained by Standard Culvert Pipes, for Various Coefficients in Talbot's Formula

Cast-iron pipe of other thicknesses and weights can also be had in the market. See Sect. 14, Art. 20, p. 1499. Sewer, corrugated iron and concrete, both plain and reinforced, pipes are also used.

6. Designs for Culverts

The Length of the barrel of a culvert between the inside faces of the head walls is **L = 2 sd + b**, in which **s** = slope ratio of the embankment (horizontal to vertical), **d** = depth to top of culvert, **b** = width of roadbed. (Fig. 8.)

End or Wing Walls. These act as retaining walls for the lower part of the embankment and are of three types (see Fig. 9):

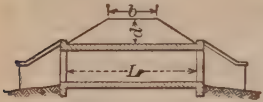

Fig. 8

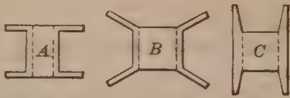

Fig. 9. Types of End Walls

Type A is the simplest form, but the volume of masonry is usually greater than that required by the other types except in narrow gorges. It is generally used for pipe and other low and small culverts.

Type B requires less masonry and is more commonly used for large culverts.

Type C is liable to the objection that the water may work its way behind the wing walls, scour them out and endanger the embankment and culvert. When this can be unquestionably prevented, the type has the advantage of simplicity and economy of construction.

The Length of an end wall of type A should be a little more than sufficient to keep the earth of the embankment spilling around its ends from reaching the opening or more than twice the slope ratio times the height under coping plus the width of opening minus twice the thickness of the wall. Type B is tapered down to a height of from 2 to 4 ft. and type C to practically nothing. The types are often combined for culverts on a skew in order better to guide the stream into the culvert.

Standard Designs. Many railroads have prepared sets of standard plans for culverts and other structures, track work, signs, etc. These usually give quantities and are convenient for both estimating and construction as the men become accustomed to their use. Some examples are given below.

Pipe Culverts should be well bedded in firm earth or have plank, concrete or even piling foundation in soft soils. If slope is light they should be laid with a small camber, and ends should usually be protected with end walls. Sewer pipe should have a cover of at least 3 ft. of earth and no stones should be allowed in contact with it. Joints should be at least partially filled to smooth surface by centering spigots in hubs and prevent scour.

Stone Box Culverts. The thickness of the roof slabs for stone culverts usually varies from 10 in. for a 2-ft. span to 15 in. for a 4-ft. span. Fig. 10

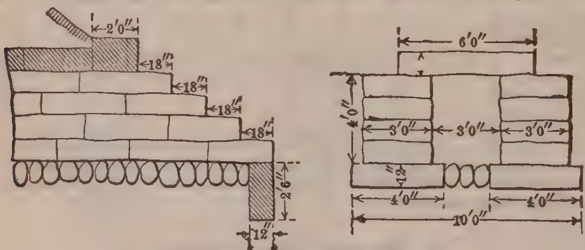

Fig. 10. Typical Stone Box Culvert

represents what may be considered a typical design. Such a culvert requires 7.0 cu. yd. of masonry for each of the end walls and 1.41 cu. yd. of masonry for each foot of length between the inside faces of the coping stones. This estimate does not include the volume of the paving. Dry masonry culverts should not be used on soft soil due to the danger of being undermined; for these conditions concrete is practically always used at the present time.

Wooden Box Culverts similar in design to the stone box, are used to save time and expense during construction, where timber is cheap. They are made large enough to allow a pipe culvert to be put through them before the timber gives out. The sides are of 12 by 12-in. timbers, laid up solid, and the top varies in thickness from 8 in. for 3-ft. span to 12 in. for 5 ft. The bottom should be planked and the ends protected from undercutting.

Masonry Arch Culverts. These usually are built as full semicircular arches unless the span is very great and the rise would be objectionably high. Designs are various, with resulting variations in quantities. Those for stone masonry and plain concrete are similar; Fig. 11 gives data for Erie Railroad standards for concrete. The subscripts to the dimensions (A_1, A_2, etc.) indicate that all of the dimensions are of the same general character. The plans illustrate a culvert of type B for the upstream end and of type C for the downstream end. If there are two or more tracks, let **Z** = distance between track centers of the outer tracks and other notation as in Fig. 11; then

For single track $L = 2\,(s_1y + T + T_1 + T_2)$.
For two or more tracks $L = Z + 2\,(s_1y + T + T_1 + T_2)$.

The neat line is supposed to be **U** inches below the surface of the ground. Carry foundations as deep as conditions may require. Minimum depth **U** inches except on rock bottom.

The volume of one of these culverts may be easily computed by the use of the quantities found in the accompanying table. These tables can also be used to compute the volumes of stone culverts if the quality of masonry is fairly good and joints thin. For rough rubble the thickness of walls and arch should be increased.

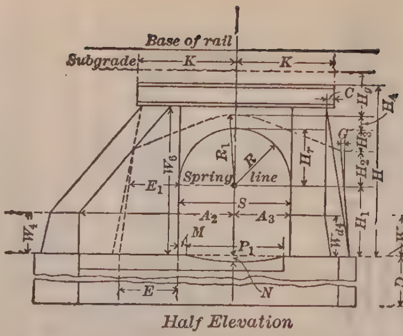
Volume of Standard Plain Concrete Arch Culverts, Erie Railroad

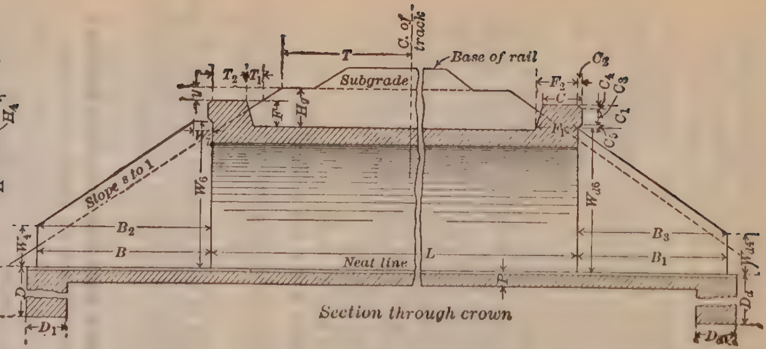
Condensed from several tables in Bulletin 105, Am. Ry. Eng. & M. W. Assoc.

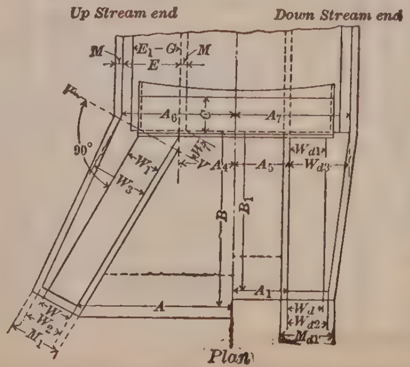
Span	Per lin. ft.		Paving between wing walls	Curtain walls, 1 ft. deep	Two portals, wing walls and parapet
	Barrel	Paving under barrel			
3	0.873	0.055	0.60	0.30	11.0
4	1.034	0.083	1.10	0.44	13.2
5	1.117	0.111	1.31	0.59	13.8
6	1.979	0.185	7.50	1.48	28.7
8	2.784	0.260	12.7	2.0	48.2
10	3.703	0.333	20.38	2.63	74.5
12	4.792	0.408	29.23	3.04	105.2
14	5.998	0.482	54.68	5.48	158.3
16	6.703	0.556	65.11	6.00	186.7
18	7.598	0.630	76.29	6.7	212.0
20	8.087	0.704	88.86	7.3	242.6

For example, if a fill for a single-rack road is 30 ft. deep and an 8-ft. culvert is to be used, since H = 12 ft. 1 in., v = 17 ft. 11 in. = 17.92,

L = 2 (1.5 × 17 ft. 11 in. + 9 ft. 6 in. + 10-1/2 in. + 2 ft. 6 in.) = 79 ft. 6 in.
Vol. = 79.5 (2.784 + 0.260) + 12.7 + 2.0 + 48.2 = 304.9 cu. yd.







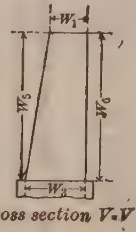


Fig. 11. Standard Plain Concrete Arch Culverts, Erie Railroad
From Bull. 105, Am. Ry. Eng. & M. W. Assoc.

In these plans A_4 and A_5 always equal the half-span, C is constant at 2 ft. 10 in., C_1 = 1 ft. 6 in., C_2 = 0 ft. 4 in., C_3 = 1 ft. 2 in., C_4 = C_5 = 0 ft. 2 in., D and Dd are variable, D_1 = Dd_1 = 2 ft. 0 in., F = 2 ft. 0 in., H_g = 3 ft. 0 in., M = 0 ft. 6 in., P_1 is one foot less than the span, S is the slope ratio 1.5 : 1, T = 9 ft. 6 in., T_1 = 0 ft. 9 in. for 3, 4 and 5 ft. spans and 10-1/2 in. for longer spans when wings are at 30° with the axis, U = 1 ft. 0 in. Wd and Wd_1 are the same as W, also W_6 and Wd_6 are the same as W_5.

The last line gives area of waterway in square feet.

Reinforced-Concrete Culverts. The ability to resist stress, which permits the use of flat slabs, both in top and bottom, makes this construction of especial value. In general, any soil which is firm enough to support an embankment will support a reinforced-concrete box culvert, with a slab bottom, with almost any span, without resorting to piling. Spread footings, unless very narrow, are less economical and less effective than the slab bottom. The design of culverts for railroad work permits the adoption of standard designs,

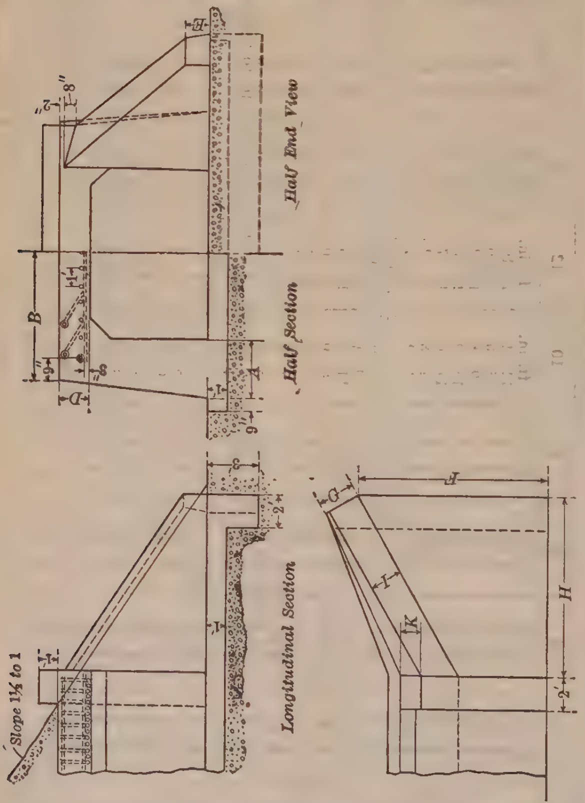

Fig. 12. Standard Reinforced Concrete Culvert

using standard forms which may be removed and used several times with great economy. The forms may be standardized regardless of the use of a slab bottom, which in any case must be laid first. Excavation in the gully or stream bed will frequently expose a rocky bottom into which trenches may be dug which will not only give a sufficient footing but will also furnish sufficient resistance against any lateral thrust of the side walls. In each case it becomes a question of judgment whether to use a slab bottom or perhaps to dig a little deeper and make the side walls a little higher in order to set the side walls in firm soil. In either case the upper corners should be filled out and suitably reinforced in order to resist any unbalanced thrust perpendicular to the barrel of the culvert. When a bottom slab is used the thrust at the bottom of the side walls may be taken up by shallow trenches in the top of the slab, immediately under the side walls, but it is cheaper and sufficiently effective to place greased plugs in the slab at the proper places for the vertical bars of the side walls. These plugs are afterward removed and the bars grouted in. Short pieces of scrap reinforcement may also be used as dowels by inserting them for half their length in the slab while still soft. Typical plans and data for them are here given. Some roads use longer spans, but reinforced-concrete girders are commonly used for spans of 15 to 30 ft. and arches for greater spans.

The longitudinal reinforcement is of 1/2-in. bars, the lower spaced 12 in. on centers for all spans, the upper used on 8- and 10-ft. spans only, and spaced 10 and 12 in., respectively. The transverse reinforcement varies with span from 9/16 to 19/16 in. and is spaced 3 in. on centers for the center section and 8 in. for the end sections. One-third the bars are straight, one-third bent up near the side walls, and one-third nearer the center as shown on the half section. Other designs carry reinforcing in the side walls and bottom as shown in Sect. 11, which see also for retaining walls and other structures.

STEAM RAILROAD TRACK

7. Classification

The following classification of railways, based on tonnage and on maximum speed of passenger trains, is that used by the American Railway Engineering Association as the basis for recommended practice in the construction of roadbed, dimensions and quality of ballast, cross-sections, etc.

Class "A" shall include all districts of a railway having more than one main track, or those districts of a railway having a single main track with a traffic that equals or exceeds the following: Freight car mileage passing over district per year per mile, 150,000; or, Passenger car mileage per year per mile of district, 10,000; with maximum speed of passenger trains of 50 miles per hour.

Class "B" shall include all districts of a railway having a single main track with a traffic that is less than the minimum prescribed for Class "A," and that equals or exceeds the following: Freight car mileage passing over district per year per mile, 50,000; or, Passenger car mileage per year per mile of district, 5000; with maximum speed of passenger trains of 40 miles per hour.

Class "C" shall include all districts of a railway not meeting the traffic requirements of Classes "A" or "B."

8. Ballast

The following definitions and specifications have been officially adopted by the American Railway Engineering Association, and are therefore quoted as desirable standards for the classification and selection of ballast.

Ballast. Selected material placed on the roadbed for the purpose of holding the track in line and surface. **Broken or Crushed Stone:** Stone broken by artificial means into small fragments of specified sizes. **Chats:** Tailings from mills in which zinc, lead, silver and other ores are separated from the rocks in which they occur. **Gravel: (a) Pit Run.** — Worn fragments of rock and sand occurring in natural deposits. **(b) Screen.** — Worn fragments of rock occurring in natural deposits that will pass through a 2-1/2-in. ring and be retained on a No. 10 screen. **(c) Washed.** — A gravel from which foreign matter has been washed and the relative proportions of gravel and sand have been determined. **Sand:** Any hard, granular, comminuted rock which will pass through a No. 10 screen and be retained upon a No. 50 screen. **Chert:** An impure flint or hornstone, occurring in natural deposits. **Cinders:** The residue from the coal used in locomotives and other furnaces. **Slag:** The waste product, in a more or less vitrified form, of furnaces for the reduction of ore; usually the product of a blast furnace. **Burned Clay:** A clay or gumbo which has been burned into material for ballast. **Gumbo:** A term commonly denoting a peculiarly tenacious clay, containing no sand. **Disintegrated Granite:** A natural deposit of granite formation, which, on removal from its bed by blasting or otherwise, breaks into particles of size suitable for ballast.

Stone Ballast. Stone shall be durable enough to resist the disintegrating influences of the climate where it is used; it shall be hard enough to resist pulverizing under the treatment to which it is subjected; it shall break in angular pieces when crushed. The maximum size of ballast shall not exceed pieces which will pass in any position through a 2-1/2-in. ring; the minimum size shall not pass through a 1/2-in. ring and the gradations between shall be fairly uniform. It should be free from dirt, dust or rubbish.

Gravel Ballast. At least 15% of sand is essential in gravel ballast to prevent the stones from shifting under their load. For Class A roads bank gravel containing more than 2% of dust (material finer than sand) or 40% of sand must be washed or screened and the product should contain between 15 and 20% of sand. For Class B roads bank gravel containing more than 3% of dust or 60% of sand should be washed or screened and the product should contain from 25 to 50% of sand. For Class C roads any material which makes better track than the natural soil may be used.

Cinders. The use of cinders as ballast is recommended for the following situations: On branch lines with a light traffic; on sidings and yard tracks near point of production; as sub-ballast in wet, spongy places; as sub-ballast on new work where embankments are settling, and at places where the track heaves from frost. It is recommended that provision be made for wetting down cinders immediately after being drawn.

Burned Clay. The material should be black gumbo or other suitable clay free from sand or silt. The suitability of the material should be determined by thorough testing in a small test kiln before establishing a ballast kiln. The material should be burned hard and thoroughly. The fuel used should be fresh and clean enough to burn with a clean fire. It is important that a sufficient supply be kept on hand to prevent interruption of the process of burning. Burning should be done under the supervision of an experienced and competent burner. Ballast should be allowed to cool before it is loaded out of the pit. Absorption of water should not exceed 15% by weight.

9. Standard Ballast Sections

The Ballast Sections in Figs. 13*a* and *b* are those officially adopted and recommended as good practice by the American Railway Engineering Associa-

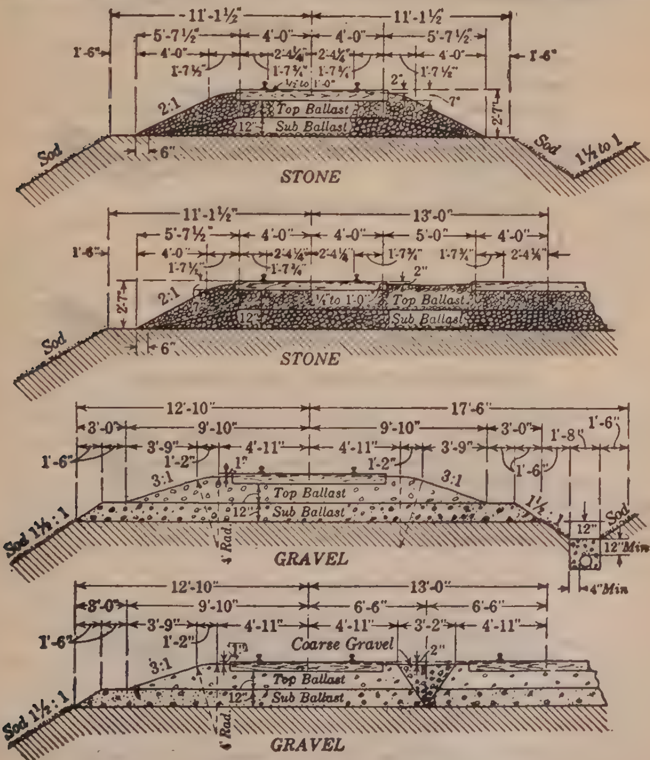

Fig. 13*a*. Standard Ballast Sections, Class A Roadbeds

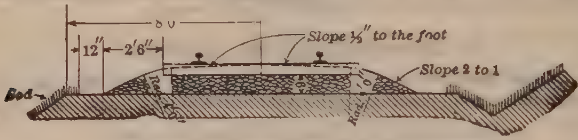
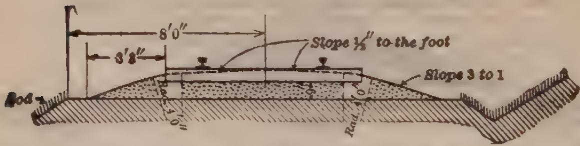
tion; and, on account of the care used to obtain the consensus of opinion of the best officials of the country, they may be considered as the most authoritative designs obtainable.

The Quantity of Ballast required in cubic yards per mile for the standard sections shown in Fig. 13*a* is as follows:

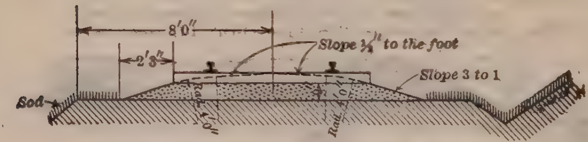
Kind of ballast	Single track		Double track	
	Sub-ballast	Top-ballast	Sub-ballast	Top-ballast
Stone	2664	3995	5206	7320
Gravel	4726	4144	7268	7626



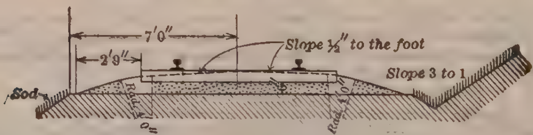
Stone and slag, Class B Railways



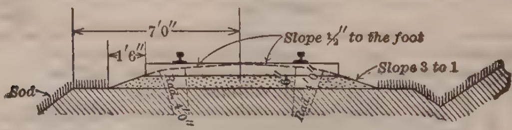
Gravel, cinders, chats, etc., Class B Railways



Cementing gravel and chert, Class B Railways



Gravels, cinders, chats, etc., Class C Railways



Cementing gravel and chats, Class C Railways

Fig. 13*b*. Standard Ballast Sections, Class B and C Roadbeds

Note. Slag is broken and similar in character to stone. For granulated slag the same section as for gravel, cinders, etc., should be used.

The Quantity of Ballast required in cubic yards per mile for the standard sections shown in Fig. 136 is as follows:

Kind of Ballast	Class B	Class C
Stone and slag	2195	....
Gravel, cinders, chats, etc.	2284	1695
Cementing gravel and chert	1882	1309

These computed volumes are based on the use of 6 in. by 8 in. by 8-ft. cross-ties, spaced 24 in. on centers, for both classifications. The use of wider ties (same depth) would slightly decrease the required volume of ballast; the use of deeper ties (same width) would increase the volume; wider spacing would increase the volume; the use of longer ties would decrease the volume slightly, except for cementing gravel and chert.

Shrinkage of Ballast. "Shrinkage of ballast" is the decrease in volume from that as loaded at the pit and measured as dumped loosely in the car to that as measured in the track after the ballast has been tamped and compressed by the passage of trains. This "shrinkage" is not a loss of ballast; and the "pay quantities," usually measured as dumped loosely in the car at the pit, must be increased sufficiently to allow for the shrinkage.

The following table from Bulletin 277, A.R.E.A., p. 84, gives results of actual measurements of this shrinkage:

Shrinkage for Various Kinds of Ballast

Kind of ballast	Number of projects	Yards of material		Per cent of shrinkage
		Purchased	Measured in track	
Stone	8	2 113 117	1 812 020	16.62
Chats	2	222 936	205 450	8.50
Gravel	3	381 586	313 295	21.80
Sand	1	74 910	65 484	14.39
Slag	1	195 159	157 234	24.12
Cinders	1	Altoona test		27.00

Cleaning Ballast. Ballast becomes **fouled** or "dead," in from 2 to 7 years, depending largely on its hardness and durability but also on account of cinders and other dirt dropped into it. It then does not drain readily and must be cleaned. The hand method, still much used, is to throw it out from between the ties with shovels and return it with ballast forks, thus leaving the dirt outside the track. This method is slow, laborious and costly; but no very satisfactory machine has been developed for getting the ballast out of the "cribs." Machines of the vacuum-cleaner type have been tried, and on mountain roads where the amount of cinders is large a machine similar to a street sweeper, but with pan and conveyor, to dispose of the dirt, is sometimes used.

For dirty ballast alongside single track or in the intertrack spaces on multiple-track roads, several types of machine are used. The first was the locomotive crane rigged with a clamshell bucket, which deposited the dirty ballast on screens. They are most effective if operated in pairs, or multiples, and the screens should be of the vibrating type. The same principle is followed in a self-contained ballast-cleaning machine recently put on the market. Another type of machine is the mechanical mole which digs its way through the material cleaning the ballast as it goes. Cleaning ballast by machine is faster and cheaper than by hand, but conditions vary so widely that cost data are conflicting. One large eastern road reports savings of about $1500 per mile of double track using four cranes and only about $870 per mile if only one is used.

Cost. The total cost is made up of three items: the cost of the material on the cars, the cost of hauling to the place of distribution, and the cost of placing and tamping under the track. The cost of **loading gravel** at a gravel pit is quoted at 7 cents per cu. yd. Another quotation, which included "washing" the gravel, was 18 cents; still other quotations ranged from 5.62 cents to 13.9 cents. The cost of crushed limestone at the crusher is quoted at 53.5 cents; other quotations for "crushed stone" were 48 cents, 59 cents, and 61.5 cents. The cost of **hauling** 50 miles is quoted as 5.5 cents; on another road, hauling 50 miles and unloading, 10.7 cents; on another road the cost of hauling combined with unloading and placing in track was given as 40 cents. The cost of **placing in track** is about 12 to 15 cents for cinders, a little more for gravel, and up to 30 cents for broken stone; the cost of placing stone ballast is given in one case as 31.9 cents, and the cost of placing gravel under the same conditions was 11.8 cents. The cost of digging out all worn-out gravel ballast was given as 15 cents per cu. yd. The tie renewals in stone ballast cost more than in gravel ballast; the relative cost (to quote one case) was 16.8 cents per tie for stone and 10.3 cents per tie for gravel.

These costs were all obtained before the present era of high prices and should be increased from 50 to 100% for the same methods. The increasing use of labor-saving machinery on many operations serves to partially neutralize these increases, but conditions are so variable that it is impossible to cover them.

10. Ties

Wooden Ties. For heavy traffic the minimum thickness should be 7 in., the width 9 to 12 in. and the length at least 8 ft. 6 in.

The following sizes are listed by the A.R.E.A., but the first two are not accepted for standard-gage track.

Size	Sawed or hewed on top, bottom and sides		Sawed or hewed on top, and bottom	
	Inches thick	Inches wide on top	Inches thick	Inches wide on top
0	5	5	5	5
1	6	6	6	6
2	6	7	6	7
3	6	8	6	8
4	7	8	7	7
5	7	9	7	8
6	7	10	7	9
			7	10

Durability. Durability depends on the weight and amount of the traffic, the character and drainage of subsoil and ballast, the use of tie plates, the climate, the time of year of cutting the timber, the age of the timber, and the amount of its seasoning before being placed in the track, and chiefly on the kind of wood. Therefore, any figures are necessarily subject to wide variations. A quoted consensus of opinion as to the life of untreated ties, which may be considered very reliable, is as follows: white oak, 7 to 12 years; pine, 5 to 8 years; chestnut, 8-1/2 years; cypress, 7 to 9 years; cedar, 15 years;

tamarack, 5 to 6 years; hemlock, 5 years. From 75 to 98% of white oak ties fail from decay, the remainder failing from rail cutting and spike cutting. For pine, chestnut, cedar, cypress, gum and similar timber, the corresponding figures for failures from decay are from 25 to 80%. The softer the wood, the greater is its liability to fail from rail cutting or spike cutting. Failures from these causes are practically eliminated by the use of tie plates. The durability of chemically treated ties depends on the kind of chemical treatment and on the protection of the ties against mechanical injury, such as rail cutting and spike cutting. It is possible to treat ties chemically so that they will resist decay for 30 years, but it is useless to do so unless they are adequately protected against mechanical destruction by the use of tie plates. Even with tie plates ties sometimes fail from wear under them, and it is now considered good practice to fasten the plates to the tie.

Spacing. The usual maximum spacing is 2 ft. on centers. An open space of 10 in. between ties is sufficient for tamping, and maximum bearing area on ballast is obtained by the use of the wider and longer ties with this spacing. The number of ties per mile for various spacings is as follows:

Number of ties per 39-ft rail.........	26	25	24	23	22	21	20	19.5	19	18	17	16
Average spacing, inches...........	18.0	18.7	19.5	20.3	21.3	22.3	23.4	24.0	24.6	26.0	27.5	29.2
Number of ties per mile.............	3520	3385	3250	3114	2980	2843	2708	2640	2573	2437	2302	2166

The Effect of Chemical Treatment on the strength of cross-tie woods has been especially investigated by the U. S. Government, and the final conclusions are: (a) A high degree of steaming is injurious; (b) the presence of zinc chloride does not decrease the static strength, but it renders the wood brittle and therefore more liable to fracture under impact; (c) cresote is not injurious.

Cost of Treatment. Neglecting the variable items of royalties on patents, profit, interest or depreciation, the cost of three of the common types of treatment will average about as follows, for a tie containing 3 cu. ft.: Zinc chloride, 16 cents; zinc chloride and creosote, 27 cents; creosote, 10 lb. to the cubic foot, 55 cents. The cost of the full creosote process is so great that many roads are now using a mixture in various proportions of creosote and petroleum as shown by the statistics in the following table. Approximately three-fourths of all the ties now used in the United States are treated.

Economics of Treated Ties. The durability of ties treated by various methods and with various amounts of chemicals is approximately proportional to the expense incurred in treating them. It is possible to waste money in extra cresote so that the tie will be worn out mechanically long before any appreciable decay has set in. The method of treatment should correspond to the other elements of deterioration. The true relative value of two ties, one of which is long-lived but costly, and the other is cheaper but less durable, may be readily determined from the table showing annual charge against a tie when the cost of each in the track and the expected life of each in years is known. For example, assume that a cheap untreated hemlock tie costs 35 cents, that the cost of placing it in the track is 20 cents, and that the tie will last 5 years. Assume that a yellow-pine tie is bought for 35 cents, is treated thoroughly with cresote at a cost of 60 cents, and that, as before, the cost of placing it in the track is 20 cents. The cheap tie costs 55 cents in the track

Number of Treated Ties — 1927

Kinds of wood	Preservative					Total	Per cent
	Creosote *	Creosote *-petroleum	Zinc-creosote *	Zinc-chloride	Miscellaneous

10	2.59	3.89	5.18	6.48	7.77	9.07	10.36	11.66	12.95	0.648
11	2.41	3.61	4.81	6.02	7.22	8.43	9.63	10.84	12.04	0.602
12	2.26	3.38	4.51	5.64	6.67	7.90	9.03	10.15	11.28	0.564
13	2.13	3.19	4.26	5.32	6.39	7.45	8.52	9.58	10.65	0.532
14	2.02	3.03	4.04	5.05	6.06	7.07	8.08	9.09	10.10	0.505
15	1.93	2.89	3.85	4.82	5.78	6.74	7.71	8.67	9.63	0.482
16	1.85	2.77	3.79	4.61	5.54	6.46	7.38	8.30	9.23	0.461
17	1.77	2.66	3.55	4.43	5.32	6.21	7.10	7.98	8.87	0.443
18	1.71	2.57	3.42	4.28	5.13	5.99	6.84	7.70	8.55	0.428
19	1.65	2.48	3.31	4.14	4.96	5.79	6.62	7.45	8.27	0.414
20	1.60	2.41	3.21	4.01	4.81	5.62	6.42	7.22	8.02	0.401

and will last 5 years. By the table, the annual charge against it is 11.55 + 1.15 = 12.70 cents. The other tie costs $1.15, and is assumed to last 20 years, hence from the table the annual charge against it is $(8.02 + 3 \times 0.401) = 9.223$ cents. Even if the treated tie lasted only 15 years, the annual charge would be only 11.076 cents. Reducing the rate of interest from 5% to, say, 4% of course reduces the annual charge against any tie; it also makes the longer-lived ties relatively more valuable, or with a smaller relative annual charge.

11. Rails

Standard Length. The standard length is 39 ft. Shorter lengths, varying by single feet down to 25 ft. are permissible up to 11% of the entire order.

Expansion. The allowance for expansion should be 0.000 006 5 of the length per degree Fahrenheit change in temperature. For a 39-ft. rail and a change of temperature of 25 deg., the expansion would be 0.00624 ft. = 0.0075 in. nearly. The following allowances are recommended by the American Railway Engineering Association.

Temperature Expansion for Laying Rails

Rail temperature, deg. F.	160 joints per mile, 33-ft. rails, Inch	135 joints per mile, 39-ft. rails, Inch	117 joints per mile, 45-ft. rails, Inch
−20 to 0	5/16	3/8	7/16
0 to 25	1/4	9/32	11/32
25 to 50	3/16	7/32	1/4
50 to 75	1/8	1/8	5/32
75 to 100	1/16	1/16	1/16
Over 100	laid close	laid close	laid close

Weight of Rail. The old rule of the Baldwin Locomotive Works requiring 10 lb. per yard for each 3000 lb. of wheel load is now generally exceeded by the practice of first-class roads, partly because of higher speeds, although these have been made less destructive by improved counterbalancing, but largely because the use of heavier rails is economical, reducing both maintenance and operating expenses. The following table shows the trend toward the use of heavier sections.

Production of Rails by Weight per Yard

Year	Under 50 lb.	50 to 85 lb.	85 to 100 lb.	100 to 120 lb.	120 lb. and over	Total, gross tons
1914	238 423	309 865	868 104	528 703		1 945 095
1915	254 101	518 292	742 816	688 995		2 204 203
1916	295 535	566 791	1 225 341	766 851		2 854 518
1917	308 258	882 673	989 704	763 526		2 944 161
1918	395 124	665 165	888 141	592 462		2 540 892
1919	263 803	495 577	965 571	478 892		2 203 843
1920	489 043	433 333	952 622	729 118		2 604 116
1921	211 568	214 936	902 748	849 566		2 178 818
1922	265 541	274 731	728 604	902 900		2 171 776
1923	272 794	300 907	864 965	1 465 850		2 904 516
1924	191 046	213 274	853 431	1 175 581		2 433 332
1925	163 607	219 648	765 371	1 636 631		2 785 257
1926	197 260	256 287	797 662	1 966 440		3 217 649
1927	161 740	173 257	539 465	1 314 424	617 524	2 806 390

The **gross tons per mile of rails** of any weight is readily found by multiplying **the weight per yard by 11/7.** For example $70 \times 11/7 = 110$, the gross tons of 70-lb. rails per mile of track. The rule is theoretically exact, but in ordering an allowance of about 2% should be made for rail cutting.

Curving. An approximate but practical rule for the middle ordinate **m** (Fig. 14) is that it is equal to the square of the length divided by 8 times the radius of the curve. Applying the approximate rule that radius of curve = $5730/D$, where D is the degree of the curve, the rule becomes, for a standard 39-ft. rail, m (in inches) = 0.395 D; or for any length rail, m (in inches) = $0.00026\,L^2D$, where L = length in feet.

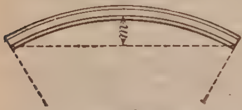

Fig. 14

For ordinary curvature and lengths up to 33 ft. there is no practical error in this rule, the maximum error below for a 30-deg. curve being 1/8 in. and that for even a 50-deg. curve being only 1/2 in. The following table was computed by its use. For greater lengths the error varies practically as the square of the distance. For curves of less than 8 to 10 degrees it is not generally considered necessary to curve the rails before laying.

Middle Ordinates for Curving Rails, in Inches

D	Length of rail in feet												
	10	15	20	24	25	26	27	28	29	30	31	32	33

Failures are classified by the American Railway Engineering Association under the following heads:

1. Broken Rail. (A) Transverse Fissure. (B) Oridinary Break.
2. Flowed Head.
3. Crushed Head.
4. Split Head.
5. Split Web.
6. Broken Base.
7. Damaged.

Complete reports are required of all failures classified as above, and must give complete data regarding characteristics, manufacture, location and condition of rail, ties and ballast, alignment, weather, etc. These reports are collected and summarized for study on various bases such as length of service, kind of steel, mills, etc.

The total average failures per 100 track-miles (32 000 rails, 33 ft.) classified on basis of length of service up to five years are given in the table below.

The steady improvement up to 1916 indicated by these statistics was due principally to the improvement in the metal used for rails, the adoption of heavier rails better adapted to the increased loads and the gradual replacement of Bessemer by open-hearth rails. Disturbance of manufacturing conditions and under-maintenance during the war are blamed for the poorer and more erratic record after 1916 or 1917, but there are doubtless other factors contributing to the failure to return to the best record, such factors being increased speed and weight of rolling stock and especially increased density of traffic, as well as increased trouble from transverse fissures in recent years. It should be noted, however, that less than one rail per thousand fails each year on the average for the first five years and that the failures per year increase with the life of the rail, which is as it should be and just the reverse of common experience some twenty-five to thirty years ago when the inferior quality of rails resulted in very heavy replacements from defects during the first two or three years of use.

Number of Rail Failures per 100 Track-Miles

From Bull. 315, March, 1929, American Railway Engineering Association.

Year rolled	Years of service				
	1	2	3	4	5
1908	....	....	....	....	398.1

Life. Rails not replaced on account of failure wear out in service unless replaced by heavier sections and the life depends on the rate of wear and the total wear permitted before renewal, each road fixing its limit of wear to suit its own conditions. Wear is usually considered proportional to tonnage, although heavy axle loads and high speeds undoubtedly increase the destructive effect of traffic. Grade also increases wear 50 to 100% due to the slipping of drivers and use of sand. The excess wear on curves may be taken at 1/6 that on tangents per degree of curve, or, the wear on a 6-deg. curve will be double that on tangents. The normal wear of rails may be estimated at 1/16 in. per 25 000 000 to 35 000 000 tons of traffic. Assuming the allowable depth of wear for main track at 3/8 in. gives, say, 200 000 000 tons as its total tonnage life in main track. It may then be used on branch lines or sidings, with or without rerolling. Since the quality of the metal inside the rail is inferior to that on the surface, some roads remove rail from main track early and reroll it, thus again securing a better wearing surface but, of course, a reduced section. The tonnage treated in this way and the practical displacement of Bessemer steel rails by open-hearth steel rails are shown by the table given below.

Sections. The section in common use originated in the so-called " flat bottom " pattern designed by Col. Robert L. Stevens, Chief Engineer of the Camden and Amboy Railroad, in 1830. It was reinvented in England in 1836 by Charles Vignoles and is used as the " Vignoles " rail in Europe and to some extent in England, although the standard in the latter country is the double-headed or " bull head " rail which requires chairs for its support. The early rails had pear-shaped heads, being designed for the use of iron, on account of the danger of the side of the head breaking down with that material. After the introduction of steel in 1865, many modifications were made by the various roads using rails until in 1891 nearly 300 different patterns were in use with 27 different weights per yard practically all 80 lb. and less. This caused needless expense and higher prices due to the large stock of rolls which the eleven Bessemer steel rail mills had to carry on hand; and in 1893 the American Society of Civil Engineers, having studied the subject exhaustively through

Production of Rails by Processes, in Gross Tons

* Small tonnages rolled but included with Bessemer and open-hearth. Rerolled rails were also included 1902 to 1910. There were also rerolled from new, second quality, and defective rails 22 010 tons in 1911; 42 586 in 1912; 43 793 in 1913; 26 772 in 1914; 9 129 in 1915; 3 860 in 1916 and 9 007 in 1917. The totals show that the practice of rerolling has decreased markedly since 1913, but total production has also decreased somewhat.

In addition to the above tonnages, alloy-treated steel rails have been produced by the open-hearth and electric processes in the quantities given in gross tons in the table on the next page.

various committees since 1873, adopted standard sections the use of which was recommended. These sections were extensively adopted, as at one time about 75% of the output conformed to those standards, but when the heavier rails came into common use much difficulty was experienced. Although much of this was due to poor quality of metal and poor methods of manufacture, a change in section was also necessary and the American Railway Association in 1905 appointed a committee to consider the matter. This committee made its final report in 1909, recommending the adoption of two types of sections, A and B, the first with shallower head and greater height than the second. The association concurred and referred the sections to the American Railway Engineering Association whose Committee on Rail reported in 1915 in favor of the "A" section for a single type for the 90-lb. rail and in favor of sections of their own design for 100-, 110- and 120-lb. rails, thus leaving the Am. Soc. C. E. sections standard for weights under 90 lb. per yard. These recommendations were adopted. Considerable tonnage of both sections A and B has been rolled, however, and they are likely to continue in use to some extent, as the A section satisfies those who believe that the head should be thin and the moment of inertia as great as possible and the B section satisfies those who believe that the head should be narrow and deep and that the moment of inertia is comparatively unimportant. The A section is used on the comparatively straight prairie roads of the Central West, whereas the B section has been adopted by some of the crooked, heavy-traffic, coal roads through the mountains in the East. Standards for heavier sections have been adopted by the American Railway Engineering Association as follows: 130- and 140-lb. in 1920 and 150-lb. in 1924.

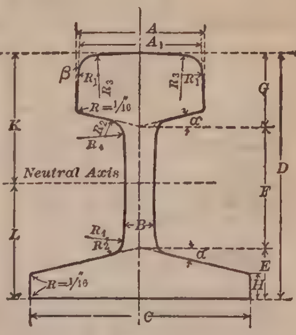

Fig. 15

In Fig. 15 is given a diagram showing the dimensions which are common to all designs and indicating by letters the dimensions which vary. The Am. Soc. designs included thirteen different weights of rails, but these were later reduced to five designs varying by 10 lb. increments from 60 to 100 lb.

Angles and Dimensions of Standard

Standard	Radii, in.				Angles		Weight of rail, lb. per yd.
	Upper corner of head R_1	Fillet corners* R_2	Top of head R_3	Side of web R_4	Bottom of head and top of flange α	Side of head β

* Fillet at bottom of web differs from that at top, R_2, in following sections: A.R.E.A. 100-lb., 110-lb., and 120-lb., 5/8 in.; 130-lb., 140-lb., and 150-lb., 3/4 in.; Penn. R. R. 130-lb., 1/2 in.; L. V. R. R. 136-lb., 3/4 in.; Dudley 105-lb., 1 in., 115-lb.

per yard. One dimension only is common to all standards and all weights of rails, the radii of the upper and lower corners of the flanges and the lower corners of the head being almost invariably 1/16 in. Some other dimensions and angles are constant for a set of standards as shown in the table given above.

Specifications. The following are the standard specifications of the American Railway Engineering Association for open-hearth carbon-steel rails:

Inspection. 1. Inspection and tests shall be made at the works of the manufacturer before shipment, and the works management shall afford all reasonable facilities for determining the satisfactory quality of the rails accepted.

and 127-lb., 3/4 in. Another variation is that the radii of the lower corners of the head of the L. V. R. R. standard are 1/8 in. instead of 1/16 as given in Fig. 15.

Chemical Composition. 2. The chemical composition of the steel, determined as prescribed hereafter, shall be within the following limits:

Constituents	Weight in pounds per yard			
	70–84	85–100	101–120	121–140
Carbon....................	0.53–0.70	0.62–0.77	0.67–0.83	0.72–0.89
Manganese.................	0.60–0.90	0.60–0.90	0.50–0.90	0.50–0.90
Phosphorus, not to exceed....	0.04	0.04	0.04	0.04
Silicon, minimum...........	0.15	0.15	0.15	0.15

Average Carbon. 3. (a) In any rolling, it is desired that the number of heats above the mean carbon percentage of the specified range shall be at least equal to the number of heats below the mean, and that the average carbon shall be as high as the mean.

(b) For information only, the manufacturer shall furnish the carbon and manganese analysis on drillings taken from both the " O " and " M " positions of the head at the top end of the " A " rail of the last full ingot rolled on each tenth heat.

Analyses. 4. Separate analyses shall be made from drillings taken from test ingots representing the second and one of the last full ingots of the heat to determine the percentage of carbon and manganese. The percentage of phosphorus, sulphur, and silicon shall be determined on equally mixed drillings from the test ingots. The average analysis of the ladle test ingots shall conform to the chemical requirements. A portion of the drillings shall be furnished to the inspector upon request for check analysis.

Physical Requirements. 5. Ductility and resistance to impact will be determined by the standard A.R.E.A. drop testing machine, with test specimens from 4 ft. to 6 ft. long cut from the top of the "A" rails from the second, middle, and last full ingots of each heat. The distance between supports shall be 3 ft. for sections under 106 lb. For sections 106 and over it shall be 4 ft.

Temperature of the test pieces must not exceed 100° F.

Drop Test. 6. The test specimens shall be placed base upward on the supports and subjected to one blow from the tup, falling free from the following heights:

For 81–90-lb. rail	18 ft.
91–100-lb. rail	19 ft.
101–120-lb. rail	20 ft.
121–140-lb. rail	22 ft.

If all these specimens endure the above tests without fracture, all the rails of the heat will be accepted, subject to final inspection for surface, section and finish.

If one of the three specimens fail, all the "A" rails of the heat will be rejected. Specimens shall then be cut from the bottom end of the same "A" rails or the top end of the " B " rails and tested. If any of these tests fail, the " B " rails of the heat will be rejected. Three additional specimens shall then be taken from the bottom end of the " B " rails or the top end of the " C " rails. If all these tests stand, the balance of the heat will be accepted. If any of these tests fail, the entire heat shall be rejected.

Elongation and Permanent Set. 7. (a) One of the three test specimens shall be given a sufficient number of blows to determine, for information only, the exhausted ductility, reported inch by inch over the entire 6 in. gaged. No ductility readings will be taken between blows. The other specimens shall be nicked and broken. The fracture of each specimen shall be examined to determine the requirements of Section 8.

(b) For information only, the permanent set measured by middle ordinate in inches in a length of 3 ft. shall be recorded after the first blow on all test specimens.

(c) For information only, one of the three test specimens shall be tested by Brinell indentation upon the head of the rail, and the diameter of the indentation shall be entered up on the test record. The ball shall be 19 millimeters in diameter and the pressure 100,000 lb.

Interior Condition. 8. If the fracture on any test specimen exhibits seams, laminations, cavities, interposed foreign matter, or a distinctly bright or fine-grained structure, all top rails represented shall be classified as " X-Rayls."

Classification. 9. No. 1 rails. No. 1 rails shall be free from injurious defects and flaws of all kinds.

X-Rayls. Rails as described in Sections 8 and 15 (c).

No. 2 Rails. Rails which conform to the following requirements will be accepted as No. 2 rails.

(a) Rails which do not contain surface imperfections in such number or of such character as will in the judgment of the inspector render them unfit for recognized uses.

(b) Rails arriving at the straightening presses with sharp kinks or greater camber than that indicated by a middle ordinate of 6 in. in 39 ft.

Discard. 10. Sufficient discard shall be taken from the ingot to insure freedom from injurious segregation and pipe.

Lengths. 11. Standard length of rails shall be 39 ft. at a temperature of 60° F. Eleven per cent of the entire order will be accepted in shorter lengths varying by 1 ft. from 38 ft. to 25 ft. A variation of 3/8 in. from the specified length will be allowed, except that on 15% of the order a variation of 7/16 in. will be allowed.

Section. 12. Section of rails shall conform as accurately as possible to the templets furnished by the purchaser. A variation of 1/64 in. less or 1/32 in. greater than the specified height will be permitted. A variation of 1/16 in. in the length of either flange will be permitted, but the variation in total width of base must not exceed 1/16 in. No variation will be allowed in dimensions affecting the fit of the joint bars, except that the fishing templet approved by the purchaser may stand out not to exceed 1/16 in. laterally.

Weight. 13. A variation of one-half of 1% from the calculated weight of section as applied to the entire order will be allowed.

Drilling. 14. Circular holes for joint bolts shall be drilled to conform to the drawings and dimensions furnished by the purchaser. A variation of 1-32 in. in the size and location of bolt holes will be allowed.

Finishing. 15. (a) All rails shall be smooth on the heads, straight in line and without twists, waves or kinks. The supports for rail in the straightening presses shall have flat surfaces and be free from hollow places, bends or crooks, and shall be spaced not less than 60 in. When placed head up on a horizontal surface, rails that are slightly higher at the ends than the middle will be accepted, provided they contain a uniform sweep, the middle ordinate of which does not exceed 1-1/4 in. in 39 ft. They shall be sawed square at the ends, a variation of not more than 1/32 in. being allowed and burrs shall be entirely removed.

(b) Rails presented for inspection which do not conform to the requirements of Section 14 or Section 15 (a) may be reconditioned by the mill, provided they can be made to meet the requirements fully.

(c) When any finished rail shows conditions as described in Section 8 at either end or at any drilled hole, it shall be cut back to sound metal, and accepted as an " X-Rayl."

Branding. 16. Brands made so plain and sharp that they may be read as long as the rails are in service shall be rolled on or hot-stamped into the side of the web of each rail in accordance with the following requirements and to indicate:

(a) Name of the manufacturer, month and year of manufacture, and weight and type of section of rail as rolled.

(b) The heat number and the ingot number as rolled shall be stamped in the web of each rail where it will not be covered by the joint bars.

(c) The top rails shall normally be lettered "A" and succeeding ones " B," " C," " D," " E," etc., consecutively, but in case top discard is greater than normal, the rail lettering shall conform to the amount of discard, the top rail becoming " B " or other succeeding letter to suit the condition.

(d) All rails shall be branded " O-H " in addition to other marks.

Classification Markings. 17. (a) Rails accepted as No. 2 rails shall have the ends painted white and shall be stamped with the figure 2 on both end faces.

(b) Rails accepted as " X-Rayls " shall have the ends painted brown and shall be stamped with the letter " X " on both end faces.

(c) "A" rails shall have both ends painted yellow.

(d) No. 1 rails less than 39 ft. long shall have both ends painted green.

(e) All rails of heats whose carbon content exceeds the mean carbon percentage of specific range shall have both ends painted blue.

Individual rails shall be painted only one color, according to the order of precedence listed above.

Loading. 18. Rails shall be carefully handled in such manner as to avoid injury, and shall be loaded as follows:

(a) No. 1 low-carbon rails shall be loaded in separate cars.

(b) No. 1 high-carbon rails shall be loaded in separate cars.

(c) No. 2 rails shall be loaded in separate cars.

(d) " X-Rayls " shall be loaded in separate cars.

(e) No. 1 "A" rails shall be loaded in separate cars.

(f) No. 1 short rails shall be loaded in separate cars.

No subdivision by classification markings other than listed above is necessary for separate loading.

Milling Practices. 19. The entire process of manufacture shall be in accordance with the best current state of the art. It is expected that thoroughly deoxidized dead-setting steel will be furnished and that in every stage of manufacture strict adherence to the standards of best practice of the individual mill will be observed.

Shall anything occur in the process of manufacture which, in the judgment of the inspector, varies detrimentally from regular care and practice, the inspector will immediately notify the chief inspector and the general superintendent of the mill, confirming such report in writing. If after full investigation the inspector is not satisfied as to the good quality of the rails in question, and the rails, complying in other respects to this specification, be loaded for shipment, the inspector will immediately forward a copy of this report to the purchaser.

Acceptance and Payment. 20. (a) In order to be accepted, the rails offered must fulfill all the requirements of this specification.

(b) No. 2 rails to the extent of 8% of the whole order will be accepted.

(c) Rails accepted will be paid for according to actual weights.

12. Elevation of Outer Rail on Curves

(See also Sect. 6, Art. 61.) The theoretic formula is $e = dV^2/gR$, where d = distance between centers of rails, V = speed of train, g = acceleration of gravity, and R = radius of curve, or, very closely for standard gage, e = 0.00069 DV^2, where D is degree of curve, V is speed in miles per hour, and e is elevation of outer rail in inches. The elevation to be chosen evidently depends on the speed, which should be that of the fastest passenger trains unless their speed is reduced on curves. The Lehigh Valley R. R. has successfully used a superelevation of 10 in.; 8 in. is generally considered the limit, while some roads limit it to 6 in. Whatever the limit, the speed of trains on sharp curves should be reduced, if necessary, to that corresponding to the limiting elevation. A common rule for level grade is one inch for each degree of curve, which agrees with the above formula for a speed of 38 miles per hour. An extension of this rule is that if the grade is over 2%, the elevation is 3/4 in.

Superelevation of Outer Rail in Inches, Standard Gage

(Elevation of center of outer rail above center of inner rail)

Deg. of curve	Velocity in miles per hour											
	15	20	25	30	35	40	45	50	55	60	65	70
1	1/8	1/4	3/8	5/8	7/8	1-1/8	1-3/8	1-3/4	2-1/8	2-1/2	2-7/8	3-3/8
2	1/4	1/2	7/8	1-1/4	1-3/4	2-1/4	2-3/4	3-1/2	4-1/8	5	5-7/8	6-3/4
3	1/2	7/8	1-1/4	1-7/8	2-1/2	3-1/4	4-1/4	5-1/8	6-1/4	7-1/2	8-3/4	10-1/8
4	5/8	1-1/8	1-3/4	2-1/2	3-3/8	4-3/8	5-5/8	6-7/8	8-3/8	10	.....	.....
5	3/4	1-3/8	2-1/8	3-1/8	4-1/4	5-1/2	7	8-5/8	.....	.....	.....	.....
6	7/8	1-5/8	2-5/8	3-3/4	5-1/8	6-5/8	8-3/8	.....	.....	.....	.....	.....
7	1-1/8	1-7/8	3	4-3/8	5-7/8	7-3/4	.....	.....	.....	.....	.....	.....
8	1-1/4	2-1/4	3-1/2	5	6-3/4	8-7/8	.....	.....	.....	.....	.....	.....
9	1-3/8	2-1/2	3-7/8	5-5/8	7-5/8	.....	.....	.....	.....	.....	.....	.....
10	1-1/2	2-3/4	4-1/4	6-1/4	8-1/2	.....	.....	.....	.....	.....	.....	.....
11	1-3/4	3	4-3/4	6-7/8								
12	1-7/8	3-1/4	5-1/8	7-1/2	.....	.....	.....	.....	.....	.....	.....	.....
13	2	3-5/8	5-5/8	8-1/8	.....	.....	.....	.....	.....	.....	.....	.....
14	2-1/8	3-7/8	6	8-3/4	.....	.....	.....	.....	.....	.....	.....	.....
15	2-3/8	4-1/8	6-1/2	9-1/4	.....	.....	.....	.....	.....	.....	.....	.....

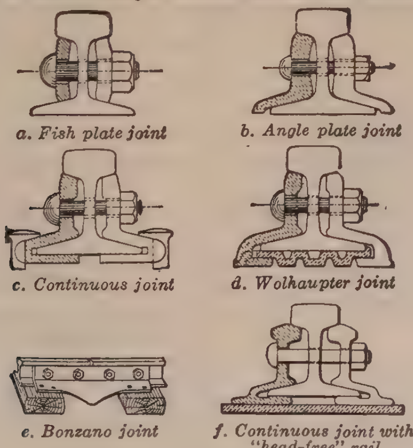
for each degree, which is the equivalent of saying that on the 2% grade the speed up the grade would not be greater than 33 m.p.h. and that the speed down the grade should be limited to that.

Standard Gage of Track is 4 ft. 8-1/2 in. on tangents and on curves of 8 deg. and less. For sharper curves gage is widened 1/8 in. for each 2 deg. of curve up to a maximum of 4 ft. 9-1/4 in. for tracks of standard gage. Gage should not be widened unless the locomotive wheels bind in going around the curve. The gage of a track is the distance between the heads of the rails, measured at right angles thereto at a point 5/8 in. below the top of the rail. Gage, including widening due to wear, should never exceed 4 ft. 9-1/2 in. Gage of track at a frog should be standard even when on a curve, although the flangeway may be widened to compensate for the increase in gage in this case.

13. Rail Fastenings

General Requirements. The ideal rail joint should have the same strength, stiffness and elasticity, no more and no less, both laterally and vertically, as the rails which it joins. Such a joint therefore would not be deformed or take a permanent set under any load which the rail can support without yielding. The joint must also permit longitudinal slipping of the rail to allow for expansion and contraction. It is impossible that any form of scarfed joint should have, at the same time, the same strength, stiffness and elasticity as the original rail. Only a perfect butt welding would accomplish this, but welding would not permit expansion and contraction. Therefore the above conflicting requirements must be filled as perfectly as possible by a compromise design whose cost is not prohibitive.

Designs. The old-fashioned fish-plate design (see Fig. 16*a*) proved so inefficient, especially in lateral strength, that its use has been abandoned except in



a. Fish plate joint *b. Angle plate joint* *c. Continuous joint* *d. Wolhaupter joint* *e. Bonzano joint* *f. Continuous joint with "head-free" rail*

Fig. 16. Various Types of Rail Joints

connection with the very light rails used in industrial railways or the light temporary track used by contractors. A typical modern design for the ordinary angle plate is given in Fig. 16*b*. Among the multitidinous designs which have been brought out the following have come into more common use: the Continuous, Fig. 16*c*; and the Wolhaupter, Fig. 16*d*. The last two designs furnish a plate which runs under the rail between the two joint ties and which keeps the ends of the rails absolutely in line vertically as well as laterally. The Bonzano rail joint, illustrated in Fig. 16*e*, is a development of the angle-plate joint with an extended flange which is bent down between the two joint, ties thus giving a stiffer joint. This can be used only in suspended joints or those in which the rail gap is midway between two ties and the two base joints shown above are also intended for such use. The supported joint, with the rail gap directly over a tie, is very little used and then generally in the so-called three-tie joint. The Bonzano bars are usually heavier and therefore more expensive than the common angle bars and the base joints are not only subject to this disadvantage but also require adzing of the joint ties or setting them on an angle, thus being more expensive to install. The consensus of opinion seems to be that their advantages over the angle bar are not commensurate with the extra cost and many roads have returned to the use of angle bars, sometimes heavily ribbed to furnish additional stiffness. On the other hand, some roads are using the continuous joint with the "head-free" rail shown in Fig. 16*f*. This is the standard RE 130-lb. rail with lower corners of the head chamfered off and the metal thus saved added to the top of the head, giving a stiffer rail and additional metal for wear. The Reading Railway has adopted this as standard and, after several years' experience with it, claims less rail battering and longer life of rail.

Specifications. Bessemer steel is no longer specified for joint bars, high-carbon steel or quenched carbon steel (both open-hearth) and quenched alloy steel being the materials covered by the present (1924) specifications of the American Railway Engineering Association. The principal requirements are:

	High-carbon	Quenched	
		Carbon	Alloy
Carbon, per cent	....	0.42 to 0.55	*
Manganese, per cent, maximum	....	0.80	....
Phosphorus, per cent, maximum	0.04	0.04	0.04
Tensile strength, lb. per sq. in.	85 000	100 000	110 000
Elastic limit, lb. per sq. in.	....	70 000	85 000
Elongation, per cent, in 2-in. length	....	$\frac{1\,600\,000}{\text{Tensile strength}}$	
Minimum, per cent	16	12	
Reduction in area, per cent	....	$\frac{3\,500\,000}{\text{Tensile strength}}$	
Minimum, per cent	....	25	
Bending	Cold bending without sign of fracture on outside of bent portion through arc of 90 deg. with diameter 3 times the thickness of the test specimen.		

* Nickel and chromium to the extent of 1.0% and 0.35%, respectively, are considered equivalent to 0.07% carbon.

All test specimens must be cut from finished bars and all bars must be punched, slotted and shaped at a temperature of not less than 800° C. (1470° F.).

"Quenched" bars must be quenched in oil, or water if so specified, from a temperature of about 810° C. (1490° F.) and kept in the bath until cold enough to handle.

Material requiring quenching in water but otherwise meeting specifications may be accepted at the option of the purchaser. All bars must be finished smooth and true with no variation in fishing angle and height, which factors affect the fit of the bar to the rail. Branding indicating manufacturer, year, design, material and treatment, if any, is required and the number of the melt must be stenciled on the bars.

Splice Bars, Bolts and Spikes for Various Weights of Rails

Rail lb. per yd.	Length of bar, in.	Pounds per foot	Pounds per pair	Proper size of track bolt, in.	Proper size of spikes, in.
30	17	4.0	13.6	2-1/2 × 5/8	4 × 1/2
35	17	4.6	14.1	2-3/4 × 5/8	4-1/2 × 1/2
40	20	5.0	16.1	3 × 5/8	5 × 1/2
45	20	5.8	18.7	3 × 5/8	5-1/2 × 9/16
50	24	6.6	25.5	3-1/2 × 3/4	5-1/2 × 9/16
55	24	7.5	28.9	3-3/4 × 3/4	5-1/2 × 9/16
60	24	8.4	32.4	3-3/4 × 3/4	5-1/2 × 9/16
65	24	9.2	35.5	4 × 3/4	5-1/2 × 9/16
70	34	10.0	54.6	4 × 3/4	5-1/2 × 9/16
75	34	10.7	58.0	4 × 3/4	5-1/2 × 9/16
80	34	11.5	62.6	4-1/2 × 7/8	5-1/2 × 9/16
85	34	12.4	68.2	4-1/2 × 7/8	5-1/2 × 9/16 or 5/8
90	34	16.6	91.3	4-3/4 × 1	5-1/2 × 9/16 or 5/8
100	34	18.8	103.3	4-3/4 × 1	5-1/2 × 5/8
110	34	20.8	114.4	5-1/2 × 1	5-1/2 × 5/8
120	34	22.6	124.3	5-1/2 × 1-1/8	6 × 5/8
130	34	24.4	134.3	6 × 1-1/8	6 × 5/8
140	34	26.2	143.0	6 × 1-1/8	6 × 5/8
150	34	27.9	153.5	6-1/4 × 1-1/8	6 × 5/8

Two hundred and seventy pairs of splice bars will be required per mile of single track, using 39-ft. rails. The maximum number permitted by the rail specification governing short-length rails is 278. Allowing individually for switches and sidings, the number per mile should not exceed 275.

Bolt Holes. The standard spacing for bolt holes recommended by the American Railway Engineering Association is 5-1/2 in., giving lengths of about 24 in. and 34 in., respectively, for the 4-bolt and 6-bolt splices. The hole in the rail should be 1/16 in. larger than the bolt used and the centers of the end holes should be 2-11/16 in. from the end of the rail to allow for expansion and contraction. This combination of measurements permits a total relative motion of the rail ends of 1/8 in. The holes in the bars are made oval, fitting the bolt and preventing it from turning.

Dimensions of Angle Bars. Although the dimensions and weight per linear foot of angle bars, even for the same weight of rail, vary with different manufacturers, the above table gives average figures. The net weight of the bars is from 2.5% to 4% less than their weight unpunched.

Spikes. It has been demonstrated that of all the various forms of driven spikes which have been proposed, the plain spike of uniform section has the greatest holding power. Making the spike jagged, twisting the spike, or even swelling the spike at about the middle of its length, actually reduces its holding power. The holding power, however, is increased by having a cutting edge at the lower end which cuts rather than crushes the fibers, and by having a beveled wedge whose length is about twice the width of the spike rather than a short blunt point. The sizes of spikes recommended for different weights of rail are given in the table on the next page.

Railroad Spikes

Size measured under head in.	Average number per keg of 200 lb.	Ties 24 in. between centers, 4 spikes per tie, quantity per mile		Suitable rail, lb. per yd.
		Pounds	Kegs	
6 ×5/8	250	8448	42.24	120 to 150
5-1/2 ×5/8	275	7680	38.40	85 to 110
5-1/2 ×9/16	340	6220	31.10	45 to 90
5 ×9/16	360	5840	29.40	40 to 56
5 ×1/2	495	4260	21.30	40
4-1/2 ×1/2	540	3920	19.60	35
4 ×1/2	600	3520	17.60	30
4-1/2 ×7/16	655	3220	16.10	25 to 30

The specifications of the A.R.E.A. require the steel to made by the Bessemer or open-hearth process. The required properties are:

Ultimate strength, not less than 55 000 lb. per sq. in.
Elastic limit, not less than 50% of ultimate strength.
Elongation, not less than 25% in 2 in.

Bending, the finished spike when bent back upon itself 180° shall show no signs of fracture. When the head of the spike is bent backward cold it shall show no signs of fracture.

Other requirements cover workmanship, finish, inspection, etc.

For soft steel spikes, the requirements are:

Carbon not under 0.06% for Bessemer process or 0.12% for open-hearth.
Bending tests as above, also workmanship, finish, inspection, etc.

The Driving of Spikes should be by blows in line with the spike. Eccentric or glancing blows tend to enlarge the spike hole and reduce the holding power of the spike. The spikes should not be driven directly opposite each other, but should be staggered. The staggering should be reversed for the two rails on one tie; that is, the spikes on the inner side of the two rails should be near the same side of the tie.

Screw Spikes. The advantages of screw spikes are: (1) The increase in the life of the tie by the avoidance of spike killing; (2) The decreased cost of maintenance (although this is denied), and (3) their greater holding power. It is said, as an objection to their use, that when they are rusted or the head broken off by accident, it is difficult or impossible to extract the stump. They were adopted as standard by the D. L. & W. R. R. (Fig. 17), after extensive trials and are reported as continuing to give satisfactory service on that and other roads. The Pennsylvania Railroad, on the other hand, rejected them in 1918 after nine years of trial and careful observation in two sections of track carrying very heavy traffic. The figures in this case showed them to be more costly, both in first cost and maintenance, than drive spikes and the reported stated that they were unsatisfactory and less efficient than the ordinary spike. One strong objection was the entire loss of holding power when the wood fiber between the threads became worn as it did under the action of the extremely heavy traffic. The screws cost considerably more than common spikes, and require more work to put them in place. The screwing must be done with a track wrench. The auger hole should have the same diameter as that of the screw at the base of the thread, or perhaps 1/16 in. larger. The A. R. E. A. specifications require them to be made of

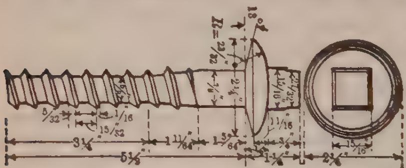


Fig. 17. Screw Spike

open-hearth steel, having not more than 0.05% of either phosphorus or sulfur. The minimum allowable figures for the finished spike are ultimate strength 60 000 lb., elastic limit 50% of ultimate strength, elongation 22% in 2 in., reduction of area 40%. The material must be capable of being bent 180 deg. and hammered down flat and the finished spike bent 90 deg. without sign of fracture.

Track Bolts. The length of track bolts necessarily depends on the distance between the outer faces of the angle plate, and to this must be added the thickness of the nut lock, if used, and the thickness of the nut. Sometimes there is a slight margin beyond this, but any unnecessary length is objectionable. The heads of track bolts are usually hemispherical. Directly under the head the bolt has an oval form which fits loosely in a corresponding oval hole in the angle plate. This prevents the bolt from turning. The table gives proper sizes of track bolts for various weights of rail and their corresponding angle bars. A typical design for a track bolt is shown in Fig. 18.

Track Bolts

Average number in a keg of 200 lb.

Size of bolt, in.	Square nut	Hexagonal nut	Suitable rail, lb. per yd.	Size of bolt, in.	Square nut	Hexagonal nut	Suitable rail, lb. per yd.
2-1/2 ×5/8	390	425	30	3-3/4 × 7/8	165	175	....
2-3/4 ×5/8	379	410	35	4 × 7/8	161	170	....
3 ×5/8	366	395	40	4-1/4 × 7/8	157	165	....
3 ×3/4	250	270	....	4-1/2 × 7/8	153	160	80–85
3-1/4 ×3/4	243	261	....	4-3/4 × 7/8	149	156	....
3-1/2 ×3/4	236	253	50	4-3/4 × 1	....	116	90–100
3-3/4 ×3/4	229	244	55–60	5-1/2 ×1	....	108	110
4 ×3/4	222	236	65–75	5-1/2 ×1-1/8	....	91	120
4-1/4 ×3/4	215	228	....	6 ×1-1/8	....	86	130–140
3-1/2 ×7/8	170	180	....	6-1/4 ×1-1/8	....	82	150

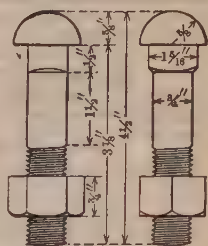

Fig. 18. Track Bolt

On the basis of 275 joints per mile, the number of bolts per mile of single track is 1100 for 4-bolt splices and 1650 per mile for 6-bolt splices. Divide 1100 (or 1650) by the number per keg to obtain the number of kegs per mile.

The specifications of the A.R.E.A. call for medium steel made by the Bessemer or open-hearth process and permit heat treatment if necessary to secure the desired properties which are:

Material	Ultimate tensile strength, lb. per sq. in.	Elastic limit, minimum, lb. per sq. in.	Elongation in 2 in. minimum, per cent	Reduction in area, per cent
Carbon steel, untreated *...	55 000	27 500	20	30
Carbon steel, treated.......	100 000	75 000	10	....
Alloy steel, treated.........	110 000	85 000	12	....

* Phosphorus not over 0.10% for Bessemer steel or 0.05% for open-hearth. For treated steels carbon must not be under 0.30% and phosphorus not over 0.04%.

The material for untreated bolts must bend cold through 180 deg. and flatten on itself without fracture; and treated bolts must bend cold through 45 deg. around a pin of the same diameter as the bolt, without cracking. Other requirements cover workmanship, finish, inspection, etc. Soft steel is required for the nuts.

Nut Locks to keep the nuts from working loose are not always effective and their use has been discontinued on some roads, notably the Lehigh Valley. It is claimed that the joints are easily kept tight by the trackwalkers without much additional vigilance or work, and of course costs of locks and their installation are eliminated. The most common kind of lock is essentially an open ring made of spring steel, the ends of the ring being bent outward. Screwing up the nut compresses the spring and makes the sharp edges bite into the nut and thereby prevents its turning backward. Another form combines a nut and nut lock, the nut being slightly open on one side. The hole is drilled through the nut and the thread is cut slightly smaller than the bolt. When the nut is screwed up, it is forced slightly open, which makes such a pressure on the screw threads that vibration cannot jar it loose. Other types use slightly different threads on the bolts from those of the nuts, but it is doubtful if the extra expense is justifiable.

Fig. 19. Nut Locks

The specifications of the A.R.E.A. cover " rail joint spring washers " of two types: elliptical springs exerting tensions on two bolts, and helical springs for individual bolts. There are two classes of the latter type, high-spring pressure and low-spring pressure. Carbon steel or an acceptable alloy steel manufactured by either basic or acid open-hearth, electric furnace or crucible process is required, with not more than 0.05% phosphorus or 0.04% sulfur. Elliptical springs are tested by subjecting them to ten applications of a load of 30 000 lb. and then to a load of 20 000 lb., under which the distance between platens must be at least 1/32 in. greater than under the last application of the 30 000-lb. load. Their hardness under the Brinnell scale must be between 321 and 418. Helical springs are tested in a similar manner in accordance with the accompanying table:

Spring washer number	For diameter of bolt in inches		Low-spring pressure		High-spring pressure	
	Body	Thread	Preliminary load, lb.	Test load, lb.	Preliminary load, lb.	Test load, lb.
1	3/4	13/16	down to solid	750	15 000	7 500
2	12/16	7/8	down to solid	850	17 500	8 500
3	7/8	15/16	down to solid	1 000	20 000	10 500
4	15/16	1	down to solid	1 250	25 000	11 500
5	1	1-1/16	down to solid	1 500	28 000	12 000
6	1-1/16	1-1/8	down to solid	2 000	36 000	15 000
7	1-1/4	1-1/4	down to solid	....	45 000	18 000

Distance between platens under tenth and eleventh applications of the preliminary load must not differ by more than 0.001 in. Washer is then removed from machine and maximum thickness of material measured by micrometer to 0.001 in. This thickness plus a reserve factor of 0.02 in. is called the test height and must be equaled or exceeded when the washer is subjected to the test load. The Brinnell hardness of helical washers must be from 402 to 477. All tests must be made with the specimen between 60° and 110° F.

Tie Plates reduce the unit pressure of the rail on the tie, and prevent it from cutting the tie. They relieve the lateral pressure of the rail against a spike, since the tie plate distributes the pressure between the two spikes. The pressure against the spikes is still further relieved by the lugs or corrugations which are found on the under side of some forms of plates, or if the plates are fastened to the tie by an independent fastening. The wear of spikes called "necking," which is caused by the vertical vibration of the rail against the spike, is very much reduced.

Design of Tie Plates. The Manual of the American Railway Engineering Association gives the following data for designing tie plates.

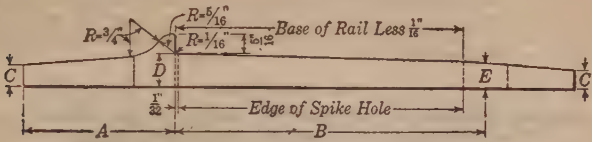

Fig. 20. Tie Plate Dimensions—A.R.E.A.

Dimensions for Tie Plates in Inches

American Railway Engineering Association

Length of plate	Range of rail bases	Same for flat and canted			Flat plates, D & E	Canted 1 in 40		Canted 1 in 20	
		A	B	C		D	E	D	E
9	4-3/4–5-1/2	2-3/8	5-3/8	5/16	9/16	9/16	7/16	3/4	15/32
9-1/2	4-3/4–5-1/8	2-5/8	5-9/16	5/16	5/8	5/8	1/2	3/4	15/32
10	4-7/8–5-1/2	2-7/8	5-3/4	5/16	5/8	5/8	15/32	3/4	15/32
10-1/2	5-1/8–5-3/4	3	5-15/16	3/8	11/16	11/16	17/32	13/16	17/32
11	5-3/8–6	3-1/4	6-1/8	3/8	11/16	11/16	17/32	13/16	1/2
11-1/2	5-3/4–6-1/4	3-1/2	6-5/16	3/8	3/4	3/4	19/32	13/16	1/2
12	6–6-1/2	3-5/8	6-1/2	3/8	3/4	3/4	19/32	13/16	1/2

Ribs not exceeding 1/4 in. deep on the bottom of plates are recommended, but the thicknesses given are exclusive of such ribs, if used. For extra heavy service D and E should be increased 1/8 in. Widths of 7 or 7-1/2 in. are recommended for hardwood ties. Spike holes should be made the size of the spike plus 1/8 in., and if splice bars are slotted, holes should be located accordingly. Plates may be rolled with a camber or crown of 1/16 in. if desired, the height of the shoulder then being measured from the center of the plate.

The specifications of the American Railway Engineering Association provide for steel, both Bessemer and open-hearth, of two grades, soft and medium, the soft to be used unless otherwise specified; and also for wrought iron and malleable iron.

The chemical requirements are that the steel shall not contain more than 0.10% phosphorus if made by the Bessemer process or more than 0.05% for the open-hearth. Carbon must be not less than 0.08% for soft steel or 0.12% for medium for the Bessemer process, not less than 0.15% and 0.20%, respectively, for open-hearth steel.

Bend test specimens taken from the finished plates or from rolled bars and longitudinally with the rolling must bend cold for 180 deg. around a pin the diameter of which is equal to the thickness of the specimen for the soft grade of steel and for wrought iron and to twice the thickness of the specimen for the medium grade of steel, without cracking on the outside of the bent portion.

An Order for Tie Plates should include the following items of information: (a) width of rail base; (b) size of spike under head; (c) number of spike holes, two, three or four; (d) spacing, lengthwise of rail, of slots in opposite angle bars on one tie; (e) net width, measured perpendicular to rail, between such slots. The proportion of joint plates to intermediates will depend on the number of ties per rail, on whether the joints are supported, suspended, or are three-tie joints. In the latter case there will be no slots in the angle bars over the middle joint tie, and the spacing of the holes must be a little wider than the extreme width, out to out, of the angle plates as assembled.

Setting Tie Plates. The efficiency depends largely on proper setting. Plates may be set on soft-wood ties by merely raising the rail, setting the plate squarely in place and driving the spikes. The first train passing over will force any corrugations or claws into the tie. The spikes should at once be driven home. Plates must be set in hardwood ties by direct driving. A follower plate of steel about 3/4 to 7/8 in. thick and about the size of the tie plate, will protect the tie plate from the direct blows of the swages used in driving. A still better method is to use a maul or beetle to strike a straddler which just straddles the rail and rests on the ends of the plate. A hand car carrying a hammer similar to a small-scale piledriver is far better and more effective than a hand maul. They are most economically and efficiently set in large numbers by means of a tie-plating machine.

14. Switches

Mechanical Features. At switches the flanges on the wheels make it necessary either to lift each wheel so that the flange may pass over the rail or else to make a break in the rail so that the flange may pass through the head of the rail. The latter method is virtually always used. The two types of switches are sketched in Figs. 21 and 22. Both use a frog at the intersection of the main rail and outer turnout rail, F, to provide **flangeways.** In the **stub switch** both of the main rails are cut at H and K (Fig. 21). The rails

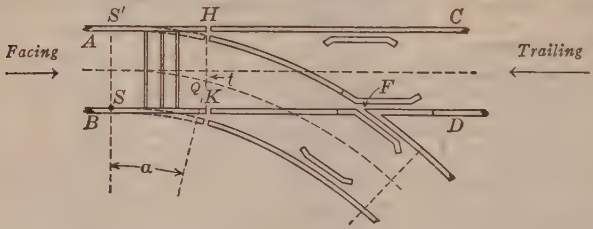

Fig. 21. Stub Switch

from S' to H and from S to K are not fastened to the ties, but are tied to each other by four or more tie-rods. The gaps at H and K are always sufficient to cause a considerable jar to the rolling stock. When operated as a trailing switch, a derailment is inevitable if the switch is incorrectly set. Their use is now confined to switches running from side tracks; they should never be usea in main tracks. In the **point switch** one main rail is unbroken. The point rail S'' H varies in length from 11 to 30 ft. and is planed and bent to give a straight gage line with a thickness of 1/4 in. at the point. The point is afterward ground to a thickness of 1/8 in. beginning at a point 2 ft. from the end. The angle of the switch point varies from about 0 deg. 45 min. to about 2 deg. 30 min. according to the dimensions and frog angle of the switch. There is an abrupt bend in the main rail at the point S', equal to the angle of the point rail. The point rails, $S''H$ and SK, are tied together with tie-rods. They are held in place by a very stiff spring (see Fig. 23) which will yield sufficiently to permit the wheels to remain on the rails if a train trails through with the switch incorrectly set. The **switch points** should fit the stock rail throughout the planing. The planing must be such that the point is 1/2 in. below the top of stock-rail at the end, rising to 1/4 in. above it in about 40% of length of point in order to care for hollow treads on car wheels. The rails of the frog are

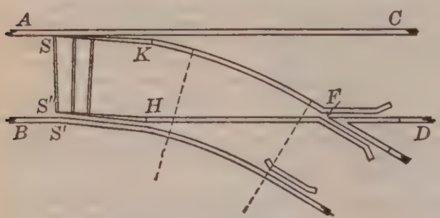

Fig. 22. Point Switch

always made straight; therefore the lead rails between the switch point and the frog must be curved to a circular arc which is tangent to both the switch rail and the wing rail.

Frogs. A diagrammatic design of a frog is given in Fig. 24. The frogs are always built up of four pieces of rail, which are usually of the cross-section and

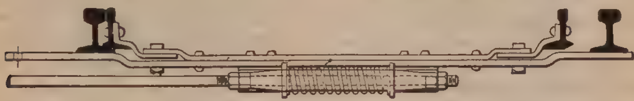

Fig. 23. Section of Main and Switch Rails about 2 ft. back of Point

weight used on the main track. The actual point of the frog is rounded off as shown. **Fixed frogs** are made either by riveting the four rails to a base plate,

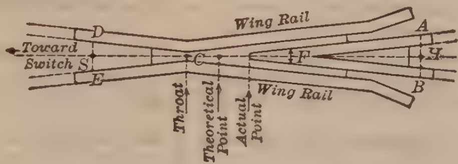

Fig. 24. Diagrammatic Design of Frogs

or else by placing cast-iron fillers between the rails and bolting or clamping the rails and fillers together or by a combination of riveting and bolting.

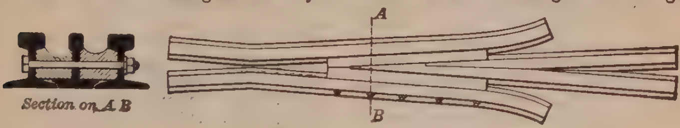

Fig. 25. Stiff Frog

Spring rail frogs usually have one wing rail (the one connecting with the main rail) movable (both may be made so) and yet normally pressing against

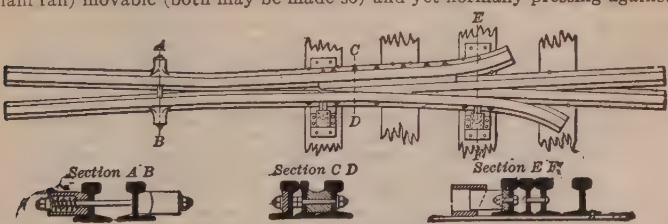

Fig. 26. Spring Rail Frog

the frog point so that there is no gap to be passed over by the wheels running on the main track. When wheels are running through the frog onto the switch, the guard rail opposite the frog forces the opposite wheel to run in its proper line, and this causes the inside of the flange of the wheel running through the frog to press against the wing rail and force it back so as to leave a sufficient opening between the wing rail and the frog point for the wheel flange to pass through. **Movable point frogs** operated with and in the same manner as switches controlling routes through them are used at slip switches in yards to avoid breaks in rail for high-speed traffic. The **frog number (n)** may be determined by dividing CH by AB (Fig. 24), or SH by $(AB + DE)$. When no tape or scale is available, use any unit of measure about 4 in. long, such as a stick or piece of paper, and find by trial two points on the frog where the distance between the gage lines (as at AB and DE) just equals the assumed unit of length. Then step off that unit of length between the points H and S and note the number of times the unit is contained in the distance HS. The result is twice the frog number.

Unbroken Main Rails. A switch which permits the use of unbroken main rails necessarily lifts the train a vertical height somewhat greater than the depth of the wheel flange, and as this must be accomplished in a distance of a very few feet, it is impossible to operate such switches at high speed. Although there are undoubted advantages in having an unbroken main rail, these devices have not come into common use.

The Dimensions of Stub Switches are usually computed on the basis that the lead rails are circular from the switch point to the frog point. For blunt frog angles such a theory may be practically applied, and the computations

Trigonometrical Functions of the Frog Angles

are very simple. Let l = the lead or the distance SF in Fig. 21, r = mean radius of the switch rails, n = number of the frog, g = gage of track. Then $\mathbf{l = 2\,gn}$ and $\mathbf{r = nl = 2\,gn^2}$. The length of switch rails ($S'H = SK$ in Fig. 21) must be such that the offset to the curve at the point Q shall equal the required switch-throw. If t = the switch-throw, then t/r = vers of the angle (α) subtended by the switch rails; then length of switch rails = $r \sin \alpha$. The above theory ignores the fact that the wing rail between the frog point and its junction with the switch rails is straight rather than curved.

A Point Switch has straight point rails also, Fig. 27. The effect of these two details, straight wing and switch rails, is to shorten the lead and therefore decrease the radius of the switch rails.

Let α = angle of point rails;
F = angle of frog = ϕ in Fig. 27;
g = gage of track;
n = frog number;
w = length of wing rail = FH;
c = chord of switch rail arc = HM;
t' = thickness of switch point;
s = length of switch rail = MD;
L = length of lead = BF;
r = radius of center line of lead curve = OT = OV;
h = heel distance = MQ;
f = distance FF',
t = thickness of frog point.

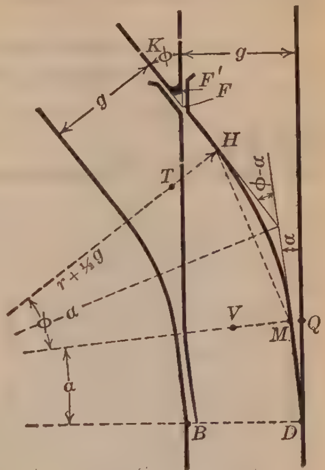

Fig. 27. Point Switch

Then

$$c = \frac{g - w \sin F - s \sin \alpha - t'}{\sin 1/2\,(F + \alpha)}$$

$$r = \frac{c}{2 \sin 1/2\,(F - \alpha)} - 1/2\,g$$

or $$r = \frac{g - w \sin F - h}{\cos \alpha - \cos F} - 1/2\,g$$

$$L = (g - w \sin F - h) \cot 1/2\,(F + \alpha) + w \cos F + s \cos \alpha + f$$

or $$L = (r + 1/2\,g)(\sin F - \sin \alpha) + w \cos F + s \cos \alpha + f$$

or $$L = (s - w)\frac{\sin 1/2\,(F - \alpha)}{\sin 1/2\,(F + \alpha)} + (g - t') \cot 1/2\,(F + \alpha) + f$$

$$\alpha = \sin^{-1}\left(\frac{h - t'}{s}\right)$$

The dimensions of a point switch for a given frog number, as computed from the above equations, depend on the values of w, s, t' and h, all of which may be chosen at pleasure with certain narrow limitations. The length of the wing rail ($w = FH$), as well as other frog dimensions, depends (within narrow limitations) on the switch manufacturer. The A.R.E.A. recommends as standard practice for standard gage (g = 4 ft. 8-1/2 in.), 6-1/4 in. for h and 1/4 in. for t' (for computation purposes, actual thickness is 1/8 in. as already given) and values of s and w for the various frog numbers as given in the table on page 2046.

The lead (L) is measured from the point of the switch to the actual blunt point of the frog (F'). This distance is greater than the distance to the theoretical point of the frog by the amount of the "frog bluntness (f)." On the basis that the actual width of the blunt point is 1/2 in. as recommended the frog bluntness equals the frog number times 1/2 in. or times 0.0417 ft. and is given in the second column in the table.

The closure is the distance from the heel of the switch rail, or "point," to the toe of the frog and equals, for the straight rail, $L-(s + w + f)$ and, for the curved rail, $2\pi\,(R + 1/2\,g) \times (F - \alpha)/360$, or, approximately $(F - \alpha)/D$.

The lengths and closures given in the table are the theoretical ones for the dimensions given, those for other values of s, t', h and w are easily computed by means of the formulas. The theoretical closures are usually modified in practice to avoid, if possible, cutting more than one rail per turnout, giving "practical" closures and "practical" leads (or lengths) as given in the table below.

Switch and Frog Dimensions

(Condensed from Manual of A.R.E.A., 1921 Ed.)

9	72.29	1–33 1–16.42	1–33 1–16.58	0.50	6	0.38	4-1/2
10	78.75	1–28 1–27.83	2–28	0.48	5-3/4	0.36	4-3/8
11	94.31	1–33 1–32.85	2–33	0.55	6-5/8	0.41	4-7/8
12	100.80	2–24 1–23.88	3–24	0.52	6-1/4	0.39	4-3/4
14	106.27	2–30 1–16.44	2–30 1–16.56	0.47	5-5/8	0.35	4-1/4
15	126.19	2–30 1–27.90	2–30 1–28	0.55	6-5/8	0.41	4-7/8
16	131.56	1–30 1–33 1–29.90	2–30 1–33	0.53	6-3/8	0.40	4-3/4
18	138.50	2–33 1–32.92	3–33	0.50	6	0.38	4-1/2
20	151.46	2–33 1–30 1–14.96	2–33 1–30 1–15.04	0.47	5-5/8	0.35	4-1/4

Rails shorter than 12 or 13 ft. should not be used. The maximum modification from the theoretical leads is slightly over 3%, but modifications up to 6 to 8% in either direction may be made without seriously affecting the riding qualities of the turnout.

Turnouts from Curved Tracks. (a) *Stub Switch, lead rails considered to be curved with uniform curvature from switch point to frog point.*

1. Dimensions for turnout from the inner side of a curved track; see Fig. 28.

$$\tan 1/2\,\theta = gn/R \qquad (r + 1/2\,g) = (R - 1/2\,g)\frac{\sin\theta}{\sin(F+\theta)}$$

$$\text{Lead} = BF = 2\,(R - 1/2\,g)\sin 1/2\,\theta$$

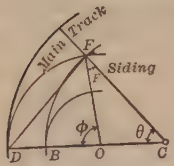

Fig. 28

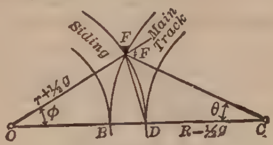

Fig. 29

2. Dimensions for turnout from the outer side of a curved track; see Fig. 29.

$$\tan 1/2\,\theta = gn/R \qquad (r + 1/2\,g) = (R + 1/2\,g)\frac{\sin\theta}{\sin(F-\theta)}$$

If the curvature of the main track is very sharp, θ may be greater than F and then the center of curvature C will be on the concave side of the curved main track. Figure 28 may then be used for this case by merely transposing O and C, ϕ and θ, and "main track" and "siding." The equation for r then becomes

$$(r - 1/2\,g) = (R + 1/2\,g)\frac{\sin\theta}{\sin(\theta - F)} \qquad \text{Lead} = BF = 2\,(R + 1/2\,g)\sin 1/2\,\theta.$$

The lead is practically the same as for straight track and is most easily found from the formula, **Lead = BF = 2 gn.** Then $\theta = 2\,gnD$ where D is degree of main track curve. The degree of the turnout curve is also approximately that of the main track curve plus or minus that of the turnout curve from straight track for the same frog number according to whether the turnout is from the inner or outer side of the main track curve.

(b) *Stub Switch, with straight frog.* Frogs are usually made straight, with the result on straight track of shortening each tangent to the turnout curve, and therefore the lead, by the length of the leg of the frog. The radius and degree of the new turnout curve are easily computed for the new tangent length. For curved track the effect on lead may be assumed the same as on straight track and the new degree of curve used as above.

(c) *Point Switch.* The gage lines of the switch rails have the curvature of the track so that the turnout at the heel of the switch rail makes the angle s with the main track the same as for straight track. The precise mathematical computations are quite complicated and it will be sufficient to assume the same difference in lead between stub and point switches as obtains on straight track, that is, use the table for leads, and to find the degree of the turnout curve in the manner described above for the stub switch.

Double Turnout from Straight Track. The computations are quite simple when it is assumed that all of the frog rails as well as the switch rails are circular throughout. As may be seen from Fig. 30, the dimensions would be considerably changed by assuming the frog rails to be straight, and much depends on the length of the straight rails. In any case, the sections of curved rails would be very short. Only the equations for curved lead rails will here be given.

$$\text{vers } 1/2\, F_m = \frac{g}{2\,(r + 1/2\, g)} \qquad MF_m = \frac{r}{2\, n_m}$$

in which n_m is the frog number corresponding to the middle frog F_m. The above equations also depend on the assumption that F_l and F_r are equal. Their values are obtained from the relation that vers $1/2\ F_m = 1/2$ vers $F_l = 1/2$ vers F_r. Although approximate, there is no sensible error in the relation $n_m = 0.707\ n$ between the frog numbers, in which n_m is the frog number of F_m, and n is the frog number of F_l and F_r.

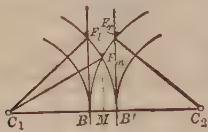

Fig. 30

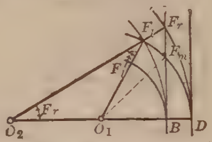

Fig. 31

If both turnouts run to the same side as indicated in Fig. 31, the relation of the frogs will be practically identical with those in the previous paragraph, since the inner switch may be regarded merely as a curved main track, and since, as previously shown, the dimensions of switches are but little altered by a moderate curvature of the main track.

Connecting Curves from Turnouts. The following solutions for connecting curves and crossovers between straight parallel tracks are based on the use of straight frog rails beyond the frog point. Let d = distance between track centers, g = gage, F = frog angle, w' = length of wing rail back of theoretical frog point = $(HK - w)$ of the Switch Table = DF in the figures,

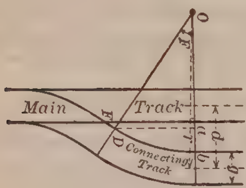

Fig. 32

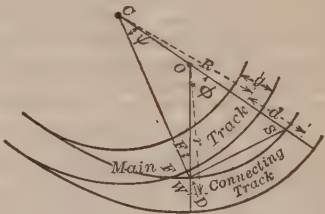

Fig. 33

R = radius of main curved track, r = radius of connecting curved track, n = f og number corresponding to frog angle F, ψ = central angle, measured at center C of main curved track, required for connecting curve, ϕ = central angle, required for connecting curve, measured at center O of connecting curve.

For a connecting curve from a straight track, see Fig. 32.

$$(r - 1/2\, g) = \frac{d - g - w' \sin F}{\text{vers } F}$$

Although the distance from F to the "fouling point" (which is on the line ab) may be shortened somewhat by using a sharper curve and using a short tangent at each end, the method indicated in Fig. 32 is preferable. Under

Connecting Curve from Turnout, Straight Main Track

Frog number	Distance, ft.	Radius, ft.	Degree of curve	Frog number	Distance, ft.	Radius, ft.	Degree of curve
			° ′ ″				° ′ ″
5	85.06	424.93	13 29 04	12	186.93	2102.35	2 43 32
6	93.41	525.63	10 54 16	14	217.91	2855.30	2 00 24
7	108.87	713.19	8 02 25	15	234.04	3292.44	1 44 25
8	124.68	935.56	6 07 37	16	248.45	3723.27	1 32 20
9	139.38	1168.59	4 54 16	18	281.30	4749.75	1 12 23
10	156.55	1464.51	3 54 47	20	312.23	5863.15	0 58 38
11	171.38	1768.46	3 14 25				

such conditions, using the standard dimensions given in the Switch Table, the distance from F to the " fouling point " measured along the main track, is a definite quantity for any frog number, and is as given in the accompanying table for $d = 13$, $g = 4{,}708$.

For a connecting curve on the outside of a main curved track, see Fig. 33.

$$\tan 1/2\, \psi = \frac{2\,n\,(d - g - w' \sin F)}{2\,R + d + w' \sin F}$$

$$(r - 1/2\, g) = (R + 1/2\, g + w' \sin F\, \frac{\sin \psi}{\sin (F + \psi)}$$

$$DS = 2\,(r - 1/2\, g) \sin 1/2\, (F + \psi)$$

For a connecting curve on the inside of a main curved track, see Fig. 34.

$$\tan 1/2\, \psi = \frac{2\,n(d - g - w' \sin F)}{2\,R - d - w' \sin F}$$

$$(r + 1/2\, g) = (R - 1/2\, g - w' \sin F)\, \frac{\sin \psi}{\sin (\psi - F)}$$

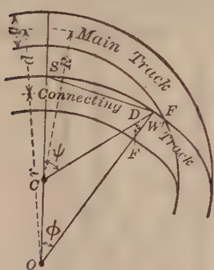

Fig. 34

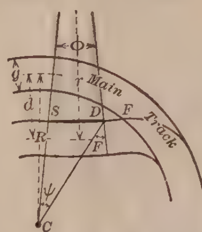

Fig. 35

In case the frog angle F is larger than ψ, the center of curvature of the connecting curve rails will be on the other side of the main track as shown in Fig. 35. Then

$$(r - 1/2\, g) = (R + 1/2\, g - w' \sin F)\, \frac{\sin \psi}{\sin (F - \psi)}$$

In case ψ should exactly equal F, the connecting rails would be straight and r = infinity. This is true when

$$2\,R - d - w' \sin F = 4\,n^2\,(d - g - w' \sin F)$$

The solution of this equation will show the value of R which makes this case possible for any given values of n, d, g and w'.

Crossover between Straight Parallel Tracks. With straight connecting track, the length between the frog wing rails

$$VZ = \frac{d - g}{\sin F} - 2\,w' - g \cot F.$$

The distance between frog points measured along either track

$$F_2Y = (d = g) \cot F - \frac{g}{\sin F}$$

The distance (measured along either track) from the switch point on one track to the switch point on the other track equals F_2Y plus twice the theoretical, or practical, lead minus twice the frog bluntness.

Distance between Switch Points, Crossover between Straight Parallel Tracks, with 13 Ft. between Track Centers

Frog number	F_2Y	Total distance, ft.		Frog number	F_2Y	Total distance, ft.	
		Theoretical	Practical			Theoretical	Practical
5	17.29	103.17	101.95	12	42.73	237.23	243.33
6	20.96	111.78	115.46	14	49.95	264.27	261.33
7	24.62	148.50	148.20	15	53.54	305.26	304.68
8	28.25	163.19	163.59	16	57.15	319.45	318.93
9	31.89	176.37	175.73	18	64.32	346.68	339.82
10	35.51	190.53	192.17	20	71.50	373.04	372.76
11	39.13	223.25	226.83				

With reversed curve connecting track, but with $F_1 = F_2 = F$, $w_1 = w_2 = w'$, and $r_1 = r_2 = r$, an indefinite number of combinations of r and θ may be selected by choosing some reasonable value of r in the following equation and solving the equation for θ, which is the only remaining unknown quantity,

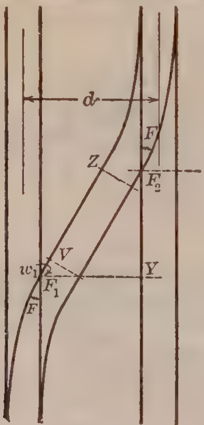

Fig. 36

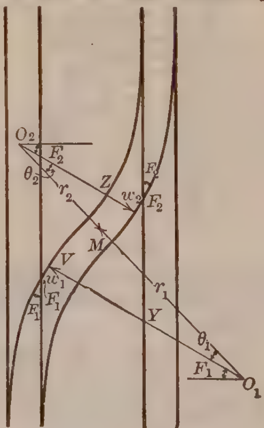

Fig. 37

provided the frog angles are equal. (Similar to Fig. 37.) In this case the point M is midway between the tracks and between the frogs. The use of reversed curves saves distance measured along the main track, as shown in the illustration.

$$1/2\,(d - g) = w' \sin F + 1/2\, g \cos F + r\,[\text{vers}\,(F + \theta) - \text{vers}\,F]$$

and $$F_2Y = 2\,[w' \cos F + 1/2\, g \sin F + r\,[\sin\,(F + \theta) - \sin F]]$$

In case it is desired to make the crossing with two unequal frogs it may be done within limitations as shown in Fig. 37. The following equation may be derived:

$$d - g = w_1 \sin F_1 + 1/2\, g\,(\cos\, F_1 + \cos F_2) + r_1\,[\text{vers}\,\,(F_2 + \theta_1) - \text{vers}\,F_1] + r_2\,[\text{vers}\,(F_2 + \theta_2) \to \text{vers}\,F_2] + w_2 \sin F_2.$$

But since $(F_1 + \theta_1)$ must always equal $(F_2 + \theta_2)$ above equation becomes

$$\text{vers}\,\,(F_1 + \theta_1) = \frac{d - g - w_1 \sin F_1 - w_2 \sin F_2 - 1/2\, g\,(\cos F_1 + \cos F_2) + r_1\,\text{vers}\,F_1 + r_2\,\text{vers}\,F_2}{r_1 + r_2}$$

All of the quantities in the right-hand side of the above equation are known except r_1 and r_2. Their values may be selected at pleasure (within limitations) and may be equal or unequal. The distance along the track

$$F_2Y = w_1 \cos F_1 - 1/2\, g \sin F_1 + r_1\,[\sin\,(F_1 + \theta_1) - \sin F_1] + w_2 \cos F_2 - 1/2\, g \sin F_2 + r_2\,[\sin\,(F_2 + \theta_2) - \sin F_2]$$

Ties for Turnouts and Crossovers. The following table gives the number of ties of various lengths for typical turnouts and crossovers given in the book of "Track Plans" of the Amer. Rwy. Eng. Assoc. These are believed sufficient to give the necessary flexibility but others may be easily worked up on the same basis. "Practical" leads with corresponding closures are used throughout. Standard ties are 7 × 9 in., 8 ft. 6 in. long and distance between track centers is 13 ft.

Number and Lengths of Ties in Turnouts and Crossovers

A.R.E.A. "Track Plans"

Total B.M.	2617	3203	3523	4407	4925	6967	8393	4880	6059	6507	8157	9282	13160	15191
Distance	19.54	22.04	26.13	35.71	37.50	54.57	73.42	5.96	6.97	7.97	9.97	10.98	15.98	19.99

These standards show a maximum spacing of 21 in. and a minimum of 17 in., the detailed spacing being arranged to give increased support to switch points and frogs and to give suspended joints with the arrangement of lead rails recommended. The two ties for the switch block are 15 ft. long and the maximum length for turnouts is 6 in. less than double the standard. For crossovers the long ties (21 ft. 6 in.) are used for the entire distance between the toes of the frogs.

Total B.M. is in feet, board measure, on the basis of 7 × 9-in. ties and the distance given in the last line for turnouts is from the actual frog point to the center of the last tie provided for in the table. Beyond that point standard ties are used. For crossovers the distance is the change in distance between frog points measured along either track due to change of 1 ft. in distance between track centers.

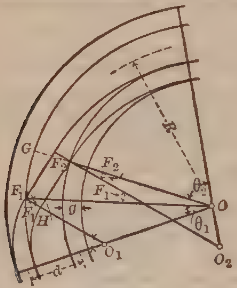

Fig. 38

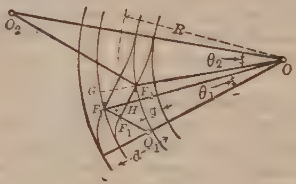

Fig. 39

Crossover between Curved Parallel Tracks. (a) *Using a straight connecting track*: There are two cases as illustrated in Figs. 38 and 39, depending on whether F_2 is greater or less than θ_2. The following equations apply to both figures. One frog (say F_1) may be chosen at pleasure within narrow limitations, then the relation between F_1 and F_2 is given by

$$\cos \mathbf{F}_2 = \cos \mathbf{F}_1 \frac{\mathbf{R} + 1/2\,\mathbf{d} - 1/2\,\mathbf{g} - \mathbf{g} \sec \mathbf{F}_1}{\mathbf{R} - 1/2\,\mathbf{d} + 1/2\,\mathbf{g}}$$

The distance between the frogs measured along the inner rail of the outer track is

$$\mathbf{GF}_1 = 2\,(\mathbf{R} + 1/2\,\mathbf{d} - 1/2\,\mathbf{g}) \sin 1/2\,(\mathbf{F}_1 - \mathbf{F}_2)$$

F_2 will not in general equal the angle of any standard frog, even though the frog F_1 is standard.

(b) *Using a reverse curve for the connecting curve*: In Fig. 40 the lead rails are assumed to be circular throughout, and the lead rail curves are assumed to have been continued until they meet at the point of reverse curve. Within narrow limitations F_1 and F_2 may be selected at pleasure, and will of course be made of standard numbers. The problem should be solved on this basis, which will determine the dimensions of the connecting curve, and then the switch rails may be altered if desired.

$$\text{vers}\,\psi = \frac{d\,(r_1 + r_2 - 1/2\,d)}{(R - 1/2\,d + r_2)\,(R + 1/2\,d - r_1)};\ \sin OO_2O_1 = \sin \psi \frac{R + 1/2\,d - r_1}{r_1 + r_2}$$

$$O_2O_1D = \psi + O_1O_2O;\ NF_2 = 2\,(R - 1/2\,d + 1/2\,g) \sin 1/2\,(\psi - \theta_1 - \theta_2).$$

Crossings. For *two straight tracks* the frog angles are the angle (and its supplement) made by the two alignments. For *one straight and one curved track*, Fig. 41 applies with these equations:

$$\cos F_1 = \frac{R\cos M + 1/2\,g}{R - 1/2\,g}, \qquad \cos F_2 = \frac{R\cos M + 1/2\,g}{R + 1/2\,g}$$

$$\cos F_3 = \frac{R\cos M - 1/2\,g}{R + 1/2\,g}, \qquad \cos F_4 = \frac{R\cos M - 1/2\,g}{R - 1/2\,g}$$

$$F_3F_4 = (R + 1/2\,g)\sin F_3 - (R - 1/2\,g)\sin F_4$$

$$HF_4 = (R - 1/2\,g)(\sin F_4 - \sin F_1)$$

$$F_1F_2 = (R + 1/2\,g)\sin F_2 - (R - 1/2\,g)\sin F_1$$

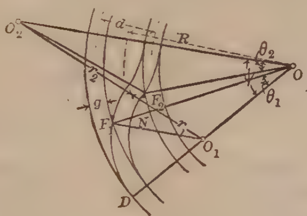

Fig. 40

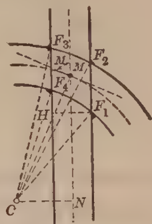

Fig. 41

For *two curved tracks* all four frogs are unequal, see Fig. 42. The radii of the two tracks are of course known and also the angle of intersection of their tangents (M). Then r_1, r_2, r_3, and r_4 become known by adding (or subtracting) 1/2 g to the known track center radii. In the triangle C_1MC_2,

$$1/2\,(C_1 + C_2) = 90° - 1/2\,M$$

$$\tan 1/2\,(C_1 - C_2) = \cot 1/2\,M\,\frac{R_2 - R_1}{R_2 + R_1}$$

From these equations C_1 and C_2 become known.

Then $$c = C_1C_2 = R_2\,\frac{\sin M}{\sin C_1}$$

For abbreviation $s_1 = 1/2\,(c + r_1 + r_4)$; $s_2 = 1/2\,(c + r_2 + r_4)$; $s_3 = 1/2\,(c + r_1 + r_3)$ and $s_4 = 1/2\,(c + r_2 + r_3)$.

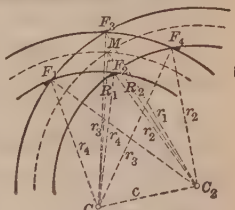

Fig. 42

Then $$\operatorname{vers} F_1 = \frac{2\,(s_1 - r_1)(s_1 - r_4)}{r_1r_4} \qquad \operatorname{vers} F_2 = \frac{2\,(s_2 - r_2)(s_2 - r_4)}{r_2r_4}$$

$$\operatorname{vers} F_3 = \frac{2\,(s_3 - r_1)(s_3 - r_3)}{r_1r_3} \qquad \operatorname{vers} F_4 = \frac{2\,(s_4 - r_2)(s_4 - r_3)}{r_2r_3}$$

$$\sin C_1C_2F_4 = \sin F_4\,\frac{r_3}{c};\quad \sin C_1C_2F_2 = \sin F_2\,\frac{r_4}{c};\quad F_2C_2F_4 = C_1C_2F_4 - C_1C_2F_2$$

$$\sin F_1C_1C_2 = \sin F_1\,\frac{r_1}{c};\quad \sin F_2C_1C_2 = \sin F_2\,\frac{r_2}{c};\quad F_1C_1F_3 = F_1C_1C_2 - F_2C_1C_2$$

From these equations the chords F_1F_2 and F_2F_4 are readily computed.

15. Stock Guards

Essential Features. A stock guard consists essentially of wing fences extending from the right-of-way fences to **aprons** which are short sections of fence, usually flaring, set parallel with the track at the track end of the wing fences; and a pit or a rough surface, on which stock will not walk, which extends the entire width of the track between the outer ends of the ties. A pit is about 3 ft. deep, 5 ft. long (parallel with track) and as wide as necessary; it has vertical walls of masonry or wood; the rails are supported on two wooden stringers spanning the pit. A surface guard covers the ties for a distance of about 8 ft. with some one of a variety of wooden or metal slats or tiles.

Recommended Practice. The American Railway Engineering Association recommends surface guards in preference to pit guards, chiefly on account of the disastrous consequences of derailment at the guard or a failure of the pit structure. A surface guard should be so designed that it will not catch dragging brake chains or other rigging; it should not endanger employees who must walk over it; it should not rattle during the passage of trains; it should be reasonable in first cost, durable and easily applied or removed for track repairs: finally, it should be effective to deter all kinds of livestock from attempting to cross and yet should not catch and hold such as should make the attempt.

Surface Guards. Home-made wooden guards consist of slats about 8 ft. long, 2-1/2 in. wide, 4 in. high, spaced 4-1/2 in. c.c. using 2-in. fillers and tied together with three 3/8-in. round rods running through slats and fillers. The slats are chamfered on the upper corners. Metal guards are usually patented and consist of rods (replacing the slats), or some one of a variety of designs in stamped sheet metal which, by bending out lugs, make a rough surface, or of rollers. A surface may also be made by a combination of interlocking tiles about 4 in. wide, 15 ft. long, and with their upper surface forming ridges. This type is free from rust or decay but is more liable to breakage.

16. Yards and Terminals

(Condensed from Definitions and Recommended Practice of the American Railway Engineering Association, as published in its " Manual.")

A Yard is a system of tracks within defined limits for receiving, separating and making up trains, storing cars and other purposes. A large yard will have some or all of the following features. An incoming train leaves the main track and enters a receiving yard where the train may wait temporarily until the separation of the cars begins or may be moved to a separate holding yard if not ready for the separating yard (or classification yard). The train runs from the receiving yard to the separating yard, in which the cars are separated according to district, commodity or other required order. Some cars will be run to a classification yard in which cars are classified or grouped in accordance with requirements preliminary to forwarding in trains although sometimes a sorting yard, in which cars are classified in greater detail, is provided between the classification and departure yards. Some cars may be sent to a storage yard, awaiting further disposition. Others will be sent to special tracks referred to later. The cars which are to be sent out of the yard are then sent to the departure or forwarding yard, where they are assembled into trains. The distribution of separate cars onto various tracks is often accomplished by pushing them over a summit, beyond which they run by gravity. Such a yard is called **a summit or hump yard.** In rare cases natural grades are such that cars will run down them onto classification tracks, giving a true **gravity yard.** A yard in which the classification is accomplished by the use of a pole operated by an engine on an adjacent parallel track is called a **poling yard.** A yard, usually small or cramped for room, in which movement of cars is accomplished entirely by engines, is called a **tail-switching** or **"push**

and pull" yard. Tracks in a group or a set of parallel tracks all used for some one purpose are called **body tracks.** They should be spaced from 13 to 14 ft. c.c. A group of such tracks all lead into a **ladder track** which should be not less than 15 ft. c.c. from any parallel track. No. 8 is the minimum frog number which should be used on such tracks. The track connecting either end of the yard with the main line is called a **lead track**, which should be interlocked with the main line. Running tracks and open tracks are provided so as to permit the free movement of cars and switching engines from any portion of the yard to any other. When riders are used to control cars on classification tracks a rider track may be used for the gasoline car which takes them back to the hump or they may be required to walk back. Many large yards are now equipped with car retarders which control the speed of cars by pressing against the sides of the wheels. These, together with switches, and "skates" for stopping cars quickly, are operated from towers by one man in each tower, thus eliminating riders and switch tenders. Caboose tracks should be located between the receiving and forwarding yards, and are preferably so constructed that a caboose may be readily pushed thereon from a receiving track and then dropped by gravity to the train departing in the direction from which the caboose has arrived. Scale tracks should be located between the receiving and separating yards. Coaling, ash-pit, sand and engine tracks should be located on the route to and from the engine house; they should be so arranged that water, coal and sand may be taken and ashes disposed of in convenient rotation and also provide that switching engines may clean fires, take coal, water and sand and pass around the waiting engines. Bad-order tracks should be convenient to the classification yard, so that bad-order cars may be set off and easily run to the repair tracks. The repair tracks should have a maximum capacity of about 15 cars each and should be spaced alternately 16 and 24 ft. apart c.c. Fifty linear feet of track should be estimated in rating the capacity of freight-car repair tracks, in order to provide working room about each car. Parts of the yards should be provided with air and water pipes with outlets 50 ft. apart for testing cars. A materials supply track should be placed in the space between each pair of repair tracks. Heavy freight car repairs should be made under cover in a shop provided with overhead traveling cranes to facilitate heavy lifting. Icing tracks should be located between the receiving and separating yards so that the cars to be iced may readily be moved from the receiving to the icing tracks and thence to the separating yard. A coach-cleaning yard should be located for ready and quick access to and from the station. The tracks should be long enough to accommodate trains without cutting, and should preferably be stub-ended, with a car cleaners' repair supply building located at right angles at their ends. Yard track capacity is estimated by allowing 42 linear ft. of track to each car. Team delivery yards should be located convenient to the freight house so that the receipt and shipment of freight may be easily under the control of the freight agent's force. The tracks should be stub tracks in parallel pairs, the tracks of each pair 12 ft. between centers and the pairs 52 ft. between centers. For convenience of shifting, the tracks should have a capacity of about 20 cars each. A crane for handling heavy freight should be provided. If possible, ingress and egress for teams should be provided for at each end of each teamway. Wagon scales should be provided near the team entrance of the yard, and track scales should be provided and located for convenient switching.

A Hump Yard should have receiving, classification and departure tracks. Trains may be handled through it faster and at less cost than through any other form of yard. The receiving tracks should be of sufficient length to hold a maximum train, and should be sufficient in number to hold as many trains, arriving in quick succession, as the character of the traffic renders

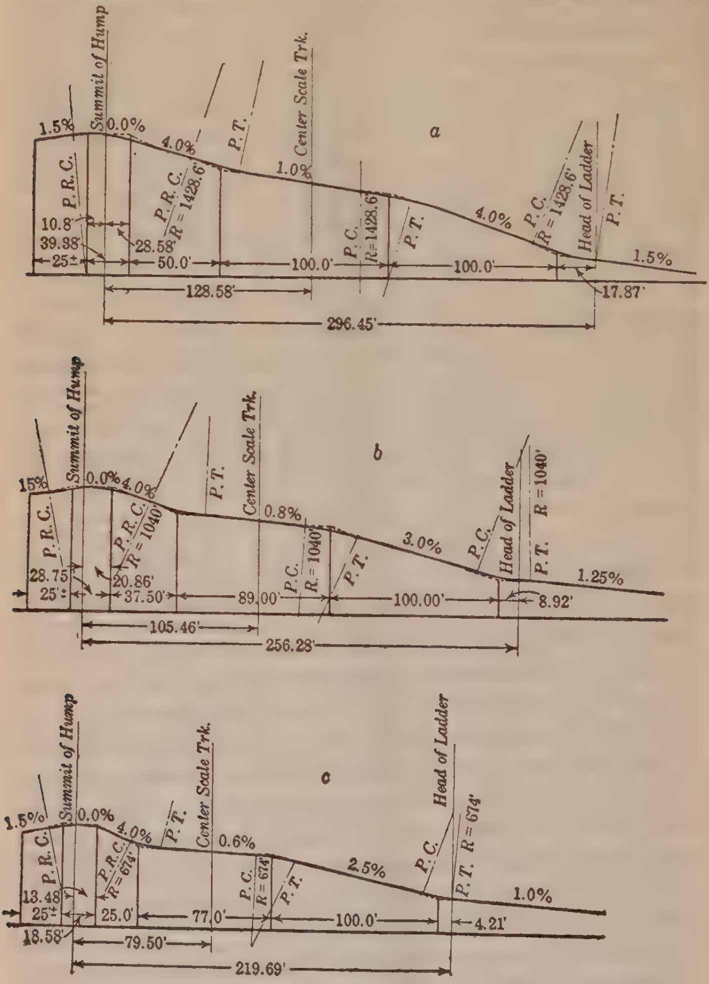

Fig. 43

probable. If possible the grades of the receiving tracks should be such that one engine can push the maximum train over the hump. The length and number of the classification tracks depend on the number of classifications required, number of cars in each classification, whether or not a sorting yard is used, etc. Classification of through traffic may often be shifted from one yard to another with advantage. The departure tracks should be of full train length and sufficient in number to provide ample standing room for trains while being tested for air and while waiting for engines. An air hose and an air brake testing plant shall be provided conveniently near the departure tracks. The grades recommended for hump yards by the American Railway Engineering Association are shown in Fig. 43, *a* being for cold, *b* for moderate and *c* for warm climate. These are for mixed traffic; empty cars require somewhat steeper grades and loaded cars lighter ones. Where the traffic and climatic conditions require it, the grades should be made steeper in winter and restored again in the spring. When required, scales should be located as shown so that when the car to be weighed reaches the scales it will be properly spaced from the following cars and running slowly enough to render correct weighing easy. For average conditions it is recommended that a No. 8 frog be the sharpest used for classification yards.

Freight Houses. For an inbound-freight house 50 ft. is recommended as good average width. Platforms should be provided beside the tracks and continuous doors so as to obviate the necessity for spotting cars. For an outbound freight house the recommended width is 30 ft. It is not advisable to load through more than four to six cars. For a very great number of cars there should be stub tracks in pairs with covered platforms between the pairs, the platforms leading to the freight house at the ends of the tracks. For a roadway between freight house on one side and wall on the other, minimum width 30 ft.; with team track or another freight house on the other side, minimum clear width 40 ft.

Stock Yards for receiving cattle vary from a small pen at a way station to a series of large pens at a terminal. They include arrangements for feeding and watering, as well as loading and unloading.

STEAM RAILROAD EQUIPMENT

17. Water Stations

Chemical Treatment is necessary when the water contains objectionable amounts of incrusting or corrosive matter or of alkali salts and is desirable for practically all natural waters, especially those containing even a fraction of a grain of calcium or magnesium sulfate. When water is boiled at a pressure of over 60 lb. the carbonates of lime and magnesia will precipitate and form mud or soft scale whose presence in the boiler is objectionable. It may be blown off but this wastes water and more or less heat. The sulfates of lime and magnesia when boiled form a hard scale which adheres to the tubes and is only removed with difficulty. Treatment with lime in a tank will precipitate the carbonates, which are thus easily removed. The cost of this treatment is very moderate. The use of sodium carbonate (or soda ash) in a water containing sulfate of lime will produce carbonate of lime, which precipitates forming soft scale and also sulfate of soda which is objectionable because of its effect on "foaming." **Foaming** is primarily due to suspended matter in the water but is aggravated by the alkali salts, sulfate, carbonate or chloride of sodium, and is objectionable because it is difficult to maintain the proper amount of water in the boiler and keep wet steam out of the cylinders. If the sulfate hardness is very great the water is practically worthless, since too much alkali salts would be developed by treatment. Even when the sulfate hardness is very low hard scale and corrosion will result unless a little soda-ash is used and boilers blown down frequently. Filters of various types have been tried in connection with water softening plants with varying results. They are more used for purifying water for drinking purposes.

The Quantity of pure reagents required to remove 1 lb. of various scaling and corroding substances is given in the following table. These should be increased to give equivalent quantities of pure reagents in case commercial products are used. The pounds of matter per 1000 gal. may be found by dividing parts per 100 000 by 12 or grains per gal. by 7. The total amount of lime must be sufficient to take care of the free carbonic acid as well as the solids.

Reagents Required for Water Softening. Per Pound of Substance

American Railway Engineering Association

Substance	Reagent and amount	Foaming Matter Increased
Sulfuric acid	0.57 lb. lime and 1.08 lb. soda ash	1.45 lb.
Free carbonic acid	1.27 lb. lime	None
Calcium carbonate	0.56 lb. lime	None
Calcium sulfate	0.78 lb. soda ash	1.04 lb.
Calcium chloride	0.96 lb. soda ash	1.05 lb.
Calcium nitrate	0.65 lb. soda ash	1.04 lb.
Magnesium carbonate	1.33 lb. lime	None
Magnesium sulfate	0.47 lb. lime and 0.88 lb. soda ash	1.18 lb.
Magnesium chloride	0.59 lb. lime and 1.11 lb. soda ash	1.22 lb.
Magnesium nitrate	0.38 lb. lime and 0.72 lb. soda ash	1.15 lb.
Calcium carbonate	3.15 lb. barium hydrate	None
Magnesium carbonate	3.76 lb. barium hydrate	None
Magnesium sulfate	2.62 lb. barium hydrate	None
*Calcium sulfate	2.32 lb. barium hydrate	None

* In precipitating the calcium sulfate, there would also be precipitated 0.74 lb. of calcium carbonate or 0.31 lb. of magnesium carbonate, the 2.32 lb. of barium hydrate performing the work of 0.41 lb. of lime and 0.78 lb. of soda ash, or for reacting on either magnesium or calcium sulfate, 1 lb. of barium hydrate performs the work of 0.18 lb. of lime and 0.34 lb. of soda ash, and the lime treatment can be correspondingly reduced.

These data will enable one to determine the quantities of reagents necessary to treat a given water and local quotations will supply data for a cost estimate. The cost of operation (aside from chemicals) will depend largely on the method used and local conditions and may be very little in addition to the cost of operating a water plant.

Concentration of foaming solids reaches the critical point between 100 and 200 grains per gal., depending on the character of the alkali salts and the amount of suspended matter in the water. Systematic and frequent blowing off and occasional complete blowing down and washing out at terminals are the best means for keeping below this limit.

The cost equals the cost of pumping, treating and heating to boiler temperature the amount of water blown off, plus cost of washing out boiler. With the limit 100 gr. per gallon the percentage of wastage equals the number of grains per gallon in the water supplied, for other limits the per cent varies inversely as the limit.

A committee of the American Railway Master Mechanics Association estimated in 1873 that the use of hard or muddy water in parts of the country cost $750 per locomotive per year. The Committee on Water Service and Sanitation of the A. R. E. A. estimated the cost at $4000 to $6000 per year per locomotive for present locomotives at present prices. This cost is made up of extra repairs, extra fuel, boiler washing, time out of service, etc.

As a further illustration of the importance of the subject, the El Paso and Southern

Railway found that even after chemical treatment of the hard-water supply on a division 128 miles long, the engine tonnage was reduced 25% and the cost of locomotive maintenance was increased $1000 per year per engine over the normal amount. To avoid this a waterworks system from a supply of pure mountain water 130 miles distant was constructed at a cost of $1 300 000. Even this expenditure was proven to be amply justified.

Tests have proven that for a scale thickness of, say, 1/8 in. the loss of heat transmission may amount to 10 or 12%. A porous scale increases the heat loss even more than a solid scale. The chemical composition has no practical effect except as it may produce a porous scale. The heat loss increases as the thickness of the scale.

In 1928 there were nearly 900 lime-soda plants treating about 120 million gallons daily, 650 plants using soda-ash, or sodium aluminate, only, treating 45 million gallons daily, 330 plants mixing anti-scale compound with 39 million gallons of water daily in wayside tanks and 35 zeolite plants softening 8 million gallons daily, while anti-scale compounds were used with 40 million gallons daily in boilers.

Supply. The American Railway Engineering Association recommends the purchase of water where it can be obtained in sufficient quantity and of suitable quality at a reasonable price. Otherwise the source may be springs, lakes, ponds, creeks, rivers or wells and it may be possible to supply the tanks by gravity, although usually pumping will be necessary. The quantity and quality of the water should be investigated for a sufficient time to give accurate results, future increased demands and possible necessity for treatment being taken into account. Ordinarily the quantity should be sufficient if economically possible, to give a 24-hour supply in 7 hours at terminal stations and 4 hours at intermediate stations, except for large stations when one may figure on 10-hour or even, 20-hour pumping service.

Pumping. The American Railway Engineering Association recommends the use of the following table for determining the size of pumping plants.

Quantity per 24 hours, gallons	Terminal stations		Intermediate stations	
	Time pump to run in 24 hours	Gallons per Minute	Time pump to run in 24 hours	Gallons per Minute
	Hours		Hours	
2 000 000	20	1 666	20	1 666
1 750 000	20	1 458	20	1 458
1 500 000	20	1 250	20	1 250
1 250 000	20	1 042	20	1 042
1 000 000	20	833	20	833
900 000	20	733	20	733
800 000	20	666	20	666
700 000	20	583	20	583

300 000	7	714	10	500
250 000	7	595	4	1 041
200 000	7	476	4	833
150 000	7	357	4	625
100 000	7	238	4	416
50 000	7	119	4	208
25 000	7	60	4	104

The effective horsepower

$$= \frac{\text{Gallons per minute} \times (\text{static head} + 1.5 \text{ friction head})}{3960}$$

The friction head should be determined from tables and the 50% added is to allow for ageing of the pipes. Heads are in feet.

With Q = the quantity pumped in 24 hours in 1000 gallon units and H = friction head in feet per 1 ft. of pipe for the given flow, the sizes recommended for discharge pipe are given herewith.

Cast-iron pipe, diameter, in.	Discharge when $\sqrt{Q}$ is most nearly
4	0.355
6	0.437
8	0.519
10	0.656
12	0.820
14	1.162

The Committee on Water Service of the A. R. E. A. stated in its report of October, 1927, that steam plants will usually prove most economical at points where it is necessary to maintain a steam plant for other purposes, as at engine terminals or where track pans are maintained in cold climates. Otherwise the medium pressure oil engine, or so-called semi-Diesel type, is generally the most economical and practicable power unit for all intermittent power service, except where the economies of automatic or remote control make the use of electricity advisable. The relative costs should be computed in detail for each case.

Tanks of ordinary size are commonly built of wood, redwood, cypress, white pine or other approved species. Steel is also used especially for the larger sizes and permanent installations, and a few reinforced-concrete tanks have been constructed with varying results. No doubt these will be more used in the future as they should be permanent and satisfactory if properly constructed. The construction of wooden and steel tanks is now a specialized business which may be left to the builders under general specifications. See Manual of the American Railway Engineering Association. Their capacity usually varies from 10 000 to 80 000 gal. Two or even three smaller tanks are preferable to one excessively large tank.

Capacity, in U. S. Gallons, of Tanks of Various Inside Dimensions

Height, feet	Diameter, feet	Gallons	Height, feet	Diameter, feet	Gallons	Height, feet	Diameter, feet	Gallons
10	12	8 460	14	16	21 057	18	22	51 185
	13	9 929		18	26 650		24	60 914
	14	11 515		20	32 901		26	71 489
	15	13 219		22	39 810		28	82 910
12	14	13 817	16	18	30 457	20	24	67 682
	15	15 863		20	37 601		26	79 432
	16	18 049		22	45 498		28	92 123
	18	22 843		24	54 146		30	105 752

The total cost of wooden tanks per 1000 gal. capacity may be roughly estimated at from \$30 to \$35 for 100 000-gal. tanks, \$45 to \$50 for 30 000-gal. tanks, \$70 to \$75 for 15 000-gal. tanks, to \$130 to \$140 for 5000-gal. tanks. Steel tanks will cost from 25% to 50% more.

Track Tanks, or Pans, are used to give a supply of water while the train is in motion. A scoop, lowered from under the tender, is attached to a pipe leading to the tender tank. The rapid motion forces the water up the pipe from the long shallow pan between the rails. The height of the top of the tender tank above the track pan is usually about 9 ft. and this means that water will not flow into the tank unless the speed of the engine is more than 16 miles per hour. Even at 20 miles an hour more water is wasted by slopping over the sides than reaches the tender. The minimum wastage is about 12-1/2% and occurs at a speed of 45 to 50 miles per hour, although with a properly designed pan the wastage is fairly constant at speeds from 25 to 60 miles per hour.

The track tank is commonly made of 3-16-in. plate, is 19 in. wide, 6 in. deep, bottom rounded to 1-1/2-in. radius, plates are 15 ft. long, riveted with 7/16-in. rivets, 20 rivets per joint; on each side is riveted an angle 1-1/8 by 2-1/4 in.; the edges are stiffened by a molding of 1-1/8 by 1/2-in. bar iron. The Pennsylvania R. R. uses 25-ft. flange sections with special lead joints, thus avoiding the use of rivets. Sides as high as practicable and lips along the sides reduce wastage. For two engines, "double-headers," it is better to increase length of pan rather than to provide storage by increased width. The ties are dapped 1-1/2 in. deep so as to lower the tank a little. At the center of its length it is rigidly attached to the ties. Ordinary track spikes are driven beside the angles, thus holding the tank in place laterally and vertically, but permitting longitudinal expansion with changes of temperature. There are inclined planes at each end, both inside and outside the tank, which will automatically raise the scoop in case the fireman neglects to raise it or lowers it too soon. About 1200 ft. is an ordinary length, although double this is sometimes used where trains are frequent, and the track must be absolutely level, which frequently requires reconstruction of the roadbed. Track tanks are usually placed on tangents but are successfully used on flat curves when necessary. To prevent freezing in winter, steam pipes having 1/8-in. nozzles are inserted every 40 to 50 ft. throughout the length of the tank, and jets of live steam are forced through them from the boiler in the pump house in the "direct" system. In the "circulatory" the water is kept in circulation and steam is fed in with it at the inlets. The size of the required boilers depends on the amount of pumping required and on the severity of the climate, as it affects the demand for steam to prevent freezing. Although 25 hp. would generally suffice for warm-weather pumping, 150 hp. might be required to prevent freezing. The cost of installation may amount to \$10 000 and the cost of maintenance may be \$125 to \$150 per month.

18. Miscellaneous Structures

Coaling Stations. These are located at division terminals and in general near engine houses. **Hand shoveling** of coal from a gondola car directly to engine tender involves delay of car until coal is required. A trestle costing \$250 to \$500, or a convenient natural embankment which lifts the car about 5 ft. above the locomotive track, facilitates the work of shoveling. The shoveling has been done for about 17 cents per ton. To save delaying the cars the coal is sometimes shoveled onto a platform, or bin with low sides, and again shoveled into the tender. This doubles the cost of shoveling and with bituminous coal produces more slack. As an improvement a **jib crane** is set on a platform, which lifts buckets of about one ton capacity and stores them on the platform from which they are again lifted and dumped in the tender when needed. Two quoted costs for this method are 23.2 and 32.0 cents per ton, but in these cases the plants handled only 12 and 13 tons per day. The use of small dump cars rather than buckets at a plant handling 235 tons a day reduced the cost to 17.8 cents per ton. The next step in reduction of operating costs by increase in cost of plant is to construct a **trestle** with coal-car track 30 to 40 ft. above the engine track, the grade of approach not exceeding 5%. Self-dumping cars, dumping the coal directly into bins, eliminate the cost of shoveling and reduce breakage of the coal. The cost of coal handling for 26 such plants varied from 9 to 12 cents per ton. When space for a 5% approach is not available, the grade may be increased to 20%, and the cars hauled up the grade by the use of cable and hoisting engine. Another type is a **locomotive crane,** which is essentially a jib crane mounted on a self-moving car. Such a crane, costing about $7500, can load 70 engines per day. It loads directly from the cars to the locomotive tender and can handle cinders and ashes as well as coal. It is also particularly useful when self-dumping cars are not regularly obtainable, especially since flat-bottom cars are almost useless for many types of coal-handling plants. The average cost of operating seven locomotive crane plants, each handling 106 to 230 tons of coal per day, was 7.3 cents per ton. Another crane handling only 45 tons per day cost 14.0 cents per ton. An added advantage in it is that such a crane may be transported and can be utilized for temporary emergencies, especially where permanent construction is for any reason inadvisable. The bucket conveyor type has the advantage of minimum ground space and indefinite flexibility to suit local conditions, provided the amount of coal to be handled is very large. The advantage and economy are in these particulars. The cost of handling coal in nine plants varied from 9.4 cents to 14.3 cents per ton. Storage bins should be constructed with hopper bottoms so as to facilitate the movement of the coal and also to prevent the accumulation of slack coal which sometimes ignites spontaneously. Coal is sometimes weighed by passing it through auxiliary bins holding 5 to 10 tons and mounted on scales. Sometimes the scales are omitted, and the measuring is done by volume. When sand and cinders are handled in the same plant, the handling machinery should be separate, since sand and cinders produce excessive wear on moving parts. The growing scarcity of lumber is constantly increasing the relative ultimate economy of plants of reinforced concrete and fireproof construction is desirable.

Ash-Pits. The simplest form of ash-pit is made by laying the rails on 12-in. by 14-in. wooden stringers, which rest on cross-ties leaving a net space 4 ft. wide. The stringers and ties are covered with old boiler plate to protect them from the hot ashes. Water service with hose to quench burning cinders and suitable drainage are essential. Although such a pit is justifiable for a road doing small business, mechanical means of handling ashes are recommended for pits serving 25 or more engines per 24 hours. The next step is to construct a pit with concrete walls and bottom and with a clear depth of about 3 ft. Light all-metal cars may be provided in the bottom of such a pit for the prompt removal of the ashes. Another method makes the pit wider and runs one rail on one side wall and the other rail on a series of cast-iron or concrete columns. This affords greater freedom in the removal of the ashes. A variety of designs agree in dumping the ashes from the locomotive into a hopper or car directly under the locomotive. The hopper or car is then drawn out sidewise, or, after the locomotive has passed on, the car is lifted vertically by some form of mechanical hoist and dumped into a gondola car on a storage track. Ashes are also handled by the belt type of conveyor, the same as coal. For large terminals the pits are often filled with water and the ashes removed by a grab bucket operated from a gantry, traveling, or locomotive crane.

Sand Houses. A sand house consists essentially of a wet sand storage bin and a sand drier and screen. The dried sand may be stored in buckets from which it may be dumped by hand into the sand boxes on the engine. A more elaborate and economical plan uses compressed air to pump the dry sand into an elevated storage tank from which it falls by gravity through a pipe to the engine.

Oil Houses. The essential features are a fireproof place of economical construction for the storage of oil, combined with conveniences for its distribution. The oil should be stored in tanks located in the basement, the basement having masonry walls and the floor above being made preferably of reinforced concrete. A trap door of fireproof materials should be the only opening into the vault beside the pipes. No illumination except electric lights should be permitted. The vault is surmounted by a house which may be of wood, and which is used for pumping the oil from the tanks into small cans for distribution. Since the oil is put in and removed entirely by pumping, the vault need not be opened except for occasional inspection and repairs.

Track Scales for freight-car service have a capacity of from 100 to 150 tons. The platform is generally from 36 to 46 ft. long, but the length is sometimes increased to 60 ft., which permits the weighing of cars without stopping them as they cross the scales on a gravity track. Scales 100 ft. long have been built, but their use is diminishing on account of greater unreliability. To economize yard room and yet not subject the scale mechanism to needless wear, a pair of through rails is run about 10 to 12 in. from the weighing rails. One of these through rails rests on the wall of the scale pit and the other rests on iron posts which extend through the platform and are separate from it. The weighing rails switch into the through rails by means of point rails at about one rail length each side of the scales. The cost varies from about $35 to $45 per ton capacity, according to capacity and style, the lower prices applying to the larger-capacity scales.

Turntables. Length for modern locomotives must be from 60 up to 100 ft., the most common length being about 80 ft. The pivot pier foundation must be designed for a load of perhaps 300 tons. The depth of the pit depends on whether a deck table or one made of two pony girders is used. The circular walls of the pit should be made of masonry, but are sometimes made of wood. They must support the circular rail on which the end of the table runs when unbalanced. The pit floor should be paved. A drain pipe with suitable outfall should be provided. The cost of an 80-ft. steel turntable will vary from $4500 to $8000 according to the details of depth of foundation, lining of pit, etc. Temporary structures which will serve the purpose for light-weight engines may be built for $700 to $800 where timber is cheap.

19. Signaling and Interlocking

(The following has been condensed by permission from the Manual of the American Railway Engineering Association. It is largely a statement of "recommended practice.")

Signals, if practicable, should be placed either over (on a signal bridge) or upon the right of and adjoining the track to which they refer. Semaphore arms which govern should be displayed to the right of the signal mast, as seen from an approaching train. A mast may have a crosspiece on which two uprights (no more) may be mounted on which to place signals. One upright may be a stub to indicate that the corresponding track has no governing signals. Not more than one track should intervene between a bracket signal mast and the track for which its left upright carries a signal arm. There should be a definite place for flags and hand lanterns when used for signals; they should be fixed by a flag socket and lantern hook on the side of the signal station toward the direction of an approaching train and convenient for the operator to reach from one of the windows. The common semaphore for either train order, interlocking or automatic block signal is as shown in Fig. 44 for indications in the lower quadrant, the upper quadrant is now recommended and many roads are discarding the semaphore signal entirely in favor of color-light or position-light indications. The greater simplicity and elimination of moving parts tend toward greater reliability. Light signals are usually mounted in a circular box much like the older "banjo" signals. The arm should have a sweep of 90 deg. The design may be used for either a two-position or a three-position signal. When the lamp is on the side (as in figure) spectacle *A* is always blank. Spectacle *B* has red glass. Spectacle *C* is red for a two-position signal and yellow or green (whichever color is used for "caution") in a three-position signal. Spectacle *D* is white or green, whichever color is used for "clear." The American Railway Association recommends use of red for stop, yellow for caution and green for clear. Sometimes for economy on a single-track road the post is cut off so that the lantern is placed on top of the post directly back of (*A*) in the figure and another arm and spectacle casting is swung on the other side of the pole. In such a case spectacle *A* is red; *B* is red for two-position and yellow or green for three-position signal (like spectacle *C* in other design); spectacle *C* is white or green and spectacle *D* is blank. It is recommended that the "electric slot," an appliance for automatically disengaging the signal arm connection from its actuating lever and returning signal arm to "stop," as a train passes, should be utilized. High-speed movements should be governed by high signals and low-speed movements by low signals. Not more than two high-speed signals should be displayed on one mast, the top arm to govern unrestricted speed and the lower arm to govern all other high speeds. All low-speed movements should be governed by one-arm low signals of dwarf construction. A distant signal should be provided for each high-speed route. "Red" should be the "color" stop indication, and the "horizontal" position of the arm should be the "position" stop indication for all home signals. A mark of distinction should be made between automatic block signals and all other home signals, whether interlocking, train-order or manually operated block signals. Home block signals should be provided at all interlocking plants used as block stations. All mechanically operated high-speed semaphore signals should be pipe-connected. Low-speed signals may be wire-connected. One distant signal only should be provided for a high-speed route, and when "clear" it should mean that all high-speed home signals along that route through the interlocking plant, including the home block signal, are "clear." Every movement within the limits of an interlocking plant should be governed by an interlocked signal.

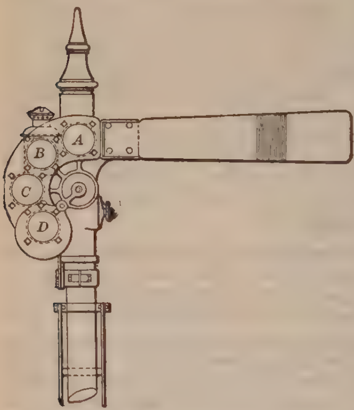

Fig. 44. Semaphore

The decrease in 1928 was due to the hesitancy of the roads to proceed with signaling programs while the question of the adequacy of existing train control and signaling installations was before the Interstate Commerce Commis-

Miles of Road Equipped with Automatic Signals, 1908-1928

Year	Miles	Year	Miles	Year	Miles
1908	1387.6	1915	1296.0	1922	1254.0
1909	2047.1	1916	1891.0	1923	2019.0
1910	3473.8	1917	2482.0	1924	2515.0
1911	2623.4	1918	1934.0	1925	2726.0
1912	1883.9	1919	1923.0	1926	4992.0
1913	4350.5	1920	546.0	1927	5127.0
1914	3294.2	1921	830.0	1928	3121.2

sion. The increasing preference for light signals is indicated by the installation of 3601 light signals out of a total of 5536 automatic signals installed in 1928; of these 3226 were color-light and 375 position-light.

The trend in interlocking practice as indicated by construction in 1928 is as follows: 88 new plants were constructed of which 24 were mechanical, 33 electrical, 8 electro-pneumatic and 23 electro-mechanical. The 382-lever electric plant installed at Buffalo, N. Y., by the New York Central is said to have the largest number of levers of any one plant in the world.

Automatic Train Control installations in 1928 were virtually limited to the completion of projects already under way and voluntary extensions by some roads of existing installations, as the Interstate Commerce Commission, believing that a far greater measure of safety will result from vigorous efforts to curtail the large number of accidents arising from other causes than disregard of signals, issued no new orders. The use of cab signal indications, however, increased rapidly and it is believed that future development will be in this direction without automatic brake control. The substitution of remote control of switches and signals for train orders and manual operation of switches is another important development which is being used to effect economies both in dispatching and operation of trains, since they do not have to stop to throw switches or for signals if the block is clear. Spring switches are also being used increasingly to eliminate stops at the ends of double track, at yard leads and at certain sidings where movements in one direction predominate.

20. Locomotives

Classification, according to wheel arrangement, is now usually indicated by three numbers, of which the first is the number of pilot-truck wheels, the second the number of drivers and the third the number of trailing wheels

Classification of Locomotives

Name	Type	Name	Type
Mikado	2–8–2	Santa Fe	2–10–2
Switching	0–8–0	Ten-Wheel	4–6–0
Switching	0–6–0	Mogul	2–6–0
Switching	0–4–0	Mastodon	4–8–0
Consolidation	2–8–0	Mountain	4–8–2
Mallett	A–B–B–C*	Atlantic	4–4–2
Pacific	4–6–2	American	4–4–0
Decapod	2–10–0	Mohawk	4–8–2

* A and C are truck wheels, usually 2 or 0, and B are drivers, usually 6 or 8. There may be three sets of drivers, as 2–8–8–8–2 for the large Mallett mentioned below, the third set being under the tender in this case.

although originally each type was given a name. All three numbers are given even though one, or two, of them is zero. For example, the common American type having four pilot wheels, four drivers and no trailing wheels is indicated by 4-4-0; the six-wheel switching engine, having neither pilot nor trailing wheels, by 0-6-0.

Steam Locomotives Built Each Year, 1896 to 1928

* Includes Canadian output.
† Includes Canadian output and those built in railroad shops.

Taken year by year the numbers are rather erratic but reflect in a general way economic conditions, modified of course by estimates of railroad officials of probable traffic requirements. Just prior to 1918 the rapid increase in traffic stimulated buying, but since that time passenger traffic has decreased approximately one-third and the rate of increase of freight traffic has been slower. These decreases together with the better utilization of equipment have made possible the storing of about 5000 serviceable locomotives for the past two years and naturally purchases have been low with this amount of power in reserve.

The trend as to types as indicated by the locomotives ordered in 1928 is definitely toward the heavier types with trailing trucks, probably influenced greatly by the increasing use of boosters to assist in starting and at low speeds though 58 tenders with auxiliary engine for booster service were ordered also. The Mountain type, 4-8-2, seems to have the preference with a total of 146, although 100 of these were ordered by one road, the New York Central. Excluding this large order, several other types had nearly the same number as follows: 2-10-4, 46; 4-8-4, 41; 2-8-4, 39; 4-6-4, 35; 2-8-2, 30 and 4-12-2, 23. Of the older types there were: 4-6-0, 11; 4-6-2, 9; 2-8-0, 7; 2-6-0, 2 and 4-4-0, 1. Eighty-six switching locomotives were ordered, a majority of them of the heavy 0-8-0 type, also 31 Malletts, 25 geared, 5 of the 4-6-6 type and 2 of the 2-6-2. Besides these steam locomotives 13 oil-electric and 50 electric locomotives were ordered for domestic use, all with all the weight on drivers except 25 electrics of the 2-6 + 6-2 type and one electric of the 2-8-2 type. On Dec. 31, 1927, there were 449 electric locomotives in use on Class 1 railways, about one-third in freight service and two-thirds in passenger.

Number and Average Tractive Force — Steam Locomotives Class 1 Railways 1916-1927

End of year	Number	Average tractive effort	End of year	Number	Average tractive effort
1916	60 990	33 188	1922	64 140	37 441
1917	61 533	33 932	1923	64 939	39 177
1918	63 531	34 995	1924	65 006	39 891
1919	64 618	35 789	1925	63 612	40 666
1920	64 368	36 365	1926	62 342	41 886
1921	64 585	36 935	1927	60 895	42 798

The steady and fairly uniform increase in the average tractive force of the locomotives operated on Class I railways is shown in the statistics of the Interstate Commerce Commission given in the above table. That this increase is likely to continue is indicated by the fact that the average tractive force for the 322 locomotives ordered in 1928 for which data are given was 64 372 pounds. The average tractive force for the 13 oil-electric locomotives was 41 923 lb. and for the 13 electric locomotives for which data are given was 24 426 lb.

Weights. These vary from about 25 tons for a 4–4–0 type of narrow-gage locomotive to that of a Mallett standard-gage locomotive weighing 853 050 lb. with 63 466 lb. on each of twelve driving axles. Between these limits there are locomotives of any total weight and any reasonable ratio of driving weight to total weight though the limits in any given type would of course be smaller.

Some general data for typical recent locomotives are given in the following table. All are simple engines except the Norfolk & Western Mallett (see cylinder dimensions). The largest locomotive built in 1928 was a single-expansion articulated, one of the 2–8–8–4 type weighing with tender 1 116 000 lb. It is exceeded in weight on drivers 554 000 lb. and tractive force (with booster) 153 000 lb. only by the Erie Triplex locomotive built in 1914 and the Virginian Triplex built in 1916. It was built by the American Locomotive Co. for the Northern Pacific Railway and was designed to burn lignite of relatively low heating value. Hence it has the largest combined heating surface, 10 892 sq. ft., and by far the largest grate area, 182 sq. ft., of any locomotive in existence. The stoker is designed to deliver a maximum of 20 tons of fuel per hour and the maximum evaporating capacity of the boiler is 14 400 gal. of water per hour.

The Tractive Force of a locomotive may be limited by any one of three factors:

(a) Frictional force or "adhesion" between drivers and rail, a function of the weight on the drivers.

(b) Capacity of the boiler to produce steam, depending on design of boiler, fuel, water and stoking.

(c) Capacity of the mechanism to convert the energy of steam into motion, depending on size of cylinders and drivers.

At low speeds, adhesion is usually the limiting factor as most locomotives are "over-cylindered" and the rate of steam consumption is low; hence they are able to "slip their drivers" and the tractive force using sand may be as much as one-third the weight on the drivers, although it is not usual to count

on more than one-fourth as a maximum. As the speed increases a point is reached where the boiler is no longer able to furnish steam at full cut-off and maintain its normal pressure. So the cut-off is reduced and the "Mean Effective Pressure" becomes smaller and smaller as the speed increases. Hence boiler capacity limits tractive force at speeds beyond the point mentioned above as could be expected, since weight on drivers and size of cylinders can be increased easily while the size of the boiler is limited.

Determination of Tractive Force. The tractive force of a locomotive may be determined by actual measurement with a dynamometer car or at a locomotive testing plant or by computation. With a dynamometer car, speeds, alignment and grades must be accurately known in order to make the proper allowances. The American Railway Engineering Association recommends that speeds be determined to the nearest 0.1 mile per hour. Cylinder power may be determined by means of indicator cards and used to find tractive force. By computation: for low speeds (or maximum tractive force) one may simply take one-fifth to one-fourth the weight on the drivers, assuming reasonably good design. For higher speeds, recourse must be had to the theoretical formula with empirical coefficients or to empirical methods. Let P = the boiler pressure in pounds per square inch; S, the length of stroke in inches; d, the diameter of piston for simple engines; d_h and d_l, the diameters of high-pressure and low-pressure pistons respectively for compound engines; R, the ratio of the area of the low-pressure to the high-pressure cylinders; D, the diameter of drivers; and T.F. the tractive force at the circumference of the drivers. In a simple engine the work done by both cylinders during a complete revolution of the drivers = piston area × effective average cylinder pressure × stroke × 2 × 2. But the work also equals the tractive adhesion developed at the circumference of the drivers × the distance traveled by the drivers during one revolution, which of course equals the circumference of the drivers. Therefore, for simple engines,

$$\left.\begin{array}{l}\textbf{Theoretical}\\ \textbf{tractive force}\end{array}\right\} = \frac{\textbf{Piston area} \times \textbf{effective cylinder pressure} \times \textbf{stroke} \times 2 \times 2}{\textbf{circumference of drivers}}$$

The effective area of the piston is reduced about 1.5% on account of the area of the piston rod. The effective energy at the wheel rim is reduced on account of friction of the piston, piston rod, crosshead and the various bearings. The effective steam pressure in the cylinder is always considerably less than that in the boiler, even at low speed and full cut-off. These reductions may be allowed for by figuring the steam pressure (effective at the drivers) to be 80 to 85% of the boiler pressure. Therefore, dividing both numerator and denominator by π(3.1416) we have

$$\text{T.F.} = 0.8\ Pd^2S/D \quad \text{(for simple engines)}$$

To prevent racking the engine frame, two-cylinder compounds or four-cylinder compounds of the Baldwin type are designed with R at such a ratio that the work done by the high- and low-pressure cylinders is approximately equal. Although there is not such necessity for balancing with a tandem compound, the same ratio is used, which averages 2.81. The formula is

$$\text{T.F.} = \frac{PS}{D}(.67d_h^2 + .25d_l^2) \qquad \left(\begin{array}{c}\text{for Baldwin compounds and}\\ \text{tandem compounds}\end{array}\right)$$

Even greater power may be temporarily obtained when starting a train, or, in an emergency, on a grade (if not limited by poor adhesion) by exhausting from the high-pressure cylinder directly to the atmosphere and by admitting high-pressure steam directly into the low-pressure cylinders. Of course all economy due to compounding is lost while this is done.

The Tractive Force of a Two-Cylinder Compound, when the work is equal in both cylinders, and when working compound, is

$$\text{T.F.} = \frac{.8\ Pd_l^2S}{(R+1)D} \qquad \text{(for two-cylinder compounds)}$$

As before, the tractive force may be increased when starting by exhausting the high-pressure cylinder directly into the atmosphere and by admitting boiler steam to the low-pressure cylinder through a special valve which proportionately reduces its pressure. Here the T. F. is the same as that of a simple engine with both cylinders of the same diameter as the high-pressure cylinder.

The Equivalent Diameter of Simple Cylinders which, with the same boiler pressure, diameter of drivers, and stroke, will have the same tractive force, may be expressed as follows, when all cylinders perform the same work:

$$\mathbf{d} = \sqrt{\frac{\mathbf{d}_l^2\mathbf{d}_h^2}{\mathbf{d}_l^2 + \mathbf{d}_h^2}} \qquad \text{(for two-cylinder compounds)}$$

$$\mathbf{d} = 1.41\sqrt{\frac{\mathbf{d}_l^2\mathbf{d}_h^2}{\mathbf{d}_l^2 + \mathbf{d}_h^2}} \qquad \text{(for four-cylinder compounds)}$$

The Tractive Force as a Function of the Velocity is expressed by the following formula by Isaacs and Adams (Bulletin 112, Am. Ry. Eng. and M. W. Assoc.), the notation being somewhat revised to correspond with that given above, and in which V = train speed in miles per hour,

$$\text{T.F.} = d^2P\frac{S}{D}\left(0.95 - \frac{392\ S}{11\ 000\ D}V\right)$$

The reduction of tractive force with increase in velocity is shown in the table (computed on the basis of the above formula) in which is given the ratio of tractive force at speeds between 10 and 30 miles per hour to the tractive force at 10 miles per hour for engines with five combinations of ratio of stroke to diameter of drivers.

Cylinder diameter is for high-pressure cylinders in compounds. Superheat of 200° F. and drop of 5 lb. per sq. in. between boilers and cylinders are assumed.

The American Railway Engineering Association recommends the following method of determining tractive force. Assuming that the maximum amount of coal that can be fired is 4000 lb. per hour for hand-fired locomotives and 6000 lb. per hour for stoker-fired locomotives with grates of less than 70 sq. ft. and 8000 lb. per hour for stoker-fired locomotives with grates of more than 70 sq. ft., find the rate of steam production from the first table on p. 2071.

The steam used per revolution at full cut-off equals the quantity given in the second table on p. 2071 multiplied by four times the length of the stroke in feet for simple and four-cylinder compounds and by twice the length of stroke in feet for two-cylinder compounds. The weight of steam produced by the boiler per minute divided by the weight used per revolution will give the maximum number of revolutions per minute at which full cut-off can be maintained. The corresponding train speed is found by multiplying by the diameter of the driver in inches and dividing by 336.13 and this speed is called M.

The pounds of steam used per i. hp.-hr. at speed M are:

	For Locomotives Using Saturated Steam						
Gage pressure...	160	170	180	190	200	210	220
Simple.........	39.45	39.10	38.80	38.53	38.30	38.11	37.99
Compound.....	26.57	26.34	26.14	25.95	25.80	25.67	25.59
	For Locomotives Using Superheated Steam						
Simple.........	24.72	24.50	24.31	24.14	24.00	23.88	23.81

The steam produced per hour, divided by the amount used per i. hp.-hr. will give the i. hp. at speed M and the corresponding tractive force = 375 times i. hp. divided by M (in miles per hour). The tractive force at other speeds may then be found by use of the preceding tables.

The cylinder tractive force must be reduced by the engine resistance (see p. 2074) to give draw-bar pull and the tractive force between drivers and rail found by the theoretical method should be reduced by items " b " and " c " of those resistances, although the uncertainty in the value of the coefficients makes it useless to attempt refinements.

The Horsepower Developed by a Locomotive equals the actual tractive force developed, multiplied by the speed in miles per hour, and divided by 375; if the speed is given in feet per second, divide by 550 instead of 375. An actual test of the draw-bar pull of a locomotive measured with a dynamometer shows that at very low velocities the pull was about 30 000 lb., which corresponded to an adhesion ratio of about 22%. At a velocity of 10 miles per hour the pull had decreased to 26 500 lb. which indicated a development of 706 hp. At 20 miles per hour the tractive force had dropped to 17 000 lb., in spite of the fact that owing to the greater velocity the horsepower developed had increased to 906. At 30 miles per hour the tractive force had dropped to 10 500 lb., which indicated 840 hp. Since the above figures represented draw-bar pulls at the rear of the tender, the actual power developed at the drivers was greater, and the actual horsepower developed by the cylinders was still greater in each case. At low velocities the horsepower increases almost directly as the velocity. At velocities above 13 miles per hour, the horsepower increases very slowly, and at high speeds it decreases as the velocity increases.

Fuel Consumption. Wood is used only where it is comparatively cheap and coal is comparatively expensive. Green wood contains about 50% of

Per cent of Cylinder Tractive Force for Various Multiples of M

moisture and has far less calorific value than dry wood. About 2.5 lb. of dry wood are required to produce the same heat as 1 lb. of average soft coal. One cord of dry hickory will weigh about 4500 lb. and in calorific value equals about 1800 lb. of average soft coal. One cord of average pine will weigh only 2000 lb. and is the equivalent of 800 lb. of coal. **Oil** is used for locomotive fuel where crude petroleum is cheap. One pound has a heat value of about 21 000 B.t.u., or 1.5 times that of the best coal. Less weight to be carried in the tender, ease of handling and firing, more uniform heat, less repairs to firebox and no expenses for ash handling are additional advantages to be considered in comparing relative economy. On Dec. 31, 1927, 7415 locomotives out of a total of 60 895, or over 12%, burned oil for fuel. Its use is constantly increasing. **Anthracite coal** is used on a few railroads passing through the anthracite regions. Its calorific value is no higher than that of the best grades of bituminous and it costs considerably more, but it makes less smoke and soot and for passenger traffic this has its advantage. Wood, oil and anthracite may be considered the exceptions. **Bituminous coal** is the standard locomotive fuel. The average cost of fuel per train-mile in the U. S. increased from 16.8 cents in 1907 to 31.6 cents in 1927. This is chiefly due to the large increase in weight of locomotives and in the weight of trains hauled.

Steam Locomotive Resistances. The American Railway Engineering Association gives (Manual, 1929 Ed.) the following formulas for steam locomotive resistances: (a) Cylinder to rim of drivers: resistance = 18.7 (tons weight on drivers) + 80 (number of driving axles); (b) Engine and tender trucks: resistance = 2.6 (tons weight on trucks) + 20 (number of truck axles); (c) Head end or " air " resistance = $0.02\ V^2A$, in which V = velocity in miles per hour and A = end area (average for locomotives, 125 sq. ft., when resistance = $0.25\ V^2$). Total resistance equals the sum. For example, a consolidation engine weighs, engine and tender, 330 000 lb., with 170 000 lb. (= 85 short tons) on the four driving axles. The resistance between the cylinders and the rims of the drivers = $18.7 \times 85 + 80 \times 4 = 1910$ lb.; the truck resistance = $2.6 \times (165 - 85) + 20 \times 5 = 308$; air resistance at say 20 m. p. h. = $0.02 \times 400 \times 125 = 100$; the total resistance is therefore 2318. At the assumed velocity of 20 m. p. h. the horsepower consumed would be $2318 \times 29.33/550 = 123$, which must be subtracted from the total indicated horsepower to determine the effective power at the draw bar. The above does not include the effect of grade. On a 1% grade there is an additional tax on the engine, merely on account of the weight of the engine and tender of $3300 \times 29.33/550 = 176$ hp. which must also be deducted. It has been found that the resistance between cylinders and rims of drivers is practically constant, regardless of speed, after the bearings have become warmed up.

Rail Motor Cars and Trailers. The use of motor cars on branch and light traffic lines is steadily increasing, the number on Class I Railways powered by self-contained units other than storage batteries having increased from 314 to 502 in the two years, end of 1925 to end of 1927. Over 80% of these are passenger-carrying cars, the remainder being about equally distributed between " company service " and other passenger-train cars. During the same period (1925–27) the number of trailers increased from 447 to 803, nearly all being passenger-cars, 153 motor cars and 22 trailers were ordered in 1928. Most of the rail motor cars built in 1928 have power plant capacities of from 200 to 400 hp., although some have run as high as 800 hp., and weights of from 100 000 to 150 000 lb. Somewhat more than half of the rail motor cars in use have electric transmission, i.e., are gas-electric or oil-electric.

21. Cars

The Total Number of Cars in Service on the roads of the United States on Dec. 31, 1927, was 2 578 535, of which 2.2% were in passenger service; 4.4% were in company service, and the remaining 93.4% were in freight service. There were 9.6 freight cars per mile of line, but only 0.22 passenger cars per miles of line, or one passenger car for 4.6 miles of line. The above figures for the number of cars do not include 288 446 cars, privately owned, largely tank and refrigerator cars. A very large proportion of the sleeping cars in use are "leased." The cars in "the company's service" include chiefly cabooses and gravel cars, together with derrick cars, officers' and pay cars, and other road cars such as maintenance-of-way cars.

The average capacity of all freight cars in 1927 was 45.5 tons. In 1916 it was 40.5 tons and in 1904 it was only 30 tons; this illustrates the growth in average capacity from about 15 tons, which was once the standard.

Only 46 060 freight cars were built for domestic use in 1928, the number each year having steadily decreased from a peak of 175 748 in 1923, this peak having followed 5 years of fairly uniform production averaging about 66 000 per year. The decrease is partly due to better utilization of equipment and partly to the use of steel or steel under-frame construction, which is not only more durable than wood construction but also lends itself better to rebuilding.

General Data for Some Recent Freight Cars

Type	Light weight	Capacity	Length	Width		Height	
				Outside	Inside	Inside	Total
	lb.	lb.	ft. in.	ft. in.	ft. in.	ft. in.	ft. in.

Hopper.....	47 000	140 000	29 6	....	....	....	....

Usual Dimensions of Passenger Cars are: length, 50 to 80 ft.; width 10 ft.; height above the rail, 14 ft. The width and height above the rail are approximately constant, the variations being chiefly in the length. The weight varies from 25 to 70 tons. The all-steel passenger car weighs about 65 tons. The nominal capacity of an ordinary passenger coach varies from 50 to 80 passengers. At 125 lb. per passenger, the total live load will vary from 6250 lb. to 10 000 lb., which is only 8 or 10% of the dead load. On the other hand, a freight car with 100 000 lb. capacity will weigh about 50 000 lb., and the live load is therefore twice the dead load. The proportion of paying load to dead load is therefore many times greater in freight service than in passenger service, which is one reason for the disparity in rates. Practically all passenger cars ordered are now all-steel, and the number averages about 1500 per year. The total number in service in 1928 was about 57 000. All-steel cars weigh from 2 to 4 tons more than wooden cars of the same dimensions but their life is greater and they are superior from the standpoints of safety and sanitation.

Car Maintenance. The relative economy of steel and wooden cars is indicated from a report made on the question of retiring from service 4600 wooden coal cars with a capacity of from 40 000 to 60 000 lb. and with ages varying from 9 to 23 years. It was shown that the annual cost of repairs per wooden car was $95.98 or 37.8% of their present value, whereas 3000 steel cars would have 20% greater capacity than 4600 wooden cars. The amount actually spent on the maintenance of the wooden cars would pay 6% on the cost of the steel cars and leave an annual surplus of $215 000. Experience on the Harriman lines has shown that the average cost of repairs on steel and wooden cars was in the ratio of 100 to 161, respectively.

22. Stations

Essential Requirements of a railroad station, given approximately in the order of their importance, are (1) platform; (2) shelter, developing from shed to waiting room; (3) station agent's office; (4) toilet facilities, developing from a mere privy to modern toilet room; (5) separate waiting room for ladies; (6) baggage and express room. In addition there is the legal requirement in many states that separate waiting rooms shall be provided for colored people. The policy of adding a freight room and agent's living quarters to the station building is debatable. For small stations there are advantages in the method.

The Cost of stations may, when necessary or advisable, be reduced to a very few hundred dollars, which will build a "shelter." As facilities and size are added the cost increases indefinitely. The reader is referred to Orrock's "Railroad Structures and Estimates," Berg's "Buildings and Structures of American Railroads," and similar works for detailed plans, accompanied by estimates of cost, of various types of structures. For use in preliminary estimates the following approximate costs of wooden frame structures, compiled from Orrock's "Railroad Structures," will be found useful, though costs should be modified to take into account differences in prices of materials and labor.

(1) Shelter: platform, 50 × 6 ft.; house, 22 × 12 ft.	$125 to $200
(2) Station: platform, 250 × 8 ft.; waiting room, 10 × 20 ft.; office, 10 × 10 ft.; baggage and express room, 10 ft. × 10 ft. 6 in.	$1000 to $1500
(3) Station: same as (2) but with four rooms in second story for agent's dwelling	$1500 to $2000
(4) Station: same as (2) but with freight room 16 × 20 ft.	$1400 to $1800
(5) Station: waiting room, 16 × 16 ft.; ladies' waiting room, 10 × 20 ft.; office, 12 × 10 ft.; baggage and express room, 16 × 16 ft.; corridor between ladies' room and waiting room and two lavatories; platform 8 × 300 ft. broadened and surrounding the station except at rear	$2000 to $2600
(6) Station: similar to (5) but with four rooms in second story for agent's dwelling	$2500 to $3500

The following unit costs per square foot of ground covered are taken from Gillette's "Hand Book of Cost Data" as being applicable to station buildings in the Mississippi Valley region. The unit costs are somewhat lower than Orrock's estimates. These figures do not include the cost of platform.

	Per square foot
Station, frame, with living rooms, on piles	$1.30
Station, frame, with living rooms, stone foundation	1.50
Station, passenger and freight, frame on piles	1.15
Station, passenger and freight, brick	1.80
Station, modern passenger, brick and stone, slate roof, hardwood finish	3.50

Another method is to allow from 7 to 10 cents per cubic foot for the cost of a frame structure with shingle roof, and from 10 to 12 cents per cubic foot for a brick building.

Add 1/2 cent per cubic foot for slate or metal roof rather than shingle. The higher figures apply to smaller buildings and the figures only apply to plain, unpretentious buildings.

23. Engine Houses and Shops

(Condensed from recommendations in Manual of American Railway Engineering Association)

The Circular Form is preferable although a rectangular house may be desirable when not more than three or four engines are to be housed, or when it is more economical to provide a Y than a turntable, or where engines need not be turned, or at shops where a transfer table is available which may serve engine house also.

A Round House implies a turntable located at its center. The turntable, preferably of the deck type, should be long enough to balance the engine when tender is empty and should be operated by power, preferably electric except where only a few light engines are turned. The turntable pit should be well drained and paved, with side walls of brick or concrete. Pivot masonry of concrete with stone cap. Ties under the circular rail should be supported on concrete walls. The distance from center of turntable to inner line of roundhouse is determined by number of stalls required in a full circle. The angle between consecutive stall tracks should be an even divisor of 180 deg. so that tracks at opposite ends of the turntable will simultaneously line up with it. The clear stall length should not be less than 15 ft. greater than the over-all length of the locomotive. The **interior arrangement** is designed on the basis that the locomotive is always run in with the tender toward the turntable. The entrance doorways should be 13 ft. by 16 ft. clear. The doors should be made of non-corrosive material, fit snugly, operate easily and permit the use of small doors. The walls and roof should be made of non-corrosive material unless protected against corrosion. Security against interruption to traffic from fire warrants the serious consideration of fire-proof construction. Engine pits should be not less than 60 ft. long, with convex floor and drainage toward the turntable. Walls and floors may be of concrete. Supports for jacking timbers should be provided. Smoke jacks with flues not less than 7 sq. ft. in area should be fixed, should have dampers and large hoods and be made of non-corrosive and non-combustible material. The bottom of the jack should be as low as the height of the locomotive stacks will permit, at least 42 in. wide and long enough to receive smoke from stack at its limiting positions, due to adjustments of the driving wheels to bring the side rods at proper position for repairs. The floor should be permanent and be crowned between pits. Drop pits should be provided for truck wheels, driving wheels and tender wheels. When hot-air heating is used, the air should be led through ducts under the floor to the pits under the engine portion of the locomotive. Ducts should be provided with dampers so that air can be turned off when workmen are in the pit. A general temperature of 50° F. to 60° F. is recommended. Air should be heated by exhaust steam in so far as possible. The supply should be taken from the external air and no recirculation allowed. Light should be obtained from the exterior as far as possible and from windows rather than skylights. General illumination, avoiding shadows, should be obtained by using a number of lights between stalls and a plug for incandescent lights should be placed in each alternate space between stalls. Provision should be made for a few necessary machine tools, preferably electrically driven. Piping for air, steam and water supply should be provided.

* Decrease.

25. Cost of Operation

The Average Cost of a Train Mile for the whole United States in the year 1890 was 96.0 cents. It decreased to 91.8 cents in 1895, and steadily increased to nearly $5.00 in 1920, decreasing again to nearly $4.00 in 1922 since which time it has been fairly constant. Although the variations from these figures are large in many cases for individual roads, the average for individual trunk lines is seldom very different from the general average. Whereas the averages for the individual short lines with light traffic will vary considerably from the general average, the average for any group of short lines is usually but little different from the general average, which means that there is no general tendency for the average figure for a short light-traffic line to be either less or greater than the general average.

Classes of Railways. For the purpose of analyzing costs of operation, etc., the Interstate Commerce Commission has divided the railroads into three classes on the basis of the gross annual operating revenue: Class I, over

Average Cost, for United States, of Operating a Train One Mile

Year	Cents	Year	Cents	Year	Cents	Year	Cents
1890	96.006	1900	107.288	1910	148.865	1919	403.972
1891	95.707	1901	112.282	1911	154.338	1920	498.554
1892	96.580	1902	117.960	1912	159.077	1921	429.113
1893	97.272	1903	126.604	1913	170.375	1922	410.594
1894	93.478	1904	131.375	1914	176.917	1923	414.850
1895	91.829	1905	132.140	1915	177.641	1924	397.221

* Excludes switching and terminal, proprietary, circular and unofficial companies, not assigned to one of the classes.

† Excludes switching and terminal companies.

$1 000 000; Class II, $1 000 000 to $100 000; Class III, less than $100 000. About 90% of the mileage comes under Class I.

Classification of Revenues and Expenses. The classification of accounts required of Class I Railways by the Interstate Commerce Commission is quite detailed as will be seen from the following list giving principal groups and number of accounts in each, as well as total amount for the year 1927 and percentage for each group.

Railway Operating Revenues

No.		Totals	Per cent
	Transportation—Rail line, Accounts, 1–16, *inclusive*		
17	Total rail-line transportation revenue	$5 987 603 165	97.58
	Transportation—Water line, Accounts 18–25, *inclusive*		
26	Total water-line transportation revenue	$14 314 408	0.23
	Incidental, Accounts 27–39, *inclusive*		
40	Total incidental operating revenue	$124 792 868	2.03
	Joint Facility, Accounts 41 *and* 42		
43	Total joint facility operating revenue	$9 589 829	0.16
44	Total railway operating revenues	$6 136 300 270	100

Rail-line transportation of freight brought in $4 632 321 165 and of passengers, $974 950 863, the same items for water-line transportation were $11 195 846 and $1 226 773, respectively. Rail-line mail was $143 364 766 and water-line, $12 911. The largest incidental item was dining and buffet, $33 804 372, while revenue from demurrage was $18 472 560.

Railway Operating Expenses

No.		Totals	Per cent
	Maintenance of way and structures, Accounts 1–106, *inclusive*		
107	Total maintenance of way and structures expenses	$868 581 432	18.91
	Maintenance of equipment, Accounts 108–146, *inclusive*		
147	Total maintenance of equipment expenses	$1 219 051 528	26.51
	Traffic, Accounts 148–156, *inclusive*		
157	Total traffic expenses	$120 349 440	2.63
	Transportation—Rail line, Accounts 158–207, *inclusive*		
208	Total transportation—Rail-line expenses	$2 127 505 968	46.31
	Transportation—Water line, Accounts 209–211, *inclusive*		
212	Total transportation—Water-line expenses	$9 481 244	0.21
	Miscellaneous operations, Accounts 213–218, *inclusive*		
219	Total miscellaneous operations expenses	$55 766 966	1.22
	General, Accounts 220–231, *inclusive*		
232	Total general expenses	$191 081 367	4.18
233	Transportation for investment, Cr.	$17 640 124	.....
234	Total railway operating expenses	$4 574 177 821	.....
235	Ratio of operating expenses to operating revenues (per cent)		74.54

The accounts for Class II and Class III railways are successively simplified into a much smaller number, giving less detail.

Some selected major items in the various groups are as follows: Maintenance of way and structures: Superintendence, $57 694 596; roadway maintenance (other than yard), $80 622 921; bridges, trestles and culverts (other than yard), $39 931 216; ties (other than yard), $102 900 409; rails (other than yard), $46 098 032; track laying and surfacing (other than yard), $193 650 381; station and office buildings, $33 451 157 and signals and interlockers, $32 847 323. Maintenance of equipment: Superintendence, $45 858 746; steam locomotives — repairs, $435 564 729; steam locomotives — depreciation, $56 187 354; steam locomotives — retirements, $4 612 516; freight-train cars — repairs, $340 695 795–depreciation, $114 126 553, and–retirements, $17 393 635; and passenger-train cars — repairs, $81 219 354,–depreciation, $18 178 446 and–retirements, $1 603 544. Transportation — rail line: Superintendence, $69 020 593; station employees, $304 859 956; yard conductors and brakemen, $154 362 250; yard enginemen, $90 005 177; train enginemen, $224 609 355; fuel for train locomotives, $321 442 975; fuel for yard locomotives, $64 213 939; trainmen, $265 024 707; and loss and damage — freight, $33 976 470. Miscellaneous operations: Dining and buffet service, $41 365 319 and hotels and restaurants, $7 432 294. General: Salaries and expenses of general officers, $19 720 910; same for clerks and attendants, $93 539 620 and pensions, $24 637 019.

Compensation of Employees increased moderately in the last five years, as shown by the following table, compared with the large increases during the war period with which comparison is difficult due to changes in classification.

Average Number and Compensation of Employees

Group		1922		1927		Percentage increase
		Number	Compensation	Number	Compensation	
Executives, officials and staff assistants	D	15 250	$15.970	16 710	$17.242	7.96
Professional, clerical and general	D	48 451	6.739	52 860	7.290	8.18
	H	229 063	0.566	223 735	0.609	7.60
Maintenance of way and structures	D	4 591	8.875	5 019	9.201	3.67
	H	358 196	0.418	411 753	0.439	5.02
Maintenance of equipment and stores	D	15 336	8.929	16 241	9.028	1.11
	H	439 975	0.602	468 799	0.616	2.33
Transportation (other than train, engine and yard)	D	25 927	3.238	25 536	3.449	6.52
	H	178 782	0.533	176 731	0.564	5.82
Transportation (yardmasters, switch tenders and hostlers)	D	6 042	8.466	6 682	8.727	3.08
	H	17 548	0.614	15 896	0.680	10.75
Transportation (train and engine service)	H	302 082	0.791	315 143	0.840	6.19
All employees	D	116 376	7.541	123 048	8.133	7.85
	H	1 528 857	0.588	1 612 057	0.615	4.59

D indicates daily basis and H indicates hourly basis.

26. Taxes on Steam Railroads

From Interstate Commerce Commission Reports for 1907, 1917, and 1927

The table on p. 2082 gives the total taxes paid per mile of line in the various States during the fiscal years ending June 30, 1907, 1917, and 1927. The figures are given for the three years so as to indicate the increase and its rate. The table is useful to give some idea of the probable taxes on some existing road or a new project, for a few years in the near future. Although all of the increase in some States is undoubtedly due to a proportionate increase, through betterments, in the real value of the roads, in many cases the increase is undoubtedly due to a modification in the method of assessment.

No figures are given to show the relation between the taxes per mile in any State and the capitalization (or any other measure of value) of the roads in that State. The total taxes paid during 1927 amounted to $399 005 000, which is 1.79% of the total capitalization, $24 302 008 000.

27. Territorial Subdivisions of the United States

In order to compare results in different sections of the country the Interstate Commerce Commission at one time divided it into ten districts, later reducing the number to three, the Eastern, Southern, and Western. Finding these rather large for some purposes, the commission divided them as shown in Fig. 45. Some data are now given by Region, others by District.

The following tables make possible interesting comparisons between the various territories. Note for instance the heavy freight traffic and consequent high earnings in the Pocahontas Region and the reverse in the Northwestern and Southwestern Regions with sparse traffic, both passenger and freight.

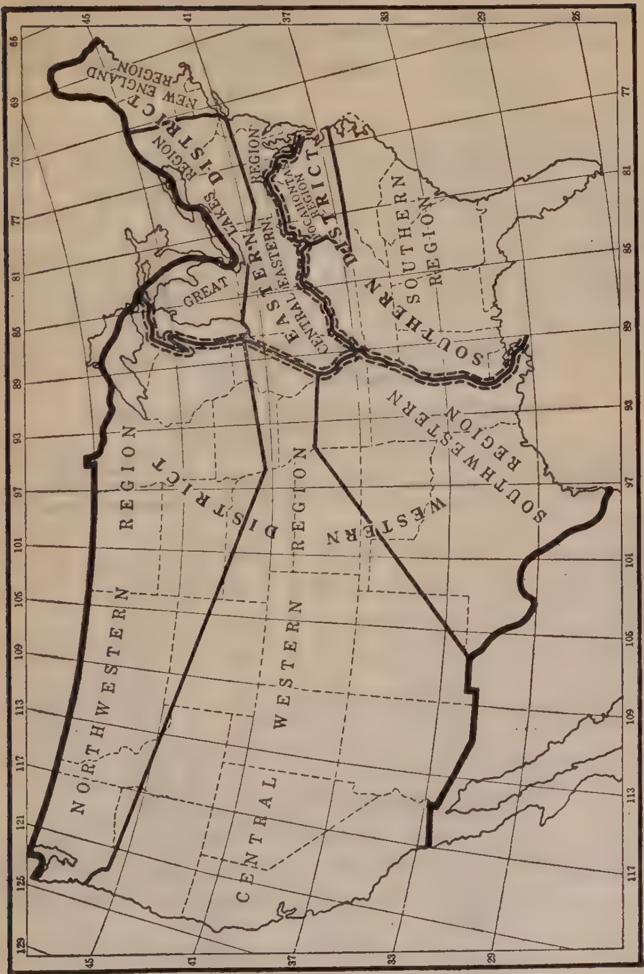

Fig. 45. Map showing subdivisions of the Interstate Commerce Commission

* Non-train accidents included in totals only.

killed in train service accidents, 138 in train accidents, and 281 in non-train accidents. As about 800 000 000 passengers were carried during that year, only one in about nine and one-half million was killed; similarly, the total passenger mileage was 31 500 000 000, which means one passenger killed per 370 million passenger miles. Of courses the chances of injury are much greater, as indicated by the table at bottom of preceding page.

Accidents are more or less fortuitous and hence the data are somewhat erratic, but those for passengers and employees give some indication of results from the " safety first " movement, since accidents to both have decreased markedly, especially in the last decade, a period of fairly constant total traffic in train-miles. Nearly one-half of those killed in 1928 (2968) were killed in grade-crossing accidents, and 6667 were injured.

29. Cost of Railroads

The following items of cost are inserted as a catalog of the expenses which are usually met with and also to give an approximate idea of average costs per mile of track, which may be utilized in approximate preliminary calculations. Except where definite unit costs are given, the estimates are frequently subject to wide variations.

Right-of-way. Land for railroad purposes is valued at a higher rate than for farm purposes on account of consequential damages and injury to adjoining property. Even State Commissions for appraising railroads make an allowance. The Minnesota Commission generally allowed three times the ordinary farm value for farm lands. In cities from 1.25 to 1.75 times the ordinary market value was allowed. In Michigan from 2 to 2.25 times the ordinary market value is allowed.

Clearing. Usually $25 to $100 per acre.

Grubbing. Usually $100 to $200 per acre where required.

Earthwork. When the grading is light, fills are frequently made from borrow pits and the material in cuts is wasted, and then the price per cubic yard applies to the sum of the yardage of cut, and fill plus shrinkage. This price is usually 25 to 60 cents per cubic yard for earth; about 90 cents to $1.50 for loose rock and $1.50 to $3.00 for solid rock. When earthwork is heavy, care is taken to make the fills from the material in the cuts. The disposition of material is directed by the railroad engineer, and the contractor is paid according to the amount excavated. Borrowing is reduced to a minimum, and the contractor is often allowed extra for overhaul, usually 1 to 3 cents per cubic yard per 100 ft., for material hauled in excess of some limit, say 500 to 1000 ft. When only the yardage excavated is paid for and the contractor must make the embankments without extra pay, the price per yard for earth is nearly double the price given above unless machine methods are used when the cost may be about the same as above or even less. Much depends on haul and on local conditions. The prices for loose rock and solid rock will be but little more than the values given above, since the extra work is chiefly due to the loosening. Work in and near cities and on lines under traffic will usually cost more. The grading on all the railroads of Wisconsin was estimated to average $5098 per mile of main line, those in Michigan, $2778 per mile; those in Minnesota, $7372. The variations in this item are evidently very large.

Tunnels. This item is so exceedingly variable that general figures are worthless except those of unit cost. The average of a large number of cases is shown in the following tabular form, condensed from Drinker's Tunneling:

Material	Cost per cubic yard				Cost per lineal foot	
	Excavation		Masonry			
	Single	Double	Single	Double	Single	Double
Hard rock	$5.89	$5.45	$12.00	$8.25	$69.76	$142.82
Loose rock	3.12	3.48	9.07	10.41	80.61	119.26
Soft ground	3.62	4.64	15.00	10.50	135.31	174.42

Bridges, Trestles and Culverts. The price per mile of road is evidently very variable. The average for the railroads of Minnesota was computed at $2576 per mile; those of Michigan, $1027 per mile. Trestle timber in place is worth approximately $85 per M feet; trestle piling in place, 75 cents per lineal foot of pile; pile trestling from $12.00 to $18.00 per foot of trestle; vitrified culvert pipe in place, $2.00 per lineal foot for 18-in., $3.50 for 24-in., cast-iron pipe culverts in place about 8 cents per pound.

Rails. Tons 2240 lb. per mile of track equals 11/7 weight of rail per yard in pounds. Allow 2% for cutting and waste. The freight from mill to delivery point is frequently a considerable gross item. The present price for standard rails is $34 f. o. b. at the mills, while light and rerolled rails are quoted at $34 to $36. Prices of **rail fastenings** at Pittsburgh are: steel splice bars 2.75 cents per pound; spikes 2.8 cents per pound; track bolts 3.8 cents per pound. Prices at Chicago and Birmingham are 0.65 to 0.75 cent higher and at St. Louis and San Francisco about 1 cent higher than at Pittsburgh. Tieplates are 2.15 cents per pound at the Pittsburgh and Chicago mills.

Cross Ties. 75 cents to $1.10 per tie, untreated, depending on kind of wood and locality. Treated ties cost 40 to 90 cents more, depending on process used.

Frogs, Switches and Crossings. Switches in place will cost from $380 to $750 per switch. The cost of a crossing of two railroads will depend on the angle of intersection, and will cost from $200 up.

Ballast. Quantities and unit costs are given under the heading of **ballasting** under track. The cost may run from $1500 to $5000 per mile for the best of broken stone. An ordinary average is $2000 per mile of track.

Track Laying and Surfacing. This really includes the three items of track laying, surfacing and the train service of hauling track materials from the point of delivery to the places where used. The train service is frequently furnished by the railroad company, but its actual cost is from $125 to $200 per mile. The contract price for track laying alone is frequently $450 per mile at present prices for labor, but there are many records of track laying by means of special track-laying cars for as little as $150 per mile. Sometimes ballasting is deferred until the road is in operation, at least for construction trains. The surfacing may then be a separate contract at about $400 per mile. Allowing an average figure of $175 per mile for the train service, the total cost to the company for this item will average about $900 per mile.

Fencing will average about $250 per mile of fence, or about $500 per mile of road when both sides are completely fenced. Often only a small fraction of the total length is fenced.

Buildings and Miscellaneous Structures. Station buildings and fixtures in Wisconsin averaged $476 per mile; those in Minnesota, $771; those in Michigan, $526. Unit allowance in valuation of a Texas railroad for small frame passenger stations, $1 per square foot; for platforms, 16 cents per square foot. The analyzed cost of six section and tool houses averaged 30.7 cents per square foot of area. The cost of water stations of ordinary capacity will vary from 3 to 4 cents per gallon of capacity. Sign boards, $10 to $15 each. Whistle posts, mile posts and rail rests, about $2 each. Road crossings require about 260 ft. b. m., which at an average price in place of $70 per M will $18.20 each. A pair of stock guards is usually required for each crossing, which may cost about $75 per pair, including the short fences from the right-of-way lines to the ends of the ties. A Y can take the place of a turntable providing that land is available at no special cost. Using a radius of 300 ft., with 100 ft. of track for the engine at the tail of the Y, about 1050 ft. of track will be required together with three switches. The tail of the Y will require land for 400 ft. from the main track.

Turntables may cost anywhere from $2000 to $4000. The turntable itself is made of cast iron or of structural steel, or sometimes of a combination of structural steel trusses with a cast-iron center.

Coaling Stations may vary from a mere platform or bunker from which the coal is shoveled into the tender (although at a considerable cost per ton) to the very elaborate and costly coal pockets in which coal is deposited by coal conveyors or dumped from cars drawn up an incline, and from which the coal slides through chutes to the tender. The cost must evidently be computed for individual cases. **Ash pits** likewise vary from a mere pit between the rails to an elaborate adjunct of a coaling station by which the ashes are immediately transported on a " conveyor " to an ash car.

Terminal Grounds. Although the area of terminal grounds may be not more than 3 or 4% of the total property area, its gross cost or its cost per mile of road may be actually more than the cost of all the remaining right-of-way. In Minnesota, the valuation of terminal grounds was 71% of the total valuation of all the line right-of-way, gravel pits, station grounds and terminal grounds.

Miscellaneous: Shops, roundhouses and shop tools and machinery will average about 3% of the total cost of a road. Snow fences, bridge ticklers, track scales, mail cranes and bumping posts must be allowed for on all large roads, but their relative cost is insignificant.

Grain elevators, warehouses, docks and wharves are mentioned as possible items of expense, but do not apply to many roads. For signals the cost is so variable, depending on the degree of elaboration of the system, that average unit prices per mile of road would only be misleading.

Telegraph Lines. Safe estimate $350 per mile of road for a single-wire line. If poles are very cheap even this cost may be materially cut.

Freight on Construction Material. This applies chiefly to track material such as cross ties, rails, etc. While very variable, it may amount to nearly 1% of the cost of the road. Frequently the item is ignored, the freight being added to the cost of each item.

Contingencies. Usually estimated at 5 to 10% of the above items.

Engineering, Superintendence and Legal. Frequently figured at 5% of all the construction work. The legal work will cost about 1%.

Equipment. The approximate cost of locomotives and cars is about $7000 per mile of road. Marine equipment must occasionally be allowed for.

Organization Expenses will amount to 1 to 1.5% of the cost and frequently even more.

Interest on Cost during Construction. Theoretically this should mean interest on money from the time that bills are payable until the road begins operation. This

State Appraisals of Steam Railroads. Average Cost per Mile

No.	Items	Minnesota (1907) Cost	Minnesota (1907) Per cent	Michigan (1900) Cost	Michigan (1900) Per cent	Wisconsin (1903) Cost	Wisconsin (1903) Per cent

Item 30 assumed to be 4.5% of items 1–28, inclusive, for Michigan and Wisconsin and of items 1–29, inclusive, and also item 36 for Minnesota.

Item 38 assumed to be 1.5% for Michigan and 1% for Wisconsin of items 1–37, inclusive.

Item 39 assumed to be 10% for Michigan, 5.5% for Wisconsin and 5% for Minnesota of items 1–37, inclusive. Item 41 assumed to be 3% for Michigan and Wisconsin of items 1–37, inclusive. Basis for Minnesota estimate not stated, but corresponding figure would be 8.75%.

should average about half the time required to build the road. Financiers sometimes require interest on the full amount from the time of signing the contract, and this will more than double this item.

Appraisal commissions appointed in Wisconsin, Michigan and Minnesota have appraised all of the railroads of each state, the appraisal value being made both from the standpoint of the cost of reproduction and also the present value as affected by depreciation. The systems of analyzing the cost are not identical, which makes comparison difficult and even slightly inaccurate as given on p. 2089, but the average prices are very instructive. The cost per mile of main line and branches and the percentage of the item to the total cost are given separately for each state.

Miles of U. S. Railroads in Operation on Dec. 31 of Each Year

* 1911 and later years to 1916 are for June 30.

30. Train Resistances

Atmospheric Resistance depends on end area and length of train and is independent of tonnage. The end-area pressure is approximately one-half of the unit pressure times the area of the car end. According to elaborate experiments by Goss, the resistance of trains of locomotives and cars of ordinary dimensions may be expressed by the following equations, in which P = total atmospheric resistance in pounds, n = the number of cars, L = length of the whole train, l = combined length of the cars composing the train, and V = velocity in miles per hour.

Locomotive, tender, and freight cars........	$P = (0.13 + 0.01n)V^2$
Locomotive, tender, and passenger cars.....	$P = (0.13 + 0.02n)V^2$
Freight cars following locomotive...........	$*P = (0.016 + 0.01n)V^2$
Passenger cars following locomotive........	$*P = (0.016 + 0.02n)V^2$
Locomotive and any kind of train..........	$P = 0.0003(L + 347)V^2$
Any train of cars (freight or passenger) following locomotives......................	$*P = 0.0003(l + 53)V^2$

* Excludes atmospheric resistance of locomotive and tender.

Oscillation and Concussion. These resistances are usually considered to vary as the square of the velocity. Their determination, independent of other forms of resistance, is impracticable and even useless, since they vary with the particular condition of the track and roadbed at the time.

Rolling Friction. The resistance to the wheel rolling on the rail, independent of other forms of resistance, has not yet been definitely determined. It evidently depends on the stiffness of the rail and on the rigidity of the support given to the rail by the ties.

Journal Friction per ton of load is (a) less for higher pressures or for heavy wheel loads; (b) greater for very low velocities; (c) a minimum for speed corresponding to train velocity of about 10 miles per hour; (d) greater for higher velocities; (e) less for higher temperatures; and (f) very dependent on perfection of lubrication. The use of roller or ball bearings very materially lowers this item but is rather limited as yet and probably will be for a long time as far as freight equipment is concerned.

Total "Train Resistance." The aggregate effect of the four kinds of resistance given above is known as the **Train Resistance.** It is of course the total resistance only on straight, level track, as neither the resistance (or assistance) due to gradients nor the extra resistance on curves is taken into account. Even with these variable resistances eliminated, no one simple formula can be devised which is equally applicable to all conditions of weight and character of cars, condition of track, weight of rail, etc. Dennis' tests, corroborated by those of Shurtleff, indicated a practically uniform resistance for freight trains at all velocities between 7 and 35 miles per hour. Later experiments by Professor Schmidt at the University of Illinois indicate some increase in resistance with increase in velocity for both freight and passenger equipment and the resistance of high-speed passenger trains unquestionably increases with the velocity, and some say, with the square of the velocity. Formulas based on tests made many years ago, when the rails were light, track conditions relatively poor, wheel loads light, and running gear not as perfect as present standards, are certainly not applicable to present standard conditions; and results obtained by tests of passenger trains are not applicable to freight trains, or vice versa.

A very few of the multitudinous formulas which have been proposed are here quoted.

Engineering News, 1892..................................	$R = 2 + 1/4\ V$
Baldwin Locomotive Works, prior to 1892......................	$R = 3 + 1/6\ V$
Shurtleff, 1906..	$R = 0.5 + (90/w)$

Manual of A.R.E.A., 1929 Ed.

A Rating, temperature above 35° (Fahr.)......................	$T = 2.2\,t + 122\,n$
B Rating, temperature 20° to 35°..........................	$T = 3.0\,t + 137\,n$
C Rating, temperature 0° to 20°...........................	$T = 4.0\,t + 153\,n$
D Rating, temperature below 0°............................	$T = 5.4\,t + 171\,n$

in which R = total resistance in pounds per short ton, V = velocity in miles per hour, T = the resistance in pounds per train, n = number of cars in train, t = weight of train in short tons, w = average weight in short tons of cars in train.

The first two are based mainly on tests with the passenger equipment of 1890–92 and may be compared with the results obtained by Prof. Schmidt in 1916 as shown below.

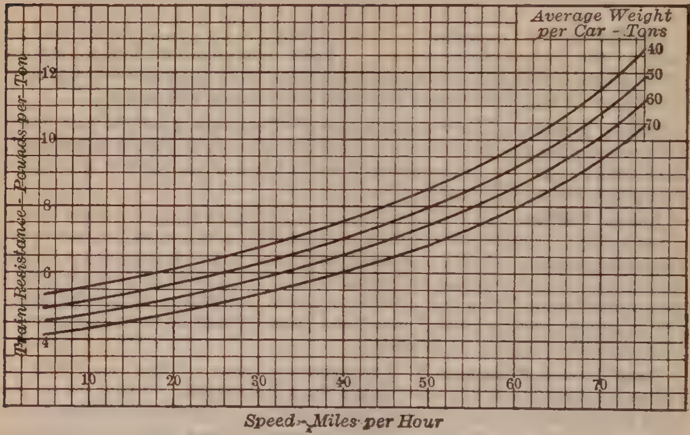

Fig. 46. Passenger Train Resistance

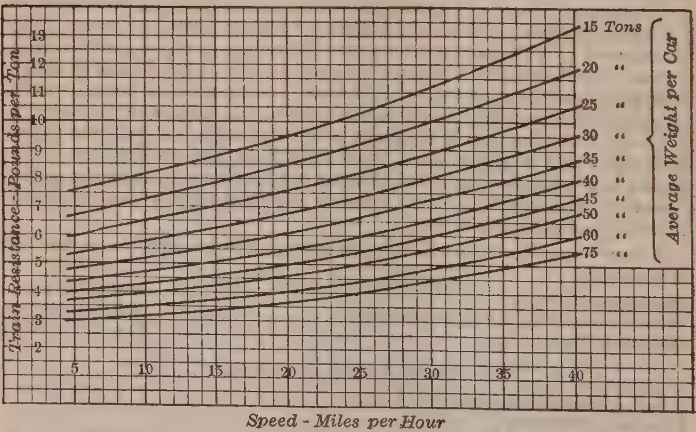

Fig. 47. Freight Train Resistance

The second two formulas are for heavy freight service and assume that the resistance per ton is constant at the ordinary freight speeds of 7 to 35 miles per hour. They may in turn be compared with the results obtained by Prof. Schmidt with freight equipment in 1908–09 given in Fig. 47.

Effect of Temperature. Decrease of temperature increases journal friction, but on the other hand, a frozen roadbed if smooth decreases the oscillatory resistances. At very low temperatures the increase in journal friction (combined with decreased power of the locomotive) requires a material reduction in the permissible train loading. Some railroads have a percentage scale for the reduction of the rating of locomotives according to the temperature. The increased tractive resistance for winter traffic over summer traffic is about two pounds per ton, with two pounds per ton additional for temperatures below zero. The American Railway Engineering Association formulas take the temperature into account by changing the constants as shown above.

Extra Resistance of Starting. The resistance of journals and axles is very much greater at the instant of starting and until they have become warmed up. Cars which have been stationary overnight, especially in cold weather, will become "frozen up" and will require a much greater force to start them, but the added resistance is only momentary and consumes but little energy, measured in foot-pounds. The frequent practice among locomotive engineers of backing the locomotive for a few feet and then immediately reversing and starting ahead has three effects, all of which help to start the train: (1) the journals are loosened from the somewhat rigid condition they will assume even during a short stop; (2) the springs in many of the couplers are more or less compressed during the backward movement, and their expansion materially assists in starting the cars; (3) if the train is very long, the total slack in the couplers is very considerable, and the locomotive will have moved forward several feet and will have a considerable velocity before the last car starts; the cars are therefore started one by one. Since so much depends on the method of handling the locomotive, there is a corresponding variation in the results of tests which have been made to determine the value of this resistance. Thirty-five tests on the Rock Island system, with trains of 34 to 45 cars, gave results varying from 10.6 to 18.2 lb. per ton. The weighted mean of the values was 14.1 lb. per ton. The same tests quoted 30 lb. per ton when a train had stood overnight and was "frozen up"; also a resistance of only 6 lb. when the stop was merely instantaneous. Other tests have shown an average of 14 lb. per ton.

Due to the above practice in starting trains and to the increased tractive force at starting this extra resistance is of little importance, i.e., it practically never limits the weight of the train.

Effect of Weight of Cars. The resistance per ton of horse cars, light trolley cars and contractors' dump cars is as high as 20 lb. per ton and even more when the rails are light or the track in poor condition. The heavier the wheel loads, the less the resistance per ton. The resistance of an empty standard gage car, weighing say 17 tons, on good track, is about 8 lb. per ton, and for a loaded car, weighing say 60 to 70 tons, about 4 lb. per ton or even less on a good track.

The American Railway Engineering Association formulas allow for the weight of cars by using two constants, one depending on the weight of the train and the other depending on the number of cars in the train. Schmidt gives curves for different weights of cars as shown in Figs. 46 and 47.

Grade Resistance is 20 lb. per short ton (2000 lb.) for each per cent of grade. This rule is not mathematically precise but the error is less than

0,5% for a 10% grade, 0.08% for a 4% grade, and is inappreciable for ordinary railroad grades. The **grade of repose** is the grade on which the effect of gravity just equals the tractive resistance. If a wagon or car is started down such a grade, it would continue to move indefinitely at a low velocity as long as the conditions are constant. The total resistance up such a grade is precisely twice that on a level.

Curve Resistance is considered the equivalent of a 0.04% grade per degree of curve, or 0.8 lb. per short ton per degree of curve. See also p. 2097.

Brake Resistance wastes the kinetic energy of the train by transforming it into heat and, unless such energy has been acquired by running down a grade, constitutes a source of double loss since the application of the brakes also requires power. For ordinary stops it may be considered as equivalent to a 7.5% grade, or 150 lb. per short ton; whereas for emergency stops it may reach double that amount. The corresponding distances may be obtained from the table on page 2096.

Rating of Locomotives. Since grade resistance varies with the total weight, while train resistance per ton depends on the weight of cars, the gross weight of cars which may be attached to a locomotive depends not only on the grade, but also on whether the cars are heavy or light. The greater the number of cars for a given weight of train, the greater the necessary drawbar pull, and therefore, for a given drawbar pull, the gross weight of a trainload of empties must be less than that of a train of loaded cars. For example, assume that an engine, weighing with the tender 336 500 lb., has a tractive effort at the rim of the drivers of 32 075 lb. On the basis of the resistance formula for "A" rating and constants given below the rating for a 0.6% grade is 2091 tons, with an allowance or "adjustment" of 8.6 tons for each car.* Then the permissible weight of the train which could be attached to that engine when the ruling grade is 0.6% may be expressed by the formula $W = A - 8.6\,n$, in which W = the weight of cars, A = the rating, and n = the number of cars.

For 30 loaded cars................2091 − 258 = 1833 tons; average 61 tons per car
For 50 partly loaded cars..........2091 − 430 = 1661 tons; average 33 tons per car
For 90 empties...................2091 − 774 = 1317 tons; average 15 tons per car

But a ruling grade of 0.6% is unusually low. As another example, with a ruling grade of 1.6%, the adjustment allowance is 3.6 tons per car, but the rating A is reduced to 770 tons. The possible train loads would be:

For 10 loaded cars..................770 − 36 = 734 tons; average 73 tons per car
For 25 partly loaded cars............770 − 90 = 680 tons; average 27 tons per car
For 40 empties.....................770 − 144 = 626 tons; average 16 tons per car

On the 1.6% grade the weight of the train of empties is 85% that of the loaded train; on the 0.6% grade it is only 72%; which shows the relatively greater importance of heavy loads with low ruling grades. Formulas for tractive force of locomotives are given in Art. 20.

The following derivation of the formula with a table for its use is condensed from a report of the Economics Committee to the American Railway Engineering Association in 1910. Let p = "pulling power of locomotive" or the tractive force as measured at the rim of the drivers; e the weight of the engine and tender; w the weight of the train, exclusive of locomotive; r the rate of grade; k a constant, depending on the weight of the train (w); n the

* This assumes that the engine and tender form part of the train which is approximately correct for A and B ratings on account of track and atmospheric resistances, not otherwise considered.

number of cars; c a constant, depending on the number of cars; and A = the "rating." Then

$$p = (e + w)(r + k) + nc$$

Transforming, $\frac{p}{r + k} - e = w + n\frac{c}{r + k}$; but $w + n\frac{c}{r + k} = A$

therefore $$A = \frac{p}{r + k} - e$$

The first formula for train resistance on a level given on p. —— is: $T = 2.2\,t + 122\,n$ in which t corresponds to $(e + w)$. But since the formula applies only to level track, $r = 0$. Therefore, the constant k, which depends on the weight of the train, = 2.2 lb. per ton or .0011 lb. per pound, and the constant c, which depends on the number (n) of cars, = 122 lb. The rating A for any grade is therefore some definite weight (depending on the grade), from which must be subtracted a constant for that grade times the number (n) of cars to obtain the actual weight (w) which may be hauled. The constant for each grade, $c/(r + k)$, is readily computed. For example, for a 0.6% grade, it equals 122/(.006 + .0011) = 17 183 lb. or 8.6 tons per car. Therefore on a 0.6% grade, $A = w + 8.6\,n$, or $w = A - 8.6\,n$. Similarly, the constant with which to multiply may be determined for any grade, and, as this is independent of the type of locomotive, it is given in the following table:

Values of c/(r + k) for Various Grades

Grade, per cent	Tons per car	Grade, per cent	Tons per car	Grade, per cent	Tons per car	Grade, per cent	Tons per car	Grade, per cent	Tons per car
Level	55	0.5	10.0	1.0	5.5	1.5	3.8	2.0	2.88
0.1	29	0.6	8.6	1.1	5.0	1.6	3.6	2.1	2.75
0.2	20	0.7	7.5	1.2	4.7	1.7	3.4	2.2	2.63
0.3	15	0.8	6.7	1.3	4.3	1.8	3.2	2.3	2.52
0.4	12	0.9	6.0	1.4	4.0	1.9	3.0	2.4	2.42

The rating of some particular engine for any and all grades may be determined by noting its hauling capacity on some one grade. For example, it hauls 50 cars, weighing 3033 tons, up a 0.3% grade at a constant speed. The adjustment for that grade (taken from the table) at the same speed is 15 tons per car. Therefore the rating is 3033 + (15 × 50) = 3783 tons or 7 566 000 lb. The engine weighs 336 500 lb. Then $A + e$ = 7 566 000 + 336 500 = 7 902 500 = $p/(r + k)$. But $(r + k)$ = .003 + .0011 = .0041. Therefore p = 32 400 lb., the pulling power of the locomotive. Then, knowing p, the rating A for any grade may be determined by substituting in the formula various values for r. For example, the ruling grade of the road is 1.2%; it is desired to know the power of that locomotive on the ruling grade.

$$A = p/(r + k) - e = 32\,400/(.012 + .0011) - 336\,500 = 2\,473\,000$$
$$- 336\,500 = 2\,136\,500 \text{ lb.} = 1068 \text{ tons.}$$

The actual tonnage of cars which may be hauled is less than this, since on this grade 4.7 tons must be subtracted for each car of the train. If there are 20 cars in the train, their aggregate weight must not exceed 1068 − (20 × 4.7) = 974 tons, or an average of 48.7 tons per car.

Using any one of the other formulas, or the curves of Professor Schmidt, the rating may be computed by finding the train load whose total resistance is slightly less than the tractive effort at the speed desired. Formerly this was the speed of maximum tractive force, but now many roads are rating for higher speeds, or the economical speed as noted below.

Locomotives may also be rated by actual trial, in fact, operating results of the use of computed ratings should be constantly studied to insure the best results.

Economical Speed. When the velocity of trains is very low (say 5 miles per hour) the coal burned per mile is greater and train wages are greater both on train under consideration and others due to greater interference with traffic, but any saving is small. For high velocities the cost per train mile is likewise comparatively high. The most economical speed is about 17 miles per hour for single track and nearly 20 miles per hour for double track according to results of computations by Isaacs and Adams, in Bul. 115 of the Amer. Rwy. Eng. and M. W. Assoc. These were, of course, based on certain assumptions but there is no doubt that it is often not most economical to haul maximum train loads or full " ratings " on account of low speeds.

Accelerative (or Retarding) Force in Pounds per Short Ton

2640	6	11	17	24	33	43	54	66	80	96

Formula: $P = 70.22\ V^2/s$, in which P = force in pounds, s = distance in feet, V = velocity in miles per hour, 5% being allowed for rotative energy of wheels.

Distances, Speeds and Times. Let P represent the net force in pounds per short ton, s be the distance in feet between two points at which the train velocities are V_1 and V_2 respectively. Then $P = 70.22(V_2^2 - V_1^2)/s$, if V_1 and V_2 are in miles per hour. V_1 is the lower velocity; when the train is starting from rest, or coming to rest V_1 is zero.

The above table may be used to find the distance in which a train may be accelerated (or retarded) from any speed to any other, or to find the change in speed for a known distance. For instance, a train traveling 20 miles an hour enters a stretch of track 900 ft. long on which the accelerative force is 94 lb. per ton. The table shows that it takes 300 ft. to accelerate from 0 to 20 miles per hour and that in 900 ft. more or a total of 1200 ft. the velocity will be 40 miles per hour. Knowing the distances and speeds, the times are easily computed, and the sum of the time intervals is the schedule time of the run. Of course the net tractive force changes at each change of rate of grade and at each curve and it is faster to plot speed-time and distance-time curves if the motive power and load are known.

31. Compensation for Curvature

The Principle involved is that the grade should be reduced by such an amount that the saving in grade resistance will compensate for the additional resistance caused by the curvature. The proper rate of compensation evidently depends somewhat on the speed of the train; it also depends largely on the resistance to the rotation of the car trucks about their king-bolts, being very greatly reduced when ball bearings are used under the center and side plates; it is apparently far less per degree of curve on very sharp curvature than on easy curvature. The rate of compensation should be made greater on a curve occurring immediately above a stopping place for trains. Since the added resistance of curvature virtually increases the grade, it is unimportant whether there is any compensation on curves which are on minor grades, provided the total resistance does not become greater than that of the ruling grade. The rules recommended by the American Railway Engineering Association are as follows: (1) Compensate 0.03 ft. per degree when the length of curve is less than one-half the length of the longest train, when the curve occurs within the first 20 ft. of rise of a grade or when curvature is in no sense limiting. (2) Compensate 0.035 ft. per degree when the curve is between one-half and three-fourths as long as the longest train and when the curve occurs between 20 ft. and 40 ft. of rise from the bottom of the grade. (3) Compensate 0.04 ft. per degree when the curve is habitually operated at low speed, when the length of curve is more than three-fourths that of the longest train, when the elevation is excessive for freight trains or at all places where curvature is likely to be limiting. (4) Compensate 0.05 ft. per degree wherever the loss of elevation can be spared.

32. Economics of Location

Economic Location is the determination of the proper relation between construction and operating expenses and the discovery, in any individual case, of that location which will afford the most economical combination of cost and operating expenses for the given or estimated traffic. The **principles** are practically applied by comparing proposed plans for new construction or by investigating changes in existing lines including abandonment of existing facilities. For new work the method must include for each proposed route these features: (1) the estimated cost of the line; (2) the annual interest charge on capital at a rate which the circumstances of the project make proper; (3) the estimated annual traffic, not only the gross tonnage, but also the number of trains required to handle it; (4) the effect, if any, of change of location on the traffic obtainable; (5) the estimated annual cost of handling such traffic; (6) the effect, as far as it is possible or proper to predict it, of future changes in traffic or in operating conditions. Having determined the gross revenue, the interest on first cost and the operating expenses, the line giving the largest net revenue is evidently the most economical line. When revenue is not affected (generally true for small changes) the line having a minimum sum of operating expenses and interest on first cost is the most economical. When studying changes of an existing line, in addition to the features above mentioned, the possible injury to existing facilities must be considered. The proposed plan should, in such a case, so increase the net income that the excess will at least pay a proper return on the entire cost of the change.

The general method of analysis consists in separating the different items of cost of operation and determining the proportion of each item which is affected by each physical element in the proposed change of line. The physical elements are Distance, Curvature, Minor Grades and Ruling Grades. The table gives the aggregate results for each of the main groups of operating expenses and illustrates the method. Both the grouping and the percentages are now changed, see present groups operating expenses on p. 2080.

The lack of agreement of these figures is partly due to some differences in the basis of computation, partly to the different times at which they were computed and partly to the fact that such figures can never be constant for all times and conditions, but must be modified to suit local conditions. It is, however, remarkable that the mean values for the large and small changes give 38.1%, 41.4% and 38.5% respectively as the percentage of total operating expenses which are affected by changes of length of line.

J. B. Berry's estimate divides changes of distance into three classes: Class (A), distance so short as not to affect wages of engine or train men, 32.10%; Class (B), distance affecting train wages but not requiring additional side tracks, 45.94%; Class (C), distances so great as to require additional side tracks and stations, 59.5%.

W. G. Raymond's estimate is 35.3% + a flat amount of $350 per year per mile for expenses which are independent of the number of trains. This flat amount is a little less than $1 per day. With ten trains per day each way or twenty train-miles over each mile, it would add a little less than five cents and make the total approximately 40%.

Reduction of Distance may also reduce the receipts as well as operating expenses and thus reduce the advantage gained by shorter distance, provided the change of distance is so great that it is measured in miles. The **effect on receipts** is not computable except in the most approximate way; it depends on the following elements: (1) Since the cost of operating additional distance is approximately 40% of the average, whereas passenger receipts and some other kinds are based more or less strictly on actual mileage, there is a real advantage and profit in added distance for such kinds of traffic. (2) For competitive business, where receipts are absolutely independent of distance, any added distance is a pure loss, without any compensation. (3) For through business, where the division of receipts between roads is more or less strictly according to the relative mileage of hauls on the two or more roads, there is profit or loss according to the percentage of length of haul on the home road to the total haul, the larger the percentage the larger the possible profit, which also depends on whether the rate is competitive or non-competitive. (4) Since a road always has varying proportions of these several kinds of traffic, the net advantage or disadvantage depends on the combined effect.

Distance. Percentage of Operating Expenses Affected by Length of Line According to Three Estimates

Division of total cost of railroad operation	Wellington, 1887			Webb, 1906			Harriman Line,* 1909		
	Total per-cent-age	Am't af-fected	Per cent to total	Total per-cent-age	Am't‡ af-fected	Per cent to total	Total per-cent-age	Amount af-fected	Per cent to total
Maintenance of way.	†23.0	§11.6 19.0	50.4 82.7	21.0	§15.7 19.0	75.0 90.3	24.97	23.45	93.9

Totals..........	100.0	24.8 51.4	....	100.0	31.3 51.6	....	100.00	38.47	.....

* Auditor's estimate for one of the Harriman lines.

† Interpretation of first line of figures: the maintenance of way expenses are estimated at 23.0% of total cost of operation; 11.6% of the total are affected by changes of length of line; the 11.6% is 50.4% of 23.0%. Other groups interpreted similarly.

‡ Including several sub-items really belonging under maintenance of way or transportation which should decrease materially the percentages for "conducting transportation."

§ The upper figures show the percentage on the basis of changes so small that they are measured only in feet, which will not appreciably affect several items of expense; the lower figures are for changes measured in miles. The Harriman figures make no such distinction.

As a final conclusion, there is always some addition to receipts to partially offset the added cost of operating added distance; for a road whose business is very largely non-competitive the increase in receipts due to added distance might be greater than the increase in operating expenses; for a road whose business is chiefly competitive the net loss will be great; in any case there is some reduction on the advantage computed above by decreasing the distance.

Curvature. The basis of the analysis of cost is the determination, first, of the degree of curve on which the power requirements are precisely double the power used on a straight level track, and then the determination of the additional cost of the doubled resistance It is then assumed that train resistance and added cost of curvature are proportional to the number of degrees of central angle and independent of the radius of curvature. The degree of curve on which the resistance is precisely double that on a level tangent has been variously estimated from 10° to 12° 30′. A mile of such continuous curvature will have from 528° to 660° of curvature. Doubling the power requirements on the engine will increase certain items of cost of a train-mile by a computable percentage of such cost. A continuous 10° (or 12° 30′) curve will increase items of maintenance of way and equipment by percentages which may be closely estimated. Many of the items of cost of a train-mile are unaffected. In this way the total increase in the cost of one mile of such curved track is computed. Dividing the total extra cost by the number of degrees (528 to 660) gives the value of 1°. The chief items affected by curvature are rails, of which the extra wear may be from 200 to 300%; repairs to locomotives, 100 to 200%, and repairs of cars which are increased from 50 to 100%. Some other items of maintenance of way are increased 25 to 50%, while fuel and water would be increased about 50%. The extra cost per degree has been variously computed as follows:

Author	Date	Degree per mile	Percentage	Extra cost per degree per cent
Wellington..................	1887	600°	35.6	0.0593
Berry.....................	1904	660	35.35*	0.0536
			29.88†	0.0498
Webb......................	1908	528	34.6	0.0655

* Uncompensated curvature. † Compensated curvature.

The percentage of extra cost per degree chosen should be multiplied by the estimated cost per train-mile and this value multiplied by the number of trains per year, which gives the yearly cost of one degree of curvature. Capitalizing this at the proper rate of interest gives the amount which may justifiably be spent to avoid one degree. For calculations of this kind, estimates must be made on the following items which will vary according to the local conditions: (1) the local cost per train-miles; (2) the percentage by which the various items of cost per train-mile are affected by curvature; (3) the number of trains which will use the tracks. For new construction even the last item is an uncertain quantity.

Minor Grades. The basis of computing the cost is to determine, first, the rate of grade which will exactly double the resistance on a level tangent; second, to compute the effect on operating expenses of a mile of such a grade; and third, on the assumption that the cost of lifting a train through so many vertical feet is proportional to the height, the extra cost of one foot of elevation equals the added cost of operating a mile of such grade divided by the number of vertical feet in a mile of that grade. It is assumed that the grade which doubles tractive resistance on a level tangent does not limit the length or weight of trains it is designed to haul with one engine, or that any limiting effect is a separate matter, and that the only effect of the grade is to increase the operating expenses over those required for operation over a level track. Minor grades are necessarily divided into three classes on account of a distinction in their effects on the operation of trains. Class A includes those grades which on account of the rate of grade or the length, do not require any change in the handling of the train, no brakes and no change in the throttle or cut-off. Class B includes those grades which are steep enough or long enough to require shutting off steam (but no brakes) in order to avoid objectionable velocity while descending and to require more steam or longer cut-off when ascending. Class C includes the grades which require that steam shall be shut off and brakes applied on down grades and full steam power used on the up grades. Since a fast passenger train may safely attain very high speed in a sag and since the effect of a hump is a relatively small reduction of a previously high velocity, a grade which should properly be classified as an A grade for fast passenger trains should be classified as a B or even a C grade for slow freight trains. The average tractive resistance of a train at ordinary velocity is about 10 lb. per short ton. For slow freight trains the figure is too high; for fast passenger trains it is too low. Ten lbs. per ton is the equivalent of the grade resistance on a 0.5% grade which has a rise of 26.4 ft. per mile. **Sags and humps:** This section applies only to the possible elimination of sags and humps, since a long uniform grade connecting two predetermined points is practically unchangeable. The problem therefore becomes the determination of the value of removing a hump or filling a sag whose height is the vertical distance from the vertex of the sag or hump from the uniform grade by which it would be replaced. **Value of 1 ft. or rise-and-fall:** Class A grades have no effect on the power required of the locomotive, and no effect on operation except a harmless temporary increase or decrease in velocity; they have also no appreciable effect on operating expenses and can therefore be ignored. The effect of Class B and Class C grades has been variously computed as follows:

Author	Date	Percentage affected		Annual value *	
		Class B, per cent	Class C, per cent	Class B, per cent	Class C, per cent
Wellington..........	1887	3.03	9.67	84	276
Webb...............	1908	6.08	7.92	168	219
Berry...............	1904	3.38	7.13	93	197

* Annual value in per cent of average cost per train-mile for each round trip daily train per foot of rise-and-fall.

The above table is based on an average train resistance of 10 lb. per ton whereas 6 to 7 lb. is more nearly correct for present rolling stock.

Ruling Grades are those which limit the length or weight of the trains which may be handled by one locomotive. The classification does not include steep grades which will always be operated by two or more engines and are called pusher grades, nor does it include very short steep grades which may always be operated by momentum. The maximum train loads which may be hauled on a given ruling grade and on the proposed lighter grade by an engine of given weight, dimensions and boiler power, may be determined by dividing the tractive force by the total resistance per ton, both taken for the same speed.

The cost per train-mile of each additional train for hauling the same tonnage of cars up a somewhat steeper grade has been computed by Webb as about 53% of the average cost of a train-mile. J. B. Berry (Bul. 49, Am. Ry. Eng. & Main. Way Assoc.) computes the cost similarly as 43.29%. Isaacs and Adams (Bul. 112 of same association) computed that 30.64% of the total operating expenses are " affected by locomotive mileage." They use the figure by multiplying the additional number of train-miles required by the higher grade by 30.6% of the average cost per train-mile and consider this as the additional cost of the higher grade.

The number of daily trains required for each grade may be found by dividing the given, or estimated, total tonnage by the maximum net train load for each grade, the difference is then the number of daily trains saved.

Pusher Grades. A road may be designed for pusher grades by determining a pair of grades such that two engines of a certain type can haul up the steeper grade the same train that will just tax the capacity of one such engine on the lower grade. This pair of grades must be selected according to the character of the country and must be such that all the grades of the line

Per Cent of Trains Necessary to Handle a Given Traffic with Single Engine, if Gradients are Changed from Those in First Column to Any Other Given Gradient

This table is taken from Bulletin 49 of Am. Ry. Eng. & M. W. Assoc., by J. B. Berry; calculated for engine and tender weighing 150.3 tons in working order, tractive force 35 268 lb., weight of caboose 17 tons, velocity and frictional resistance 6 lb. per ton. As percentages, the figures apply approximately to almost any freight engine.

may be reduced, without unreasonable cost, to the limit of the grade for one engine, except such grades as it is intended to operate with pusher engines. Little or nothing is saved by reducing these pusher grades below the limit computed for two engines. In exceptional cases a combination of three grades may be computed, of which the two lower grades are to be operated as above, and the highest grade is such that three engines are required to haul the same train over it. The following table is computed for one type of engine. The precise balance between any through grade and the corresponding grades for one and for two pushers depends on the type of engine, the available ratio of adhesion and the tractive resistance; but it may be demonstrated that reasonable variations in the type of engine or tractive resistance will only alter the required grades by a few hundredths of one per cent. The corresponding pusher grades may therefore be accepted as approximately true for all cases. The accuracy of the table is theoretically impaired by the fact that the rating tonnage on the pusher-engine service is somewhat different from that on the through-engine service. The variation will depend on the ratio of rating-ton resistance to tare-ton resistance. As an illustration, a 1.9% one-pusher grade corresponds to a 0.92% through grade according to the table. Working out the corresponding grade, using the values proposed by Dennis of 2.6 lb. as the resistance of a rating ton and 9 lb. as the resistance of a tare ton, the corresponding through grade is computed to be 0.99%. Some increase should be expected since the pusher locomotive has a higher resistance per ton than average train resistance. This shows that, although no table can be compiled which will suit all conditions, the differences will not probably exceed a few hundredths of one per cent. The variations are of less importance with the higher pusher grades. The cost of a pusher engine mile as a percentage of the average cost of a train-mile was estimated by Wellington (8187) as 38.3%; by Berry (1904) 34.4%; by Webb (1908) 38.8%.

Balanced Grades for One, Two, and Three Engines

Through grade, per cent	Track resistance, 6 lb.			Track resistance, 8 lb.		
	Net load for one engine in tons (2000 lb.)	Corresponding pusher grade for same net load, per cent		Net load for one engine in tons (2000 lb.)	Corresponding pusher grade for same net load, per cent

Basis: Through and pusher engines alike; consolidation type; total weight, 107 tons; weight on drivers, 53 tons; adhesion, 9/40, giving a tractive force for each engine of 23 850 lb.; normal track resistance 6 (also 8) lb. per ton. It is assumed that the engine is so designed and that the velocity and steam pressure are such that the engine can always develop a tractive force of 23 850 lb.

The mileage must be computed as twice the total distance between the sidings at top and bottom of the grade, this distance being always somewhat in excess (and sometimes very much so) of the length of the pusher grade on the profile.

Momentum Grades are grades which, although somewhat steeper than the ruling grade, can invariably be approached at such a velocity that the kinetic energy of the train will assist the engine sufficiently to carry the train past the summit with a minimum velocity of say 10 miles per hour. If the resistance

of trains were independent of velocity, the mechanics of the problem would be much simplified, but the extensive dynamometer tests of Dennis, confirmed by those of Shurtleff, have shown that the resistance per ton of freight trains at velocities between 10 and 35 miles per hour is so nearly uniform that the following method gives a close approximation to accuracy. It is also fortunately true that a very considerable error in velocity height at high velocities is comparatively unimportant. Assuming that a train could run without track resistance, its kinetic energy at a velocity v in feet per second would lift it up a grade to a total vertical height $h = v^2/2\,g$, in which g is the acceleration of gravity. If V = velocity in miles per hour, $h = 0.03344\ V^2$; adding 5% for the rotative kinetic energy of the wheels, we have $h = 0.0351\ V^2$. The values of h (or " velocity heights ") are given in the table.

An engine properly loaded will haul its train up the ruling grade and the test of the momentum grade or hump is the possibility of hauling the train up the excess grade with the help of momentum. For example, a train, with the engine loaded for a 0.7% grade, approaches a 1.2% grade 7850 ft. long with a velocity of 35 miles per hour. The excess grade is 0.5%, and in a distance of 7850 ft., the excess rise is 39.25 ft. The velocity head corresponding to 35 miles per hour is 43.01 ft.; subtracting 39.25, we have left a velocity head of 3.76, which corresponds to a velocity of 10.3 miles per hour, which is a safe speed for going over the summit. The secondary question, whether it is safe to assume that no fully loaded freight train will ever need to stop, or even slacken speed, along this grade of 7850 ft., is a matter of practical operation rather than of engineering.

The accuracy of this method depends on the assumptions that the resistance is uniform within the range of the velocities, and also that the work done by the engine is uniform. Although the resistance may be considered substantially uniform, the tractive force of the engine decreases as the velocity increases. When, as in the above illustration, the train approaches the grade at a velocity of 35 miles per hour, the engine is not producing as much tractive force as it can produce at a lower velocity. But if the rating of the engine (see p. 2094) is based on a fairly high velocity on the ruling grade, the excess tractive force at lower velocities may so balance the deficiency at the higher velocities that the method is applicable without material error. Experience has shown this to be true.

Sags in Grade Line. Economies are often possible where sags having grades exceeding the ruling grade on one or both sides may be harmlessly introduced. Their harmlessness may be tested by the velocity-head table. It is of course assumed that running through the sag without a stop may be depended on. Deciding first the maximum-permissible speed for freight trains in the bottom of the sag, the ability of the train to mount the grade in either direction and have sufficient speed at the top of the grade may be tested. It must also be determined what speed of approach is necessary at the other end of the sag in order to attain that maximum speed at the bottom, and whether it is practicable to approach the sag at that speed.

As an illustration: the ruling grade is 1.2%; economical construction suggests a down grade of 2.0% for a distance of 4500 ft., followed by an up grade of 2.0% for 7000 ft. Assume a maximum-permissible freight-train velocity of 45 miles per hour, the velocity head being 71.10 ft. The excess grade is 0.8%, which in 7000 ft. has a rise of 56 ft. At the top of the grade the remaining velocity head is 15.10 ft., which corresponds to 20.7 miles per hour, which shows that a speed of 45 miles per hour through the sag would be unnecessary. The drop on the other slope of the sag is 90 ft., which would give to the train a velocity of over 50 miles per hour, even without using steam. There is therefore no question in this case of the ability of the train to acquire that speed at the bottom of the sag. It will also be still easier to run the train through the sag in the opposite direction.

Classification of Grades. The velocity-head table may be utilized to predict the behavior of trains, and therefore to classify the grades into the A, B, and C classes discussed under Minor Grades. The above case should be classified as C grade, since steam must be shut off and brakes used to prevent objectionably high speed in the sag, for either direction of movement.

SECTION 22

ELECTRIC RAILROADS

ASSOCIATE EDITORS

WILLIAM A. DEL MAR

PAST VICE-PRESIDENT OF AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

CHARLES J. McCARTHY

ASSOCIATE MEMBER—AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

* By **Walter Loring Webb**, who was the author of this section for the first edition and who made the revisions for the 2nd and 3d editions. He was also asked to make the revisions for the 4th edition and commenced the work, but service in the U. S. Army in France prevented, and the work was taken up by William A. Del Mar.

GENERAL

1. Classes of Traffic Suitable for Electric Traction

General. The essential characteristic of electric traction which distinguishes it from other forms, is the separation of the source of motive power from the rolling stock. This gives it a virtual monopoly for street and interurban systems because it permits the generation of motive power to be concentrated in a single economical plant instead of being distributed over a number of comparatively uneconomical ones, as in the case of steam traction.

Conditions for Electric Traction on Railroads. On electrified railroad trunk lines the generating and distributing systems must have large capacity in order to handle the heavy trains, but are not kept fully employed due to the comparative infrequency of traffic. This results in the investment of a great deal of capital which becomes idle, the fixed charges on which generally exceed the operating economies Exceptions to this generalization occur under the following conditions:

(a) When the cost of coal is very high, the operating economies may be sufficient to counterbalance the fixed charges, as electric traction requires only half the amount of coal needed with steam traction.

(b) When cheap water power is available, a similar condition may occur.

(c) When it is desired to increase the weight of trains to be hauled on steep grades, the elimination of the power generating system from the locomotive, in electric traction, permits an increased concentration of motors on the locomotive, thereby obtaining the desired increase of hauling power, at a lower cost than by the elimination of grades.

(d) When it is desired to increase the capacity of a mountain division and this can be accomplished by increasing the weight of trains as described above, rather than by increasing the number of tracks so as to permit more trains to be hauled.

(e) When it is necessary to eliminate smoke and gases in tunnels or city streets, the element of economy being necessarily subordinated to safety or convenience.

(f) When the traffic density is unusually great, as in certain suburban zones.

(g) When by the elimination of smoke and gases, trains through cities can be run underground and the ground surface utilized for lucrative building purposes.

2. Systems of Electric Traction

Economic Differences between Systems. The stationary equipment of an electric traction system consists of three parts — the generating, transmission, and distribution systems. These must have sufficient capacity to carry the peak loads and are therefore likely to be comparatively idle during a large part of the time. The activity of these parts depends upon the number of cars in operation.

The moving equipment of an electric railway system consists of the motors, controllers and other parts of the rolling stock necessary for electric operation. The activity of these parts does not depend upon the number of cars in operation, but only upon the activity of each car.

There are several systems of electric traction which differ in the distribution of the investment between stationary and moving equipment. Stationary equipment costs less than moving equipment of the same capacity, because it is concentrated in larger units and its design is not restricted by the limitations of car construction. It is, therefore, obvious that for railways operating a large number of cars, it pays to have a comparatively large investment in stationary equipment: whereas, railways with few cars must economize in stationary equipment and concentrate their investment as far as practicable on their limited rolling stock.

Technological Differences between Systems. The various systems of electric traction now in use may be classified as follows according to the above principle:

Low-voltage, direct current
High-voltage, direct current
Three-phase
Single-phase.

In every practical electric railway system current is generated for transmission at a high voltage and utilized in the motors at low voltage. In the direct-current systems, the transformation from high to low voltage is accomplished at stationary substations, which also change the alternating current from the transmission lines, into direct current, which is fed to the trolley or third rail, and thence to the motors. In the alternating-current systems, the high-voltage current is delivered to the trolley lines and transformed down to a voltage suitable for the motors by means of transformers on the cars or locomotives. Locomotives used with high voltage alternating-current transmission may have direct-motors, which are supplied with direct current from a motor generator set in the locomotive. As the direct-current systems carry a greater proportion of investment in their stationary equipment, they are especially adapted to urban and important interurban lines. The alternating-current systems, which carry a proportionately greater investment in moving equipment, are especially suitable for trunk lines having infrequent service.

The high-voltage, direct-current system is intermediate, in the above respect, between the low-voltage, direct-current and the alternating-current systems.

The choice of systems does not depend merely upon the investment, but also upon the operating costs. It has been found, however, that, with the present high rate of interest, these are seldom the governing factor.

3. Costs and Economics

General. Even more than in the case of steam railroads, electric urban and interurban railways labor under the difficulty that their rates are fixed by law, whereas their operating costs are constantly rising. This, added to the uncertainties of limited franchises and hostile regulation, makes it difficult to obtain capital for electric railways except at excessive rates of interest. The consequence is that the utmost economy must be exercised in construction and operation.

Revenues and Expenses of Street and Interurban Railways. The tables on page 2110 show the average annual revenues and expenses of 231 street and interurban railways for the year 1926.

Cost per Mile for Street and Interurban Railways. Later in this article is given the prescribed classification of capital charges used by the New York State Public Service Commission (2d District). It is useful in preparing estimates. An average total capital cost, including all items shown in the following classification, is $72 000 per mile of road. This figure covers all electric railways in New York State except those in the city of New York, and two lines of a very special character, namely, the New York, Westchester and Boston R.R. and the Niagara R.R. The former cost $1 269 219 and the latter $308 602 per mile of road owned.

Cost of Steam Railroad Electrification. The total cost of steam railroad electrification depends so much upon the amount of traffic and the character of the line that no general average figures are of use. The distribution of those features of annual expense which are purely electrical is shown for a typical electrified steam railroad, in a table near the end of this Article. Valuable data on this subject were published by J. B. Cox for the Butte, Anaconda & Pacific Railway, Trans., A.I.E.E., 1914, Vol. 33, p. 1369, and by W. S. Murray for the New York, New Haven & Hartford R. R., Trans. A.I.E.E., 1915, Vol. 34, p. 85, the data in both cases being too voluminous to abstract.

Annual Revenues and Expenses of Electric Railways

(Street and Interurban)

(From Reports to the American Electric Railway Association 1926)

Car Mile Basis

Income	**Cents per car mile**
Railway operating revenue	44.83
Railway operating expense	33.77
Net operating revenue	11.06
Net revenue — auxiliary operation	0.22
Taxes	2.80
Operating income	8.48
Non-operating income	0.84
Gross income	9.32
Deductions from gross income	7.50
Net income	1.82

Operating expense	**Cents per car mile**
Way and structures	4.86
Equipment	4.45
Power	4.57
Conducting transportation	14.74
Traffic	0.18
General and miscellaneous	4.87
Transportation for investment (Cr.)	0.04
Total operating expense	33.77

Note. The above figures are averaged from reports of 98 companies operating city lines exclusively; 50 operating interurban lines exclusively and 83 operating combined city and interurban lines. (From A.E.R.A., May, 1927.)

Unit Costs of Electrical Construction. Due to rapid engineering and economic changes in the electrical industry, a list of unit costs can never be relied upon. The following are typical average costs in 1927.

Third rails cost from $5000 to $8000 per mile, depending largely upon whether the railroad is operating during construction.

Ordinary trolley construction costs from $1500 to $2500 per mile of single-track road or from $3500 to $5000 per mile of double track. The cost of catenary construction is between $10 000 and $15 000 per track-mile.

Substations cost from $40 to $60 per kilowatt capacity, the former figure being for large substations, cost of real estate and building being omitted in each case.

Power stations cost from $100 to $125 per kilowatt capacity.

Underground conduits for railways cost from 75 cents to $1.25 per duct-foot, the latter figure being appropriate where the conduit lines are built along the narrow right-of-way of an operating railroad, or where paving must be replaced.

Transmission pole lines cost from $2000 per mile for wooden poles, to $4000 per mile for light steel poles.

Classification of Capital Expenditures

(New York State Public Service Commission, Second District)

Intangible Street Railway Capital

1. Organization.
2. Franchises.
3. Patent rights.
4. Other intangible street railway capital.

Direct Expenditures for Tangible Street Railway Capital

5. Right-of-way.

Distribution of Annual Expenses for Typical Electrified Eailroad

	Per cent
Fixed charges	59
Operating charges:	
Power station	12
Transmission and distribution	5
Substations	3
Signals and communications	5
Trains	16
	100

Notes. The above table excludes all items not peculiar to electric operation. It includes multiple-unit cars but not standard cars drawn by electric locomotives. The cost of train crews, except for electric locomotives, is omitted. Taxes on real estate are also omitted.

Life Expectancy Table of Electrical Equipment

(W. S. Gorsuch)

Equipment	Total life in years
Steam power plants:	
Buildings	75
Boilers	30
Stokers and grates	20
Conveyors, elevators and hoists	20
Turbines, complete	15
Engines and condensers	15
Piping	15
Heaters	15
Pumps	15
Alternators	15
Switchboard apparatus and instruments	15
Synchronous converters	30
Transformers	20
Exciters	25
Motors	25
Storage batteries	10
Tools and sundries	15
Substations:	
Synchronous converters	30
Transformers	20
Motor generator sets	25
Switchboard apparatus and instruments	20
Storage	10
Tools and sundries	15
Transmission and distribution:	
Conduit (vitrified clay)	50
Feeders (direct-current)	20
Feeders (alternating-current)	25

Note. In estimating the time in years during which equipment of a generating station may be reasonably expected to perform its functions, three elements must be clearly kept in mind; namely, obsolescence, inadequacy and inefficiency. How long apparatus or equipment will remain in service before it becomes obsolete, inadequate or ineffective, is purely a speculative matter, and can only be predicted in advance by past experience and a knowledge of the art, and with careful judgment.

4. Power Consumption in Relation to Schedule

Forces Acting on a Train. The forces tending to accelerate a train are the tractive effort developed by the motors and the component of the weight along the track on down-grades. The forces which retard the motion of the train are the various frictional forces and the component of the weight along the track on up-grades; also in braking, the frictional force due to the brakes. All the various frictional forces, except the braking resistance, such as track friction, journal friction, air friction, etc., which oppose the motion of a train on a straight track, are usually considered together and are referred to as the "train resistance." The extra friction due to track curvature is usually considered as an equivalent up-grade.

Train Resistance for Electric Train. Let

N = number of cars (including electric locomotive, if any);
w = average weight of car loaded, in tons (= total weight of train divided by N);
r = train resistance in pounds per ton;
v = speed in miles per hour;
a = cross-section of car in square feet;

A and B are constants in the formula; K taken as 0.0030 throughout.

$$r = A + Bv + \frac{Ka(0.9 + 0.1\,N)v^2}{Nw} \tag{1}$$

The constant A depends chiefly upon the average total weight of car and load. Thus

for w =	15	20	25–30	35	40–45	50	70
A =	6.0	5.5	5.0	4.5	4.0	3.5	3.0

The constant B depends primarily upon the nature of the track and roadbed and also to some extent upon the weight and type of the car. Burch gives the following values:

Passenger cars on excellent track	0.06–0.11
Passenger cars on ordinary track	0.10–0.15
Freight cars on ordinary track	0.05–0.06

The heavier the car the higher the value of this coefficient.

Grades and Curvatures. An actual up-grade of $G\%$ produces a retarding force of $20\,G$ lb. per ton and a down-grade of $G\%$ produces an accelerating force of $20\,G$ lb. per ton. A curve always gives rise to a retarding force, which ranges from 0.5 to 1 lb. per ton per degree of curvature. Using the higher figure, each degree of curvature may be taken equivalent to an up-grade of 0.05%. Note that for angles of curvature up to 12 deg. the angle in degrees may be taken equal to $5730 \div R$, where R is the radius of curvature in feet.

Average Acceleration Rates

Service	Miles per hour per second
Steam locomotive, freight service	0.1 to 0.2
Steam locomotive, passenger service	0.2 to 0.5
Electric locomotive, passenger service	0.3 to 0.6
Electric motor cars, interurban service	0.8 to 1.3
Electric motor cars, city service	1.5 to 2.0
Electric motor cars, rapi. transit service	1.5 to 2.0
Highest practical rate	2.0 to 2.5

Acceleration Constant. The tractive effort required to give to 1 ton (2000 lb.) a linear acceleration of 1 mphps is 91.2 lb. To accelerate a train of W tons requires a tractive effort of 91.2 aW lb. to produce a linear acceleration of a mphps; but on account of the accompanying angular acceleration of the rotating parts, an additional force is required.

The acceleration constant is raised by the flywheel effect by about 5% (i.e., $Wr/W = 0.05$) for heavy cars and locomotives, and between 5% and 10% for light, low-speed cars, 8% being an average figure. However, C is usually taken as 100, corresponding to an increase in effective weight of about 10%. A given linear acceleration of a mphps then requires an accelerating force of 100 a lb. per ton.

Tractive Effort and Adhesion Coefficient. Let

F = tractive effort, in pounds per ton, exerted by motors;
G = per cent actual grade (+ for up-grade);
g = degrees of curvature;
r = train resistance, in pounds per ton;
a = acceleration in mphps (− for retardation).

Then the tractive effort required per ton of total train weight is

$$F = 100\,a + r + 20\,G + g \qquad (2)$$

The adhesion or "tractive" coefficient is the quotient (expressed usually as per cent) of the tractive effort in pounds which will slip the drivers, divided by the weight in pounds on the drivers. Burch gives the values in the accompanying table. The maximum possible tractive effort is the product of the adhesion coefficient (as a decimal fraction) by the weight (in pounds) on the drivers.

Adhesion Coefficients

Condition of track	Without sand	With sand
Most favorable condition	35	40
Clean, dry rail	28	30
Thoroughly wet rail	18	24
Greasy moist rail	15	25
Sleet-covered rail	15	20
Dry snow-covered rail	11	15

The Weight of Locomotive required to accelerate a train weighing W tons at the rate of a miles per hour per second up a grade of G% on a g degree curve against a frictional resistance of r lb. per ton, when q% of the weight is on the drivers and the coefficient of adhesion, is p%, is given by the following formula:

$$\text{Weight of locomotive} = \frac{5\,W}{pq}\,(100\,a + r + 20\,G + g).$$

Example. What weight of locomotive is required to accelerate a 400-ton train at the rate of 0.5 mile per hour per second up a 0.1% grade against a frictional resistance of 8 lb. per ton, when 80% of the weight is on the drivers and the coefficient of adhesion is 20%?

$$\text{Weight of locomotive} = \frac{5 \times 400}{20 \times 80}\,(50 + 8 + 2) = 75 \text{ tons}.$$

Maximum Over-all Efficiency of Motors and Gears at Rated Voltage

Horsepower, 1-hour rating	Kind of motor	Maximum efficiency, per cent
30–100	D-C. geared	83–88
100–250	D-C. geared	88–89
250–500	D-C. gearless	91–83
50–200	A-C. series geared	70–80 *
200–500	3-phase induction geared	85–89

* Including step-down transformers.

Power Required at Given Speed. Let

r = train resistance in pounds per ton of total weight of train;
G = per cent grade;
g = degree of curvature;
a = degree of acceleration in mphps;
v = speed in mph;
W = total weight of train in tons.

Then the power required *at the rims of the drivers* is $1.99\,v\,(r + 20\,G + g + 100\,a)$ watts per ton, or $2.67 \times 10^{-3}\,vW\,(r + 20G + g + 100\,a)$ horsepower, total.

The power input, p_i, to the car or locomotive is equal to the power at the rims of the drivers divided by the over-all efficiency ϵ of the controller, motors and gears, that is,

$$p_i = \frac{1.99\,Wv(r + 20\,G + g + 100\,a)}{1000\,\epsilon} \text{ kilowatts} \qquad (5)$$

Approximate Method of Calculating Energy Consumption. The following method is based upon simple kinetic principles, and, if certain characteristics of the run are known, gives the actual energy output at the wheel rims. This fact makes the method useful, not only for rough calculations, but also to check calculations made by the more accurate step-by-step method.

When the method is applied to checking purposes, the column of the table below headed " Actual energy output " should be used and the input calculated from the known efficiencies. When applied to rough calculations, the column headed " Approximate electrical energy input " should be used. In the latter case the maximum speed and length of run with power on are not known, but it is possible to assume certain values, based upon experience, which will give a rough approximation to the energy required. The total energy in watt-hours per ton-mile will be the sum of the amounts required for acceleration and overcoming frictional train resistance grades and curves.

Let V = average running speed in miles per hour;
V_m = maximum speed in miles per hour;
L = length of run in miles;
L_p = distance traveled, with power on, in miles;
$n = l/L$ = number of stops per mile including one terminus;
r = average train resistance, in pounds per ton (say that corresponding to a speed from 10 to 20% greater than the average speed);
G = average equivalent grade, in per cent;
g = average curvature in degrees;
$K = \frac{V_m}{V}$ = ratio of maximum to average speed; see accompanying table of values of K;
$Q = \frac{L}{L_p}$ = ratio of length of run to distance traveled with power on.

See table of values of K and Q on next page.

Output at Wheel Rim and Input to Cars in Watt-hours per Ton-mile

Energy for	Actual energy output at wheel rims of cars	Approximate electric energy input to cars
Acceleration........................	$\dfrac{V^2m}{36.2\ L}$	$\dfrac{K^2nV^2}{25}$
Frictional train resistance................	$\dfrac{1.99\ r\ L_p}{L}$	$\dfrac{2.9\ r}{Q}$
Grades..............................	$\dfrac{39.8\ GL_p}{L}$	$\dfrac{57\ G}{Q}$
Curves..............................	$\dfrac{1.99\ gL_p}{L}$	$\dfrac{2.9\ g}{Q}$
Total..............................	Sum	Sum

Note. $25 = 36.2\ \epsilon$, $57.8 = 39.8 \div \epsilon$, and $2.9 = 1.99 \div \epsilon$, where ϵ is the efficiency, taken as 0.7. The formula for energy due to curves assumes each degree of curvature to be equivalent to a train resistance of 1 lb. per ton, which is probably high.

Values of K and Q

Stops per mile, n	K		Q
	Locomotive passenger trains	Single cars multiple unit trains and freight trains	All trains
0	1.0	1.0	1.0
0.1	1.2	1.1	1.1
0.2	1.35	1.2	1.25
0.3	1.5	1.25	1.4
0.4	1.6	1.3	1.5
0.5	1.7	1.35	1.7
0.6	1.75	1.4	1.8
0.7	1.8	1.45	1.9
0.8	1.85	1.45	2.0
0.9	1.9	1.5	2.1
1.0	1.95	1.5	2.15
1.2	1.95	1.6	2.2
1.4	1.95	1.6	2.3
1.6	1.95	1.6	2.4
1.8	1.95	1.65	2.5
2.0	1.95	1.7	2.6
2.5	1.95	1.75	2.7
3.0	2.0	1.8	2.8
3.5	2.0	1.85	2.9
4.0	2.0	1.9	2.9
4.5	2.0	1.95	2.95
5.0	2.0	2.0	3.0

More exact methods involve a knowledge of the motor characteristics, gears, brakes, and control.

Power Required for Car Heating and Lighting. In addition to the energy required for propelling the cars, a very appreciable amount is also required in the winter, for heating them, and a small amount at night for lighting. See table below. In making up a load diagram this energy should be included. See Art. 17 for power required for heating.

Lighting of Cars

Length of car, feet	Average * Kw for lighting
14–20	0.25
20–28	0.35
28–34	0.55
34–40	0.70

* During the hours lights are on, using tungsten lamps.

POWER STATIONS AND SUBSTATIONS

5. Power Stations

General. The power plant of an electric railroad should be located with reference to the load center, the water and coal supply, and the cost of real estate. The load center is usually the least important consideration as the cost of transmission lines and the losses therein do not rank in importance with considerations of plant economy.

Water is required for boilers and condensers. The coal supply should be brought by water where practicable, with auxiliary rail connection.

Buildings. Buildings are usually of brick with steel frames and concrete floors. Floors are of concrete with cement or tile finish for engine rooms and concrete with cement finish or bricks laid on edge in cement mortar for boiler rooms. Foundations for machinery are usually made of concrete and separate from the wall foundations in order to reduce vibration. Boiler-room equipment is carried on the steel structure.

Tidal limits and flood-water stages fix the levels of both condenser intake and outlet tunnels, and sometimes of engine- and boiler-room floors.

Standard Design. Present practice for large stations provides a boiler room and generating room side by side and separated by a thick wall. The generating room is divided into two parts, either with or without a separating wall, the part nearer the boiler room containing the generating equipment and provided with a crane; the other part, without a crane, having the electrical control apparatus.

Equipment. The table on page 2119 shows the principal items in a typical electric railway power station, and their relation to the general processes of the plant. At the head of the upper part of the table are listed the raw materials which enter the plant, followed by the machinery and apparatus through which they pass to the boiler. At the head of the lower part of the table are listed the products of the boilers, followed by the machinery and apparatus through which they are dissipated.

6. Substations

General. A substation is a group of apparatus or machinery which receives current from a transmission system, changes its kind or voltage, and delivers it to a distribution system. Most commonly, substations transform high-voltage alternating current to low-voltage direct current, the former affording the most economical transmission, and the latter the most economical conversion of electrical into mechanical energy. Substations are usually housed in substantial brick and concrete buildings, although where the current has to be changed only in voltage and not in kind, as on single-phase railway systems, the building is often unnecessary, as no rotating machinery is required, and the transformers and switching apparatus can be built for out-door operation. In some locations, the high tension bus, transformers, and switching equipment may be installed in an out-door substation adjacent to the building housing the rotating equipment, meters, etc.

Economical Location. Substations are located at intervals of 3 to 20 miles along the railroad, the spacing being limited by consideration of line voltage, regulation at the cars and economy, both of first cost and operation. Theoretically, substations should be located so as to give the least annual expense, taking into account both the fixed charges on the investment in substations and feeders, the operating charges and the cost of energy losses in the system. An investment in copper feeders, especially in the case of bare or weatherproof aerial cables, causes little annual expense beyond the interest and taxes on the investment, whereas, a substation involves, in addition, heavy depreciation charges and labor charges for operation. In recent years the use of automatic substations has been spreading rapidly, as it enables the operating force to be reduced, and in many cases eliminated with the exception of a small force for inspection and maintenance, one group of men being responsible for the care of several substations. Automatic substations have the further advantage that they act instantly in case of trouble, reducing the damage to equipment caused by abnormal conditions within or external to the station.

Automatic stations are usually controlled from a central point by a load dispatcher or supervisor by means of one of several forms of supervisory control which by the use of a very few wires, usually from one to four, enables all switches in a large group of substations to be operated, and all desired indications such as switch positions, machine temperatures, station output, to be relayed to the supervisor's board.

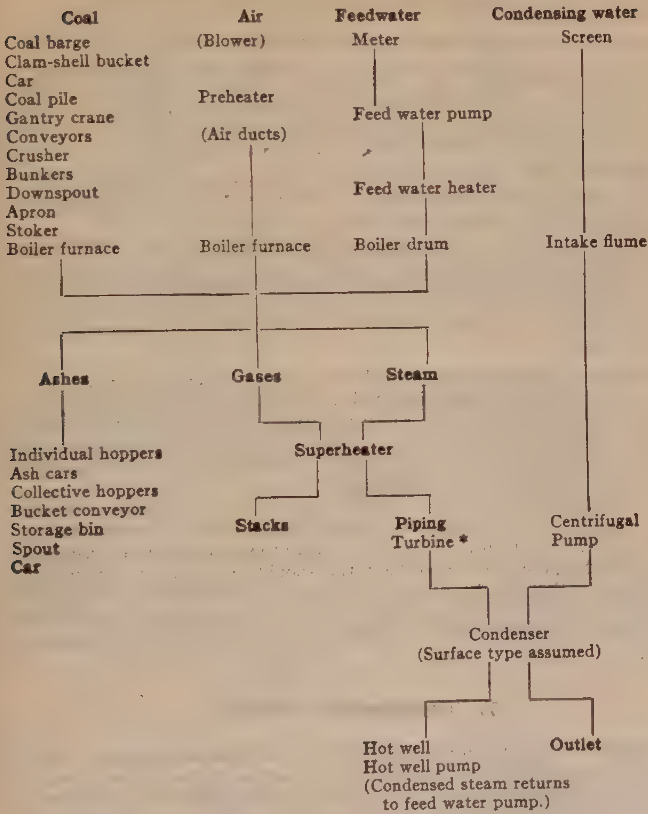
On interurban systems where the traffic density is low automatic stations may be equipped to start automatically as a car approaches the section fed by the substations, and shut down as soon as the load has dropped.

The permissible distance between substations depends on the voltage of distribution, being greater the higher the voltage. On an ideal line, doubling the operating voltage quarters the distance between substations. This ratio is not strictly adhered to, however, as the location of substations is also influenced by physical conditions such as availability of a suitable location for the substation, or the location of concentrated loads caused by yards, grades or sharp curves.

Where a length of track receives its power from only one direction, the distance that can be fed, with a given voltage drop, is one-fourth the distance allowable between substations.

Apparatus. In the usual type of substation for the conversion of high-pressure alternating current into low-pressure direct current, the high-pressure current first passes through oil-switches to the high-pressure bus, then through oil-switches to the primary windings of the transformers. From the secondary windings of the transformers, the low-pressure alternating current enters the slip-rings of the converters, and emerges from the commutators as direct current of a slightly higher pressure. From the commutators it passes through circuit-breakers to the direct-current bus bars and thence through circuit-

Relation of Machinery in Typical Power-house



* Turbine drives electric generators, which supply current to the switching and protective apparatus and thence to the outgoing feeders.

breakers to the outgoing feeders. In the design of substations, it is good practice to arrange all the apparatus so as to make the route of the electric current as direct as possible.

All substations are not equipped with synchronous converters, motor-generators having been used especially for pressures in excess of 750 volts. Such a motor-generator usually consists of a synchronous motor driving a direct-current generator.

For voltages below 750 volts, the rotary converter has a virtual monopoly, although in special cases both motor-generator sets and mercury-arc rectifiers are used.

For direct-current voltages of the order of 1500 volts, all three classes of equipment are used, the rotary converter and motor-generator set now meeting competition from the mercury-arc rectifier.

For voltages above 1500 volts, motor-generator sets have been used exclusively, but the development of the mercury-arc rectifier is making rapid strides and many installations are now operating at this voltage in Europe.

Portable Substations. Portable substations, that is, substations of small size installed in a box car, are sometimes used where unexpected or occasional loads are liable to occur. They are especially useful to carry holiday loads for which it would not pay to install a permanent substation.

Power Capacity. The power capacity required in a substation depends upon the size, number, acceleration and speed of cars; on the length of line fed and upon the number of stops per mile.

Railway substation machines and transformers are usually rated by the kilovolt-ampere output which, having produced a constant temperature, may be increased 50% for 2 hours without producing temperatures or temperature rises exceeding by more than 5° C. the standard limiting values established by the American Institute of Electrical Engineers. This is known as the nominal rating.

Buildings. Substations having all apparatus on one level require about 0.2 sq. ft. per kilowatt of nominal rating. Buildings are usually of brick with concrete foundations for walls and machines, except where the machines are small, in which case the machines are often carried by the floor beams. It is usual to provide a crane which, in important substations, may be equipped for both manual and electrical operation.

Provision must be made for ventilation and good illumination, but roofs must be constructed so that there will be no danger of leaks over the machines and other live apparatus. In locations where the air contains a considerable amount of dust, the air entering the station should be drawn through air filters, circulation of the air being obtained by means of motor-driven fans blowing the air into the station through louvers in the floor near the machine. Lavatory, toilet and telephone booth should be conveniently near the operators' desks.

7. Transformer Stations

General. A transformer station, as used on alternating-current railway systems, is an aggregation of apparatus for converting high-voltage alternating current from transmission lines into lower-voltage alternating current for use in the trains, the apparatus being usually out-of-doors and protected only by a fence.

Special designs of oil-cooled transformers, switching apparatus, and lightning arresters must be used for this purpose.

All apparatus is set on concrete foundations, and steel structures are used to support overhead wires and switching apparatus.

Auto-transformer System. The New York, New Haven & Hartford Railroad system transmits at 22 000 volts between trolley and feeder, but the locomotives receive current at 11 000 volts between trolley and track rail. This is accomplished by transformer stations about 2 miles apart, where the trolley and feeder are each connected to the track rails through a separate auto-transformer. This arrangement not only effects economy in transmission, but also greatly reduces the current in the track rails and earth, with consequent reduction of disturbances to telephone lines.

TRANSMISSION AND DISTRIBUTION

8. Duct Lines and Underground Conductors

General. Underground cables in the United States are almost invariably installed in conduits made either of glazed tile, concrete or fiber. The conduits are laid so as to form a series of continuous ducts in length not over 400 ft., which are terminated in brick or concrete chambers from which the cables are pulled into the ducts.

Conduit lines are used for the distribution of electrical energy wherever the unsightliness, danger or instability of pole lines prohibit the use of the latter. They are used for both the transmission and distribution cables of many railways, and for telephone and telegraph lines.

Types of Conduits. Figs. 1 and 2 show the tile conduits used by the New York Central Railroad Company, and are representative of the best modern practice except that 4-in. and 4-1/2 in. sizes are now preferred. The single-duct conduit weighs 16-1/2 lb. per length of 18 in., and the four-duct conduit weighs 100 lb. per length of 3 ft.

Fiber conduit consists of tubes made of wood pulp or paper, saturated with bituminous compound and formed around a mandrel. Lengths of fiber conduit are joined by screw and coupling, socket, sleeve or drive joints. Fiber conduit should be laid in concrete, with from two to three inches of concrete between each duct at the point of minimum concrete section, to allow for thorough tamping of the concrete. Typical dimensions of fiber conduits are given in the table.

Sizes and Weights of Fiber Conduits

Inside diameter, inches	Thickness of walls, inches	Approximate average weight, per foot, pounds	Length of section, inches	Inside diameter, inches	Thickness of walls, inches	Approximate average weight, per foot, pounds	Length of section, inches
Sleeve joint				Sleeve joint			
1	1/4	0.45	30	1	1/4	0.45	30
1-1/2	1/4	0.75	60	1-1/2	1/4	0.75	60
1	1/4	0.90	60	2	1/4	0.90	60
2-1/2	1/4	1.05	60	2-1/2	1/4	1.05	60
3	1/4	1.30	60	3	1/4	1.30	60
3-1/2	1/4	1.60	60	3-1/2	7/16	2.50	60
4	1/4	1.85	60	4	1/2	3.20	60
Screw joint				Drive joint			
1-1/2	5/16	0.85	60	2	1/4	0.90	60
2	3/8	1.35	60	2-1/2	1/4	1.05	60
2-1/2	3/8	1.70	60	3	1/4	1.30	60
3	7/16	2.20	60	3-1/2	1/4	1.60	60
3-1/2	7/16	2.50	60	4	1/4	1.85	60
4	1/2	3.20	60				

Wrought-iron pipe is used in city streets where the conduit line has to twist about sub-surface obstructions. It is more expensive than tile conduit, and does not last as long on account of rusting. The usual sizes are 3-in. and 3-1/2-in. pipe, 20 ft. long, provided with threaded ends and couplings.

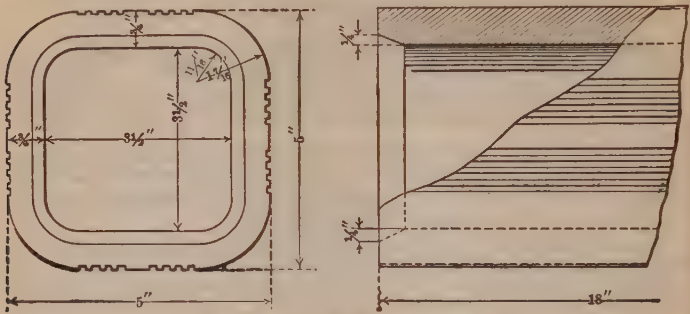


Fig. 1. Typical Single-Duct Conduit

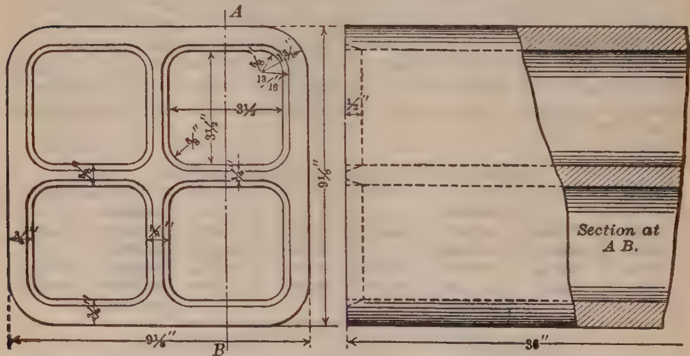

Fig. 2. Typical Four-Duct Conduit

Splicing Chambers. Splicing chambers for straight runs are usually built in the shapes shown in Figs. 3, 4, 5, and 6. The height of large splicing cham-

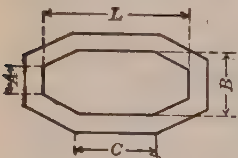

Fig. 3

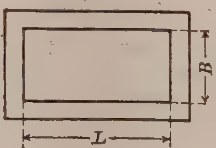

Fig. 4

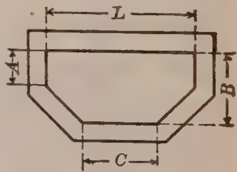

Fig. 5

Splicing Chambers

bers is usually determined by the height in which a man can stand upright and is seldom less than 6-1/2 ft. The width is similarly influenced by the space required for working, which is at least 4 ft. The length depends upon the length of splice and the space required to curve the cable from the ducts to the supporting shelves or racks, considerations which make a length of 8 ft. a practical minimum where there are large cables. The usual dimensions are tabulated herewith.

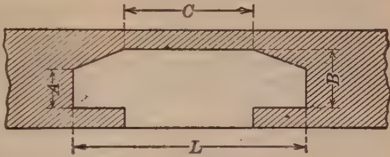

Fig. 6. Splicing Chamber

Cables in splicing chambers are usually supported on iron brackets attached to the chamber walls. This construction is very satisfactory, especially if the power cables are protected with fireproofing; but some engineers consider a shelf preferable, as it affords insulation and provides more protection between cable splices.

Type	A	B	C	L
Fig. 3	2 ft. 2 in.	5 ft. 0 in.	3 ft. 6 in.	9 ft. 0 in.
Fig. 4	....	4 6	....	8 0
Fig. 5	2 0	4 6	3 8	10 0
Fig. 6	1 6	3 0	4 0	10 0

Testing of Duct Lines. Ducts are usually tested by rodding with a mandrel in order to ascertain whether they are continuous and unobstructed. The rods used for this purpose are of hickory 1 in. in diameter and 3 or 4 ft. long, and are fitted at the ends with steel couplings such as that shown in Fig. 7. The first rod is attached to a mandrel and pushed into the duct. Another rod is coupled to the first, and the pair pushed farther into the duct. By successively coupling other rods and pushing them into the duct, the mandrel is made to travel from one chamber to another.

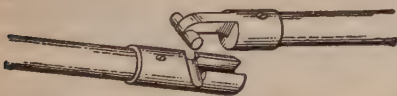

Fig. 7. Testing Mandrel

As soon as the mandrel emerges into the receiving chamber, the rods are pulled through and uncoupled. If an obstruction stops the mandrel, an attempt is made to force it through by repeated blows, failing which it becomes necessary to break into the conduit line from the side. It is usual to attach a No. 10 or No. 12 galvanized steel wire to the last rod, and leave the wire in the duct after the removal of the rods. This wire is subsequently used for drawing a heavy rope through the duct, by means of which the cable is pulled in place.

Types of Cables Used. Cables for underground conduit lines are almost invariably insulated with impregnated paper and covered with a lead sheath. Three-conductor cables are used for high-pressure, three-phase transmission, and either single-conductor or two-conductor concentric cables for low-pressure distribution. Single conductor cables are now being applied to high-voltage three-phase transmission in metropolitan areas.

9. Pole Lines and Aerial Cables

General. The most usual construction for street and interurban railways consists of wooden poles spaced about 100 ft. apart, carrying wooden cross-arms, porcelain insulators, and strung with bare or weatherproof copper wire.

Where the transmission line parallels the railway, the same poles are used for supporting both trolley system and transmission lines. Steel towers are used on electrified steam railways.

Tubular steel poles are largely used for urban railways and reinforced-concrete poles are gaining favor.

Dimensions of Wooden Poles. Poles are specified by their total length and their diameter or circumference at the top. Standard lengths are multiples of 5 ft. and vary from 30 to 60 ft. Standard diameters are even multiples of 1 in. and vary from 7 to 8 in., except on the Pacific Coast, where 8 to 10 in. prevail. The taper is expressed as the difference in inches between two circumferences 10 ft. apart and is usually as follows:

Michigan white cedar	5.2
Maryland chestnut	3.8–4.0
California yellow pine	4.0
Montana lodgepole pine	3.0
Texas loblolly pine	2.4
Washington cedar	3.5

The minimum dimensions specified by the American Electric Railway Association are given in a table on page 2126.

Tubular Steel Poles. Tubular steel poles are made of three pieces, each of a different size, of steel tubing. The three pieces are joined by shrinking the larger onto the smaller, until an overlap of 18 in. is obtained. Such poles are made in lengths of 28 to 35 ft. and vary in weight from 384 to 1688 lb. Comprehensive tables of data for such poles are given in A.E.R.A. Engineering Manual.

Reinforced-Concrete Poles. Reinforced-concrete poles are made in lengths of 28 to 35 ft. and with butt sections from 5 to 15 in. square, the corners, however, being eliminated. They are reinforced with four steel rods. Hexagonal poles are also used, containing six steel rods. Comprehensive tables of data for such poles are given in A.E.R.A. Engineering Manual.

Location of Poles. Side poles should have a minimum clear distance of 7 ft. 6 in. from the center line of track at level of top of rail; center poles should have a minimum clear distance of 7 ft. from the center of track, these clearances to be suitably increased at curves. Poles are usually spaced between 90 and 110 ft. apart.

Depth of Setting. The usual depth of pole setting for tangent construction is shown in the table on page 2127. On curves, and other special localities, an extra depth may be necessary.

Wires and Cables for Pole Lines. Three classes of wire are used for aerial conductors: Bare, weatherproof and insulated. Bare and weatherproof wires are usually made of hard-drawn copper, the stranding being as shown in the table below. Bare wires are used for operating pressures over 2500 volts, but where the pressure is not above this amount, weatherproof wire is preferred by many engineers, because it affords some protection from grounds due to the contact of foreign bodies, especially tree twigs.

Insulated cables, except telephone cables, are seldom used on pole lines on account of their expense, but where used are made of soft annealed copper either insulated with paper and sheathed in lead, or insulated with varnished cambric or rubber and covered with impregnated cotton braid. Such cables must be supported from a steel messenger cable by means of clips spaced from 12 to 18 in. apart. Where rubber insulation is used on aerial lines, a high-grade compound is essential if it is to withstand the effects of the weather.

Stranding of Concentric Lay-Cables for Aerial Use

Size (See note 1)	Number of wires (See note 2) Bare, insulated or weatherproof cables for aerial use	Size (See note 1)	Number of wires (See note 2) Bare, insulated or weatherproof cables for aerial use
Cir. in.			
2.0	91	0000 A.W.G.	19 or 7 (See note 3)
1.5	61	00 A.W.G.	7
1.0	61	2 A.W.G.	7
0.6	37	7 and smaller	1
0.5	37		
0.4	19		

1. For intermediate sizes, use stranding for next larger size.
2. Conductors of 0000 A.W.G. and smaller are often made solid and this table of stranding should not be interpreted as excluding this practice.
3. Cables of sizes 0000 and 000 A.W.G., are usually made of 7 strands when bare and 19 strands when insulated or weatherproof.

Guy Wires. Galvanized iron cables are used for guying poles. They are usually made of 7 strands of No. 12 or 14 B.W.G. wire, having an ultimate breaking strength of 2300 or 5000 lb. per cable, respectively.

Preservation of Poles. It is estimated that it takes 190 years to grow a 30-ft. cedar pole, which, when set in the ground, will not last over 15 years. When butt-treated, the life is increased to about 20 years. The preservatives most generally used are creosote, zinc chloride and bichloride of mercury. (See U. S. Forest Service Circulars 84 and 147.) Decay occurs at the butt of the pole, which must be particularly well protected.

Cross Arms. Cross arms are rated by the number of pins they are made to carry, the number being from 2 to 10. The usual cross-sections are 3-1/4 or 3-3/4 by 4-1/4 or 4-3/4, the length depending upon the number of wires to be carried and their voltage. Cross arms, 3-1/4 by 4-1/4 in. in cross-section are attached to wooden poles by a through-bolt driven from the back of pole toward and through the arm, having a washer at each end, with hole at back of pole counterbored to secure a good seat for the washer. Cross arms should be steadied by strap braces secured to the pole by a large screw and to side of arm away from pole by carriage bolts on the center line of arm, with nuts next to the braces. Arms up to and including 48 in. in length should have braces 24 in. long fastened to arm 16 in. from center; arms over 48 in. long should have braces 28 in. long fastened to arms 19 in. from center. Cross arms larger than 3-1/4 by 4-1/4 in. should be steadied by angle braces.

10. Trolley Systems

General. The trolley wire is usually of hard-drawn copper but under unusual conditions, bronze or steel wires are sometimes used. The wire is suspended from insulators some 16 to 30 ft. above the ground, and presents a continuous contact surface to a trolley wheel or bow attached to the rolling stock. There are two classes of trolley construction, the span wire and the side bracket; each may have either simple or catenary suspension. (See Art. 9 for details of poles.)

Minimum Circumference of Poles in Inches

(A.E.R.A. Engineering Manual)

A. For span construction where a 35-ft. span is required, or for heavy feeder lines carrying from one to six cross arms

B. For span or bracket construction where spans are not more than 35 ft. or bracket line or construction carrying two transmission circuits, one feeder arm and two telephone and signal arms.

C. For telephone, signal and other light auxiliary lines where no side strain is required.

Span-wire and Side-bracket Construction. In the simple span-wire construction the trolley wire is supported by wires stretched across the tracks between poles or building walls. The side-bracket construction resembles the span-wire except that instead of the supporting wire being stretched between two poles, it is stretched between two supports on the same pole. In both of these types of construction, the trolley wire is supported at intervals of 100 ft. or more and sags between supports, making it necessary for the trolley to be in vertical vibration as the cars move.

Catenary Construction. The speed attained upon modern electric roads makes it difficult to obtain satisfactory service with a trolley wire which dips between supports and sways with every impulse. The catenary construction was devised to meet this condition. In general, it consists of a grooved copper trolley wire suspended horizontally from a sagging messenger cable, which is suitably insulated and firmly held in place. The supporting structure employed for interurban single- or double-track roads usually is of the side-bracket type, but for some conditions cross-span construction becomes necessary. The latter method of support differs only in the substitution of a catenary cross-span for the bracket arm and doubling the number of poles required for single track.

Applications of Various Types of Construction. The overhead trolley system is used on urban railways, wherever the unsightliness or danger of its exposed construction is not considered objectionable. It is used on interurban, suburban and trunk lines, wherever, by reason of low load or high voltage, the current taken by the trains is not too great to be economically carried on copper wires.

Center-pole construction is approved practice for double-track railways, side-pole construction being generally used for single-track lines. Span-wire construction is used where, for any reason, it is impracticable to have the poles near the tracks or where, as is commonly the case in Europe, the span wires are supported from the walls of buildings. Prejudice against overhead lines is often due to the excessive loading of poles, which is both unsightly and dangerous.

Parts of Overhead Trolley Construction. The trolley wire is secured to an "ear" by soldering, clamps or other means and the ear is bolted to a "suspension" which may or may not be provided with an insulating portion. These suspensions are carried by span wires which in turn are fastened to the poles or brackets, or they may be fastened directly to the bracket. If the "suspension" is not insulated, "strain" insulators are inserted in the span wire between the ear and its point of attachment to the poles or brackets. A slightly different form of suspension, called a "pull-off," is used on curves. At turnouts "trolley frogs" must be used to guide the trolley wheel. These various parts are illustrated in the accompanying cuts.

Trolley Ears. Figs. 8 to 12 show ears for round wire. Fig. 8 shows an ear with flaps, which are bent around the wire to hold it in place; this type is

Fig. 8

Fig. 9

Fig. 10

Fig. 11

Fig. 12

Trolley Ears for Round Wire

seldom used on account of arcing at the flaps. The ear shown in Fig. 9, which has a deep groove into which the wire is soldered, is the type in common use. These ears may be provided with rings as in Fig. 10 to which guy wires are attached to relieve the strain at curves and for steadying the line at intervals. Fig. 11 shows the type of ear used at points where the trolley is spliced, which should always be at an ear. Fig. 12 shows an ear with a terminal for a feeder connection.

Figs. 13 to 15 are designed for grooved or "figure 8" trolley wire. Special grooved (Fig. 16) or "figure 8" wire affords a smoother running surface for the

Fig. 13

Fig. 14

Fig. 15

Trolley Ears for "Figure 8" Wires

trolley wheel or bow as the ear only grips the upper part, leaving the lower part absolutely even. This construction is practically essential for bow trolleys.

Suspensions for Straight Line Work. Fig. 17 shows an insulated suspension with ear attached at each end; this is also used on curves for double-track work. Figs. 19 and 20 show solid insulated suspension for span wire and side-bracket construction respectively. These types are frequently used, and are quite satisfactory if the insulating material used in their construction is properly made. Fig. 21 shows a section of an assembled cap and cone suspension. Fig. 22 shows a cap and cone suspension with ear attached. The type in which cap and cone are made separate is preferred by some engineers on account of the possibility of replacing injured bolts and insulation without removing the whole suspension. This advantage is partly offset by the greater liability to trouble due to multiplicity of parts.

Strain Insulators. Fig. 23 shows a "globe" strain insulator, the type most commonly used. Fig. 24 shows a "Brooklyn" strain insulator. This type is used on wooden pole and light iron pole construction to draw span wires taut. It is required for heavy iron pole construction if spans are long and temperature variation great. Bolts may be provided at both ends if an extra amount of adjustment is required. A globe strain and a Brooklyn strain may be used in series where extra insulation is required.

Pull-offs. Fig. 25 shows a cap and cone pull-off for single-curve construction and Fig. 26, a cap and cone pull-off for double-track curve construction.

Types of Suspensions

Trolley Frogs. A trolley frog is a malleable iron casting used at switches or crossovers where trolley wires from different tracks unite. Its function is to hold the diverging wires together and afford a smooth running path to the trolley wheel when a car passes or enters a switch. A common type is illus-

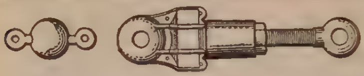

Fig. 23 Fig. 24

Strain Insulators

Fig. 25 Fig. 26

Pull-offs

trated in Fig. 27. Frogs are made for various angles of divergence and both right- and left-handed. The usual angles are 8, 15 and 20 degrees.

Sag and Tension in Overhead System. Particular attention must be paid to designing the overhead structure in such a manner that it will safely stand the extra tension due to the contraction of the wires at low temperatures and the extra loads due to wind and sleet, and a sufficient allowance should be made in the height of the trolley wire to take care of the extra sag which it experiences at high temperatures.

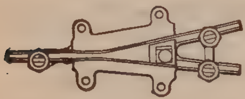

Fig. 27. Trolley Frog

Height of Trolley above Rail. The height of wire varies between a minimum of 16 ft. and a maximum of 22 ft., the usual height being about 18 ft. It is usual to raise the wire at railroad crossings to a height of 22 ft. or more.

Rake of Poles. Bracket-arm poles on tangent construction should have a rake backwards not exceeding 3 in., and span-wire poles in hard ground a rake of from 4 to 5 in. In soft ground a rake of 12 in. is not uncommon. Center poles should be set vertically except at curves, where they should bend away from the curve along the perpendicular to the tangent at that point of the curve.

Anchorage. At both ends of every grade and curve, there should be a permanent anchorage. If there are not many grades and curves, anchorages should be provided at intervals of from 1/4 to 3/4 mile. An anchorage is made by means of a steel cable running from the trolley wire to one or more anchor poles through an anchor ear and strain insulators.

Curves. At curves in the track the trolley wire should be made to follow the curve by means of pull-offs or wires pulling the trolley wire outward as shown in Fig. 28 and 29.

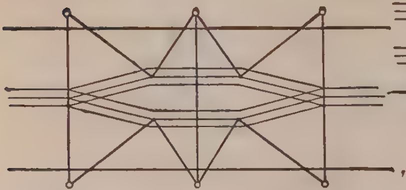

Fig. 28

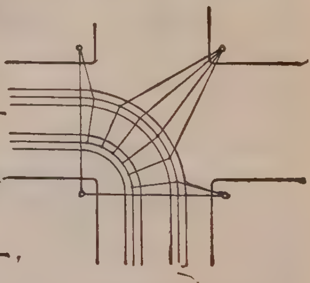

Fig. 29

Simple Pull-off Arrangement

Wherever possible the pull-off wires should be radial to the trolley wire. This, however, requires a large number of poles, and is therefore impracticable

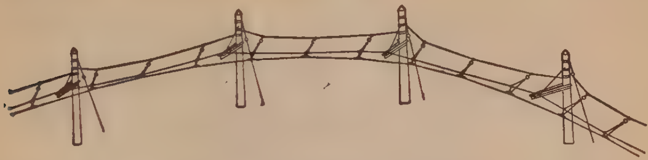

Fig. 30. Bridle Construction at Curve

in cities. In such cases the bridle, bowstring or backbone construction shown in Fig. 30, 31 and 32 is resorted to. Here the pull-off wires, instead of being

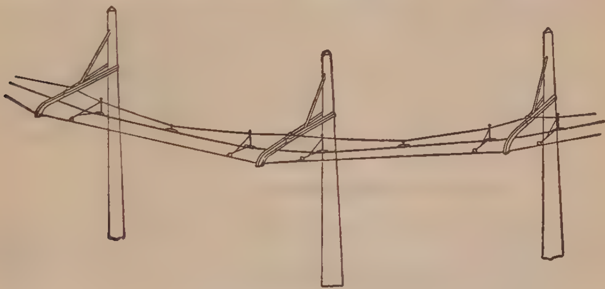

Fig. 31. Bow String Construction at Curve

anchored to individual poles, are fastened to a wire which is stretched between poles. While this construction is almost universally used in cities, it is more

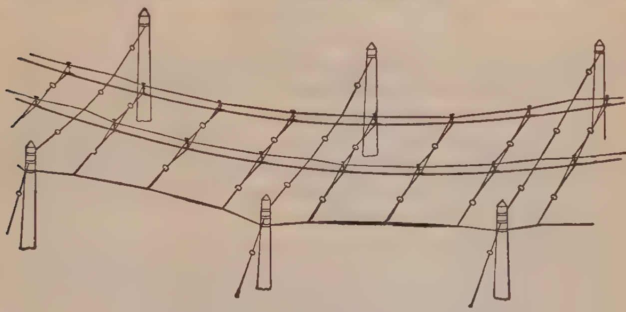

Fig. 32. Backbone Construction at Curve

expensive to maintain than single pull-offs, and is therefore less favored for interurban lines.

A combination of the two types of construction is shown in Fig. 33 (Fig. 28 to 33 are from General Electric Co. publications).

Spacing of Pull-offs at Curves. The number of pull-offs should be sufficient to keep the wire within about 2-1/2 in. from the theoretical curve. This may

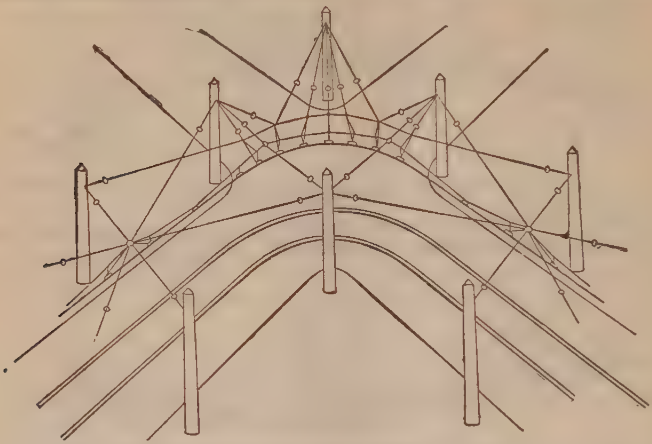

Fig. 33. Combination Construction at Curve

be accomplished by spacing the successive ears in accordance with the following relations:

Let L = distance between pull-offs in feet;
R = radius of curve in feet;
a = offset of wire in inches from theoretical curve, midway between pull-offs, the ears being assumed to lie on the theoretical curve.

Then
$$L = \sqrt{\frac{2\,aR}{3} - \left(\frac{a}{6}\right)^2},$$

Or
$$L = 0\,815\,\sqrt{aR},$$

with an error less than 1-4% for all radii greater than 40 ft.

If a is to be 2-1/2 in., then,approximately

$$L = 1.29\,\sqrt{R}$$

If the ears are set exactly on the theoretical curve, the wire will depart 2-1/2 in. from the correct position half way between the two ears; if the ears are set 1-1/4 in. from the curve, the mid-point of the wire will be only 1-1/4 in. when L is taken equal to 1.29 $\sqrt{R}$.

Offset of Trolley Wire at Curves. It is usual, at curves, to offset the trolley wire from the center of the track because the trolley wheel is tilted inward due to the elevation of the outer rail, and because in order to keep the wheel on the wire, the latter must be so placed that the projection of the pole on the plane of the track is always tangential to the wire.

(a) The former offset, measured horizontally toward the inside of the curve, equals $h \tan \theta$ where h is the normal height of the wire above the top of rail, and θ is the angle of elevation between the plan of the track and the horizontal. For standard gage and wire 18 ft. above the top of rail this offset is about 4 in. for every inch of elevation.

(b) The latter offset, also measured horizontally toward the center of the curve, is calculated as follows, assuming the curve to be longer than the car itself; for shorter curves the offset will be less.

Let R = radius of curve;
L = horizontal distance of center of trolley wheel to center of trolley base usually about 11 ft.;
G = distance from center of car to center of truck.

In the case where the trolley base is located over the truck center, as on cars with two trolleys, the offset is

$$R = \sqrt{R^2 - L^2}.$$

If the trolley base is located over the car center as on cars with one trolley, the offset equals

$$R - \sqrt{R^2 - G^2 - L^2}.$$

The total offset is the sum of the offsets (a) and (b).

Curves of Small Curvature. If the curvature * is less than 10 deg., the poles are frequently spaced closer together and no pull-offs used. The table may be considered typical, the divergence of the wire from the theoretical curve being kept within 3-1/2 in.

Spacing of Poles on Curves, Interurban Road

Degree of curvature of track	Pole spacing, feet	Divergence of trolley wire from track center, inches	Degree of curvature of track	Pole spacing, feet	Divergence of trolley wire from track center, inches
Tangent	120	0.	6	60	2.87
1	120	1.87	7	50	2.34
2	110	3.37	8	50	2.64
3	90	3.06	9	50	2.94
4	80	3.37	10	50	3.24
5	70	3.06			

Turnouts. The location of the trolley frog at turnouts may be determined as follows: Referring to Fig. 34, from switch point A draw a line to center point D of track frog distance BC and from switch point B draw a line to center point E of arc AEC. The intersection of these two lines at F will be the proper location of the frog. While certain variables, such as superelevation of the outer rail on the curve, length of wheel base and projection of trolley pole rearward from center of car, may necessitate slight variation of setting, this location will be found so nearly correct that a very small alteration, which must be determined by experiment, will compensate for the variable conditions.

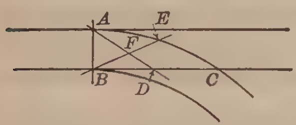

Fig. 34. Location of Frog

* The degree of curvature of a track is the angle which subtends a chord 100 ft long, between points on the center line of the track.

The following table gives the range of distance from track switch point to track frog with which each set of trolley frogs may be most satisfactorily used:

Track-frog distance	Divergence angle of trolley frog
Up to 22 ft.	20°
From 20 to 30 ft.	15°
Above 28 ft.	8°

The minimum frog distance given in the table with which the 15° frogs may be used to best advantage corresponds to a turnout radius of 40 ft., but when suburban cars, using high-speed trolley wheels, run over city tracks it is advisable to use 15-deg. frogs rather than 20-deg. frogs throughout the city construction even where the minimum frog distance is less than 20 ft.

Simple and Compound Catenary Construction. Catenary construction may be divided into simple and compound. In the former the trolley wire or wires are carried by one or two messenger cables which are supported only at the poles, bents or span wires; in the latter, the horizontal wire or wires are carried by a messenger cable, which is itself suspended from another messenger cable which is supported at the poles, bents or span wires. The advantages of the compound catenary are greater flexibility, reduced stresses in the supporting wires, shorter hangers, better lightning protection and superior curve construction.

To obtain a line which will not require frequent readjustment, the messenger cable must be installed with practically uniform tension throughout its length, making it necessary to have less sag in the shorter spans. For this reason certain definite pole spacings and corresponding hanger lengths have been standardized.

Number of Suspensions. The number of suspensions depends upon the speed at which the cars are to be run, and upon whether a bow or wheel trolley is used. The three-point suspension, in which, with 150-ft. spacing, the hangers are 50 ft. apart, has been found ample for wheel collectors. With the sliding pantograph or bow trolley an eleven-point suspension has been found sufficient, with 150-ft. pole spacing. (See following Table.)

Hangers. Where only one horizontal wire is suspended from the messenger cable, the hangers should hang loosely from the cable and should be screwed fast to the trolley wire. This permits the trolley wire to rise slightly as the trolley passes under it, thereby making the wire equally flexible along its entire length. Where a steel contact wire is clipped to the horizontal conductor, the hangers are usually rigidly attached at both ends, as the duplication of horizontal wires assures uniform flexibility, regardless of the hangers. (See following Table.)

Wear of Trolley Wheel Bow and Trolley Wire. The wear of the trolley wires is not serious with either wheel or bow collectors. On the lines of the Indianapolis & Cincinnati Traction Company, a copper trolley wire lost less than 1% in weight after it has experienced 39,000 car movements, each car taking an average of about 40 amperes by an aluminum slider.

The vertical wear of the steel contact wire on the N. Y., N. H. & H. R.R. was 0.028 in. in 30 months, which is practically 4.5% per year of the half diameter of the wire (one-half taken to permit wire to be held in clips) which, even on this vertical diameter basis, indicates a life of over 20 years; but as a

Tangent Construction

70	2	......	......	......	......	......	......	......	2
55	2	......	......	......	......	......	......	......	2

matter of fact it will be much more than this, for the reason that as the vertical diameter lessens the breadth of contact increases throughout, thus diminishing the rate of vertical wear. Of further interest is the fact that there is practically no corrosion of the wire as the wire is covered with a film of grease deposited by the pantograph shoe (W. S. Murray).

Change in Length of Trolley Wire. The change in length of copper due to changes in temperature is one of the greatest difficulties in the maintenance of overhead work. A drop of 100° F. in temperature will cause a copper bar to contract approximately 1 in. for every 100 ft. of length. If it is restrained at the ends this will cause an additional stress of 2500 lb. in the case of a No. 0000 trolley.

European catenary lines are usually maintained at constant tension by means of weights pulling on the free ends of the trolley wire at the end of every section.

Prevention of Formation of Sleet. Sleet may be prevented from forming on the wires by greasing the latter with petroleum jelly and if it does form it may be easily removed by any of the numerous commercial forms of sleet cutters.

11. Third Rail Systems

General. Third rails are used for low voltage railways where the power requirements are in excess of the current carrying capacity of a trolley wire, and where there is private right-of-way.

Collector Shoes. Current is collected from the third rail by projecting collector shoes on the cars. These shoes are placed on each side of each truck, and are all alive, when any one is alive.

Rails are usually made of special high conductivity steel, it being not unusual to have a conductivity 1/6 or 1/7 that of copper. (See Article 12 for resistance of rails of various sections.)

Types of Construction. Third-rail construction may be classified into the top-contact and under-contact types, each of which is susceptible of important variations in design, especially with reference to the type of protection.

(a) **Interborough Top-contact Type.** One of the most commonly used type is illustrated in Fig. 35. It is often called the "Interborough Type" on account of its use in the subways of the Interborough Rapid Transit Co., of New York. The rail is a standard T-section and rests on reconstructed granite insulators. A board protection is attached to the rail itself by means of clamps and uprights and is thereby kept in perfect alignment.

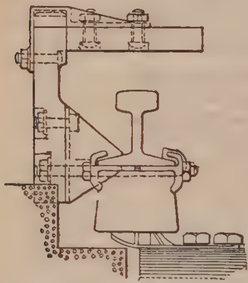

Fig. 35. Interborough Top-Contact Type

(b) **Pennsylvania Top-contact Type.** (Fig. 36.) Another type has the protection supported on separate brackets independent of the third rail itself. It is claimed that this reduces the amount of labor which has to be done on the live rail, when repairs are being made, but it cannot be relied upon as well as the Interborough type to keep the rail and protection in perfect alignment.

(c) **Under-contact Types.** (Fig. 37.) While the top-contact types have given first-class service, they are considered to have certain disadvantages for exposed locations as they cannot be wholly protected from snow, ice and sleet. The lower part is only a few inches from

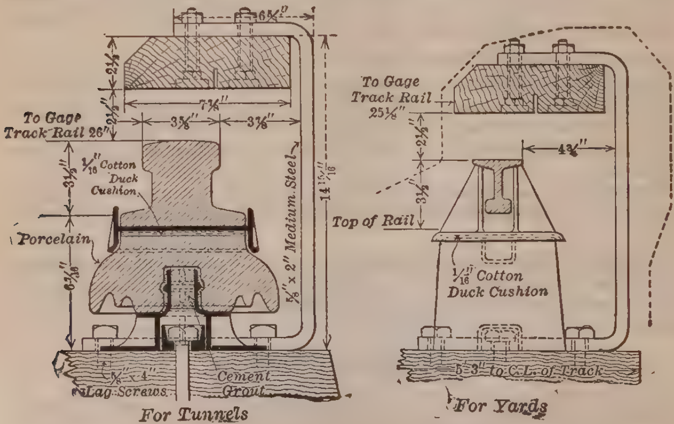

Fig. 36. Pennsylvania Top-Contact Type

the ties, while holding clips generally reduce this clearance, increasing the danger of grounding from accumulation of wet snow, and from flooding. The occasional suspension of traffic during sleet and snowstorms and floods, on railroads using the top-contact type of third rail, led to the idea of an under-contact third rail loosely clasped in insulators by hook-bolts hung from brackets, with the top and sides of the rail completely sheathed in a flexible insulating material for protecting the rail from accidental contact with man and beast, and from sleet, snow and spray. With this type of rail the protection is of such character that there is no packing of snow between the sheathing and the contact rail, as in some other forms, and in sleet storms no ice forms on the contact surface; some icicles may form at the edge of the petticoats, but, hanging down clear of the edge of the rail, are easily broken off by the passing shoe.

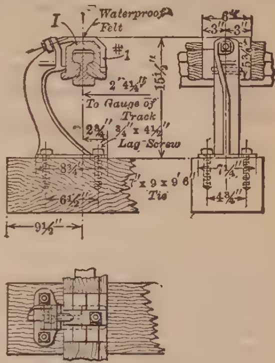

Fig. 37. N. Y. C. R. R. Under-Contact Type

Where the rail is buried in snow, the passage of the contact shoe breaks the snow away, leaving the rail surface clear, instead of ironing the snow down on the rail, as may happen with the top-contact type.

Location and Weight of Third Rails. There is no standard gage for contact rails, corresponding to the standard track gage. This unfortunate condition arises from lack of uniformity in the clearance lines of the right-of-way and in the maximum equipment lines of various railroads. The following standard has been recommended (1911 and 1912) by the American Electric Railway Engineering Association:

The gage line of the third rail to be located not less than 26 in. and not more than 27 in. from the gage line of the track and the contact surface of the third rail to be not less than 2-3/4 in. or more than 3-1/2 in. above the plane of the top of the track rail.

This standard has since been abandoned and three standard clearance lines adopted instead. The maximum equipment line for rolling equipment is given in Art. 13; those for third rail structures and permanent way, respectively, are given below:

Third-rail Structures Must be Contained within the Line Indicated by the Following Ordinates and Abscissas

Height above top of rail, inches	Distance out from gage line, inches	Height above top of rail, inches	Distance out from gage line, inches
Top of tie	19-3/4	9-7/8	33-3/4
5/8	19-3/4	6-1/8	36-3/4
3-11/16	25	1/4	36-1/4

* Bottom-contact surface. All others have top-contact surface.

Inclines. Where it is necessary to break the third rail at cross-overs, grade crossings or electrical section breaks, **end declines** are required to catch the contact shoes and bring them to the normal level of the third rail.

The exact location of the inclines on each side of a track-rail intersection depends upon a number of conditions, an important one of which is the extent to which the car equalizer bar and journal box project outward. If there is a train-bus line connecting all the cars, the end inclines may be situated many feet back from the switch point of frog, but if there is no such bus line, the contact rail will probably have to be terminated in a cross incline extending as near as possible to the switch point or frog.

12. Rail Bonds

General. Rail bonds are electrical conductors for bridging the joints of rails. They consist either of a series of thin strips of annealed copper, or of one or more cables of copper wire, the ends of which are usually pressed or cast into solid terminals. Ribbon is more compact, but stranded wire is more flexible; the latter should always be used if space permits.

Types of Bonds. Bonds may be classified, according to the method of fastening them to the rail, as soldered bonds, brazed bonds and bonds applied

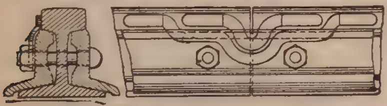

Fig. 38

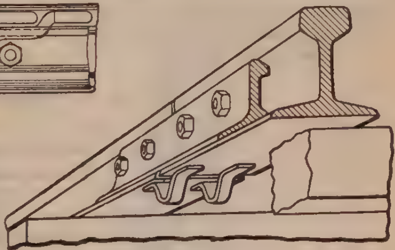

Fig. 39

by mechanical pressure. Soldered bonds and compressed terminal head bonds find their best application in third-rail work, where good electrical contact is of greater importance than mechanical strength. Expanded terminal web bonds, especially of the concealed type with two stranded conductors, are regarded as the best for heavy track work, where mechanical strength and cost of installation are of the utmost importance.

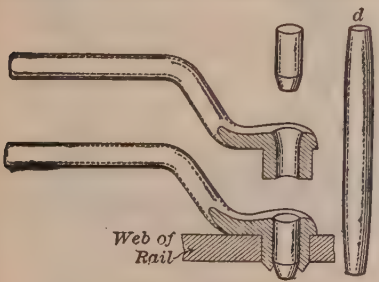

Fig. 40

Soldered Bonds usually consist of a series of thin strips of annealed copper with tinned terminals as shown in Figs. 38 and 39. They are soldered direct to the head, foot or web of the rail. One or more bonds per joint may be used.

Brazed Bonds resemble soldered bonds except that the terminals are enveloped in brass. They are brazed or welded to the rail by heat generated electrically in a carbon electrode which constitutes one jaw of a clamp holding the bond against the rail.

Expanded and Compressed Terminal Bonds. Bonds fastened to the rail by mechanical pressure may be divided into two general classes, expanded terminal and compressed terminal bonds.

Pin-expanded Terminal Bonds (Fig. 40) have their heads drilled with an axial hole, through which a tapered steel pin *d* is driven, forcing the copper outward and against the steel. This type of bond is fastened to the web of the rail.

Compressed Terminal Bonds. (Figs. 41 and 42.) There are two kinds of compressed terminal bonds, in one of which direct pressure is applied at both ends of the head, and in the other, at one end only. The first type of bond is usually applied to the web of the rail by means of a heavy screw or hydraulic press (Fig. 43) which engages the bond head and causes it to compress longitudinally and expand laterally as the pressure is applied, bringing

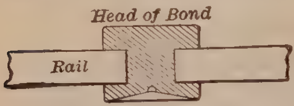

Fig. 41

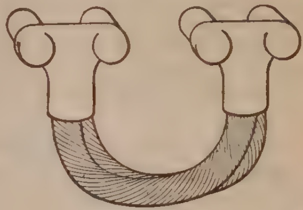

Fig. 42

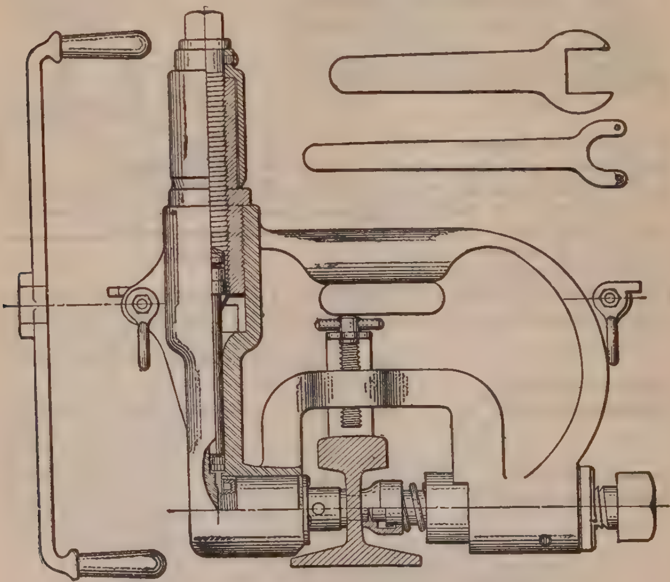

Fig. 43

the copper into firm contact with the steel and spreading the projecting end of the terminal into a button-shaped rivet-head, as shown in Fig. 41. The second type of bond (Fig. 42) is applied only to the head of the rail, the terminal lugs being set in holes therein and expanded into contact by means of hammer blows.

Exposed Versus Concealed Bonds. Whether soldered, brazed, expanded or compressed, bonds may be either exposed or concealed (Fig. 44) under the fish-plates. The former condition is preferable, if there is no likelihood of theft, as it permits inspection to be easily made. Where the bonds are exposed to theft, as, for example, on track rails unprotected by paving, concealed bonds are almost a necessity.

While concealed bonds are necessarily applied to the web of the rail, exposed bonds may be applied to the foot or head. Head bonds have the advantage of greater contact surface at the terminal studs, while foot bonds are less exposed to mechanical violence. Web bonds, unless concealed, have to be excessively long in order to span the fish-plates.

Substitutes for Bonding. Several efficient substitutes for bonding are now in use, such as electrical welding and thermit welding. (See Article 21.)

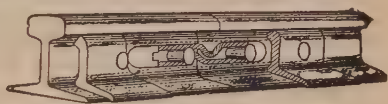

Fig. 44

Installation of Bonds. The foremost consideration in the installation of bonds is the cleanliness of the bonds and bond holes, or other adhesion surface. Unless this is secured the bonds will be electrically defective whatever their mechanical strength may be.

Soldered Bonds. The rail surface is brightened by means of a carborundum or emery wheel, and tinned, using an acid flux. The bond is then clamped in place and the rail and bond heated by means of a blow-torch, to a temperature at which the solder will melt and cause the bond to adhere firmly to the rail.

Brazed Bonds. The preliminary processes are the same as for soldered bonds except that a special clamp is used, the terminals of which are the electrodes of an electrical circuit, one being of copper and the other of carbon. The surface of the rail being previously ground bright at the point where the braze is to be made, the brass-enveloped bond terminal is pressed against the rail by the carbon electrode, the copper electrode being in contact with the opposite side of the rail. The current on passing from one electrode to the other, traverses the bond terminal and rail, the carbon becoming incandescent. The incandescent carbon (pressing the copper against the rail) quickly transmits sufficient heat at exactly the point where it is required to produce the weld.

Welding Outfit. It is claimed by the manufacturers that an average of over 100 bonds per day are readily installed by a car operating with four men, a bonder and three helpers. Such a car carries a rotary converter and transformer, with accessory apparatus. To weld an average-sized rail bond to the rail, an alternating current of about 2000 amperes at 5 volts is employed. On direct-current railways this is obtained by converting and transforming current taken from the trolley wire.

Pin-expanded Bonds. The rail is drilled, usually through the web, with or without lubricant, using some form of drill especially adapted to the service. Drilling without lubricant has the advantage of giving a perfectly clean hole, but is believed by some to cause excessive wear of the drills. It is doubtful, however, whether the small amount of oil which would be used could be kept constantly at the cutting edges, the only places where it would be useful. Dry drilling has been found successful on many railroads. If oil is used, it should be wiped out with a clean cloth saturated with gasoline, in which case the joint resistance will be increased less than 3%. Lubricants containing water are likely to cause rust, especially if the drilling gang precedes the bond installers by any considerable time. The hole having been drilled, the bond head is inserted into it and a long taper punch lubricated with grease is driven entirely through the terminal. Then a short drift pin is driven home, as shown in Fig. 40.

This type of bond requires a smaller equipment in tools and materials than most other types and does not necessitate the use of any apparatus which obstructs the track and would thereby endanger traffic.

Compressed-Terminal Web and Foot Bonds. The drilling having been performed as for a pin-expanded bond, and the bond heads inserted into their respective holes, a screw or hydraulic compressor, as shown in Fig. 43, is applied at both ends of the bond head, the conical point of the press fitting into the conical depression of the bond. Pressure is applied, either until a collar on the ram touches the rail, or until the head of the bond acquires the proper shape. Where no collar is used the point of the press (if of the screw type) sometimes cuts into the bond head; this may be avoided by placing a small amount of flake graphite mixed with oil in the depression of the bond head.

Compressed-Terminal Head Bonds. A four-spindle drill is used to drill four holes simultaneously in the rail heads. It is important to avoid drilling the holes too deep lest the copper should not touch bottom and therefore be unable to expand laterally. If, on the other hand, the hole is too shallow, expansion will occur too soon.

Tests of Bonds after Insulation. Every rail in service should be periodically tested and a complete record of the tests kept. The frequency of the tests will depend upon local conditions, once in 9 to 12 months being an average.

Resistance Test. The usual method of testing is to measure the drop of potential across the bonded joint and find simultaneously the length of con-

Resistance of T-rails, A.S.C.E. Standard Section (20° C.)

(Full Cross-section)

Weight, pounds per yard	Cross-section, square inch	Area, millions of circular mills	Specific resistance 12.5 times that of copper		Specific resistance 8 times that of copper *

* To find the resistance of rails of any specific resistance x referred to copper as unity multiply these resistances by x and divide by 8.

tinuous rail in which the same drop occurs, that is, the "equivalent" length of the bonded joint. Several ingenious instruments have been devised for making this comparison with ease and accuracy.

Mechanical Strength. The mechanical adhesion of soldered bonds may be tested by means of a lever as shown in Fig. 45. It may be used as the terminals are cool. The operation of testing consists simply in submitting each bond terminal to a predetermined pull. A properly soldered bond should stand a shearing force of 1200 lb. per square inch of contact. Calling S this shearing force per square inch, A the square inch of contact, and P the pull, as registered on the balance, then

$$P = \frac{ASl}{L}.$$

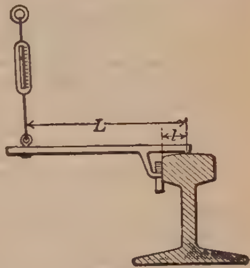

Fig. 45

Rebonding. The resistance at which a joint should be rebonded depends upon how much potential drop is permissible in the tracks, and upon the relative cost of the energy loss and the cost of rebonding. The equivalent length, calculated on this basis, ranges from 2 to 12 ft., with an average of 6 to 7 ft.

CARS AND LOCOMOTIVES

13. Cars

City cars vary in length from 42 to 50 ft., the average of twenty typical city cars being 45 ft. 6 in. over the bumpers. The width varies between 8 ft. and 8 ft. 10 in., the average of twenty typical cars being 8 ft. 4 in. Truck centers vary from 19 to 24 ft., averaging 21 ft. 10 in. The number of seats varies from 32 to 56, the average of twenty typical cars being 47.

The standard height of couplers for city cars, measured from top of rail to center of coupler, is 1 ft. 8 in. The standard height of bumpers is 2 ft. 7 in. from top of rail to top of bumper. The standard height of platform is 2 ft. 7 in. from top of rails.

Recent trend has been toward the drop platform type with rear entrance, and front exit, as it is one of the safest types and seems ideal for quiet loading and unloading of passengers. The center door type has also found favor. These types lend themselves readily to the pay-as-you-enter system of fare collection.

Another design of car which facilitates rapid loading and unloading employs front entrance, with center exit. Passengers having exact fare stay in the front of the car while passengers desiring change pay their fare to the conductor who is stationed in the center of the car and pass to the rear of the car from which they leave at will.

Interurban Cars vary in dimensions from those of city cars to those of standard steam passenger cars, depending on the class of service, speed and length of run. Interurban cars vary in length from 40 to 75 feet, with corresponding weights of from 25 000 to 75 000 pounds.

Suspension of Motors. Motors, on double-truck cars, are hung between an axle and the transom. A lug cast on the side of the motor frame away from the axle rests on the transom either with or without intervening springs. About 60% of the weight is carried directly on the axles.

Maximum Equipment Line. The maximum equipment line for cars on third rail systems has been standardized as follows by the American Electric Railway Engineering Association and other interested bodies.

Points Determining Maximum Equipment Line

Height above top of rail, inches	Distance out from gage line, inches	Height above top of rail, inches	Distance out from gage line, inches
6	0	24	9
6	2-1/2	25-7/8	10-7/8
20	2-1/2	31	10-7/8
24	4-11/16	34-1/4	24

Trucks. Cars not more than 20 ft. long can be satisfactorily carried on single trucks having a wheelbase of about 7 ft. Longer cars should have two trucks of the swivel type, having a wheelbase of from 4 ft. to 6 ft. 6 in., the shorter wheelbase being used where there are sharp curves. Maximum traction trucks have unequal-sized pairs of wheels, the bolster being near the larger pair, to the axle of which the motor is geared. This has the effect of throwing from 70% to 85% of the total weight on the driving wheels, although only two motors are used on the car, an especial advantage where high acceleration is desired.

Wheels. Electric railways use the standard gage of 4 ft. 8-1/2 in. A typical standard form of wheel flange is shown in Fig. 46.

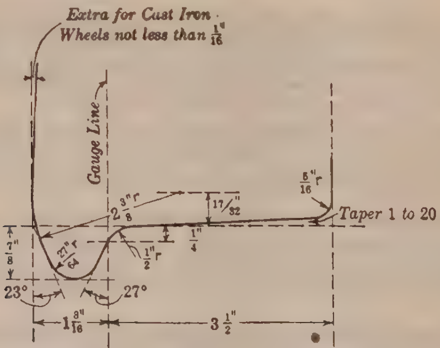

Fig. 46. Standard Sections of Wheel Flanges

14. Locomotives

General. Electric locomotives, unlike steam locomotives, can be made of practically any desired power capacity without excessive complication and without increase in the number of operators. This arises from the absence of boilers and the possibility of controlling a number of motors or even a number of complete locomotive units as if they were a single unit.

Rating. The rating of electric locomotives is usually expressed in terms of the weight on drivers, the nominal 1-hour tractive effort, the continuous tractive effort and corresponding speeds.

(a) Weight on Drivers. The weight on drivers, expressed in pounds, shall be the sum of the weights carried by the drivers and of the drivers themselves.

(b) Nominal Tractive Effort. The nominal effort, expressed in pounds, shall be that exerted at the rims of the drivers, when the motors are operating at their nominal (1-hour) rating. (See Art. 15.)

(c) Continuous Tractive Effort. The continuous tractive effort, expressed in pounds, shall be that exerted at the rims of the drivers when the motors are operating at their full voltage continuous rating. (See Art. 15.)

In the case of locomotives operating on intermittent service, the continuous tractive effort may be given for one-half or three-fourths voltage, but in such cases the voltage shall be clearly specified.

(d) Speed. The rated speed, expressed in miles per hour, shall be that at which the continuous tractive effort is exerted.

Classification. Locomotives may be classified as follows, with reference to trucks:

1. Rigid wheelbase.
   (a) Without leading and trailing trucks.
   (b) With leading and trailing trucks.
2. Separated bogie truck (the trucks being connected through the upper frames as in a car):
   (a) Symmetrical.
   (b) Unsymmetrical.
3. Articulated (wherein the two trucks are hinged back to back).

All of these types of locomotives are practically steady at speeds under 40 mph., but above this speed marked differences appear: the steadiest riding machines, according to G. Gibbs, having high centers of gravity and long unsymmetrical wheelbases. Considerable difference of opinion prevails in regard to proper mechanical design for high speeds.

Transmissions. Motors are connected to locomotive drivers by the following forms of transmission:

(a) Gearless, the motor armatures being mounted direct on the axles.

(b) Gearless quill, each motor armature being mounted on a hollow shaft or quill which surrounds the axle, but is free with respect to it. At each end of the quill is a disk having projecting arms which fit into spaces between the spokes of the driving wheels. The arms are connected to the driving wheels by springs which tend to keep the arms centered between spokes but allow sufficient play to relieve the excessive starting stresses in the armature.

(c) Direct gears, the motors being mounted either between or over the axles, a motor having a pinion engaging a gear wheel on the locomotive axle.

(d) Quilled gears, the gear wheel being on a hollow shaft or quill which engages the drivers through springs, thereby relieving both the armature and gears of excessive starting stresses.

(e) Cranks and Scotch yoke, in which two motors are connected together and have crank shafts which operate three sets of drivers.

(f) Crank and countershaft, in which the motors are located above the tracks and are connected through a countershaft to side rods joining the drivers.

Control. Practically all modern electric locomotives have multiple-unit control, so that two or more locomotives may be coupled together under the control of one operator. Indeed, some locomotives consist of two sections —

each of which is virtually a separate locomotive — coupled together permanently.

Weight. The weight per driver axle for high speed locomotives should not exceed 40 000 lb. with ordinary track, and 50 000 lb. with very good track, and in slow-speed service more usual weights are 15 000 to 20 000 lb. per driver axle. European practice indicates a maximum of 35 000 to 40 000 lb. per axle.

The weight in pounds per foot of total wheel base usually varies from 4500 to 7500 lb., but is occasionally as high as 11 000 lb.

The following weight analysis by E. P. Burch (Electric Traction for Railway Trains) is based upon data for about twenty representative American and European locomotives.

Weight Distribution, Electric Locomotives

Per cent

Distribution of weight	Direct-current		Three-phase		Single-phase		Motor-generator
		Ave.		Ave.		Ave.	Ave.
Mechanical parts.......	50–72	68	48–76	51	46–59	58	43
Motor................	20–27	24	26–40	30	26–36	27	30
Transformer...........	0	0	0–10	10	8	7	6
Other electrical parts....	5–10	8	7–10	9	7–11	8	21
Hp. 1 hr. per ton, about.	....	16	....	18	....	14	8

The mechanical parts of direct-current locomotives are high in percentage because the total weights are low. Three-phase motor weights appear high because European designers use light frames.

15. Motors and Controllers

Selection of Motor. The following information, relative to the service to be performed, is required, in order that an appropriate motor may be selected.

(a) Weight of total number of cars in train (in tons of 2000 lb.) exclusive of electrical equipment and load.

(b) Average weight of load and durations of same, and maximum weight of load and durations of same.

(c) Number of motor cars or locomotives in train, and number of trailer cars in train.

(d) Diameter of driving wheels.

(e) Weight on driving wheels, exclusive of electrical equipment.

(f) Number of motors per motor car.

(g) Voltage at train with power on the motors — average, maximum and minimum.

(h) Rate of acceleration in miles hour per second.

(i) Rate of braking (retardation in miles per hour per second).

(j) Speed limitations, if any (including slowdowns).

(k) Distances between stations.

(l) Duration of station stops.

(m) Schedule speed including station stops in mph.

(n) Train resistance in pounds per ton of 2000 lb. at stated speeds.

(o) Moment of inertia of revolving parts, exclusive of electrical equipment.

(p) Profile and alignment of track.

(q) Distance coasted as a per cent of the distance between station stops.

(r) Time of layover at end of run, if any.

Rating of Motors. The *one-hour rating* of a railway motor shall be the output at the motor shaft measured in horsepower (or kilowatts) which the motor can carry for one hour on stand test, starting cold, at its rated voltage and frequency (in case of alternating-current motor) with the ventilation system as in service without exceeding the temperature limits given in the table of limiting temperature rises.

The *continuous rating* of a ventilated railway motor shall be the output at the motor shaft measured in horsepower (or kilowatts) which the motor can carry for an unlimited period on stand test, at its rated voltage and frequency (in the case of alternating-current motor), with the ventilation system as in service without exceeding the temperature limits given in the table. Direct-current ventilated railway motors may also be given a continuous rating in amperes at full, three-fourths and half-rated voltage.

The *continuous rating of totally enclosed* direct-current railway motors shall be given in amperes at three-fourths, and half rated voltage.

In the absence of any specification as to the kind of rating the *one-hour rating* shall be understood.

The ratings of a *field-control direct-current motor* shall relate to its performance with the field connection which gives the maximum motor rating. (This is usually the minimum field.) Each section of the field winding shall

Limiting Temperature Rises

Item		Type of enclosure	Method of temperature determination to be employed	Limiting temperature rise, deg. C.			
				One-hour rating		Continuous rating	
				Class A insulation	Class B insulation	Class A insulation	Class B insulation
1	Armature and field winding	Ventilated	Resistance	100	120	85	105
			Thermometer	80	95	65	80
		Totally * enclosed	Resistance	110	130	95	115
			Thermometer	90	105	75	90
2	Cores and mechanical parts in contact with or adjacent to insulation	Ventilated	Thermometer	80	95	65	80
		Totally * Enclosed	Thermometer	90	105	75	90
3	Commutators	Ventilated	Thermometer	95	110	80	95
		Totally * enclosed	Thermometer	105	120	90	105
4	Miscellaneous parts (such as brush holders, brushes, pole tips, etc.) other than those whose location is such that they may injuriously affect the adjacent insulation may attain such temperatures as will not be injurious in any other respect.						

* The temperature rises of totally enclosed motors are taken as 10° C. higher than the ventilated motors since the cooling on stand test will be inferior to that obtained in service.

be adequate to perform the service for which it is designed without exceeding specified temperature rises.

Voltages. Direct-current motors are usually made for line voltages of 500, 550 or 600 volts and sometimes for 1200 volts or somewhat more. On 2400-volt lines, it is usual to have the motors in pairs connected permanently in series.

Alternating-current single-phase motors, are usually made for 400 to 500 volts, the required voltage being obtained by transforming down the line voltage by means of a transformer or auto-transformer on the train.

Weight. Motors vary in weight from 30 lb. per horsepower (40 lb. per kilowatt) for the largest sizes (200 hp.) to 70 lb. per horsepower (93 lb. per kilowatt) for the smaller sizes (35 hp.), the ratings being the nominal.

Controllers. The speed of direct-current motors is controlled by connecting resistance in series with the motors, by connecting the motors at first in series and then in parallel, and sometimes by varying the strength of the fields. Alternating-current motors are similarly controlled, except that auto-transformers are used instead of resistances.

The direction of rotation, in both kinds of motors, is changed by reversing the current in *either* the fields *or* armature, this being usually accomplished by rotating an auxiliary handle of the controller.

The type *K* controller is largely used for light weight cars, and consists of an operating handle which moves a cylindrical drum with projecting contact pieces which come in contact with stationary fingers. The first three points correspond to accelerating steps, by means of which the resistance in series with the motors is gradually cut out. The fourth step, full series, gives about half speed and is a continuous running point. The following steps restore the resistance and put the motors in parallel. The last step leaves the motors in parallel without any resistance.

Multiple-unit control is used on large cars, especially where the combined motor capacity exceeds 300 hp. The equipment consists of a small master controller which enables a comparatively weak current to operate contactors large enough to make the necessary changes in the circuit, as in the case of type *K* controllers. The master controller on any car will operate the contactors on all cars, if a jumper cable be run from car to car connecting together all the control circuits.

The weight of control equipment of type *K* varies from 1200 to 2250 lb., and of multiple-unit equipment from 2800 to 3200 lb.

16. Brakes

General Principles. Practically all existing brakes make use of the frictional adhesion between the wheels and track, and between the brake shoes and wheels. The frictional adhesion between wheels and track varies from 15% to 30% of the weight on the wheels. An adhesion of 15% applies to normal track and the higher values to sanded track. This refers to rolling friction; if the wheel begins to slide, the coefficient of friction drops. For this reason braking must be such as to to allow the wheels to slip. The frictional adhesion between brake shoes and wheels is given by the formula,

$$h = \frac{1 + 0.000\,472\,l}{1 + 0.00\,2390\,l} F,$$

where h = coefficient of friction after elapsed distance l;
l = distance wheel has traveled in frictional contact with the brake shoe;
F = coefficient of brake shoe friction at speed and pressure at which brake shoe was applied at the beginning of the distance l

$$= \frac{0.382}{1 + 0.02933\,S}, \text{ where } S = \text{speed, mph.}$$

The braking retardation depends upon the various factors involved, approximately as indicated by the following formula:

$$a = 0.01098\,k\,(Ph + fW);$$

where a = retardation, mph. per second;
k = ratio of linear inertia to total inertia of train;
P = total braking pressure applied normal to wheel treads by brake shoes, pounds;
h = coefficient of brake friction;
f = train resistance, pounds per ton weight of train;
W = weight of train, tons.

If we neglect rotational energy and train resistance

$$a = 0.01098\,\frac{R}{W},$$

where R = total retarding force, in pounds.

The usual rate of retardation for multiple-unit electric trains is from 1.5 to 2.0 mphps., and on street cars from 2 to 2-1/2 mphps.

Construction. Any brake which depends upon the friction between the wheels and brake shoes is composed of four parts; the shoes, the truck rigging, the foundation rigging and the source of braking force.

Brake Shoes. In order to avoid excessive costs for the renewal of brake shoes, the weight should be limited so that no individual shoe should weigh more than 24 lb. To avoid an excessive loss of weight in scrap, the minimum weight should be 20 lb. The cast iron should be closely granular, of uniform texture and with the combined and graphitic carbon evenly balanced. The graphitic carbon should be in the form of nodules rather than flakes.

Wear averages 3.75 to 6.5 lb. per 1000 wheel-miles and the minimum scrap weight should be 6-1/4 lb. per shoe; at 5-1/2 lb. there is danger of cutting the head.

Ordinarily, brake shoes are placed to bear on the inside of the truck frame; that is, between wheels. With this arrangement, it is possible, by varying the angularity of the hanger link, to introduce a force which will equalize, to any desired degree, the transfer of weight from the rear to the forward axle.

Truck Rigging. The braking force must be distributed equally between the brake shoes, or there will be danger of sliding the wheels. Separate levers are used for each shoe. On double-truck cars, which must travel around sharp curves, the bar connecting the brake levers is made of circular form, and is then known as a "radius bar"; and the brake pull rod is connected to it through, a roller working in a clevis, which allows the brakes to act in spite of the swiveling of the truck.

Foundation Brake Rigging. The pull rods which pull on the radius bar rods are each attached to one end of the cylinder levers, the centers of these levers (which are normally about parallel) being joined by a rod. The other ends of the cylinder levers are connected to the piston and the slack adjuster, respectively.

The purpose of the slack adjuster is to pull back the piston without loosening the brakes in case it travels so far as to unduly reduce the cylinder pressure. This is usually accomplished by causing the excess piston motion to operate a device which shifts the fulcrum of one of the cylinder levers. The normal piston travel is 8 in. on standard equipment.

Hand Brakes. It is usual to provide all cars with hand brakes, even if also equipped with air brakes. Hand brakes communicate their motion to the foundation rigging by means of a chain which winds on the brake staff at one end and is attached, through a multiplying lever, to the pull rods. In high-ratio hand brakes, the bottom of the brake staff carries a gear, the chain connection being made through the meshing gear.

Air Brakes. Air brakes have the advantage of being capable of quicker application than hand brakes, and they save power both by permitting more coasting and by making sure that the brake shoes do not rub when the car is running, a condition which frequently occurs with hand brakes due to the desire of the motorman to be able to apply the brakes as quickly as possible.

The maximum pressure of the brake shoes on the wheel may be definitely limited by proper design and wheel skidding prevented. Air brakes also relieve the motorman of severe manual strain.

There are two kinds of air brakes: the " straight " and the " automatic." In the former, the pressure of a main reservoir acts directly on the foundation rigging; in the latter, the pressure comes from an auxiliary reservoir, the main air pressure being used to control the admission of air to and from the auxiliary reservoir and to release the air from the brake cylinder to the outside atmosphere. In " straight " air brakes, the control consists essentially of a valve which can connect the cylinder to the main reservoir, can disconnect the cylinder yet allow it to retain the air, or can release the air from it. This system is used for single car operation.

In long trains, the air has so far to flow from the reservoir on the forward car or locomotive that the brakes on the rear cars are applied later than on the front cars. This may impose severe stresses in the draw bars and may cause the train to break in two. This trouble does not exist with the " automatic " air brake. In this system, under normal running conditions, the auxiliary reservoirs on each car are fully charged to the pressure of the train pipe and the brake cylinders are open to the atmosphere. To apply the brakes, the train pipe pressure is reduced, an air operated " triple valve " automatically disconnects the auxiliary reservoir from the train pipe and connects it with the brake cylinder, meanwhile closing the cylinder exhaust. Where rapid brake applications are desired on long trains, the air-operated triple valve is not fast enough, and electrical train lines are now being used for this purpose.

Inspection of Air Brakes. The American Electric Railway Association gives the following instructions for inspection: Start the air pump to its maximum capacity; see that brake-valve handle is in release position and where automatic air is used see that gages indicate 20 lb. difference between train line and auxiliary. If they do not, the governors need to be reset. Apply brake to show reduction of 40 lb. Place brake-valve handle to lap position; see that air gage operates properly and that no leaks are in or around the brake-valves or pipes leading thereto; examine all pipes, reservoirs, triple valves, cylinders, etc., while brake is set and see that none are leaking and that brake does not release while the brake-valve handle is in lap position. If the cylinder piston has a travel of more than 5 in. an adjustment of brakes is necessary. Where slack adjuster is used, see that it is placed to its minimum of travel before any adjustment of brakes.

Inspect all shoes and see that they are in alignment with the wheel so that none are broken and renew those that will not give sufficient wear until the next inspection.

In renewing brake shoes put shoes of same thickness on opposite wheels, be they either old or new.

Examine all keys, bolts, pins, beams, turn-buckles, rods, etc., and lubricate where necessary.

Compressors. Independent motor-driven air compressors are most commonly used for air brakes, and are usually directly connected. Compressors should be of a size such as will not be required to operate more than one-third the time.

17. Car Heating

General. Street cars should be heated to a temperature of 55° to 60° F. which is found to be comfortable for passengers in street attire. Suburban and interurban cars, which have longer runs, should be heated to between 65° and 70° F. in order that the passengers may be comfortable without their wraps.

Systems. Three systems of heating are in use on modern railways. The steam boiler, hot water furnace, and the electric heater. Steam is used on locomotive trains, hot water for some interurban cars making long runs and electric heaters for urban cars and most interurban cars. In locomotive trains, the steam boiler is oil-fired and built into the locomotive or carried on a tender behind the locomotive.

Electric Heating. The electric system of heating, although more expensive to operate than the others, finds the greatest favor for urban and interurban service and has the advantage of good distribution of heat, cleanliness, ease of regulation, low fire hazard and no attendance.

Electric heaters are all equally efficient in regard to the amount of heat developed but may differ in respect to durability and cost of maintenance. They are usually made of resistance wire wound on porcelain forms, but sometimes the wire is embedded in insulating material. The latter type has greater heat storage capacity than the former.

The power required for car heating is as follows:

Power for Car Heating

Length of car, feet	Average kilowatts for heating	
	Average conditions	Severe conditions
14 to 20	3.5	4.
20 to 28	4.5	5.5
28 to 34	5.5	7.5
34 to 40	7.5	10.5

CAR BARNS AND OTHER BUILDINGS

18. Car Houses and Inspection Sheds

General. Car houses are used for the storage and inspection of street and interurban cars and on small railways are combined with the repair shop. On electrified railroads, car houses are for inspection only, as out-of-door storage is the usual practice.

When about to design a car house, the engineer should first acquaint himself with municipal and underwriters' regulations and, conforming with these, should provide room for car storage and inspection, administration offices, line department, road department, car employees' lobby, car sign storage, sand drying and storage, salt storage, oil storage, wash-room and toilets.

Concrete foundations are used for walls and columns, and the walls are usually made of brick; but where cheapness is essential, a mill frame with 2-in. cement curtain wall may often be used. Heavy wooden columns and roof trusses are generally used; although cast-iron columns are favored by some designers. Wooden roofs covered with felt, pitch and gravel are usual, and they are provided with copper flashings and counter-flashings of either copper or lead.

Floors are made of concrete with cement finish, and are sloped to provide ample drainage. It is especially important to keep the inspection pits clear of water.

Inspection Pits. Inspection pits are placed between the rails and are usually 4 ft. 6 in. deep below the top of rails. The track rails are carried on wooden stringers (usually 10 by 12) on the masonry side walls of the pit. More modern practice in large car houses is to have a basement as deep as an ordinary pit but extending under all the tracks. In this case the track rails are supported on stringers or T-beams resting on posts.

Tracks. Car tracks should be spaced not less than 11 ft. between centers where there are no posts between tracks, and not less than 13 ft. where there are posts. Ordinary T-rails are used. The dead ends of the car-house tracks should be provided with bumpers. The trolley wire should be at least 16 ft. 6 in. above the top of rail in order to avoid injuring the trolley springs by keeping them in undue compression. It is usual to support the trolley wire on a flat board to prevent the trolley rising and striking the building structure if it should leave the wire.

Tracks at Entrance. The tracks at the entrance to the car house should be be designed to facilitate the rapid entrance and departure of cars with the least interruption to traffic on the main tracks. This is sometimes accomplished by having an extra track in front of the car house and running all storage tracks into it; the extra track being connected at either or both ends to the main tracks.

Heating. Car houses are best heated by means of a blower system where the air is blown over steam coils and through the building. The heating plant should be either in a separate building or enclosed in fireproof walls.

Doors. Where there is sufficient clearance, swinging and sliding wooden doors are preferred; but where space is restricted, rolling steel doors are used for large openings.

Lighting may be either by incandescent lamps or mercury vapor lamps, the former being most usual. Lamps should be fed, wherever practicable, from a regular lighting system, as the voltage fluctuations of the trolley or third rail circuit are usually excessive. Where, however, the lights must be fed from the traction circuits, the requisite number of lamps must be grouped together in series. The pits or basements should be well lighted.

Painting. Car-house walls are usually covered with cold water paint except for distances of several feet from the ground, where oil paint is to be preferred.

Fire Risks. Due to the great value of cars and the loss of revenue which would result from their destruction, it is important to make the fire risk as low as possible by the adoption of the following precautions:

(1) Use of automatic sprinklers.
(2) Provision of two sources of water supply such as mains and tank.
(3) Division of building by fire-proof walls. The underwriters stipulate that no section shall contain cars to the value of over $200 000.
(4) Avoiding proximity to inflammable buildings.
(5) Having ample provision of water pails, sand pails, chemical extinguishers and short hoses, the last being usually 2-1/2 in. in diameter and provided with 1-1/8-in. nozzles.
(6) Locating car house near a fire station.
(7) Building tracks on a grade so that cars may be easily pushed out by hand.
(8) Having numerous auxiliary fire alarms.
(9) Consulting underwriters when planning.

The Operating Force should be located at the front of the house and starters should be in a position to see all incoming and outgoing cars.

19. Repair Shops

General. Car repair shops are used for the repair and renovation of cars and are generally similar in construction to car houses, being often combined therewith. The details of building construction, heating and lighting given under Car Houses apply equally well to car shops, except that only about half

Space Distribution in Car Repair Shops

No.	Department	Work of department	Per cent of floor area occupied: Departments with car tracks	Per cent of floor area occupied: Departments without car tracks
1	Repair shop.....	General repair work on cars:		
		(a) Main repair shop..........	15	....
		(b) Truck repair shop.........	....	5
2	Machine shop...	Metal work on parts, including slotting commutators..........	....	10
3	Blacksmith shop.	Forgings, welds, etc., on parts....	....	4
4	Carpenter or erecting shop.	Heavy repairs on car bodies......	17	....
5	Store-room and offices.	Stock storage exclusive of heavy material....................	....	15
6	Electrical shop..	Electrical repairs to armatures, etc., except as cited under No. 2.	....	5
7	Wood mill......	Machine work on wood.........	....	8
8	Paint shop and wash-rooms.	Painting of cars and storage of painting materials, etc.:		
		(a) General paint shop..........	18	....
		(b) Cabinet room, varnish room..	....	3
	Total.......	....	50	50

the floor area need be equipped with tracks, the remainder being devoted to departments where unassembled parts are handled. Where tracks are installed, the usual spacing is from 15 to 16 ft. between centers.

Heating. While large repair shops are usually heated by the blower system (see " Car House "), an exception must be made in the case of the paint shop where direct radiation is preferred. Small shops are usually heated directly by steam or hot-water radiators.

Space Distribution. The table on 2153 gives the principal subdivisions of a typical repair shop with the average space distribution, the actual space required being from 140 to 240, averaging about 200 sq. ft. of shop floor per car owned, exclusive of yard space or transfer tables. Other departments, not included in the table either because they are affected by the amount the shop depends upon outside aid or because of their smallness, are: Dry kiln, lumber store, boiler room, brass foundry, pattern store, indoor transfer table, locker room and toilets.

Means for Moving Cars. Cars are lifted by any of the following means: Traveling cranes, jacks, hydraulic lifts, screw hoists and chain hoists. Traveling cranes are generally used except in the smallest shops.

Transfer tables are preferred to ladder tracks for moving cars between departments.

Proportion of Cars in Shops. The percentage of cars in the shops varies from 8 to 12 depending upon the quality of the equipment, and its usage.

Storage Space around Shops. Shop buildings should be surrounded with sufficient ground to serve for storage of trucks, lumber, scrap material, etc. The total area of land required for shops and storage varies from 1 to 2 acres per 100 cars owned, depending upon whether all departments are concentrated in one building or scattered among several.

SIGNALS AND TRACKS

20. Signals

General. The purposes of signals are to promote safety and to increase line capacity.

In addition to audible signals such as bells, whistles, and torpedoes, movable visible signals, such as lanterns, flags and fuses, single-aspect fixed signals such as slow, stop, whistle and drawbridge signs, electric railways use two-aspect or three-aspect fixed signals, such as switch targets, train order signals, interlocking signals and block signals.

Signal Indications. The two- or three-aspect fixed signals are either semaphores or lamps, or more commonly, a combination of both. Where semaphore signals are used, they are usually arranged to indicate three positions in the upper right-hand quadrant. These positions are, horizontal for " stop," 45 deg. for " proceed with caution " and vertical for " proceed."

Where semaphores have pointed ends, the horizontal position indicates " stop and proceed " and 45 deg. indicates " proceed, next signal at stop."

Where colored lights are used, a large variety of indications may be obtained, a simple set of which would be as follows:

$$\left.\begin{matrix}\text{Red}\\\text{Red}\\\text{Red}\end{matrix}\right\}\text{Stop and stay}$$

Red Red Red Yellow	Stop and proceed
Yellow Yellow Yellow	Proceed, next signal at stop
Green Green Green	Proceed

A " stop " signal combined with a yellow flag indicates " proceed under control, prepared to stop short of any obstructions."

Location of Poles. The standard location for a signal pole is 7 ft. 9 in. from the center of the track to the center of the pole, with semaphore 15 ft. from top of rail to bottom of arm. The wooden blade of the semaphore is 3 ft. 6 in. by 7 in. and from top to vertical projection of center of rotation when horizontal is 3 ft. 11-1/2 in., the center of rotation being 16 ft. 7 in. from top of rail.

Lenses. (a) For high-speed interurban service, a lens not less than 8-3/8 in. in diameter should be used on all light signals operated by continuous track circuits.

(b) For moderate speed roads, a lens not less than 5-3/8 in. in diameter should be used where light-signals are operated by trolley contact or other end-set devices.

Manually Operated Signals. Signals employing a wire circuit are used on the shorter interurban roads and on some city roads. A typical system is shown in Fig. 47 in which a double-throw electric switch is installed on a pole

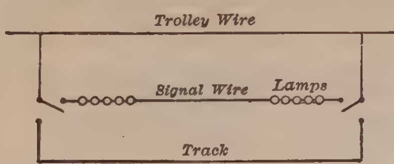

Fig. 47. Manually Operated Signal System

at each end of the block, so as to be accessible to the motormen. When a car enters the block at either end, the conductor or motorman throws the switch to the opposite position, thereby lighting the lamps at both ends. (If there is already a car in the block, the lamps will not light, as the motorman coming the other way will have thrown up his switch.) When he leaves the block he throws up the switch, thereby extinguishing lamps at both ends. The man on the next car puts down the switch and if it lights he proceeds. A light always means safety, whereas no light means unsafe.

A development of this is a semaphore in place of lamps and automatic throwing of the switches by mechanical trip or magnet on the car.

Manual Block System. This is similar to the system used on steam roads, wherein block signals are operated manually upon information received by telephone or telegraph.

Controlled Manual Block System. This is similar to the simple manual block system except that the signals at the end of each block are interconnected electrically, so that a clear signal cannot be obtained without the cooperation of the signalmen at each end of the block.

Token System. This is a manual block system applied to single-track lines. In this system no train is allowed to occupy a block section without obtaining possession of a tablet, staff or other characteristic token. These tokens are taken from signals at the ends of blocks and form part of an interconnected electric system, such that but one token can be removed at a time from a pair of signals, and until the token has been replaced in one signal, no token can be taken from the other. The possession of a token is authority to proceed.

Where it is desired to admit two trains to a block, divided tokens are used, each train taking one, and no further tokens can be withdrawn until all of the pieces of the first are replaced.

Automatic Block System. This is a system in which signals controlled by trains govern the entrance to each block, thereby affording both head and rear protection.

Protection is obtained either by a sectionalized trolley wire, sectionalized track rails or short insulated sections of track rail at the ends of blocks.

Due to the use of the track rails as part of the traction current circuit, some means must be adopted to keep the signal and traction currents separate. On direct-current railways, this may be accomplished either by bridging the insulated rail joints by inductance bonds, which permit the traction current to flow and choke back the alternating signal current, or by confining the traction current to one rail, and the signal current to the other, the latter system being favored where the track work is complicated, as in yards, junctions, etc. On alternating-current railroads, it is usual to reserve one track rail for signal purposes.

Insulating Rail Joints. Insulating joints at the ends of blocks are made by inserting a piece of insulating fiber between the rail ends, insulating bushings around the bolts and a plate of insulating fiber between the joint plate and rails, the former being prepared especially for the purpose.

Effect of Preservatives in Ties. Zinc-treated ties when new tend to short-circuit the rails, due to the conductivity of the zinc salts. Circuits 2000 ft. long may be operated successfully with 50% of ties so treated, but 5000-ft. circuits with all new zinc-treated ties will not operate.

Crossing Protection. Automatic highway crossing protection is usually accomplished by means of a gong (200 cycles per min.) operated by a " setting switch " placed in the trolley wire at the approach to the crossing and a " restoring switch " at the crossing.

Dispatcher's Signal Systems. These are for the operation of special signals to control train movement from a dispatcher's office.

One system has a pendulum of a different length at each signal, and a duplicate of each of these in the dispatcher's office. When the dispatcher starts one of his pendulums, it makes and breaks an electric circuit, thereby periodically energizing electromagnets near all the line pendulums. Only that pendulum which is synchronized with it starts into motion and it trips a release which both sets the signal and closes a sounder circuit in the dispatcher's office, thus indicating that the signal has been set.

Standard Practice. The reports of the Joint Committee on Block Signals for Electric Railways, American Electric Railway (Engineering) Association, give full details of actual and recommended practice. See proceedings American Electric Railway Engineering Association and A.E.R.E.A. Engineering Manual. The standards cited in this article are those of the above association.

21. Track

(By Walter Loring Webb)

General. Track for interurban electric roads is identical with that for steam roads of equal carrying capacity except that the rails must be so effectively bonded as to facilitate the return of the current to the power house with minimum power loss and electrolytic effect. Urban tracks have the additional difference of requiring high rails to comply with paving and street traffic requirements.

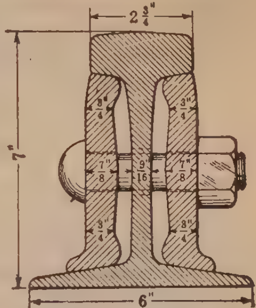

Fig. 48. Shanghai Rail

Rails. Some of the forms of high rails together with suitable rail joints are shown in Figs. 48, 49 and 50. All such rails, being embedded in pavement and prevented from lateral displacement, are laid with close joints, no allowance being made for temperature changes. Being buried in the pavement the range of temperature is less than if fully exposed to the atmosphere, and temperature changes merely produce a harmless tension or compression in the metal. This permits the use of **welded joints**, which have the advantage of greater permanency, less cost for maintenance and better conductivity.

Thermit Process: A mixture of powdered aluminum and oxide of iron is placed in a crucible and ignited. The chemical reaction develops a heat of about 5000° F. The oxygen combines with the aluminum, and the iron becomes a molten low-carbon steel. The molten iron sinks to the bottom of the crucible. An iron pin, covered and protected by an asbestos washer, forms a plug for a

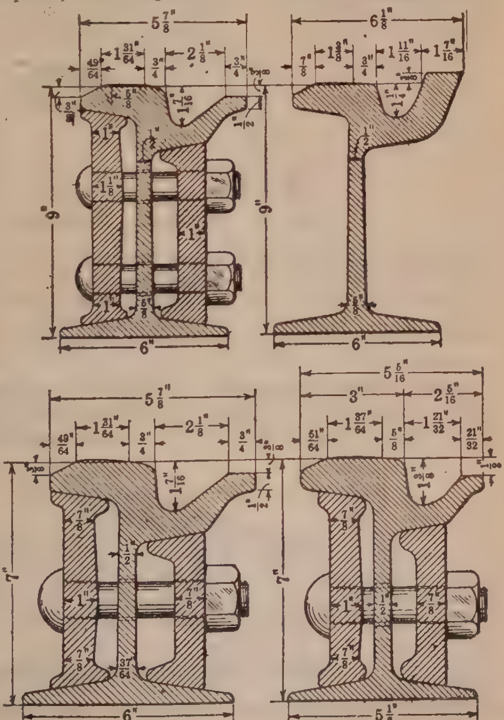

Fig. 49. Girder Rails

hole in the bottom of the crucible. When the iron is thoroughly melted, the pin is struck up so that the molten metal escapes from the bottom and pours into a mold which has been made surrounding the joint. The intense heat welds the ends of the rails together and to the molten iron surrounding them, producing a solid welded joint.

Jacobs process, as used by the Lorain Steel Co., is applicable only to new work. A flux is interposed between the ends of the rails; a comparatively small

Fig. 50*a*.

current of electricity starts chemical action in the flux which develops intense heat and heats the ends of the rails above the melting point of steel, the rail ends being forced together by hydraulic pressure. While the end of the rails are being heated, they are surrounded by the flux, which prevents air from oxidizing the rail ends and thus permits a clean strong weld.

The **bar weld process**, see Fig. 50*b*, as used by the Lorain Steel Co., welds two plates 18 in. long by 3 in. wide and 1 in. thick to the webs of the rails.

Fig. 50*b*. Standard Bar for Welding

Each plate has three raised bosses on the surface, the bosses being the only portions of the plate actually welded to the rail web. The plates are pressed against the web with a pressure as high as 35 tons, while a current which may amount to 25 000 amperes runs through the joint. The mechanism for making such joints is carried on a car and the current taken directly from the trolley wire.

Repair of Broken-Down Joints. A reinforcement of the ends of the rails at a joint may be made by placing a welded chock under the head for support, as shown in the figure. See Fig. 50*c*. In case the ends of one or both rails

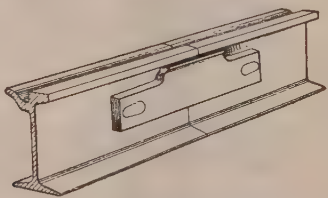

Fig. 50*c*. Welded Joint with Head Support

are broken down, it may be necessary to cut out a foot or more of old rail, replace it with new rail and make an extended joint as shown. By welding a chock under the head at each end of the short piece, the rail ends are secured against breaking down. By such means the life of an otherwise worn-out track may be extended many years. See Fig. 50*d*.

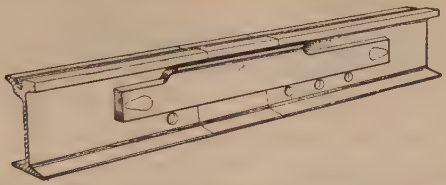

Fig. 50*d*. Welded Joint with Head Support of Special Length

Track Gage. The convenience of operating standard-gage steam railroad equipment on electric roads has resulted in the almost universal adoption of standard gage (4 ft. 8-1/2 in.) for electric roads. Philadelphia (5 ft. 2-1/4 in.) and St. Louis (4 ft. 10 in.) are the most prominent exceptions to this rule. The flanges of wheels have conoidal surfaces and there are therefore no definite points on their surfaces between which the gage of the wheels may be measured. The gage is therefore arbitrarily measured between points on the flanges 1/4 in. from (or below) the treads, and this gage-width for the wheels is made 1/4 in. less than the gage-width between rails.

Track Clearances. The spacing between track centers for double track or turnouts depends on the width overall of the cars in use, and also indirectly on the speed, which would affect the clearance. The extreme width of cars out to out varies from 8 ft. to 9 ft. 1 in. This width plus the clearance, which usually varies from 5 to 13 in., equals the distance between track centers, which therefore varies from 8 ft. 6-1/2 in. in Philadelphia to 9 ft. 5 in. in Chicago. When streets are very wide, the clear distance between cars may be increased to 2 ft. For center-pole construction even greater space must be

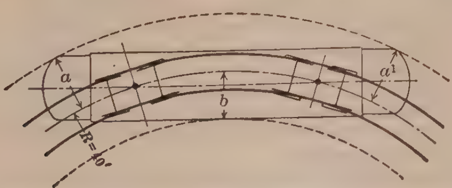

Fig. 51. Clearance for Car on Curve

used and the distance between track centers may be increased to 15 ft. The large cars now commonly used overhang the track so much when going around sharp curves that the standard clearance between the tracks on the tangents is too narrow to permit the passing of two cars on sharp curves. It is frequently impossible to increase the track clearance so that the largest cars may pass on the curves, and it is then necessary to require one car to wait for another and not permit them to turn on the curve simultaneously. The amount of added clearance depends on whether the car is mounted on single or double trucks, its length (including the possible fender at either end) and the spacing between the center pins of the trucks. The simplest rule for determining the extra width between track centers is to draw at a proper scale the curves at the desired radius, and draw a plan view of a car together with its wheel base, somewhat as shown in Fig. 51. The excess over the width of the car of the sum of the distances (*a* and *b* in Fig. 51) from the track center to the extreme projecting points of the car on both sides is the required excess in track clearance. When no excess clearance is provided, both tracks have a common center of curvature. By using curves with different centers of curvature and with suitable radii, the desired extra clearance may be obtained. Since the projection of the car over the rails varies with each change of curvature, the necessary combination of curves to provide sufficient clearance for a given type of rolling stock must usually be determined by trial.

Transition Curves or Spirals should be used at the beginning and ending of all curves. The spirals for easy curves should be those already developed for steam railway work. The curves around street corners are usually so sharp that spirals having more rapid changes of curvature must be used. The manufacturers of " special work " now use spirals not only in constructing approaches to simple curves but also for branch-offs, Y's, etc. The design of such spiral work may be left to them by furnishing them with the following items: (a) total central angle of curve, (b) total required clearance at center of curve between curb and nearest rail or distance from vertex to inner rail, (c) distance from rails to curb in each street.

The American Electric Railway Engineering Association has recommended a system of spirals especially designed for the sharp curves of street railway work, which has been generally adopted. In principle, it is the Searles Railroad Spiral, of multiform compound curves, but using much shorter chord lengths. Characteristics of these curves are quoted as follows:

" All spirals are similar to Searles Spirals and consist of compound curves composed of a series of circular arcs of equal length.

" Rate of change of central angles of arcs is uniformly one degree.

" Corresponding angles and angular functions of all spirals are the same.

" Corresponding lineal dimensions of all spirals are proportional in their respective arc lengths.

" For convenience the base spiral has arc lengths of 10.0 ft.

" The number of any spiral is the length in feet and tenths of its individual circular arcs measured on the center line of standard gage track.

" C = central angle for any arc. S = total central angle of spiral.

" A = arc lengths. R = radius for any arc = $360\ A/2\ \pi C = 57.2958\ A/C$.

" C and S are the same for corresponding arcs of all spirals.

" A is constant for each spiral and its center line length in feet and tenths is the same as the spiral number.

" The standard spirals are numbers 4.0, 4.5, 5.3, 6.5, 8.5 and 10.0.

The coordinates for the commonly used " 5.3 plain end spiral " are tabulated herewith.

Radius	Angle A	X	Y	S°	Total
R_1 = 301.313	1° 00′	0.046	5.259	1° 00′	5.259
R_2 = 149.480	2° 00′	0.228	10.473	3° 00′	10.477
R_3 = 98.868	3° 00′	0.634	15.633	6° 00′	15.654
R_4 = 73.563	4° 00′	1.349	20.718	10° 00′	20.789
R_5 = 58.379	5° 00′	2.451	25.690	15° 00′	25.884
R_6 = 48.257	6° 00′	4.012	30.494	21° 00′	30.939
R_7 = 41.027	7° 00′	6.089	35.052	28° 00′	35.950
R_8 = 35.604	8° 00′	8.721	39.265	36° 00′	40.912

Fig. 51, which is drawn to scale, graphically illustrates the form of one of the spirals using six chords. The spiral commences at B' (or B) with a radius of 301.313 ft. At the end of such a curve 5.259 ft. long, the curve compounds into a curve with 149.480-ft. radius, and so on to the end of the spiral at the point C'. At the other end of the uniform circular curve (C), the spiral is repeated in inverse order.

Each system of chord lengths (5.3, 6.5, etc.) has a corresponding " switch easement " system " which will permit the conversion of a plain curve into a

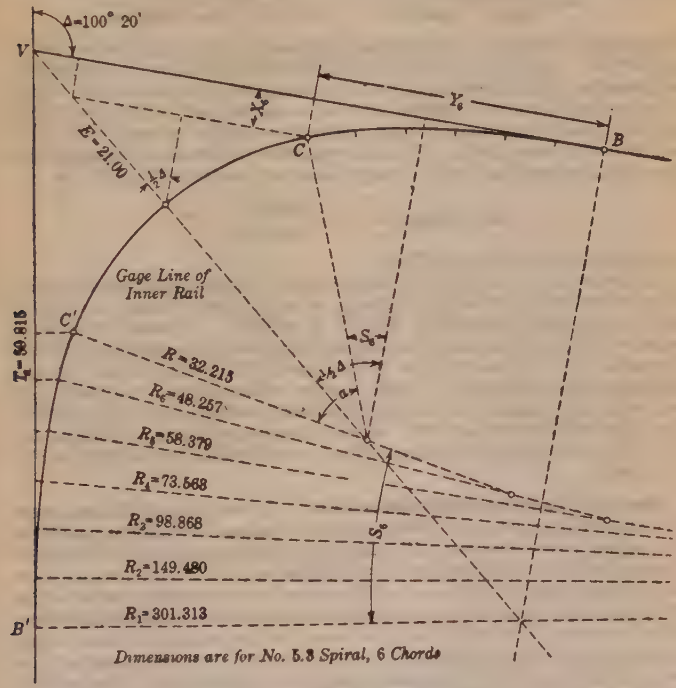

Fig. 52

branch-off with a minimum disturbance of existing work." The total angle S of the spiral is the same and the sharper-curved part is identical, but the flatter part of the spiral is modified so that a switch may be subsequently introduced with a minimum change in trackage.

A 25-page book of tables gives the ordinates and other measurements for the various spirals and their corresponding switch easements.

To Select a Curve with Spirals. Given the central angle Δ and the desired external distance E from the intersection of the tangents to the desired middle point of the inner rail curve. As a trial $R' = E/\text{exsec } 1/2\,\Delta$, which gives the radius of a simple curve through that point and connecting the tangents. The radius R for the central part of the curve must be somewhat less than R'

and also somewhat less than the radius of the last chord of the spiral which it is proposed to use. For example, with $\Delta = 100° 20'$ and $E = 21'$, $R' = 37.424$. (Note that R, E and R' here refer to the gage line of the inner rail and not to the track center line.) The proper spiral must be selected by trial, perhaps after several computations. The six-chord spiral, No. 5.3, shown in the tabular form and Fig. 52, has for ordinates at the end of the spiral, $X = 4.012$; $Y = 30.494$; and $S = 21° 0'$.

$$\mathbf{R} = \frac{\mathbf{E \cos 1/2\,\Delta - X}}{\mathbf{\cos S - \cos 1/2\,\Delta}} = \frac{\mathbf{E \cos 1/2\,\Delta - X}}{\mathbf{2 \sin (S + 1/4\,\alpha) \sin 1/4\,\alpha}}$$

The central part of the curve, with radius R, has a central angle of $\alpha = \Delta - 2S = 100° 20' - 42° 0' = 58° 20'$. Solving the above equation, $R = 32.215$ ft., which is less than the radius of the sixth chord, which is 48.257 ft. Similar computations for a seven-chord, and for an eight-chord, spiral would show them as possible solutions, but the radius R would be reduced to 30.375 ft. and 28.084 ft. respectively. The easier radius would evidently be preferable. The distance from the vertex V to the point of tangency B (and B') is

$$\mathbf{T_s = X \tan 1/2\,\Delta + R \frac{\sin 1/2\,\alpha}{\cos 1/2\,\Delta} + Y}$$

which on the above basis, = 59.815 ft.

As another example, where the central angle is comparatively small, assume a curve in a track following a highway, where the central angle $\Delta = 30° 20'$ and the maximum permissible distance $E = 6.5$ ft. A simple curve (inner rail curve) through the desired middle point and joining the tangents will have the radius $R' = E/\text{exsec } 1/2\,\Delta = 6.5$ ft./exsec $15° 10' = 180.11$ ft. R must be somewhat less than this. Using the first three chords of a 10.0-ft. plain end spiral, the ordinates of the end of the third chord point are $X = 1.210$ ft. and $Y = 29.715$ ft. $S° = 6° 0'$. Solving the above equation for R, we find $R = 171.73$ ft., which is less than 188.632 ft., the radius of the third chord of the spiral.

Spacing of Turnouts; Single-Track Road. Economical and efficient operation absolutely requires that turnouts shall be located as nearly as possible at the points where the cars will naturally meet (according to the system adopted) without requiring one car to wait for another at any meeting point. Before these meeting points can be determined, the maximum number of cars to be operated on one section and their effective schedule time must be known. When there are unusually steep grades on the line which will cause certain sections to be run more slowly than others, allowance must be made by a corresponding shortening of the sections having the steep grades. The necessity for slow speed through village streets and the possibility of comparatively high speed through the open country or on private right-of-way, and even excessive curvature, will have substantially the same effect in modifying the distance between adjacents turnouts. The principles of spacing turnouts may be best stated by an example. Assume a road 6 miles long, operating six cars; assume maximum velocity of 20 miles per hour with stops averaging 800 ft. apart. Assume that the grades are equivalent to an average of 2%, but that there is a half-mile stretch of 6%. The energy which will move the car at 20 miles per hour on a 2% grade will move it only 9 miles per hour on the 6% grade. The half mile will require 200 sec., which at 20 miles per hour would run the car 1-1/9 miles or 5867 ft. Therefore that half-mile stretch must be increased to 5867 ft. in Fig. 53, and the virtual length of the line must be considered as increased by 5867 − 2640 = 3227 ft. = 0.61 mile, or that the line is virtually

6.61 miles long. On the basis of 10-sec. stops every 800 ft., 20 mph. maximum velocity, and an acceleration (and deceleration) of 1.25 mphps., the mean velocity will be 10.2 miles per hour and the entire 6.61 miles will be run in 38.9 min. With an allowance of say 6 min. for terminal wait, the run must be practically on 45-min. schedule. Lay off on profile or cross-section paper, at suitable scales, times as vertical ordinates and distances as horizontal spaces. The 2640 ft. of 6% grade is expanded to the 5867 ft. of virtual distance requiring the same time interval. Two inclined lines represent the course of

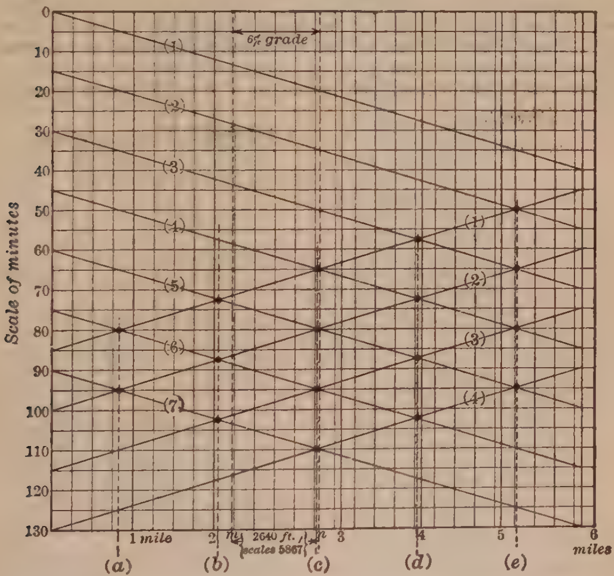

Fig. 53. Chart to Determine Location of Turnouts or Passing Points

the car during the round trip. The six cars run at 15-min. intervals. The location of the meeting places is graphically determined. The location of turnout (*c*) must be determined by scaling 2640/5867 of the space from *m* (or *n*) from the line (*c*). From the above example the following general principles may be determined:

(a) The number of cars is one greater than the number of turnouts.

(b) The running time between consecutive turnouts is one-half the running-time interval between cars.

(c) The time interval between consecutive turnouts is necessarily uniform throughout.

(d) When, as illustrated above, the velocity for any section is necessarily reduced, the spacing must be reduced accordingly.

(e) If variation in traffic density seem to require a temporary or periodical reduction in number of cars, it must be done by cutting out one or more cars from the regular schedule, or perhaps by cutting out every alternate car, and operating the others precisely as before. This merely means that some turnouts are not always utilized.

(f) Since in the example given the lay-over is 6 min. and the time interval between successive car passings at (*a*) is 15 min., the time interval from the terminus to (*a*) is 9 min. and the distance is 0.6 times the normal distance between turnouts. The distance between (*e*) and the other terminal is the same. There are therefore 4 + 0.6 + 0.6 = 5.2 intervals in the virtual distance of 6.61 miles. The interval is therefore 6.61/5.2 = 1.271 miles, = 6711 ft., which is the distance (*a*) to (*b*) and (*d*) to (*e*). If (*b*) to *m* is 920 ft., then *m* to (*c*) is virtually 6711 − 920 = 5791 ft., which multiplied by 2640/5867 = 2606 ft., the actual distance. The spacing from (*b*) to (*c*) is therefore 920 + 2606 = 3526 ft. 5867 − 5791 = 76, which multiplied by 2640/5867 = 34 ft., the true distance from (*c*) to *n*. As a check, 2606 + 34 = 2640. (*a*) and (*e*) are each distant from their termini by 6/10 of 1.271, or 0.76 mile.
