The Charpy Impact Testing Machine is used for tests of small specimens of metal under impact. The specimen is held in a horizontal position and is in flexure over a short span. It rests against the vertical face of an anvil. The impact is furnished by a pendulum which is let fall from a predetermined height, striking the specimen at the bottom of its swing. The pendulum is of known weight, and is so hung that its center of percussion is at the point of impact against the specimen. After breaking the specimen the pendulum continues its swing, and an indicating apparatus shows the maximum height to which it rises. The energy supplied by the pendulum is the product of its weight and its height of fall; the energy left after the fracture of the specimen is the product of its weight and the height of rise; the difference is the energy required to break the specimen. Specimens for the Charpy machine are notched at the middle of their length to insure a sharp plane of fracture, and the uniformity of size of specimen and of size and shape of notch is very important.

The Izod Machine acts on a principle similar to that of the Charpy machine. The Izod specimen is a short notched cantilever beam held vertically and struck by a swinging pendulum. The energy required for fracture is measured in a manner similar to that used with the Charpy machine. The significance of the results of either Charpy or Izod tests is a matter of considerable uncertainty.

Repeated-stress Testing Machines. The commonest type of repeated-stress testing machine uses a specimen which acts as a rotating beam (either a simple beam or a cantilever beam). Known weights producing computable unit stresses are hung on the specimen, and for every revolution of the specimen there is a cycle of stress involving a complete reversal of flexural stress. A revolution counter records the number of revolutions necessary to cause fracture. For the general method of determining the endurance limit (fatigue limit) by the use of such a testing machine see p. 555.

The Haigh repeated-stress testing machine sets up cycles of repeated axial stress (tension-compression) by the use of low-frequency two-phase alternating current electromagnets. The force developed is measured by the current induced in coils of wire on the armature which is attached to the specimen, and which is caused to vibrate between the poles of the pair of magnets. The Haigh machine is a very expensive machine, capable of a high degree of accuracy.

For descriptions of other types of repeated-stress testing machine see

Bulletins 124, 136, 142, and 152 of the Engineering Experiment Station of the University of Illinois.

Tests of Magnetic Permeability of steel and iron seem to give some indication of the hardness, strength, and uniformity. They possess the great advantage that the test does not destroy the sample tested, and hence may be made on the actual parts to be used. Magnetic tests as an indication of hardness or strength are not standardized yet, but hold promise of future usefulness.

The variation of magnetic qualities in a bar or disk of metal has been used as a means of locating small invisible flaws. (See article by J. A. Capp, Proc. American Society for Testing Materials, Vol. 27, Part II, p. 268 (1927)).

Macroscopic and Microscopic Examination of Metals. The term **macroscopic** is applied to the examination of metals either by the unaided eye or by the use of a glass magnifying not more than 10 diameters. The term **microscopic** is applied to the examination by means of a magnifying lens or lenses yielding magnifications greater than 10 diameters. In both types of examination the surface of the metal is polished. Usually for macroscopic examination polishing with fine emery paper is sufficient; for microscopic examination emery paper polish is usually followed by a polish with jewelers' rouge or with very fine alumina. In most cases, after polishing, the surface of the metal is etched; nitric acid, picric acid, copper chloride, and ammonium persulfate are among the etching agents used. For inspection purposes the etched surfaces are examined by direct observation; where a permanent record is desired a micrograph of the surface is taken by means of a photographic camera attached to the microscope. For macrographs an ordinary camera may be used.

Macroscopic examination brings out the general features of the internal structure of the metal, but not the details. Macrographic examination has proved useful in showing the presence of segregation of ingredients in metals, the presence of small cracks and flaws, the " grain " or flow lines in forgings, and the slag streaks which distinguish wrought iron from steel.

Microscopic examination brings out the details of crystalline structure of metals. It shows the size and shape of the crystalline grains, the homogeneity of the internal structure, the presence of fine bands of segregated material, the presence of " slip bands " due to inelastic action, and the presence and growth of minute cracks. Magnifications commonly used for micrographs are 100, 500, 1000, and 1500 diameters. Micrographs with good detail have been made with a magnification of 3600 diameters.

X-ray Examination of Metals. X-ray apparatus has been used for the examination of metals with two distinct purposes in view: (1) to reveal internal defects, and (2) to determine the geometric pattern in which the atoms of a metal are arranged—the space lattice. X-ray examination for internal defects in metals is made with a very powerful X-ray apparatus. Defects have been shown in steel up to 4 in. thick. X-rays penetrate aluminum much more easily than they do steel, and lead much less easily. Defects shown by X-ray examination are not magnified, and the examination can detect no flaw smaller than one which could be detected by the unaided eye if the defect were on the surface of the metal. The technique of handling the powerful X-ray apparatus is very difficult, and unless elaborate precautions are taken to enclose the whole job in a thick lead chamber, there is great danger from X-ray burns and injury to the eyes of the attendants and persons in nearby rooms.

X-ray determination of the space lattice of a metal is as yet a problem for the physicist rather than the testing engineer The wave length of X-rays is much shorter than that of ordinary light rays, being of the order of magnitude of the distance between atoms. By the dispersion and reflection of X-rays as they pass through thin sheets of metal, or through finely powdered metal, it is possible to construct a diagram of the geometric arrangement of the atoms in a crystalline grain of metal—a diagram of the space lattice of the metal. This application of X-rays is known as X-ray spectroscopy, and it holds great promise for the more fundamental study of the atomic structure and the inherent strength of metals.

25. Tests of Stone and Brick

The Specific Gravity Test for stone shall be made on a specimen that has been dried to constant weight at a temperature of 212° to 230° Fahr. After removing all sharp corners and grains that are loose, the specimen shall be carefully weighed, then placed in water and put under the receiver of an air pump and all bubbles of air exhausted. The weight in water shall be noted and the specimen removed from the water and all surplus surface moisture removed either with a cloth or blotting paper. After again weighing, the specific gravity will be determined from the formula Sp. Gr. = Wt. of dry stone in air ÷ (Wt. of saturated stone in air − Wt. of saturated stone in water). Where an air pump is not available, the specimen may be weighed in the water after an immersion of 24 hours, all surface air bubbles being removed with a small brush or feather.

Tests for Crushing Strength of stone shall be made on cubes, the size of which will depend upon the capacity of the testing machine. Specimens shall be sawed out and not chiseled. They shall be tested on their natural beds, and the opposite faces shall be ground parallel and tested between steel plates in a machine having a spherical socket in the crushing head. At least three specimens shall be tested, and the load at which the specimen first cracks and the ultimate resistance shall be noted in the report.

Transverse Strength of stone shall be determined by placing a beam whose length is not less than 10 times its depth on slightly rounded knife-edges and applying a load at the center. The modulus of rupture shall be computed by the formula $\mathbf{R} = \frac{3\,Wl}{2\,bd^2}$, where W is the center load. l the span, b the width, and d the depth.

The Absorption Test shall be made by drying the stone to constant weight at a temperature of 212° to 230° Fahr., carefully weighing, then placing in water for 48 hours. At the end of this period the stone shall be removed from the water, all surplus water wiped off and the stone reweighed. The percentage of water absorbed shall be noted in terms of the original dry weight of the stone.

In the Freezing Test, five clean stone cubes of the same size shall be dried, weighed, and immersed in water for 24 hours. They shall then be alternately frozen and thawed twenty-five times. After the final thawing, they shall again be dried in an oven, and all loose particles removed. The loss of weight shall then be noted.

The Quenching Test shall consist of heating the stone specimens to 500° to 600° Fahr., and plunging them while hot in water of a temperature of about 70°. The loss due to spalling or disintegration shall be noted in terms of the weight of the original dry stone.

Toughness Test for rock. The following is from the 1927 Standards of the American Society for Testing Materials (Part II, p. 464):

"Test pieces shall be cylinders 25 mm. in diameter and 25 mm. in height, cut perpendicular to the cleavage of the rock. One set of three specimens shall be drilled perpendicular and another parallel to the plane of structural weakness of the rock, if such plane is apparent, otherwise one set of specimens shall be drilled at random.

"Any form of impact machine which will comply with the following essentials may be used in making the test:

"(a) A cast-iron anvil weighing not less than 50 kg. firmly fixed upon a solid foundation;

"(b) A hammer weighing 2 kg., arranged so as to fall freely between suitable guides;

"(c) A plunger made of hardened steel and weighing 1 kg., arranged to slide freely in a vertical direction in a sleeve, the lower end of the plunger being spherical in shape with a radius of 1 cm.;

"(d) Means for raising the hammer and for dropping it upon the plunger from any specified height from 1 to not less than 75 cm., and means for determining the height of fall to approximately 1 mm.;

"(e) Means for holding the cylindrical test specimen securely on the anvil without rigid lateral support, and under the plunger in such a way that the center of its upper surface shall, throughout the test, be tangent to the spherical end of the plunger at its lowest point."

Fig. 67 shows, in diagram, the testing machine.

The test consists of a 1-cm. fall of the hammer for the first blow, a 2-cm. fall for the second blow, and an increase of 1-cm. fall for each succeeding blow until failure of the test specimen occurs.

Paving Brick are tested for abrasion in the method described on p. 603.

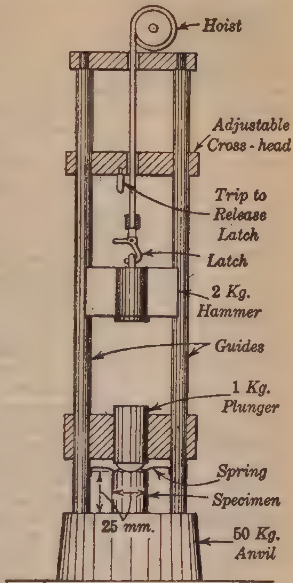

Fig. 67

26. Miscellaneous Tests

Tests of Strength of Wood have not been standardized to an extent which allows their inclusion in specifications for timber, but compression tests, flexure tests, shearing tests, and impact tests are frequently made. Compression tests are made both along the grain and across the grain. Compression specimens are usually rectangular blocks, and should be tested with spherical-seated bearing blocks. Wood has a rather poorly defined proportional limit in compression. In compression along the grain there is a well-defined ultimate. Shearing tests along the grain are made by the use of shearing blocks placed in the testing machine, or for larger specimens by testing short, deep beams. The shearing strength of wood along the grain is of great importance. Flexure tests both of small selected specimens and of large beams are common. In flexure tests the failure may be by longitudinal shear along the neutral axis, by compression along the upper side of the beam, or by tension along the lower side. Impact flexure tests show the shock-resisting qualities of wood. Hardness tests are made by using a steel ball 0.444 in. in diameter, and noting the load which causes the ball to penetrate to one-half its diameter.

Special Tests of Materials, Structures, and Machines

Structural part, machine part, structure, machine or material tested	Test	Measurements
Floor panel of building.	Proof test with dead load, not to destruction.	Deflections, tensile and compressive deformations in beams and columns.
Bridge	Proof test with dead load or with moving load.	Deflections, tensile and compressive deformations in various members.
Riveted joints	Tests of samples to destruction.	Ultimate load, slip of rivets.
Rivets, metal plates	Shearing test of samples to destruction using special shearing tools.	Ultimate load, results depend on hardness of shearing tools used.
Bolts	Tests of samples to destruction in tension or torsion.	Ultimate load.
Boilers	Tests with hydrostatic pressure. Proof tests with pressures somewhat above working pressures.	Observation of leaks, cracks, or permanent distortion of parts.
Car couplers and coupler yokes.	Proof tests, tests of samples to destruction under tension and impact tension.	Ultimate load, distortion under proof load.
Wire rope	Tests of samples to destruction in tension.	Ultimate load, observation of manner of fracture.
Brake beams for railway cars.	Tests of samples to destruction in flexure.	Ultimate load, deflections.
Chain	Proof tests of entire chain in tension, tests to destruction of sample sections.	Set after removal of proof load, ultimate strength.
Large pipe	Hydrostatic pressure proof test.	Observation of leaks, cracks, or other evidence of failure.
Gear teeth	Scleroscope or Rockwell test for uniform hardness.	Hardness for various teeth.
Engraver's plates	Brinnell, Rockwell, or scleroscope tests for uniform hardness of samples.	Hardness at various points.
Strain insulators for electric transmission lines.	Proof load in tension, tension test of samples to destruction.	Evidences of failure under proof load, ultimate strength.
Eyebars	Tension test of sample eyebars to destruction.	Yield point, ultimate load, stretch.
Columns	Compression tests of models or samples to destruction.	Yield point, ultimate load, deflection, axial compression.

Tests of concrete and of cement are discussed in Sect. 11 of this handbook. Further discussion or tests of road materials are given in Sect. 20.

The Turner-Hatt impact testing machine is in common use in the United States for impact testing of wood. This machine consists of an anvil on which the specimen is placed, and of a weight which can be dropped from various heights. Attached to the weight is a pencil which draws a record on a rotating drum. From this record the deflections of the specimen can be measured, as the weight is dropped from successively increasing heights until rupture occurs, or until the deflections increase abnormally, showing that the proportional limit has been passed. Another method of making an impact test consists in dropping the weight from such a height that the specimen is fractured by one blow. The pencil attached to the weight traces a curve on the rotating drum whose steepness is a measure of the velocity of the falling weight. Measuring the velocity of the weight before and after fracture of the specimen the energy absorbed in fracturing the specimen can be determined. For detailed description of tests of timber, see the 1927 Standards of the American Society for Testing Materials, Part II, p. 635.

Special Tests of materials, structures, and machines are often made. The table on p. 618 gives some such tests.

27. Inspection

A Shop Inspector has duties suggested largely by the specifications governing the work. Primarily his duties are to see that workmanship, method of fabricating material, and finished product are all in accordance with the plans and specifications, a complete set of which should be furnished him. The tools needed are inside and outside calipers, micrometer calipers, rule, steel tape, testing hammer, and report blanks. In structural work he should measure finished material, particularly with reference to field connections, examine abutting joints to see that they are full and square, test all rivets with a light hammer and have all loose or cock-headed ones cut out and replaced, should see that all members are free from twists, kinks, or bends, that pin holes are at right angles to the web of the member, countersunk rivets are chipped, that surfaces for rollers, splice plates, and bearing plates have been planed, that eyebars intended for the same pins should when piled all take the right pins at both ends at the same time, that threaded ends are wrapped with burlap, or otherwise protected against damage in transportation, etc. All accepted material should be marked with the inspector's private stamp.

The Cold Bend Test is of great importance as a shop test of ductility. It is made by bending cold a specimen of iron or steel flat on itself or round a mandrel of specified diameter. The bending may be accomplished either by pressure or by blows of a hammer. During and after bending the specimen must develop no cracks. For detailed requirements for cold bend tests of metals see the 1927 Standards of the American Society for Testing Materials, Part I.

Flattening or Upsetting Tests are made on rivets, on boiler tubes, and on pipes. Boiler tubes are also subjected to flanging tests in which a flange is formed on a cold specimen of tube. In flanging, upsetting, or flattening tests the distortion of the specimen must be accomplished without the development of cracks.

Hot Bend Tests and Quench Bend Tests are made on wrought iron, and quench bend tests are also made on material for boiler flues. Hot bend tests are made at a cherry-red heat, and quench bend tests are made after heating the specimen to redness and cooling in water. For both tests the specimen must bend round a mandrel of specified size without cracking.

Nick Bend Tests are made on wrought iron to show the fibrous structure and show the absence of scrap steel in the iron. A sharp nick is made across a test bar, which is then bent, opening out a cross-section. For round bars the specimen is nicked 25% around the circumference, for rectangular bars it is nicked along one side. The tool used to nick the bar has a 60-degree cutting edge, and the depth of the nick is not less than 8 nor more than 16% of the diameter or the thickness of the specimen. For the finest grades of iron the fracture at the nick shall be entirely free from bright crystalline spots; for cheaper grades not over 10% of the fractured surface shall show crystalline.

Wrought iron shows a gray, fibrous section, while the presence of scrap steel is indicated by bright, crystalline spots. This is a valuable shop test, but is not entirely conclusive.

IRON, STEEL, AND OTHER METALS

28. Cast Iron

Cast Iron is a saturated solution of carbon in iron, the amount of carbon varying ordinarily from a minimum of 1.7% to about 4%, depending upon the amount of silicon, sulfur, phosphorus, and manganese present in the solution. Other elements may also be present, but they are considered impurities.

Metallurgy. In the production of cast iron two steps may be necessary: First, the preparation of the ore for the blast furnace, involving the washing or dressing of the ore, and the calcination; and, second, the reduction in the blast furnace. In the case of the richer ores the first step is not always required, and this is the condition in the United States. The purpose of the roasting or calcination is the expulsion of volatile ingredients. The reduction or smelting of the ore is accomplished in a blast furnace, which, as the molten metal is drawn off at the bottom through the tapping-hole, is kept filled to the top or throat by adding metal in the form of iron ore, fuel in the form of coke, and flux, usually in the form of limestone, allowing the charge to work down. By means of tuyeres near the base of the furnace, a supply of air, or "blast," under a pressure of from 3 to 9 lb., is provided to maintain combustion at sufficiently high temperatures to reduce the ore. The molten iron is tapped from time to time near the bottom of the furnace. The flux combines, in the process of reduction, with the earthy matter of the ore and of the fuel, forming the slag. The slag, being very much lighter than the iron, floats on the surface of the molten metal and is tapped off near the top of the melting zone, through the cinder notch or cinder fall, into trucks called cinder tubs, by which it is transported to the cinder heap.

Pig Iron is the term applied to the form in which cast iron is obtained from the blast furnace. Pigs are usually cast in casting machines consisting of traveling metal molds, although some pigs are cast in open sand molds. A pig of iron weighs approximately 100 lb. and is approximately 3 ft. long. Machine-cast pigs are in the shape of rather thin slabs with rounded bottom side; sand-cast pigs have approximately equal width and depth with rounded bottom side. In its more restricted sense, cast iron is the form assumed after it has been again melted and cast into the finished form.

Composition. Commercial pig iron varies widely in chemical composition, depending on the uses to which it is to be put. The tendency of the present day is to purchase pig iron according to analysis instead of by grades. The constituents of good commercial pig iron vary as follows: Carbon from 2 to 4%; silicon from 0.5 to 5.0%; sulphur from 0.005 to 0.3%; phosphorus from 0.62 to 1.50%; and manganese from 0.10 to 1.75%. But these limits are by no means fixed.

Carbon. The amount in cast iron is largely dependent on the presence of other elements. While 4% is the ordinary maximum, the carbon may run as high as 7% if much manganese is present. The presence of silicon in large proportions, on the other hand, may reduce the solubility of the carbon to as low as 1%. The percentage of carbon present in cast iron in the combined form influences very largely the physical properties of the cast iron; thus, to get the maximum tensile strength, the combined carbon should be about 0.47%; for the maximum transverse strength it should be about 0.70%, and for the maximum crushing strength it should be over 1%. The hardness of cast iron increases regularly with the increase in the percentage of combined carbon. In Gray Iron the carbon exists almost wholly as graphite, having been precipitated as such in the process of solidifying. The graphite, known as "kish," gives the iron a somewhat spongy nature and a dark color. The condition is brought about in part by slow cooling, which tends to produce large crystals as well as graphite carbon. In White Iron the carbon is almost wholly combined and the iron has a more homogeneous texture, lighter appearance, and is composed of smaller crystals. Rapid cooling in solidifying tends to produce white iron. In Mottled Iron the proportions of combined and graphite iron are nearly equal, the fracture having, as the name indicates, a mottled appearance, due to the dark gray portions in the white matrix.

Silicon. The amount in cast iron determines, to some extent, the suitability of the material for various purposes. A certain amount is always desirable. Up to 0.8% it increases the hardness of the iron, but above that point it makes the iron soft and brittle. Silicon gives the iron a gray appearance, and if the proportion of silicon is large the iron is gray and highly crystalline. The shrinkage of cast iron is largely influenced by the presence of silicon, decreasing as the amount of silicon increases. A small proportion of silicon makes sound castings, free from blowholes.

Sulfur. The presence of sulfur is generally considered objectionable. A quantity greater than about 0.08% produces what is known as red shortness, that is, brittleness when in a heated condition. This condition makes the material unfit for use.

Phosphorus. The effect of phosphorus is to increase the fusibility and fluidity of the metal. Its presence, therefore, is desirable for light and ornamental castings, where well-defined impressions in the mold are wanted. At the same time, it tends to increase the brittleness of the iron. The maximum amount should not exceed 0.7% in good foundry pig for ordinary castings.

Manganese. This element is present in most pig iron and the amount varies greatly. For foundry use its presence is of no benefit when it exceeds about 1.0%. The value of the pig iron to the steel maker, however, increases in proportion to the amount of manganese present. Its presence prevents the absorption of sulfur in remelting. Hardness and closeness of grain are produced by the presence of manganese. **Spiegeleisen,** so called on account of its white glistening fracture, is a pig iron containing a large proportion of manganese, that is, from 5 to 20%. It is very hard, resisting cutting by cast-steel tools. When the proportion of manganese rises above 20% reaching sometimes as high as 80%, it is known as **ferro-manganese.**

The Grades of Pig Iron. Pig iron was formerly classified by grades, such as No. 1 soft, No. 2 soft, No. 1 foundry, No. 2 foundry, forge pig, etc., but to-day the practice is to buy pig iron by chemical analysis rather than by trade names of grades. Specifications for buying pig iron by analysis are given in the Standards of the American Society for Testing Materials. The accompanying table gives typical analyses of pig iron for various uses. All values are in per cent.

Use	Graphite carbon	Combined carbon	Silicon	Sulfur	Phosphorus	Manganese
Bessemer pig, for making steel by the acid Bessemer process or the acid open-hearth process.	3.50	0.05–0.10	1.00–2.00	Not more than 0.05	Not more than 0.10	0.25
Basic pig, for making steel by the basic open-hearth process.	3.50	0.05–0.10	Not more than 1.00	Not more than 0.05	0.30–1.00	0.25
Malleable pig, for making malleable cast iron	0.10	3.00	0.75–2.00	Not more than 0.05	Not more than 0.200	0.10
Foundry pig, for general casting.	3.15–3.90	0.05–0.10	0.75–4.00	0.02–0.08	0.10–1.00	0.20–0.25

Molding is the preparation of hollow molds to receive the molten metal. A wooden or metal pattern of the shape of the finished piece is prepared and imbedded in molding sand placed in wooden boxes so arranged in two parts, called the lower and upper flasks, that after the molding sand is thoroughly rammed and packed around the pattern, the upper flask may be taken off, the pattern withdrawn and the flask replaced and secured, leaving on the interior a hollow space of the size and shape of the finished piece. An opening is left through which the molten metal is poured into the mold. Smaller holes are also provided connecting with the hollow interior, to allow for the escape of the air and other gases that may be generated during pouring. When the finished casting is to be hollow a core is employed. Fig. 68 shows the cross-section of a mold ready to receive the molten iron. This particular mold is for a cast-iron pulley.

Wooden Patterns are generally made of thoroughly seasoned white pine or mahogany, the wood being carefully shellacked to keep the pattern from warping or being otherwise affected by moisture. If much used, patterns are often made of metal, in which case after being cast they are filed and scoured smooth, warmed and coated with wax. Aluminum patterns are coming into rather wide use. Patterns are sometimes also made of plaster of Paris, especially for highly ornamental castings in architectural iron work. The **shrinkage** of cast iron in cooling must be allowed for in the making of the patterns. The usual allowance is 1/8 in. per foot, but this cannot be laid down as a hard and fast rule, as the shrinkage varies with the relative dimensions of castings and with the character of the metal.

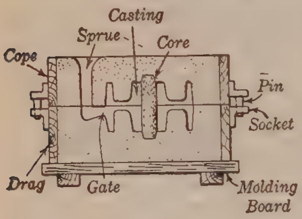

Fig. 68

Molding Sand consists chiefly of silica, 90 to 95%, which makes the sand sufficiently refractory; alumina and magnesia, 3 to 8%, which furnishes the necessary cohesion and plasticity to the sand; oxide of iron, about 1.5%; lime about 0.5%; and sometimes a small quantity of coal dust. Fine sand compacts too much, preventing the gases from escaping readily and causing blowholes in the castings, while coarser sand lacks cohesion and makes inferior castings.

Green Sand Molds are made of molding sand and are the molds most generally used, being most readily made and cheap. **Dry Sand Molds** are molds which have been baked in an oven to fix their shape and to give a hard surface. **Loam Molds** are generally used for large castings. They are built up of brickwork to the rough outline of the casting and are then finished off on the surface with loam laid on by a trowel.

Chills are metal molds used for certain castings, such as car wheels, where a hard surface is wanted, this being produced by the sudden cooling of the hot metal as it comes in contact with the comparatively cold surface of the mold.

Cores are used for the production of the hollow spaces in castings, and are made of baked sand and clay formed into shape and fixed in the molds. For large cylinders and other large castings, the cores are built up of brickwork to the approximate size and the surface finished off by facing with loam. For water pipes and similar castings the brickwork is often replaced by iron tubes.

The Cupola is the usual means for remelting pig iron to produce cast iron in its more restricted sense, namely, the finished castings. It consists of a cylindrical shaft provided with one or two rows of tuyeres near the base, through which air is forced at a pressure of about one-half pound per square inch. The charge consists of pig iron and coke in the proportion of about 200 lb. of coke for each ton of metal. A little limestone is usually also introduced as a flux. The molten metal drawn off at the bottom is poured into the molds by means of cup-shaped ladles fitted with long handles, one of which has a cross bar for tipping the ladle in pouring, or, for larger work, in ladles carried on wheels or by cranes and tipped by gears.

Malleable Castings are made in the same manner as ordinary castings, but are subjected to a further annealing process. Only small castings can be treated in this way. The castings are placed in cast-iron boxes called annealing pots, with decarbonizing material packed around them. For the decarbonizing agent an iron oxide in the form of hematite ore or forge iron scale is used. Only white iron low in sulfur can be used, and generally the best charcoal cast iron is selected. The castings, packed as stated, are placed in an oven in which the temperature is quickly raised and the castings kept at a cherry-red heat for three to five days, depending on their size, after which the furnace is allowed to cool slowly. The effect of this process is to make the castings " malleable " and to nearly double their strength. Castings of this kind may be bent cold, forged, or welded to a greater or lesser extent. They are used for pipe fittings, iron handles for tools, wheels, pinions, small parts of machinery, etc.

Semi-steel is the somewhat misleading trade name given to cast iron in the production of which 30 to 60% of steel scrap is used. With great care in foundry practice such " semi-steel " may be produced having higher strength than ordinary cast iron.

The Air Furnace which is sometimes used instead of a cupola to melt cast iron comprises a hearth on which fuel is burned and a separate chamber in which the pig iron and scrap are melted without direct contact with the fuel. Air furnace iron is freer from impurities than is cupola iron, but is much more expensive. Except for producing malleable cast iron the air furnace is not very extensively used.

The Fusibility of Cast Iron is dependent on the percentage of carbon and some of the other elements. The average fusion point is about 2200° Fahr. Its heat conductivity is 35.9, silver being 100.

The Specific Gravity of cast iron varies with its composition from about 6.9 to 7.5. It is usually taken at 7.22 (water at 2° F. being unity) corresponding to a weight of 450 lb. per cu. ft. In a general way the specific gravity increases with the strength of the metal and the number of remeltings.

The Coefficient of Expansion of cast iron may be taken at 0.000 0062 for 1° F. as an average. If exposed to continued heat, cast iron becomes permanently expanded 1-1/2 to 3%, a fact that must be remembered in installing grate bars or other castings exposed to heat.

The Modulus of Electricity varies from 12 000 000 to 14 000 000 lb. per sq. in. for ordinary commercial cast iron, and from 16 000 000 to 18 000 000 for special grades of strong cast iron, such as are used for ordnance.

The Elastic Limit. Cast iron has no clearly defined elastic limit either in tension or compression. For malleable iron the yield point in tension is about 30 000 lb. per sq. in.

The Ultimate Strength in Tension for ordinary castings can be taken at 15 000 to 18 000 lb. per sq. in., and for special grades of iron or for alloys of nickel with cast iron at 40 000 to 60 000. Malleable iron has a strength of about 50 000 lb. per sq. in.

Compressive Strength. 80 000 lb. per sq. in. may be taken as the average ultimate strength in compression. Tests show as low as 44 500 and as high as 215 000 lb. per sq. in.

Modulus of Rupture. The average value may be taken as 35 000 lb. per sq. in., the tests varying from a minimum of 9700 to a maximum of 80 000.

Shear and Torsion. Under torsion cast iron fails by tensile strain on an inclined section so that it is not safe to consider the shearing strength of cast iron as greater than the tensile strength.

Defects. The most common defects in cast iron are (1) blowholes, caused by the formation of steam when the hot metal comes in contact with the damp molding sand: (2) sand holes, and (3) roughness of surface, due to breaking down of the mold in spots; (4) cold-shuts or cold-shorts, which are seams caused by the too rapid congealing of the metal so that it does not completely fill the mold or join together solidly at points where two streams of iron meet, and (5) cracks resulting from uneven shrinkage in parts of the castings of unequal thickness. The last is sometimes not discoverable until the casting is put under load. Castings to be acceptable should present smooth, clean surfaces with all angles true and sharp, and should be soft enough to be dented on the edges by a hammer blow instead of breaking off.

For Cast-iron Pipe the metal shall be "of good quality and of such character as shall make the metal of the castings strong, tough and of even grain, and soft enough to satisfactorily admit of drilling and cutting." (Standard Specifications, American Society for Testing Materials.) For strength tests, see p. 613.

For Cast-iron Car Wheels the metal shall be soft, clean gray iron, closely approximating the following composition: Graphitic carbon 3.25%, combined carbon 0.60%, silicon 0.70%, manganese 0.60%, phosphorus 0.40%, sulfur 0.14%.

For Gray Iron Castings, that is, ordinary castings, the following standard specifications have been adopted by the American Society for Testing Materials (1927 Standards):

Unless furnace iron is specified, all gray castings are understood to be made by the cupola process.

The sulfur contents to be not over following percentages: Light castings, 0.10; medium castings, 0.10; heavy castings, 0.12.

In dividing castings into light, medium, and heavy classes, the following standards have been adopted: Castings having any section less than 1/2 in. thick shall be known as light castings. Casting in which no section is less than 2 in. thick shall be known as heavy castings. Medium castings are those not included in the above classification.

Transverse Test. The minimum breaking strength of the "Arbitration Bar" under transverse load shall be not under 1500 lb. for light castings, 1750 for medium castings, and 2000 for heavy castings. In no case shall the deflection be under 0.20 in. (See p. 613.)

Borings from the broken pieces of the "Arbitration Bar" shall be used for the sulfur determinations. One determination for each mold made shall be required. In case of dispute, the standards of the American Foundrymen's Association shall be used for comparison.

Castings shall be true to pattern, free from cracks, flaws, and excessive shrinkage. In other respects they shall conform to whatever points may be specially agreed upon.

The inspector shall have reasonable facilities afforded him by the manufacturer to satisfy him that the finished material is furnished in accordance with these specifications. All tests and inspections shall, as far as possible, be made at the place of manufacture prior to shipment.

For **Malleable-iron Castings** the 1927 Standards of the American Society for Testing Materials specify tensile tests for acceptance.

The tension test specimen is a round specimen machined from a test lug on a casting 7-1/2 in. long, 5/8 in. in minimum diameter, and with a 2-in. gage length. Such tension tests shall show a yield point of not less than 30 000 lb. per sq. in., a tensile strength of not less than 50 000 lb. per sq. in., and an elongation in 2 in. of not less than 10%. Malleable castings shall be made from iron melted either in an air furnace, an open-hearth furnace, or an electric furnace.

Working Unit Stresses for cast iron depend upon the character of the applied loads and upon the grade of metal. Common average values for tension fibers of flexure members are 4000 lb. per sq. in. for steady loads and 3000 lb. per sq. in. for variable loads, while for compression values about four times as great may be used. In shearing the working unit stresses may be taken as about the same as those for tension. The properties of castings depend upon the quality of the ores and upon the method of manufacture. Cold-blast pig produces stronger iron than hot-blast pig, but it is more expensive. Drying the air before admitting it to the blast tends to secure uniformity of product. The darkest grades of foundry pig make the smoothest castings, but they are apt to be brittle; the lightest grades make tough castings, but they are apt to contain blowholes or imperfections.

Very low unit stresses should be used when cast iron is subject to repetitive stresses alternating from tension to compression; probably 2000 lb. per sq. in. is the highest value allowable. Cast iron is a brittle material which is unsuited to resist shocks, and since 1900 it has not been used in bridge construction. It is not generally used in direct tension.

29. Wrought Iron

Composition. Wrought iron is a product of the reverberatory furnace, and is composed principally of ferrite (pure iron) and slag (iron silicate); in these exist small amounts of impurities, an idea of the percentage of which can be obtained from the following analysis (Macfarlane):

	Common wrought iron	Best wrought iron
Carbon	0.05	0.06
Phosphorus	0.35	0.18
Sulfur	0.06	0.04
Silicon	0.23	0.20
Manganese	....	0.06
Slag ..... about	3.3	2.80

Metallurgy. Wrought iron is made in a reverbatory furnace from pig iron and less frequently from molten metal taken directly from the blast furnace. This method of manufacture is known as the puddling process. The furnace consists essentially of a firebox, puddling or working chamber, suitable draft openings and flue. The working chamber is provided with openings for the purpose of charging and working the metal, and for the removal of slag and the puddled metal. There are two distinct puddling processes, Wet Puddling and Dry Puddling.

In the **Wet Process** the hearth of the furnace is felted with high-grade iron ore or mill scale which acts as an oxidizing agent for reducing impurities. The reduction of impurities occurs in different stages, namely in the melting-down stage, during which most of the silicon and manganese and some of the phosphorus are removed; in the clearing stage, during which phosphorus and sulfur are removed, and in the boiling stage, during which carbon is removed and most of the remaining phosphorus and sulfur. Since pig iron melts at a much lower temperature than metallic iron, as the mass becomes purified it assumes a pasty condition. It is then collected in balls weighing about 80 lb., carried to the squeezers or a forge and most of the slag expelled. The resulting bars are then run through roughing rolls, the rolled bars trimmed, and thereafter known as " muck bar." The muck bars are then cut up into short lengths, and these short lengths are " box piled " in alternate layers with lengthwise and crosswise bars. These box piles are tied together with wire, placed in a furnace and heated to welding heat, and then rolled out into plates, rods, or other shapes. The piling and rerolling removes slag, and gives a metal with interlacing fibers of slag.

In the **Dry Process,** which is infrequently used, white pig iron is charged and subjected to the action of an oxidizing flame. The oxygen in this case is supplied by the furnace instead of from the fettling.

Appearance. A section of a wrought-iron rod or plate when polished shows more or less regular laminations of slag and iron. By notching one side of a bar and bending one end away from the notched side, the iron will break along the slag laminations and give a fracture known as "barking." If a bar is notched all around and then struck a blow heavy enough to cause it to break, the fracture will be coarsely crystalline; when broken in tension, the fractured section is generally irregular and fibrous.

To distinguish between Wrought Iron and Soft Steel (Iron Age, Dec. 23, 1909): The sample is cleaned from grease and scale and immersed in a solution of the following: water, 9 parts; sulphuric acid, 3 parts; muriatic acid, 1 part. The acids are poured into the water and the mixture allowed to cool. The specimen is allowed to remain in the solution for 15 or 20 minutes, when it is removed and rinsed in water. The fibers will now show plainly, or if not, the process is continued. Soft steel dissolves uniformly and without the fibrous structure found in wrought iron.

Grades. Wrought iron may be graded as follows: (1) Charcoal iron, the purest grade of wrought iron; (2) Puddled iron, classified according to quality into stay-bolt iron (grade A) and merchant iron, grades B and C; (3) Busheled scrap, a heterogeneous product made from iron scrap; steel is frequently mixed with the iron scrap, causing considerable irregularity in the resulting product.

Properties. Wrought iron possesses the important qualities of toughness, ductility, malleability, and weldability, but its properties are only slightly changed by tempering.

Coefficient of expansion..	0.00000648 per degree F. (Clarke)
Electrical conductivity...	0.16 (Cu = 100) (Lazare Weiler)
Melting temperature....	2732° to 2912° F. (Pouillet, Claudel, Wilson)
Specific heat...........	0.1138 (Röntgen)
Specific gravity.........	7.4 to 7.9 (Kent)

Tension. The average results of a great many tensile tests made at the Testing Laboratory of Columbia University on good wrought iron for general purposes give the following:

Yield point, lb. per sq. in..................	31 000
Ultimate strength, lb. per sq. in..............	51 000
Elongation in 8 in., per cent.................	21
Reduction of area, per cent..................	30
Modulus of elasticity, lb. per sq. in...........	28 200 000

Shear and Torsion. J. Platt and R. F. Hayward (Proceedings Inst. C. E., Vol. 90) give the following values for "crown" best wrought iron which had an ultimate tensile strength of 48 400 lb. per sq. in.:

Ultimate strength in single shear, lb. per sq. in.	42 050
Elastic limit in torsion, lb. per sq. in.........	20 530
Modulus of elasticity in torsion, lb. per sq. in..	12 800 000

Compression. The ultimate compressive strength of good wrought iron is not well defined. Practically, its yield point in compression should be considered as the ultimate for compression. This yield point is about the same as the yield point in tension.

The Strength of wrought iron is affected by its chemical composition, the mechanical work and heat treatment it has undergone, and also varies for different temperatures. Wrought iron has a well-defined yield point in both tension and compression which is from 2000 to 4000 lb. per sq. in. higher than the elastic limit. Beyond the yield point wrought iron is a plastic material which flows rapidly as the maximum strength is approached. The ultimate strength in tension increases with the amount of carbon, which, however, is rarely greater than 1/10 of 1 per cent. The strength of iron entirely free from carbon and phosphorus is probably between 39 000 and 40 000 lb. per sq. in.

Effect of Work of Rolling on Wrought-iron Plates (Holley)

Thickness in inches	Elastic limit, lb. per sq. in.	Ultimate strength, lb. per sq. in.	Elongation in 8 in., per cent	Reduction of area, per cent
1/4	32 400	51 800	11.2	18.4
1/2	31 180	49 760	14.2	22.0
5/8	30 775	50 200	15.5	22.5
3/4	30 400	49 050	16.0	22.4

The effect of the work of rolling on circular sections exhibits the same variation, that is, a material increase in the strength of the bar results from a reduction of the cross-section.

Wrought-iron Wire is manufactured by cold drawing through dies. Tensile tests on wire (U. S. Report on Tests of Metals, 1897) have given 110 000 lb. per sq. in. for wire 0.01 in. in diameter and 65 280 lb. per sq. in. for wire 0.2 in. in diameter. A rod 0.8 in. in diameter of the same kind of material as the wire gave 50 000 lb. per sq. in.

The Effect of Temperature upon the ultimate strength of wrought iron is shown by the following table (M. Rudeloff, Trans. Internat. Soc. Testing Materials, 1909).

Temperature, degrees C.	Ultimate strength, lb. per sq. in.	Elongation, per cent	Temperature, degrees C.	Ultimate strength, lb. per sq. in.	Elongation, per cent
20	49 300	30.5	250	70 700	23.0
50	51 400	25.5	300	68 600	30.0
100	54 300	16.0	350	57 100	35.0
150	60 700	14.0	400	46 100	40.0
200	67 100	17.5	....	....	....

Effect of Reheating and Rerolling. Within limits, puddled iron is much improved in quality by being cut up, piled, reheated, and rerolled or hammered. However, it is found that only in special cases is it advantageous to reheat puddled iron more than twice. The following figures (Johnson) show the effect of reheating and rerolling on the tensile strength: The original bar had a tensile strength of 43 900 lb. per sq. in.; after the second working this rose to 52 860 lb. per sq. in., and after the sixth working it became 61 820 lb. per sq. in.; the tensile strength then diminished with the number of workings until after the twelfth working it became the same as that of the original bar.

Uses. Wrought iron is used for spikes, nails, bolts and nuts, wire, chain rod, horseshoe bars, sheets and plates, stay bolts, pipes and tubing, third rails, armatures, electro-magnets, and in the manufacture of crucible steel. Wrought iron is sold as " merchant bar " for subsequent working into various wrought shapes.

Wrought iron was extensively used in bridge and building construction prior to 1890, but since 1900 structural steel has entirely taken its place on account of being about 20% stronger, as also lower in price. The permissible tension P on a wrought iron chain of the usual form is $\mathbf{P} = 0.4\ \mathbf{d}^2\ \mathbf{S}$ for open links and $\mathbf{P} = 0.5\ \mathbf{d}^2\ \mathbf{S}$ for stud links, where d is the diameter of the metal and S is the safe working unit stress (Goodenough and Moore, Bull. Univ. Ill., No. 18, 1907).

Behavior under Stress. Good wrought iron shows a fibrous structure when broken by tension or flexure. A stress exceeding the elastic limit causes a permanent set and raises the elastic limit higher than before. It is a fundamental rule that working unit stresses should not exceed the elastic limit. Under variable loads the allowable unit stress which is specified should seldom be greater than one-half of the elastic limit.

Defects. The principal defects in wrought iron as classified by Turner are rough edges, spilly places and blisters. To these might be added the presence of excess of slag. Rough edges are due to careless workmanship, imperfections in the rolls, and also to red shortness. Spilly places are spongy or irregular spotted parts, noticed particularly in sheets and occasionally in all kinds of wrought iron. They are generally attributed to imperfect puddling.

Specifications for wrought iron for various uses are given in detail in Part I of the 1927 Standards of the American Society for Testing Materials.

Working Unit Stresses for wrought iron will depend upon the kind of loading, the highest being for steady loads and the lowest for alternating stresses or shocks. The following values are for wrought iron of an average quality and these may be increased 30% for the very best grades. All values are in pounds per square inch.

	Steady Stresses or Stress Not Reversed	Alternating Stress
Tension..........	14 000	7000
Compression......	13 000	7000
Shear (torsion)....	8 000	5000

Wrought iron has a decided "fiber" due to the slag entrained in the process of rolling. The above values for tensile strength and working unit stresses apply to those along the fiber, and about 12% is to be deducted from them for cases where the tension acts across the fiber.

30. Classification of Steel

Steel and Iron. Steel was originally produced directly from pure iron ore by the action of a hot fire, which did not remove the carbon to a sufficient extent to form wrought iron. The modern processes, however, involve the fusion of the ore, and the definition of the United States law is that "steel is iron produced by fusion by any process, and which is malleable." Chemically, steel is a compound of iron and carbon generally intermediate in composition between cast and wrought iron, but having a higher specific gravity than either.

	Per Cent of Carbon	Specific Gravity	Properties
Cast iron......	5 to 2	7.2	Not malleable, not temperable
Steel.........	1.50 to 0.02	7.8	Malleable and temperable
Wrought iron..	0.30 to 0.05	7.7	Malleable, not temperable

It should be observed that the percentage of carbon alone is not sufficient to distinguish steel from wrought iron; also, that the mean values of specific gravity stated are in each case subject to considerable variation; further, only the hard steels are much affected by tempering, the softer grades resembling wrought iron.

Manufacture. The four principal methods are the crucible process, the electric-furnace process, the open-hearth process, and the Bessemer process. In the crucible process impure wrought iron, with carbon and a flux, is fused in a sealed vessel to which air cannot obtain access; some high grades of tool steel are thus made. In the electric-furnace process steel is refined out of contact with air by heat produced by means of an electric arc. In the open-hearth process pig iron is melted, scrap and iron ore being added until the proper degree of refining is secured. In the Bessemer process pig iron is completely decarbonized in a converter by an air blast and then recarbonized to the proper degree. The metal from the open-hearth furnace or from the Bessemer converter is cast into ingots which are rolled in mills to the required forms. The open-hearth process produces steel for machines, shafts, axles, springs, armor plates, rails, and for structural purposes. The Bessemer process mainly produces steel for railroad rails and for the cheaper grades of structural steel. A combination method known as the duplex process is sometimes used. In this process the refining action is started in a Bessemer converter, and after partial refining the molten steel is transferred to an open-hearth furnace, where the refining process is finished. The following description of these methods is taken mainly from Kent's Mechanical Engineers' Pocket Book:

Crucible Steel is commonly made in pots or crucibles holding about 80 lb. of metal. The raw material may be steel scrap; wrought iron with charcoal; cast iron with wrought iron or with iron ore; or any mixture that will produce a metal having the desired chemical constitution. Manganese in some form is usually added to prevent oxidation of the iron. Some silicon is usually absorbed from the crucible, and carbon also if the crucible is made of graphite and clay. The crucible being covered, the steel is not affected by the oxygen or sulfur in the flame. The quality of crucible steel depends on the freedom from objectionable elements, such as phosphorus, in the mixture, on the complete removal of oxide, slag, and blowholes by "dead-melting" or "killing" before pouring, and on the kind and quantity of different elements which are added in the mixture, or after melting, to give particular qualities to the steel, such as carbon, manganese, chromium, tungsten, and vanadium.

Bessemer Steel is made by blowing air through a bath of melted pig iron The oxygen of the air first burns away the silicon, then the carbon, and before the carbon is entirely burned away, begins to burn the iron. Spiegeleisen or ferro-manganese is then added to deoxidize the metal and to give it the amount of carbon desired in the finished steel In the ordinary or "acid" Bessemer process the lining of the converter is a siliceous material which has no effect on phosphorus, and all the phosphorus in the pig iron remains in the steel. In the "basic" or Thomas and Gilchrist process the lining is of magnesium limestone, and limestone additions are made to the bath, so as to keep the slag basic, and the phosphorus enters the slag. Basic Bessemer steel is not made in the United States.

Open-hearth Steel. Any mixture that may be used for making steel in a crucible may also be melted on the open hearth of a Siemens regenerative furnace, and may be desiliconized and decarbonized by the action of the flame and by additions of iron ore, deoxidized by the addition of spiegeleisen or ferro-manganese, and recarbonized by the same additions or by pig iron. In the most common form of the process pig iron and scrap steel are melted together on the hearth, and after the manganese has been added to the bath it is tapped into the ladle In the Talbot process a large bath of melted material is kept in the furnace, melted pig iron, taken from a blast furnace, is added to it, and iron ore is added which contributes its iron to the melted metal while its oxygen decarbonizes the pig iron. When the decarbonization has proceeded far enough, ferro-manganese is added to destroy iron oxide, and a portion of the metal is tapped out, leaving the remainder to receive another charge of pig iron, and thus the process is continued indefinitely. In the Duplex Process melted cast iron is desiliconized in a Bessemer converter, and then run into an open hearth, where the steel-making operation is finished. The open-hearth process may be either acid or basic, according to the character of the lining. The basic process is a dephosphorizing one, and is the one most generally available, as it can use pig irons that are either low or high in phosphorus.

Electric-furnace steel. Instead of using the gas flame of an open-hearth furnace the heat of an electric arc may be used to heat a charge of steel, which can be kept out of contact with air under a protecting blanket of molten slag. The purifying ingredients, iron oxide, manganese dioxide, etc., are in the slag, and the impurities are absorbed by it. Electric heat is very uneconomical for producing low temperatures, but much more economical for producing high temperatures, such as are used in the final refining stages of steel making. The electric furnace is sometimes used for the final stages of the steel making process, the earlier stages being carried out in an open-hearth furnace or a Bessemer converter.

Carburizing steel consists in heating it below its melting point in contact with material rich in carbon. Charcoal is sometimes used, also gas rich in carbon. There are a number of special carburizing compounds on the market. This gives the steel a " case " or skin of high-carbon steel with a " core " of lower-carbon steel.

Case Hardening consists in a carburizing process followed by suitable heat treatment. Case-hardened steel is used for service in which severe surface wear has to be resisted, and for giving a strong material at the surface of the metal, where strength is especially needed in parts subjected to bending or to torsion. A very thin skin of hardened steel may be given to soft steel by heating it in contact with a cyanide salt and subsequently heat-treating; this is called **cyaniding.**

The Physical Properties of steel depend upon method of manufacture, the heat treatment, and chemical composition, the carbon having a controlling influence upon strength. Phosphorus increases strength, but it promotes brittleness; manganese increases strength in a less degree, and it promotes malleability; sulfur causes red-shortness or a tendency of the steel to crumble while being rolled; and silicon increases hardness. Acid steel is regarded as of higher quality than basic steel having the same percentage of carbon. Since 1900 more than three-fourths of the open-hearth steel produced in the United States has been basic, the Bessemer product on the other hand being entirely acid.

The products described above are sometimes called carbon steel, because carbon is the controlling element in regard to strength. When the strength is largely governed by other elements the steels are called **alloy steels.**

The Methods of Manufacture greatly influence the strength of steel. Forged steel is stronger and more reliable than cast steel. Heat treatment by annealing and tempering has also a marked influence.

Forging and drawing greatly increase the strength of steel. Forging under a hammer or press renders the material more compact and increases both specific gravity and strength. The process of drawing steel bars into wire has a similar result, and wire has been made having a tensile strength of 300 000 lb. per sq. in., while the wire used for the cables of suspension bridges usually has a tensile strength of from 150 000 to 200 000 lb. per sq. in. By compressing steel while it is fluid, the strength may also be increased, and this process is used for the steel from which large guns and hollow shafts are made.

Annealing consists in raising cold steel to a light red heat and then allowing it to cool slowly. This process reduces the ultimate strength, but it increases the ductility. Quenching consists in plunging heated steel into a bath of water or oil, or by applying these fluids to its surface. The hardness of the steel and its ultimate strength are thereby much increased. Tempering consists in heating quenched steel to a temperature somewhat below that required for annealing.

Steel Castings have in recent years replaced steel forgings for many structural and machine parts. Their tensile strength is not widely different from that of steel forgings of the same chemical composition, but their elastic limits and their fatigue strengths average about 20% lower. Their strength and ductility are usually markedly improved by suitable heat treatment, usually an anneal to relieve internal strains. Detailed specifications for steel castings are given in Part I of the 1927 Standards of the American Society for Testing Materials. Steel castings are usually made by the open-hearth process, although some high grade castings are made by the electric-furnace process.

Carbon is the controlling element in regard to strength of plain carbon steels, and the same is the case with respect to ultimate elongation. The higher the percentage of carbon, within a reasonable limit, the greater is the strength and the less the ultimate elongation. The strength, especially for high-carbon steels, depends on the heat treatment used. Fully annealed high-carbon steel is not very much stronger than low-carbon steel.

General Classes. According to the percentage of carbon and its capacity for taking temper or being welded, steel may be classified as follows:

Soft, 0.05–0.20 C........	Not temperable, easily welded
Medium, 0.15–0.40 C.....	Slightly temperable, weldable
Hard, 0.30–0.70 C........	Temperable, welded with difficulty
Very hard, 0.60–1.00 C...	Highly temperable, not weldable

Uses. Plain carbon steel is frequently classified with reference to its uses, and the following classification gives a rough general idea of the elastic and ultimate strength and of the Brinell hardness of steels for various uses. Wide variations from these values occur for individual cases.

Steel	Elastic limit, lb. per sq. in.	Tensile strength, lb. per sq. in.	Brinell hardness, number
Steel for rivets..........................	25 000	50 000	100
Steel for plates and shapes..................	35 000	60 000	120
Machinery steel as rolled....................	40 000	75 000	145
Machinery steel, oil quenched...............	65 000	100 000	200
Axle steel as forged.........................	45 000	90 000	180
Axle steel quenched and tempered...........	65 000	100 000	200
Spring steel, oil quenched...................	95 000	180 000	350
Iron or soft steel wire.......................	*	85 000	....
Crucible steel wire..........................	*	200 000	....

* Elastic limit poorly defined.

31. Structural Steel

Specifications. The following clauses give essential features of the specifications for structural steel which have been adopted by the American Society for Testing Materials and the American Railway Engineering Association:

1. Structural steel shall be made by the open-hearth process. (Structural steel for buildings may be made by the Bessemer process.)

2. Each of the three classes of structural steel shall conform to the following limits in chemical composition: Sulfur shall not exceed 0.05%; phosphorus shall not exceed 0.06% when the steel is made by the acid process and not exceed 0.04% when it is made by the basic process.

3. There shall be two classes of structural steel for bridges, buildings, locomotives, cars, and ships, namely, rivet steel and structural steel, which shall conform to the following physical requirements: Rivet steel shall range in tensile strength from

46 000 to 60 000 lb. per sq. in., have a yield point not less than 0.5 of the tensile strength, and the percentage of elongation in 8 in. shall be

$$\frac{1\,500\,000}{\text{tensile strength}}$$

Soft steel shall range in tensile strength from 55 000 to 68 000 lb. per sq. in., have a yield point not less than 0.5 of the tensile strength, and the elongation in 8 in. shall not be less than 25%.

4. For each increase of 1/32 in. in a flat specimen above a thickness of 3/4 in., a deduction of 1/4 shall be made from the above specified percentage of elongation. For each decrease of 1/32 in. below a thickness of 5/16 in., a deduction of 1-1/4 shall be made from the above-specified percentage of elongation.

5. For details of cold bend tests see the 1927 Standards of the American Society for Testing Materials, Part I.

6. The standard specimens are shown in Figs. 55*a* and 56. The flat specimen is used for plates and shapes, and the 2-in round specimen for pins, rollers, and bars. Rivet rounds and small bars are tested full size.

7. One tensile test specimen shall be taken from the finished material of each melt or blow, but in case this develops flaws, or breaks outside of the middle-third of its gage length, it may be discarded and another test specimen substituted therefor.

8. Material which is to be used without annealing or further treatment shall be tested for tensile strength in the condition in which it comes from the rolls. Where it is impracticable to secure a test specimen from material which has been annealed or otherwise treated, a full-size section of tensile-test specimen length shall be similarly treated before cutting the tensile-test specimen therefrom.

9. For the purpose of this specification, the yield point shall be determined by careful observation of the drop of the beam or halt in the gage of the testing machine.

10. In order to determine if the material conforms to the chemical limitations prescribed in paragraph No. 2 herein, analysis shall be made of drillings taken from a small test ingot.

11. The variation in cross-section or weight of more than 2-1/2% from that specified will be sufficient cause for rejection, except in the case of sheared plates, which will be covered by special allowances tabulated in the 1927 Standards of the American Society for Testing Materials.

When plates are ordered to gage, a variation of more than 1/100 in. below that specified for any dimension will be sufficient cause for rejection.

12. Finished material must be free from injurious seams, flaws, defective edges, or cracks, and have a workmanlike finish.

13. Every finished piece of steel shall be stamped with the melt number and name of the manufacturer and steel for pins shall have a melt number stamped on the ends. Rivets and lacing steel, and small pieces for pin plates and stiffeners, may be shipped in bundles, securely wired together, with the melt number on a metal tag attached.

14. The inspector representing the purchaser shall have all reasonable facilities afforded to him by the manufacturer to satisfy him that the finished material is furnished in accordance with these specifications. All tests and inspections shall be made at the place of manufacture, prior to shipment.

Structural Nickel Steel. The following is a summary of the principal items in the specifications for structural nickel steel as given in the 1927 Standards of the American Society for Testing Materials:

1. The steel shall be made by the open-hearth process.

2. The phosphorus content shall not exceed: for acid structural steel, 0.05%; for basic structural steel, 0.04%; for acid rivet steel, 0.04%; for basic rivet steel, 0.03%. The sulfur content shall not exceed: for structural steel, 0.05%; for rivet steel, 0.45%. The nickel content shall not be less than 3.25%.

3. The following table summarizes the requirements as to tensile strength and ductility.

Properties considered	Rivet steel	Plates, shapes and bars	Eyebars, flats and rollers unannealed	Eyebars, flats and rollers annealed
Tensile strength, lb. per sq. in....	70 000–80 000	85 000–100 000	95 000–110 000	90 000–105 000
Yield point, min. lb. per sq. in...	45 000	50 000	55 000	52 000
Elongation, in 8 in., per cent., min.	1 500 000 / tensile str.	1 500 000 / tensile str.	1 500 000 / tensile str.	20*
Elongation, in 2 in., per cent., min.	....	18†	16†	20†
Reduction of area, per cent., min..	40	25	25	35

* Flat test specimens from plates and shapes.
† Round test specimens from pins and rollers.

4. For plates, shapes, and unannealed bars over 1 in. in thickness a deduction of 1/4 from the percentage of elongation specified in the above table shall be made for each increase of 1/32 in. thickness above 1 in., to a minimum of 14%.
5. The test specimens are similar in size and form to those used for structural carbon steel.
6. For details of cold bend tests see 1927 Standards of the American Society for Testing Materials, Part I.

Structural Silicon Steel. The following is a summary of the principal items of the specifications for structural silicon steel as given in the 1927 Standards of the American Society for Testing Materials.

1. The steel shall be made by the open-hearth process.
2. The phosphorus content shall not exceed: for acid steel, 0.06%; for basic steel, 0.04%. The sulfur content shall not exceed 0.05%. The silicon content shall not be under 0.20%.
3. The tensile strength shall be between 80 000 and 95 000 lb. per sq. in.; the yield point shall be not less than 45 000 lb. per sq. in.; the percentage of elongation in 8 in. shall not be less than 1 500 000/tensile strength; and the reduction of area shall not be less than 30%.
4. For material over 3/4 in. in thickness a deduction of 1/4 in the percentage of elongation and of 1/2 in the reduction of area shall be allowed for each increase of 1/16 in. in thickness, with a minimum value of 14% for elongation and 24% for reduction of area.

Items 5 and 6 for structural nickel steel apply to structural silicon steel.

Steel Castings should not contain over 0.07% of phosphorus, or over 0.06% of sulfur. The minimum physical qualities prescribed by the American Society for Testing Materials are:

	Soft Castings	Medium Castings	Hard Castings
Tensile strength, lb. per sq. in......	60 000	70 000	80 000
Yield point, lb. per sq. in..........	0.45 of the tensile strength		
Elongation, per cent in 2 in........	24	20	17
Reduction of area, per cent.......	35	30	25

Rivets. The ultimate strength of steel rivets as determined by various British authorities from experiments on riveted joints, assuming that the distribution of load was uniform on all rivets and that the friction of the plates is negligible, varied for iron from 42 582 to 62 362 lb. per sq. in., and for steel from 49 683 to 80 035 lb. per sq. in. Tests made at the University of Illinois gave average bearing strengths of 36 950 for boiler rivet steel, 40 950 for structural rivet steel, and 37 950 lb. per sq. in. for wrought iron. These values were, respectively, 76.4, 74.5, and 77.6% of the tensile strengths of the same material. The tests were made on 1/2, 3/4, and 1-in. rivets in single and double shear. More recent tests made by the American Railway Engineering Association on riveted steel joints gave for the rivets an average shearing strength of 48 580 lb. per sq. in.

Working Unit Stresses for members of roof and bridge trusses are given in Sect. 12. Working stresses under repeated loading may be taken as approximately one-third the endurance limit for the range of stress to which the metal is subjected. See p. 558. It is important to allow for localized stress in parts subjected to oft-repeated loading.

32. Alloy Steels

Three basic limitations of plain carbon steels are, according to Aitchison:

1. The impossibility of obtaining high strength with reasonably high toughness.
2. Irregularity in toughness, even with rather moderate strength.
3. A mass effect in hardening, making uniformity unlikely throughout parts of large masses.

By introducing alloying elements other than (usually in addition to) carbon, steels may be produced with tensile strength ranging from 80 000 to 250 000 lb. per sq. in. with a good degree of toughness and ductility. Such steels are capable of more effective heat treatment than plain carbon steels, especially in large masses. The accompanying table gives the general effects of various alloying elements; it is a summary of a table given by R. H. Aborn in the Iron Age for March 5, 1925.

Alloy steels give more trouble with shrinkage cavities (pipes) in ingots, and are more difficult to forge and stamp to shape than are low-carbon steels, and seem to be fitted for use where there are demanded properties which cannot be furnished by plain carbon steels.

In addition to nickel steel and silicon steel which are mentioned on p. 633, certain complex alloy steels are in common use, such as:

Chrome-nickel steels. Range of content, nickel, 1.5 to 3.5%; chromium, 0.7 to 1.5%; carbon, 0.2 to 0.4%. Similar in physical properties to nickel steel, but have higher elastic strength for same ductility, harder than nickel steel, more susceptible to heat treatment, more liable to embrittlement by improper heat treatment.

Chrome-vanadium steels. Content about 1.5% chromium, 0.2% vanadium. More easily machined than chrome-nickel steels, cleaner steel due to deoxidizing effect of vanadium, freer from scale and seams than steels containing nickel.

Chrome-molybdenum and chrome-nickel-molybdenum steels. Content, molybdenum, 1.0% minimum. Has advantages of chrome-vanadium steels over chrome-nickel, quenching and tempering ranges of temperature particularly large; disadvantages, loss of molybdenum by volatilization with resulting non-uniform composition, narrow range of temperature for forging.

Alloy steels have been widely used in the construction of long-span bridges. Owing to their increased strength over plain carbon structural steel lighter members can be used, thus diminishing the dead load on the bridge structure. It should be noted that the **stiffness** (as measured by modulus of elasticity) of alloy steels is not greater than that of ordinary structural steel, so that the elastic stiffness of such long-span structures is somewhat less than that of structures of plain carbon steel. In the case of long columns the strength is to some extent a function of the modulus of elasticity, and hence alloy steel loses some of its strength-increasing property when used in long columns.

Effect of Alloying Elements in Steels

Alloying element	General effect	Specific effect	Advantages and uses	Disadvantages
Manganese (Mn)	Deoxidizes; desulfurizes; stiffens atomic structure; gives finer crystalline grains.	Up to 2% acts mainly to deoxidize, desulfurize, and to increase strength.	Standard deoxidizer.	
		10–12% gives an amorphous structure, with a great resistance to abrasion.	Great resistance to abrasion. Used for mining and milling equipment, safes, frogs, switches, curved rails.	Extremely difficult to machine.
Nickel (Ni)	Stiffens atomic structure; gives finer crystalline structure.	Up to 4% increases tensile strength without great loss of ductility.	Makes heat treatment of large pieces possible with gain of strength. Used for structural and machine parts.	Scale formed in rolling; rough surface.
Silicon (Si)	Deoxidizes; stiffens atomic structure; gives finer crystalline structure.	Up to 1-3/4% increases elastic strength with little loss of ductility.	Standard deoxidizer. Used for structural steel, spring steel (with manganese).	Silico-manganese steel not very tough.
Aluminum (Al)	Deoxidizes.	Lessens harmful effect of gases in steel.	Standard degasifier. Used up to 0.05%.	Tendency to cause graphite formation if used in excess.
Chromium (Cr)	Forms carbide or double carbide; more stable than iron carbide. Intensifies hardening and embrittling effect.	Gives great hardness; makes quenching effective for considerable depth.	Very effective in adding strength. Used for cutting tools, ball bearings, cold rolls, 9–16% "stainless" irons and steels with nickel for general machine steels.	Danger of embrittlement with certain heat treatments.
Tungsten (W)	Similar to chromium. Forms extremely stable carbide.	Gives very fine crystalline structure; quenching effect not so deep as that of chromium.	Gives great cutting hardness, even at quite high temperatures. Used for cutting tools, permanent magnets.	Increased strength accompanied by brittleness, not suited for structural steel.
Molybdenum (Mo)	Similar to chromium and nickel.	Next to carbon most effective hardening element.	Allows very effective control of heat treatment. Used in combination with chromium, vanadium, or nickel.	Expensive; erratic in quality; volatilizes from surface layers on rolling. Tendency to seams and brittleness.

Effect of Alloying Elements in Steels — Continued

Alloying element	General effect	Specific effect	Advantages and uses	Disadvantages
Vanadium (V)	Deoxidizes; stiffens atomic structure; gives fine crystalline structure; forms carbide; intensifies hardening and embrittling effect.	Deoxidizing effect (0.1%); hardening agent; high elastic and tensile strength.	Forms fluid slag in deoxidizing, giving clean metal; inhibits growth of crystalline grains. Used for spring steel; with other elements for machine steel.	Expensive.

Alloy steels and heat-treated high-carbon steels are more susceptible to injury by grooves, holes, sharp shoulders and other causes of high localized stress than are the ordinary low-carbon structural and machine steels.

Invar steel is a special nickel steel with a nickel content of 36%. It has a coefficient of thermal expansion of 0.0000015 in. per inch of length per degree Fahrenheit as compared with 0.0000066 for ordinary steel. It is used for measuring tapes and scales.

33. Welding of Steel

Welds in steel may be divided into two classes: (a) welds made while the metal is heated to a plastic stage, and (b) welds made by actual fusion of the adjacent metal in the parts joined. In plastic welding the edges to be joined are pressed or hammered together. Wrought iron and soft steel can be thus welded without much difficulty, high-carbon steel can be welded by a skilled workman, while cast iron cannot be thus welded.

Plastic Welding is sometimes done in a forge fire, as is the case when the ordinary blacksmith shop welds rods or chain links, or the heat may be supplied by means of an electric current passing through the parts to be welded. Special welding machines are used for the welding of rods and the seams of vessels by this resistance heating method; such machines are to be distinguished from the machines for making electric welds by fusion of the metal, which are noted a little later.

Fusion Welding. If the edges of two adjacent pieces of metal are heated to fusion and then allowed to cool the process is known as **fusion** or **autogenous** welding. The high localized temperature required for such fusion may be obtained by the heat of a flame of acetylene gas burning in pure oxygen, by the heat of an electric arc, or by the heat from superheated molten iron produced by the burning of a mixture of iron oxide and aluminum.

Oxyacetylene Welding. In this process the oxygen and the acetylene are fed through a blowpipe and ignited at its tip. The flame has a temperature of approximately 5000° F., and a narrow strip of metal at the junction of the parts is fused. Usually additional metal is added to the joint by melting into it a small steel or iron rod. If an excess of oxygen is supplied to the torch it becomes an effective cutting, or more correctly burning, tool. The heated steel burns in the presence of the excess of pure oxygen, and a narrow gash in the iron or steel is burned. The oxyacetylene torch is widely used to cut up iron and steel scrap.

Electric Arc Process. In this process of fusion welding an arc is struck between the metal to be welded and an electrode, usually an iron or steel rod, held in an insulator and guided by the gloved hand of the operator. The heat of the arc melts the electrode and also melts metal at the surface to be joined. The strength and soundness of the weld depend to a considerable degree on the composition of the welding rod used. In England welding rod coated with some fluxing material is widely used. With coated rod there is some danger of slag inclusions in the weld unless the welding is very skillfully done. Oxidation at the weld is minimized by surrounding the arc with a jet of burning reducing gas, such as hydrogen; such a reducing atmosphere around the arc seems to serve the purpose of a coated rod without the danger of slag inclusions. Automatic welding machines are available for manufacturing purposes, and their use both cheapens the welding process and increases the uniformity of the welds produced.

Thermit Process. Fusion welding by means of the heat generated by the burning of iron oxide and aluminum is carried out in the thermit process, which is patented. A specially prepared mixture of aluminum and iron oxide is placed in a crucible and ignited. The heat of the resulting combustion raises the temperature of the mass to about 4800° F., and there is produced superheated molten iron which is poured around the joint to be melted, melting the edges and forming a solid casting at the joint.

Uses of Welding. Forge welding is confined to the welding of rods and small pieces. Plastic welding by the use of electric current is essentially a manufacturing process, and is used in quantity production of welded rods, tanks, etc. Thermit welding is used for welding heavy sections, such as rail joints, punch frames, and large shafts. Fusion welding either by the oxy-acetylene process or by the electric arc is very widely used for general repair work and for manufacturing processes. It is being used to some extent as a substitute for riveting in structural work, and its more general use in buildings and pressure drums is under consideration at the present time. A recent development of electric welding is the building up of machine frames of structural shapes welded together.

Strength of Welds. Plastic welds, if skillfully made and if hammered while cooling, form almost perfect joints, and the structure of the metal in such perfect welds is very similar to the structure in good forged steel. However, it is not safe to count on more than 75% of full strength for machine-made plastic welds, nor more than 50% of full strength for forge welds.

Fusion welds are steel castings at the joint, and the crystalline structure is that of a steel casting rather than that of rolled steel. Welds made under carefully controlled shop conditions involving automatic welding machinery are frequently produced which show strength **under static load** equal to that of the material welded. Under repeated load, available test data indicate that fusion welded joints cannot be counted on for more than 50% of the strength of the material welded. Welded joints made under field or repair shop conditions are not so strong as joints made by automatic machines under carefully controlled manufacturing conditions.

In using the fusion welding processes one of the marked sources of weakness is the presence of cooling strains set up by the unequal cooling of different parts. Where the welded parts can be heat-treated (usually normalized) or can be hammered while cooling such procedure should always be carried out.

34. Non-ferrous Metals

Aluminum is a white, malleable, and very light metal, its specific gravity being 2.75 when rolled and 2.55 when cast. It is almost non-corrodible, since even sulfuric acid has little effect upon it. Pure cast aluminum has a tensile strength of about 18 000 lb. per sq. in. When rolled into plates or drawn into wire this is raised to 30 000 or 40 000 lb. per sq. in. with an elastic limit one-half as great. On account of the softness of the pure metal it is usually alloyed with copper, iron, tin, or zinc. (Art. 35.)

Common impurities in aluminum are silicon and iron. It can, however, be obtained 99 or 99.5% pure. In making castings the great shrinkage must be taken into account. The melting point of pure aluminum 1150° F.

Its electric conductivity ranks next to that of copper among the commercial metals.

Copper is a reddish, malleable and ductile metal which can be drawn or rolled and also cast; its specific gravity varies from 8.9 in the first form to 8.6 in the second. It unites with oxygen at a red heat and melts at about 1900° F. It does not corrode in dry air. Its most important use is for electric conductors.

Copper wire has a tensile strength of about 50 000 lb. per sq. in. and a poorly defined elastic limit of about 37 000 lb. per sq. in. owing to the stiffening due to drawing; by annealing it may be softened and both ultimate strength and elastic limit thus lowered. Copper plates 1/4 to 3/4 in. thick have tensile strength of 32 000 lb. per sq. in. Cast copper has a tensile strength of about 25 000 lb. per sq. in. and a very poorly defined elastic limit of about one-third of this value. The strength of copper rods decreases as the temperature rises above 100°, the loss in strength being 16% at 500° F.

Small cylinders of annealed copper are used to measure the high pressures developed by the explosion of powder in guns, the pressure being inferred from the shortenings which the cylinders undergo. In this way pressures as high as 30 000 lb. per sq. in. have been noted.

Copper is alloyed with zinc, tin, and other metals to produce many useful alloys which are used in the arts and in engineering. (See Art. 35.)

Tin is a white, malleable metal of specific gravity 7.3. Commercial tin contains as impurities copper, iron, bismuth, and other metals. It melts at 450° F., and hence is often used for safety plugs in steam boilers. Its main commercial use is as a coating in the manufacture of the tin plates which are used for roofing, for household utensils, and for cans.

Roofing tin is thin sheet steel coated with an alloy of about 25% tin and 75% lead. A box of 112 sheets 14 by 20 in. in size will cover approximately 192 sq. ft. of roof with the flat-seam method of laying. For the standing-seam method a box of 112 sheets 20 by 28 in. in size will cover closely 370 sq. ft.

Lead has a low strength and is almost devoid of elasticity, but is very plastic, so that it flows readily under stress. The weights per square foot of sheet lead ordinarily rolled are 2-1/2, 3, 3-1/2, 4, 4-1/2, 5, 6, 8, 9, 10 lb. and upward. Small lead pipes are often lined with tin in order to prevent the lead from dissolving in the water; the common commercial sizes of these are 1/4 and 1/2 in. The use of lead pipes in bath rooms should usually be confined to the waste pipes. Lead melts at 625° F.

Zinc, called spelter when cast, has a tensile strength of about 9000 lb. per sq. in. and about 24 000 lb. per sq. in. rolled into thin plates. It is mainly used in coating iron and steel surfaces (galvanizing) in electric batteries, and for making brass and other alloys. Its melting point is 780° F.

Nickel is a ductile, hard, and tough metal. It is mainly used for plating and in alloys. Its melting point is about 3000°, so that it is very difficult to fuse. Not corrodible from the atmosphere. Its tensile strength, rolled and annealed, is about 70 000 lb. per sq. in. (See Art. 31.)

Mercury is a silver-white metal which is liquid at common temperatures. It boils at 680° F. and freezes at −38° F. When liquid its specific gravity ranges from 13.58 to 13.59. Its coefficient of cubical expansion for temperatures from 32° F. and 212° F. is 0.000101 per degree.

For other metals and for other properties of those above briefly described see Sect. 13, Art. 5. For atomic weights see Sect. 3, Art. 1.

35. Non-ferrous Alloys

An alloy is a mixture of two or more metals which is made by combining them when in a molten condition. The mixture is usually only mechanical, although some slight chemical union may take place in special cases. It is impossible to predict the properties of an alloy from the properties and proportions of its constituent metals.

Brasses are alloys of copper and zinc, the most valuable of which have from 60 to 80% of copper and from 40 to 20% of zinc. Brass can be cast or rolled. It is harder than copper. Tensile strength of castings is about 20 000 lb. per sq. in. The mean specific gravity of cast brass is 8.95.

Delta metal is brass with a small amount of iron. Its strength and ductility when rolled are equal to those of medium steel; when cast, its tensile strength is about 45 000 lb. per sq. in. Its resistance to corrosion is high.

Tobin bronze is an alloy of copper, tin, and zinc. It is of high tensile strength, is very non-corrodible, and can be obtained either in castings or in rolled sheets.

Strength of Copper-Zinc Alloys (Brasses)

Based on the report of the U. S. Board to Test Iron, Steel, and Other Metals, the report of Roberts Austen to the British Alloys Research Committee, and tests by J. M. Lohr.

Composition, per cent		Ultimate strength, lb. per sq. in		
		Tension		Compression cast
Copper	Zinc	Cast	Rolled	
0	100	9 000	24 000	5 000
20	80	9 000	10 000	55 000
40	60	7 000	7 000	......
50	50	30 000	65 000	115 000
55	45	47 000	77 000	90 000
60	40	48 000	61 000	75 000
65	35	38 000	53 000	65 000
70	30	37 000	50 000	55 000
75	25	35 000	51 000	45 000
80	20	33 000	50 000	39 000
85	15	32 000	45 000	37 000
90	10	31 000	41 000	30 000
100	0	25 000	40 000	40 000

Copper-Tin Alloys are called bronzes. The tin is added to harden the copper, and the alloy is denser, harder, and more fusible than copper. Bronze for making statues has about 87% copper, 7% tin, 3% lead, and 3% zinc. Bronze for medals has only 2% tin. Bronze is used to a slight extent for telegraph and telephone wires. Bronzes containing more than 24% of tin have insufficient strength for practical uses.

Strength of Various Non-ferrous Metals and Alloys

Average values for strength based on test data from various testing laboratories. Data are lacking for values of strength in compression. In the absence of such data a safe practice would be to consider the ultimate in compression as having a value equal to the elastic limit in tension.

Metal	Approximate composition, per cent	Weight, lb. per cu. in.	Strength in tension, lb. per sq. in.	
			Elastic limit	Ultimate
Copper, cast	Copper, 100	0.310	8 000	25 000
Hard drawn	Copper, 100	0.321	30 000	40 000
Zinc, cast	Zinc, 100	0.253	....	9 000
Rolled	Zinc, 100	0.253	4 000	24 000
Lead, rolled	....	0.411	800	* 2 700
Lead alloy, cast	Lead, 95.5; antimony, 4.5	0.380	4 000	6 400
Nickel, rolled and annealed	Nickel, 100	0.340	12 000	70 000
Cold-rolled	Nickel, 100	0.340	70 000	165 000
Aluminum, cast	Aluminum, 100	0.093	....	13 000
Rolled and annealed	Aluminum, 100	0.097	8 500	14 000
Cold-rolled	Aluminum, 100	0.097	20 000	30 000
Hard-drawn wire	Aluminum, 100	0.097	30 000	40 000
Duralumin, rolled and heat-treated	Aluminum, 96; magnesium, 1.5; copper, 2.5; iron and silicon, trace	0.102	19 000	55 000
60-40 Brass, cast	Copper, 60; zinc, 40	0.310	12 000	35 000
Rolled and annealed	Copper, 60; zinc, 40	0.310	16 000	60 000
Cold-drawn	Copper, 60; zinc, 40	0.310	43 000	96 000
Phosphor bronze, cast	Copper, 95; tin, 5; phosphorus, trace	0.320	16 000	32 000
Rolled and annealed	Copper, 95; tin, 5; phosphorus, trace	0.320	13 000	46 000
Cold-drawn	Copper, 95; tin, 5; phosphorus, trace	0.320	60 000	85 000
Aluminum bronze, cast	Copper, 90; aluminum, 10	0.270	25 000	60 000
Hot-rolled	Copper, 90; aluminum, 10	0.270	30 000	70 000
Cold-drawn	Copper, 90; aluminum, 10	0.270	80 000	90 000
Manganese bronze, cast	Copper, 60; zinc, 39; iron and manganese, 1	0.30	30 000	70 000
Rolled	Copper, 60; zinc, 39; iron and manganese, 1	0.30	45 000	70 000
Monel metal, hot-rolled	Nickel, 67; copper, 28; iron, silicon, carbon and manganese, 5	0.32	48 000	88 000
Cold-rolled and annealed	Nickel, 67; copper, 28; iron, silicon, carbon and manganese, 5	0.32	60 000	110 000

* Under long-continued static load lead will flow very slowly under stresses as low as 500 lb. per sq. in.

Phosphor Bronze is an alloy of copper and tin containing less than 1% of phosphorus. For hard castings of great strength from 4 to 10% of tin and from 0.5 to 1.0% of phosphorus is used. It is remarkable for its complete fluidity, so that most perfect castings can be made. It has been used for journal bearings, valve seats, and even for cannon. In the form of wire it is has been used for telephone service. It is hard and tough, and its ultimate tensile strength may range from 40 000 to 100 000 lb. per sq. in.

Copper-Zinc-Tin Alloys have been made in large numbers and are also called bronzes, or sometimes composition metals. The strongest of these was found by Thurston to be that which had 55% of copper, 44.5% of zinc, and 0.5% of tin, the tensile strength of a cast bar being 68 900 lb. per sq. in. With 55% copper, 40% zinc, and 5% tin the tensile strength was 28 000 lb. per sq. in.

Aluminum Bronze has from 5 to 12% aluminum with from 95 to 88% copper. These alloys have high ductility and great strength. With 6% aluminum it has a modulus of elasticity of about 18 000 000 lb. per sq. in. It has a high shrinkage in casting.

Composition of a Few Miscellaneous Alloys, in Per Cent

Manganese Bronze is an alloy with a copper content of about 60%, a zinc content of about 38.5%, an iron content of about 1.5%, and a trace of manganese. The manganese " cleanses " the metal of oxide. Manganese bronze has a high strength and also a high ductility. Its elongation in 2 in. is about 25%. It resists corrosion remarkably well either in salt water or in fresh water, and is used for propeller blades and other submerged parts of ships.

Duralumin is an alloy having aluminum for its principal ingredient, with small percentages of magnesium, copper, iron, and silicon. By " aging " and heat-treating it can be given a tensile strength about that of structural steel while its weight per cubic inch is but little greater than that of aluminum. Its elastic strength and its fatigue strength are relatively low. Under the influence of salt water some heats of duralumin corrode badly, but, in general, it is highly resistant to corrosion. It is used in airplane construction and in other machines where extreme lightness combined with good strength is required.

Monel Metal is an alloy whose principal constituents are nickel and copper with small amounts of iron, silicon, carbon, and manganese. It is made from special ores containing these constituents. It is highly resistant to corrosion, and can be made about as strong as structural steel. It is used for steam turbine blades, tubing, and other parts exposed to corrosive agents.

Bearing Metals. A group of soft alloys of low strength is used mainly for forming the surfaces of bearings in machines. Steel rubbing on steel soon gives a rough torn surface. Steel rubbing on cast iron gives a smooth surface, but cast iron is so brittle that it is in danger of cracking in service. For heavy loads brasses or bronzes are used for bearing metals. They serve excellently, but are expensive. For bearings carrying light loads alloys of lead, antimony, and tin are used. These alloys have a low melting point and can be cast in place. One alloy in common use has the composition, lead 80%, antimony 20%. "Babbitt Metal," much used for high-grade bearings, has the composition, tin 89%, copper 4%, antimony 7%.

Platinite is an alloy of iron with 42 per cent of nickel which has the same coefficient of expansion as glass and hence may be used in glass to prevent cracking under heat.

36. Corrosion of Metals

Steel and Iron. The corrosion of structural steel and iron may be divided into five classes: (1) atmospheric, (2) water-immersion, (3) soil, (4) chemical, and (5) electrolysis. In atmospheric corrosion there is present a large excess of oxygen, and the quantity of moisture which reaches the surface of the metal, and the time of contact between metal and moisture are factors of prime importance. Structural steel with a copper content of 0.2% is more resistant to atmospheric corrosion than ordinary structural steel.

For steel immersed in water the amount of dissolved oxygen in the water and the acidity or alkalinity of the water are prime factors in producing corrosion. In general, acidity tends to increase corrosion, and alkalinity to decrease it.

In soil corrosion and chemical corrosion the chemical ingredients coming in contact with the steel are the prime factors, rather than the variations in composition of the ordinary structural steels and irons.

Disastrous corrosion by electrolysis by stray currents from power circuits sometimes occurs, but it can be guarded against in nearly all cases by suitable electrical precautions.

Corrosion of structural steel takes place rather slowly, and **careful inspection** of structural steel parts will give ample warning before corrosion has gone far enough to cause structural danger.

Mechanism of Corrosion. Iron when first brought into contact with moist air or with water containing dissolved oxygen goes into solution at a high initial rate. This initial rate is quickly retarded by an invisible film of hydrogen formed on the iron, and by films of the products of initial corrosion. If these films are sufficiently hard and dense they may stop the progress of corrosion altogether. Free oxygen, however, tends to combine with the film of nascent hydrogen formed, and to remove it, thus permitting the further progress of corrosion. Acidity also facilitates the progress of corrosion by the prevention of the formation of protecting films, and by the evolution of nascent hydrogen.

Corrosion of Wrought Iron, Steel and Cast Iron. The relative corrodibility of steel and wrought iron is a matter of dispute among chemists and engineers. It seems fairly certain that for either metal care in manufacture and homogeneity of metal are very vital factors in producing metal with a minimum of corrodibility. Ordinary cast iron seems to be rather more resistant to corrosion by water than either wrought iron or steel, and it is frequently used for the larger sizes of water pipes in spite of its brittleness.

Protection against Corrosion. Painting is the commonest means used for protecting structural steel against corrosion. Paint to be effective should be renewed every three or four years, so it is not suitable for protecting parts which cannot be reached for ordinary repainting. Clean metal is essential for the placing of an effective coat of paint. This may be secured by sand blasting and the use of a wire brush. Railway engineers report that the cost of cleaning and painting the structural steel of bridges averages about 50 cents per ton per year.

Asphalt or coal tar rubbed molten over a priming coat on the steel give good protection against water. A layer of rich concrete about 2 in. thick is perhaps the best protective coating for structural steel.

For further reference see Frank N. Speller, "Corrosion, Causes and Prevention" (McGraw-Hill, N. Y.)

Galvanizing iron or steel consists in coating with zinc. Zinc is resistant to atmospheric corrosion, and a coating of zinc blankets the iron or steel against attack. Moreover, zinc is electro-positive with respect to iron, and when two metals are in contact the one which is electro-positive with respect to the other tends to corrode, protecting the electro-negative metal against corrosion.

The common galvanizing process is the **hot dip process,** in which the metal to be coated is first cleaned (pickled) with acid, then washed, then dipped in, or drawn through, a bath of molten zinc. The thickness of coating of zinc depends on the temperature of the bath and the time the iron stays in the bath.

The approximate weight of zinc used for coating iron and steel is given by the following figures, which are based on the current Standards and Tentative Standards of the American Society for Testing Materials.

Sheets	1.75 to 2.75 oz. per sq. ft.
Wire	0.70 to 0.80 oz. per sq. ft.
Wire fencing:	
Wire less than 0.12 in.	0.35 to 0.70 oz. per sq. ft.
Wire, 0.12 in. or more	0.20 to 0.35 oz. per sq. ft.
Chain-link fence fabric:	
Galvanized before weaving	0.50 to 0.70 oz. per sq. ft.
Galvanized after weaving	0.12 oz. per sq. ft.

A heavy coating of zinc offers greater resistance to wear than does a light coating, but is more likely to crack and spall if the metal is bent than is a light coating. For galvanized plates or wire which have to be bent and shaped sometimes even lighter coatings of zinc are used than the minimum values given in the above table. Tests for the weight of zinc per square foot on wire or sheet are made in the laboratory by removing the zinc by chemical means and noting the loss of weight. Field tests sometimes employ chemical removal; sometimes the weight of zinc per square foot is estimated by the rise of temperature produced by attacking a standard sample of plate with a standard chemical reagent; and a third field test consists in determining the amount of hydrogen evolved from a given area of plate by the attack of a standard solution of hydrochloric acid and antimony chloride. See the 1927 Standards of the American Society for Testing Materials, Part I, p. 343.

Galvanizing is a fairly effective protection to iron and steel exposed to atmospheric conditions, unless the zinc coating is cracked or worn off mechanically. For iron or steel submerged in water galvanizing is less effective than it is for iron or steel in air.

Besides the hot dip method of galvanizing, iron or steel is cometimes coated with zinc by electroplating. **Sherardizing** is the process of coating iron or steel with zinc by the condensation of volatilized zinc dust. The bond between zinc and iron seems to be stronger for sherardized iron than for ordinary galvanized iron. Sherardizing is used on small pieces of hardware, parts of agricultural implements, wire clips, pipe fittings, etc.

Other Metal Coatings. Nickel, chromium, and cadmium plated on the surface of metal are used to protect against corrosion. Tin plate consists of sheet steel coated with molten tin. Any "pin hole" defects in the tin coating may lead to serious corrosion of the metal underneath.

Stress and Corrosion. Metals under stress, especially stress beyond the yield point, corrode more rapidly than do unstressed metals. Corrosion under repeated stress has already been discussed in Art. 7. Certain boiler waters seem to be particularly liable to cause dangerous corrosion at points of high localized stress around the riveting of boiler shells. This " caustic embrittlement," as it is called, can usually be prevented by adding suitable chemicals to the boiler feed water.

Stainless Iron and Steel. Iron and steel containing 13% or more of chromium are much more resistant to corrosion than are ordinary structural steels. Chromium in iron seems to cause the formation of a dense hard film of oxide on the surface of the metal, which acts as a protection against further corrosion. The name " stainless " iron or steel is given to such high-chromium metals. Stainless iron and steel present problems of manufacture and of fabrication of no small difficulty, and at present are rather too expensive for general structural use; their use, however, is rapidly growing.

The Non-ferrous Metals (Arts. 34 and 35) and their alloys are non-corrodible compared with iron or steel. Aluminum is one of the most non-corrodible. Lead dissolves in water to a slight extent, but carbonates or sulfates of lime deposited upon it from the water form a film on the surface which prevents further action. Nickel resists corrosion to a high extent. On zinc coatings a thin skin of zinc carbonate forms in the atmosphere which prevents corrosion.

NON-METALLIC MATERIALS

37. Stone

Data for Building Stones of Good Quality

Values based mainly on test data from the Watertown (Mass.) Arsenal

Kind of stone	Weight, lb. per cu. ft.	Compressive strength, lb. per sq. in.	Shearing strength, lb. per sq. in.	Modulus of rupture, lb. per sq. in.	Modulus of elasticity, lb. per sq. in.	Coefficient of expansion per degree F.	Absorption of water, per cent of weight of stone
Granite, range...	160 to 170	15 000 to 26 000	1800 to 2800	1 200 to 2 200	5 900 000 to 9 800 000		
Average......	165	20 200	2300	1 600	7 500 000	0.0000040	0.5
Sandstone, range	135 to 150	6 700 to 19 000	1200 to 2500	500 to 2 200	1 000 000 to 7 700 000		
Average......	140	12 500	1700	1 500	3 300 000	0.0000055	5.0
Limestone, range	140 to 180	3 200 to 20 000	1000 to 2200	250 to 2 700	4 000 000 to 14 700 000		
Average......	160	9 000	1400	1 200	8 400 000	0.0000045	7.7
Marble, range...	160 to 180	10 300 to 16 100	1000 to 1600	850 to 2300	4 000 000 to 12 600 000		
Average......	170	12 600	1300	1 500	8 000 000	0.0000045	0.4
Slate, range.....	170 to 180	14 000 to 30 000	....	7 000 to 11 000	13 900 000 to 16 200 000		
Average......	175	15 000	....	8 500	14 000 000	0.0000058	0.5
Trap, average...	185	20 000	....	....	....	....	....

Trap. This name is applied to a class of eruptive rocks, notably those of the Hudson River Palisades. Its most important properties are not among those in the table, for its most notable characteristics are resistance to wear and a high degree of binding power when powdered and moistened. Few tests have been made on its strength.

Artificial Building Stones. These as a rule are lower in compressive strength than the natural building stones, and without special test they may be rated with common building brick with a compressive strength of 3000 to 4000 lb. per sq. The Arsenal Tests for 1906 give for four varieties of "manufactured stone" values ranging from 2570 to 3390 lb. per sq. in.

38. Brick and Terra Cotta

Bricks are commonly made of clay, whose chief characteristics are a plasticity when wet and a rocklike hardness after being heated to a high temperature. Pure clay, or kaolin, is white, and is employed in the manufacture of china and porcelain ware, whereas the lower-grade clays are used in making building brick. Bricks are also made from pulverized shale, which is simply a clay that has been consolidated through geological processes. The more siliceous shales and clays are adapted to the manufacture of vitrified paving blocks. At the present time building bricks are also made from sand and lime.

Clay Bricks may be broadly classified as building and paving. The former include the common and the pressed bricks. Of more limited and yet important use are enamel brick, glazed brick and fire brick. The enamel brick are those that have a coating of enamel on one or two sides, while the body of the brick is usually of fire clay. Glazed bricks differ from enamel bricks in being coated with a transparent glass instead of an opaque enamel. Fire brick are ordinarily made of a mixture of flint clay and plastic clay. They are usually white, and are used in lining fire boxes and passages.

Defects. The finished brick may be defective because of errors in manufacture or because the clay contains harmful materials. Notable among these are limonite and pyrite. When the brick is fired, limonite concretions will cause fused blotches and weak spots, while pyrite burns away, leaving flaws in the brick.

Terra Cotta is a burnt clay product made in the same general way as brick. Hard terra-cotta blocks and tile are made by burning clay at a very high temperature. Porous or soft terra cotta, sometimes called terra-cotta lumber, is made by burning a mixture of clay and straw or sawdust. The straw or sawdust burns out, leaving a light, porous material. Nails and screws can be driven into porous terra cotta, and it can be cut with a wood saw. Terra-cotta lumber is weaker than hard terra cotta. Terra-cotta building blocks are made hollow with walls 3/4 in. to 1 in. thick.

Sand-Lime Brick are made from an intimate mixture of sand and lime in proportion of about 16 to 1, molded in a press, and hardened in a large cylinder

Properties of Brick of an Average Good Quality

Kind	Weight per cu. ft., lb.	Crushing strength, lb. per sq. in.	Shearing strength, lb. per sq. in.	Modulus of rupture, lb. per sq. in.	Modulus of elasticity, lb. per sq. in.	Absorption, per cent of weight
Common....	125	4 000	1000	600	2 000 000	15
Face........	130	6 000	1000	800	3 000 000	10
Paving.......	150	10 000	1400	2000	7 000 000	2
Sand-lime...	115	3 000	800	450	1 000 000	12
Terra cotta..	....	4 000	....	800	....	13

filled with steam at 125 lb. pressure. The bonding is a result of the union between the sand and lime which forms calcium silicate.

Average Compressive Strength of Brick Masonry

Brick or block used	Mortar	Ultimate stress in compression on test pier, lb. per sq. in.
Vitrified brick	1 : 3 Portland cement	2800
Face brick	1 : 3 Portland cement	2000
Face brick	1 : 3 lime mortar	1400
Common brick	1 : 3 Portland cement	1000
Common brick	1 : 3 lime mortar	700
Hard terra-cotta block	1 : 3 Portland cement	3000
Sand-lime brick *	1 : 3 Portland cement	750
Sand-lime brick *	1 : 3 lime mortar	500

* Estimated from the relative strength of individual sand-lime bricks and common bricks.

Strength of Brick Masonry. As in the case of stone masonry, brick masonry is always used in compression. The strength in compression of brick masonry is much less than the strength of individual bricks. The strength depends not only on the strength of the bricks, but to a large degree on the strength of the mortar joints, and on the skill used in laying the brick. The preceding table, based on test data from the Watertown Arsenal, Cornell University, the U. S. Bureau of Standards, and the University of Illinois, gives average values for ultimate strength in compression.

39. Timber

Classes of Timber Trees. Wood, as a building material, is produced by the spermatophyta, or seed-bearing trees, which may be divided into three groups, the conifers, the broad-leaved, and the tropical trees. The conifers and the broad-leaved trees produce the structurally valuable timbers and give rise to the general classification of timber in the lumber trade into **Soft Woods** (pines, spruce, cedar, cypress, larch, and fir) and **Hard Woods** (oak, walnut, maple, chestnut, hickory, ash, boxwood, whitewood, etc.). Of the tropical trees the products are the bamboos, palms, and rattans. Between the hard woods and the soft woods there is no sharply defined distinction in hardness, some of the hard woods, such as the basswood, poplar, and sycamore, being softer than the pines.

The conifers and the broad-leaved trees are known as the outward-growing or exogenous trees. The structure consists of three parts, the bark, the sapwood, and the heartwood. On the outside of the tree trunk is found from 1/4 to 2 in. or more of bark or protective tissue. As a structural material this is valueless and is always removed soon after the tree is felled, as it hastens the decay of the wood. Inside of the bark there is a soft portion made up of thin-walled cells which constitute the living portion of the tree, called the sapwood. Arranged in a circle inside of this soft tissue are many fibrous bundles making up the middle of the stem, giving it strength and stiffness and known as the heartwood. As the stem grows, new and branching bundles of these hollow fibers appear under the bark and form each season an annular ring. At the end of the season growth stops, to be resumed the following spring; and the rapid open growth of the spring against the slow and condensed growth of the summer gives rise to the peculiar marking in the bundles which indicates each year's increase. The last few rings formed constitute the sapwood, usually from 1/2 to 4 in. in thickness and light in color. The rings inside of the sapwood form the heartwood. The rings are interrupted by plates of tissue or radial cells communicating between the pith at the center of the tree and the soft tissue on the outside. These form the medullary rays. In the pine, the sapwood constitutes 40 to 60% of the cross-section of the tree, and the time required for sapwood to transform into heartwood varies from a few years in the case of the fir to many years in the oak tree. The approximate composition of all woods when dry is nearly uniform and consists by weight of the following elements: 49% of carbon, 6% of hydrogen, 44% of oxygen, and 1% of ash.

White Ash. Heavy, hard, very elastic, coarse-grained, and compact. Tendency to become decayed and brittle after a few years. Color, reddish-brown, with sapwood nearly white. Used for interior and cabinet work, but unfit for structural work.

Red Ash. Heavy, compact, and coarse-grained but brittle. Color, rich brown, with sapwood a light brown sometimes streaked with yellow. Used as a substitute for the more valuable white ash.

Green Ash. Heavy, hard and coarse-grained; brittle. Color, brown, with lighter sapwood. Used as a substitute for white ash.

Balsa. Extremely light, about half the strength of white pine. Appearance like poplar. Used for heat insulation and, when waterproofed, for life preservers.

White Cedar. Soft, light, fine-grained, and very durable in contact with the soil; lacks strength and toughness. Color, light brown, darkening with exposure. Sapwood very thin and nearly white. Used for water tanks, shingles, posts, fencing, cooperage, and boat building.

Red Cedar. Strong pungent odor repellent to insects. Very durable and compact, but easily worked and brittle. Color, dull brown tinged with red. Used as posts, sills, ties, fencing, shingles, and lining for chests, trunks, and closets.

Chestnut. Light, moderately soft, stiff, and of coarse texture. Shrinks and checks considerably in drying; works easily. Durable when exposed to weather. Color, heartwood dark and sapwood light brown. Used for cabinet work, cooperage, railway ties, telegraph poles, and exposed heavy construction.

Cypress. One of the most durable of woods, light, hard, close-grained but brittle. Easily worked, polishes highly and gives a satiny gloss. Color, bright clear yellow with nearly white sapwood. Used for interior finish and cabinet work, but used as extensively in the South as pine is in the North.

White Elm. Heavy, hard, strong and tough and very close-grained. Difficult to split and shape, but warps badly in drying. Capable of high polish. Color, light clear brown often tinged with red and gray, with broad whitish sapwood. Used for car, wagon, boat, and shipbuilding, bridge timbers, sills and ties, and furniture, also barrel staves.

Greenheart. Very heavy, strong, durable heartwood, dark green to dark chestnut color, free from knots. Used for shipbuilding, docks, implements, rollers.

Gum. Heavy, hard, tough, compact and close-grained. Tendency to shrink and warp badly in seasoning. Not durable if exposed. Takes high polish. Color, bright brown tinged with red. Used in the manufacture of furniture, wagon hubs, hat blocks.

Hickory. Medullary rays very numerous and distinct. Heaviest, hardest, toughest, and strongest of American woods. Very flexible. Color, brown, with very thin but valuable sapwood nearly white. Used for carriages, sleighs, handles, and bent-wood implements. Unfit for building material because of extreme hardness and liability to attack of boring insects.

Hemlock. Brittle, splits easily and likely to be shaky. Soft, light, not durable, with coarse and uneven grain. Color, light brown tinged with red and often nearly white. Used for cheap rough framing timber, crates and packing boxes.

Locust. Heavy, hard, strong, and close-grained. Very durable in contact with ground. Hardness increases with age. Color, brown and rarely light green, with yellow sapwood. Used for posts and turned ornaments.

Lignum Vitæ. Exceedingly heavy, hard, resinous, difficult to split and work, and has a soapy feeling. Color, rich yellow brown varying to almost black. Used for small turned articles, tool handles, and sheaves of block pulleys.

Hard Maple. Heavy, hard, strong, tough and close-grained. Medullary rays small but distinct. Curly and circular inflexion of fibers gives rise to "curly maple" and "bird's-eye maple." Susceptible of good polish. Color, very light brown to yellow. Used for flooring, interior finish, and furniture.

White Maple. Fine-grained, hard, strong, and heavy. Characteristics of grain the same as hard maple and more marked. Light colored. Used for flooring and furniture.

Mahogany. Strong, durable, and flexible when green, but brittle when dry. Free from shakes and less liable to attacks of dry rot or worms. Rapid seasoning causes deep shakes. Color, red-brown of various shades and degrees of brightness, often varied and mottled. Inferior qualities contain large numbers of gray specks. Used for interior finish, handrails, patterns, etc.

White Oak. Heavy, strong, hard, tough, and close-grained. Checks if not carefully seasoned. Well-known silver grain and capable of receiving high polish. Color, brown, with lighter sapwood. Used for framed structures, shipbuilding, interior finish, carriage, furniture making, and railway ties.

Chestnut Oak. Very durable in contact with soil. Color, dark brown. Used for railroad ties.

Live Oak. Very heavy, hard, tough, and strong. Difficult to work. Color, light brown or yellow, with sapwood nearly white.

Red and Black Oak. More porous than white oak and softer. Color, darker and redder than white oak. Used for interior finish and furniture, and railway ties.

Palmetto. Light but difficult to work when dry. Very durable under water and less subject to attacks of teredo. Color, light brown, with dark-colored fibers. Used for wharf piles, canes and handles.

White Pine. Light, soft and straight-grained and easily worked, but not very strong. Color, light yellowish brown often slightly tinged with red. Used for interior finish and pattern making.

Red Pine (**Norway Pine**). Light, hard, coarse-grained, compact, with few resin pockets. Color, light red, with a yellow or white sapwood. Used for all purposes of construction.

Yellow Pine (**Long-leaf**). Heavy, hard, strong, coarse-grained, and very durable when dry and well ventilated. Cells are dark colored and very resinous. Color, light yellowish red or orange. Cannot be used in contact with ground. Used for heavy framing timbers and floors. As house sills, sleepers, or posts it rapidly decays.

Yellow Pine (**Short-leaf Pine**). Varies greatly in amount of sap and quality. Cells broad and resinous, with numerous large resin ducts. Medullary rays well marked. Color, orange, with white sapwood. Used as a substitute for long-leaf pine.

Oregon Pine (**Douglas Fir**). Hard, strong, varying greatly with age, conditions of growth, and amount of sap. Durable but difficult to work. Of two varieties, red and yellow, of which yellow is the more valuable. Color, light red to yellow, with white sapwood. Used in all kinds of construction.

Poplar (**Whitewood**). Soft, very close and straight-grained, but brittle and shrinks excessively in drying. Warps and twists exceedingly, but when dry will not split. Easily worked. Color, light yellow to white. Used in carpentry and joinery.

Redwood (**California**). Light, soft, coarse-grained, and easily worked. Durable in contact with soil, but brittle. "Shrinks lengthwise as well as crosswise." Color, dull red, resembling pine. Used for railroad ties, fence posts, telegraph poles, and general building material.

Alaska Spruce (**Sitka Spruce**). Light, soft, medium strength. Heartwood, light, reddish brown; sapwood, white; trees very large. Used for general structural purposes; also for airplane frame-work.

Red Spruce. Light, soft, close and straight-grained and satiny. Color, light red and often nearly white. Used for piles, lumber, and framing timber, submerged cribs and cofferdams, as it well resists decay and the destructive action of crustacea.

White Spruce. Similar to black variety, but not so common. Color, light yellow, sapwood indistinct. Used as lumber for construction.

Tamarack (**Larch**). Wood like pine in appearance, quality and uses. Used for telegraph poles, railway ties, and in shipbuilding.

White Walnut (Butternut). Light, soft, coarse-grained, compact, and easily worked. Polishes well. Color, light brown, turning dark on exposure. Used for interior finish.

Black Walnut. Heavy, hard, strong, and checks if not carefully seasoned. Coarse-grained but easily worked. Color, rich dark brown, with light sapwood. Used for interior finish and cabinet work.

Standard Names for Structural Timber. The following classification of standard commercial names for structural timber is from the 1927 Standards of the American Society for Testing Materials:

1. Southern Yellow Pine. This term includes the species of yellow pine growing in the southern states from Virginia to Texas, that is, the pines hitherto known as long-leaf pine (*Pinus palustris*), short-leaf pine (*Pinus echinata*), loblolly pine (*Pinus taeda*), Cuban pine (*Pinus heterophylla*) and pond pine (*Pinus serotina*).

Under this heading, two classes of timber are designated: (*a*) dense southern yellow pine and (*b*) sound southern yellow pine. It is understood that these two terms are descriptive of quality rather than of botanical species.

(*a*) Dense southern yellow pine shall show on either end an average of at least six annual rings per inch and at least one-third summer wood, or else the greater number of the rings shall show at least one-third summer wood, all as measured over the third, fourth, and fifth inches on a radial line from the pith. Wide-ringed material excluded by this rule will be acceptable, provided that the amount of summer wood as above measured shall be at least one-half.

The contrast in color between summer wood and spring wood shall be sharp and the summer wood shall be dark in color, except in pieces having considerably above the minimum requirement for summer wood.

(*b*) Sound southern yellow pine shall include pieces of southern pine without any ring summer-wood requirement.

2. Douglas Fir. The term " Douglas Fir " is to cover the timber known likewise as yellow fir, red fir, western fir, Washington fir, Oregon or Puget Sound fir or pine, northwest and west coast fir.

3. Norway Pine, to cover what is known also as " Red Pine."

4. Hemlock, to cover Southern or Eastern hemlock; that is, hemlock from all states east of and including Minnesota.

5. Western Hemlock, to cover hemlock from the Pacific coast.

6. Spruce, to cover Eastern spruce; that is, the spruce timber coming from points east of and including Minnesota.

7. Western Spruce, to cover the spruce timber from the Pacific coast.

8. White Pine, to cover the timber which has hitherto been known as white pine, from Maine, Michigan, Wisconsin and Minnesota.

9. Idaho White Pine, the variety of white pine from western Montana, northern Idaho, and eastern Washington.

10. Western Pine, to cover the timber sold as white pine coming from Arizona, California, New Mexico, Colorado, Oregon and Washington. This is the timber sometimes known as "Western Yellow Pine," or " Ponderosa Pine," or " California White Pine," or "Western White Pine."

11. Western Larch, to cover the species of larch or tamarack from the Rocky Mountain and Pacific coast regions.

12. Tamarack, to cover the timber known as " Tamarack," or " Eastern Tamarack," from states east of and including Minnesota.

13. Redwood, to include the California wood usually known by that name.

Sizes of Timber. The following is summarized from the 1927 Standards of the American Society for Testing Materials.

Joist and Plank (joists, rafters, scaffold plank, factory flooring, etc.):

Nominal thickness	2 to 4 in.
Nominal width	4 in. and wider
Standard thickness	Nominal thickness less 3/8 in. finished on one or two sides
Standard width	2 to 7 in., nominal width less 3/8 in. finished on one or two sides 8 in. and wider, nominal width less 1/2 in. finished on one or two sides

Beams and Stringers (Beams, girders, stringers, etc.):

Nominal thickness .... 5 in. and wider

Nominal width .... 8 in. and wider

Posts and Timbers (posts, caps, sills, timbers, etc.);

Nominal size .... 6 by 6 in. and larger

Rough structural joist and plank shall not be thinner than the nominal dimension less 1/4 in., and not narrower than the nominal width less 1/4 in. for sizes 2 to 7 in. inclusive, and less 3/8 in. for sizes 8 in. and wider.

Rough structural beams and stringers, and posts and timbers shall not be smaller than the nominal size less 1/4 in. for sizes 7 in. and less, and less 3/8 in. for sizes 8 in. and over.

Sawing. The manner in which the stick of lumber is sawed from the tree has a remarkable influence upon its qualities and behavior, and the selection of cutting is determined by the character of the wood and the purpose for which it is destined. **Flat sawing** consists in cutting the timber tangential to the annular rings. **Rift sawing** is cutting the boards out of the log in such a manner that the annular rings are cut through as nearly as possible in a radial direction. Rift sawing and flat sawing give rise in the lumber trade to the terms edge grain and flat grain respectively. Rift sawing is done for the sake of the beauty of the grain thus obtained, as well as to expose the edge of the hard bands of summer wood. Edge-grain lumber shrinks and checks less, does not sliver, and wears more evenly and smoother than flat-grain lumber.

Air Seasoning. In the preparation of lumber for construction purposes, it is necessary to expel the moisture from the pores of the wood by the process of seasoning. The drier the timber, the less likely is it to shrink and decay. Natural seasoning consists in exposing the planks and boards, after sawing, to a free circulation of the air. The lumber is placed on skids in large square piles under shelter in a dry place, the layers being separated by three or four narrow strips or boards laid in the opposite direction. The lowest layer should be at least 2 ft. from the ground. At frequent intervals the decayed pieces are removed and the timber repiled. The time required for thorough seasoning varies from one to three years, depending upon the character of the wood, the purpose to which it is to be adapted, and the dimensions. Green wood contains from 30 to 35% of water. Air seasoning reduces this to 12 to 15%.

Artificial Seasoning or Kiln-drying hastens the evaporation of the moisture but at the same time tends to cause a rapid drying of the surface and ends of the material and a slow or imperfect drying of the interior. This may impair both the strength and elasticity of the wood. The timber is stacked in a drying kiln and exposed to a current of hot air, the temperature depending on the kind and the dimension of the stack. Sometimes the heat is supplemented by the employment of vacuum pumps. The best temperature to be employed depends on the kind and dimensions of the lumber, and varies from 100° F. for oak to 200° F. for pine. The time required depends on the thickness of the stack. About four days is necessary for one-inch pine, spruce, or cedar boards. Hard woods are usually dried in air from three to six months and then placed in the drying kiln from six to ten days. Kiln drying reduces the moisture content of wood to less than 10%.

Shrinkage. The concentric annular zones of wood are made up of pores or cells enclosed by walls of cellulose and are pierced at right angles by plates of similar fibers. As the average width of cell is 1/100 of the length, the greatest shrinkage will take place in the cross-section of the fibers or tangentially to the annular rings. This is known as the circumferential shrinkage. By rift sawing the medullary rays are cut across the length, in which direction shrinkage is least. Flat sawing produces lumber which checks and cracks to a greater extent in shrinking. The average values for shrinkage in width are:

Hard woods: radial, 3–8%; tangential, 7–14%
Soft woods: radial, 3–6%; tangential, 5–8%

The longitudinal shrinkage is usually less than 0.1%. The change in volume is therefore due to radial and tangential shrinkage, and expressed in percentage is approximately twice the figures given, as shrinkage takes place in two directions by approximately equal amounts.

The harder timbers are more compact in structure, with thicker cell walls, and therefore produce the greater shrinkage. The opposite effect to shrinkage is produced by the absorption of moisture, and protective checks must be resorted to in applying timber to construction; the expansion joints in wooden block pavement serve as checks. A roadway 40 ft. wide has been observed to expand 8 in.

Decay of Timber. The life of timber depends on its manner of felling, seasoning and working, and timber is subject both in its growing and converted states to decomposition and attack of animal and vegetable life. The proper time of year for cutting the tree is important. In the spring and late summer the sapwood contains an abundance of moisture with starches, sugars, and oils in solution, which tend to hasten its decay. In the drier summer months and in winter the growing and conducting cells are less active or altogether dormant, and the best wood is secured if the tree is cut during those seasons. Oak is claimed to be more durable if cut just after the leaves have fallen.

Trees are felled with the ax or saw, and hewed lumber is commonly accepted as more durable than sawed lumber, as the former process closes the cells at the cut and prevents the absorption of moisture. The agencies which produce the decay of wood may be classed as follows: alternate moisture and dryness, heat and confined air, bacteria and fungi, insects and worms. Well-seasoned wood in a uniform state of moisture or dryness, when well ventilated, should never decay. Timber kept constantly immersed may soften and weaken but does not decay; the elm, elder, oak, and birch in this condition possess great durability.

Dry Rot. This is caused by the fermentation and breaking down of the chemical compounds of wood when a certain fungus is introduced in the presence of moisture. These lower organisms excrete ferments which dissolve out parts of the cell wall and crumbling of the wood follows. Dry rot is prevalent in ill-ventilated places, such as the wall pockets at the ends of floor timbers, and is often prevalent in the core of timber columns in mill construction. The growth of the fungus is stimulated by moderate warmth, presence of damp, and lack of ventilation. In practice the decomposition is often accelerated by the use of unseasoned wood, the surfaces of such unprepared timber often being painted and tarred. Dry rot is indicated by the swelling of the timber, a change in color, the material gradually becoming covered with moldiness and emitting a musty odor. Sometimes reddish and yellowish spots appear on the timber and the fibers are gradually reduced to a powder. It is difficult to eradicate when once established, the only remedy being to remove all traces of the fungus and to disinfect the wood.

Wet Rot. Moisture, especially in the presence of warmth, will dissolve out the substance of the cell walls of sapwood and cause the decay of lumber. Wood felled between the months of April and October is especially subject to wet rot. **Common Rot** is manifested by the presence of external yellow spots on the ends of timber sticks and often by a yellowish dust in checks and cracks, especially where the pieces are in contact. The cause of common rot is improper seasoning in badly ventilated sheds.

Teredo. Of the worms most destructive to wood, the *Teredo navalis*, or shipworm, a species of mollusk, is the most active. It deposits its eggs on timber immersed in water, from which soon emerge small but rapidly developing worms. The head of the worm is equipped with a shell-like substance shaped like an auger, by means of which it bores its way into the timber in a direction generally parallel to the grain. As it progresses it lines the hole with a calcareous deposit and maintains communication with the outside through two small lids at the external opening. The teredo continually increases in size as its boring progresses, and specimens varying from 1/4 to 1/2 in. in diameter and 15 in. to 6 ft. in length have been found. Its habitat is the salt water of the warmer climates, though occasionally found in cold water. It avoids fresh water entirely, always prefers clear to muddy water, and is most active in the vicinity of calcareous shores. It may be found at work from half tide level down to the ground.

The Limnoria or gribble (*Limnoria terebrans*), is a crustacean about the size of a grain of rice and resembles the wood louse. It is able to swim, crawl, and jump, and requires both air and water for existence. In contradistinction to the teredo, it works only to a depth of 1/2 in., devouring the wood by means of claws or mandibles. The surface of the wood becomes undermined and brittle and is finally washed away, exposing a new surface to the action of the worm. The limnoria devours wood at the rate of 1 to 3 in. per annum, and is always found in large colonies, as many as 20 000 having been observed on a surface 12 in. square. It is found both in cold and in warm water, being capable of inhabiting colder climates than the teredo. It has a preference for siliceous shores, and confines its work to a space between high and low water marks. It is usually most active in brackish waters at low-water level.

The Lycoris fucata is a little worm with numerous legs, somewhat similar to the centipede. It lives in the mud and crawls up piles inhabited by the teredo, against which it is an active enemy. It enters the tunnel, devours the teredo, enlarges the entrance to the burrow and lives in it.

Impregnation of timbers with creosote is a rather uncertain protection for piles but seems to be somewhat more effective for piles in cold water than for piles in the warmer tropical waters. Creosote becomes ineffective if there exists or is formed in the pile a crack extending from the surface to the center where the creosote has not penetrated.

Various protective coatings, paints, asphalt, etc., have been applied to piling in the hope of preventing or retarding the attack of marine borers. Such protection is temporary at best. It becomes ineffective at any point where the surface is broken. No coating for which records are available has proved an effective protection over a period of years in water infested by active borers.

Tile pipe of burnt clay have been used for protective armor on piling. Tile is effective but is so brittle that it is in very great danger of being broken by the impact of vessels and floating logs against the piling. Copper sheathing makes an excellent non-corrosive armor for piles. It is, however, very expensive and is in danger of being stolen from piles in lonely locations. Timber piles have been successfully covered by concrete and not at very great cost but usually where permanent piles are required it is best to use precast concrete piles. They generally cost less per ton of load to be supported than wooden piles treated by a permanent cover of metal, tile or concrete.

Certain timbers from South American countries are found containing many minute grains of silica. These timbers give some promise of being somewhat resistant to rapid destruction by borers. They are under study at the present time. Hard wood resists the borers very much better than the softer woods; it is therefore recommended that oak or hickory instead of pine be used if the piles are not to be treated or protected. Piles from palm trees, on account of their structure, are not attacked by borers. Some of the hard tropical trees such as the Jucaro of Cuba are almost teredo proof.

Wooden hulls are often protected against the teredo by copper but sometimes by wood sheeting. This outer sheeting is quite effective until destroyed by borers because they will not usually cross a joint between timbers.

Under the general auspices of the National Research Council an extensive investigation of marine borers has been carried out in Los Angeles Harbor by Col. Wm. G. Atwood, U. S. Army. It was shown that marine borers could exist in water of lower salt content than had been previously supposed, and that creosote impregnation, properly carried out, and certain metallic armors, notably cast iron, were the most effective defence found against borers. (See The Military Engineer for May-June, 1923, and for Nov.-Dec., 1924.)

Classification of Lumber (Simplified Practice Recommendation No. 16, U. S. Department of Commerce). Lumber is the product of the saw and planing mill, not further manufactured than by sawing, resawing, and passing lengthwise through a standard planing machine, cross-cut to length and matched.

Use Classification

Yard Lumber. Lumber that is less than 6 in. in thickness, and is intended for general building purposes.

Structural Timbers. Lumber that is 6 in. or over in thickness and width.

Factory or Shop Lumber. Lumber intended to be cut up for further manufacture.

Size Classification

Strips. Yard lumber less than 2 in. thick and under 8 in. wide.

Boards. Yard lumber less than 2 in. thick, 8 in. or over in width.

Dimension Lumber. All yard lumber except boards, strips, and timbers; that is, yard lumber not less than 2 and under 7 in. thick, and of any width; this includes (1) Planks, yard lumber not less than 2 and under 4 in. thick and 8 in. and over wide; (2) Scantlings, yard lumber not less than 2 and under 6 in. thick and under 8 in. wide; (3) Heavy joists, yard lumber not less than 4 and under 6 in. thick and 8 in. or over wide.

Timbers. Lumber 6 in. or larger in least dimension.

Manufacturing Classification

Rough Lumber. Undressed as it comes from the saw.

Surfaced Lumber. Lumber that is dressed by running through a planer. It may be surfaced on one side (S1S), two sides (S2S), one edge (S1E), two edges (S2E), or a combination of sides and edges, (S1S1E), (S2S1E), (S1S2E), or (S4S).

Worked Lumber. Lumber which has been run through a matching machine, sticker, or molder. Worked lumber includes: (1) Matched lumber, which is edge dressed and shaped to make a close tongued and grooved joint at the edges or ends when laid edge to edge or end to end; (2) Shiplapped lumber, which is edge dressed to make a close rabbetted or lapped joint; (3) Patterned lumber, which is shaped to a patterned or molded form.

40. Data for Timber

Tests of Strength of Wood. The elastic limit of wood is not so clearly defined as is the elastic limit of structural steel. The values for elastic limit given in the table on p. 657 are values of the proportional limit as determined by tests with an extensometer. The tensile strength of wood is slightly higher than the compressive, but is rarely of practical importance, on account of the difficulty of attaching a piece of wood in tension without making the critical stress a shear along the grain. Wood is weak in shear along the grain, and in timber beams the shearing strength nearly always has to be considered.

Time Element in the Strength of Wood. Under long-continued steady load wood will fail under stresses much lower than those found at the ultimate strength in laboratory tests, which cover only a few moments. Under long-time loading test pieces of wood have broken under stresses only a little above 50% of the ultimate as given by short-time laboratory tests. This very pronounced time effect is one of the reasons why working stresses for timber are low as compared with ultimate strength.

Effect of Moisture on Strength of Wood. Up to a moisture content of about 25% for soft woods the fibers absorb water and are weakened and softened by it. For moisture content above this "fiber saturation point" water no longer affects the strength and stiffness of wood. The effect of moisture content is shown in the accompanying table, which is based on the results of tests by the U. S. Forest Service, principally by H. D. Tiemann.

Effect of Long Seasoning. Tests by A. C. Alvarez at the University of California on wood from the interior timbers of old buildings which had stood for some 37 years showed that Douglas fir and redwood did not deteriorate in strength with age when preserved from decay.

Effect of Slope of Grain (from 1927 Standards of the American Society for Testing Materials). "Slope of grain, resulting either from diagonal sawing or from spiral or twisted grain in the log, is limited in accordance with the recommendation of the Forest Products Laboratory based on the results of detailed study of the effect of cross and spiral grain upon strength, and the weakening of material by checks which invariably develop and, without exception, follow the grain. There is not much reduction in strength from cross grain until an angle of grain of 1 in 40 is reached. From that slope in a beam an angle of 1 in 20 reduces the strength about one-eighth; 1 in 15, about one-quarter; 1 in 11, about three-eighths; and 1 in 8, about one-half. In a post or column an angle of grain of 1 in 15 reduces the strength about one-eighth; 1 in 11, about one-quarter; 1 in 8, about three-eighths; and 1 in 6, about one-half."

Working Stresses for Timber are given in Sect. 9 on Timber Structures.

Inspection. The inspection of timber must be undertaken with two view-points, namely, the quality of the stock and the dimensions of the pieces; and all condemned pieces must be plainly marked with paint or branding iron. Strong and durable timber possesses the following characteristics: It is obtainable from the slowest-growing trees, as indicated by the narrowness of the annular rings. Wood containing the least amount of resin or sap in the pores is the strongest and most durable. The wood should be uniform in substance, straight in fiber, free from large and dead knots and all flaws, shakes, and blemishes. Freshly cut, sound timber smells sweet and shows a firm and bright surface with silky luster when planed. The surface should

Effect of Moisture on Strength of Wood

Based on test data from U. S. Forest Products Laboratory

Values are given in per cent of strength of oven-dry wood (moisture content negligible)

Moisture content, per cent of fiber saturation point	10	20	30	40	50	60	70	80	90	100
Modulus of rupture, flexure.....	91	82	73	66	60	55	50	46	43	39
Ultimate compression along grain	88	76	66	57	48	43	37	33	30	28
Ultimate shear along grain.....	93	85	77	70	64	58	54	51	48	46
Modulus of elasticity, flexure...	94	88	83	79	75	72	69	66	64	61
Modulus of elasticity, compression along grain............	93	85	77	71	66	63	59	57	54	52

never be woolly, and when cut should not clog the teeth of the saw. In highly colored woods, strength of color is generally indicative of strength and durability. Sound timber when struck lightly or scratched at one end transmits the sound to the ear placed at the other extremity through sticks of lumber 50 ft. in length. Sound material is sonorous when struck, while decaying timber gives forth a dull sound. Dull, chalky appearance and disagreeable odor are signs of bad timber. In the absence of the usual external signs, dry rot may be detected by boring test holes in the wood for the appearance and odor of the wood dust.

Relation of Strength of Wood to its Specific Gravity

Based on the work of Newlin and Wilson of the U. S. Forest Service. (See Bulletin 676 of the U. S. Department of Agriculture.)

G is the specific gravity of the wood, based on the weight oven-dry and the volume at the time of test and the condition when tested.

All values are in lb. per sq. in.

Strength property	Green wood	Air-dry wood
Flexure under steady load:		
Elastic limit	$10\,300\sqrt[4]{G^5}$	$19\,000\sqrt[4]{G^5}$
Modulus of rupture	$18\,500\sqrt[4]{G^5}$	$26\,200\sqrt[4]{G^5}$
Modulus of elasticity	$2\,500\,000\,G$	$3\,000\,000\,G$
Impact flexure with 50-lb. hammer:		
Elastic limit	$23\,500\sqrt[4]{G^5}$	$35\,000\sqrt[4]{G^5}$
Modulus of elasticity	$3\,000\,000\,G$	$3\,550\,000\,G$
Compression parallel to grain:		
Elastic limit	$6\,800\sqrt[4]{G^5}$	$11\,000\sqrt[4]{G^5}$
Ultimate strength	$6\,900\,G$	$12\,000\,G$
Modulus of elasticity	$2\,860\,000\,G$	$3\,500\,000\,G$
Compression perpendicular to grain:		
Elastic limit	$2\,900\sqrt[4]{G^9}$	$5\,200\sqrt[4]{G^9}$
Shear along grain		
Ultimate strength	$2\,650\sqrt[3]{G^4}$	$3\,800\sqrt[3]{G^4}$

Volume shrinkage of wood, per cent, 28 G.
Radial shrinkage of wood, per cent, 9.5 G.
Tangential shrinkage of wood, per cent, 17 G.

Defects. The following are adopted as standard by the 1927 Standards of the American Society for Testing Materials, Part II, p. 697. The diameters of knots and holes are mean or average diameters:

Knots. A **sound knot** is one which is solid across its face and which is as hard as the wood surrounding it; it may be either red or black, and is so fixed by growth or position that it will retain its place in the piece. A **loose knot** is one not firmly held in place by growth or position. A **pith knot** is a sound knot with a pith hole not more than 1/4 in. in diameter in the center. An **encased knot** is one whose growth rings are not intergrown and homogeneous with the growth rings of the piece it is in. The encasement may be partial or complete; if intergrown partially or so fixed by growth or position that it will retain its place in the piece, it shall be considered a sound knot; if completely intergrown on one face, it is a watertight knot. A **rotten knot** is one not as hard as the wood it is in. A **pin knot** is a sound knot not over 1/2 in. in diameter. A **standard knot** is a sound knot not over 1-1/2 in. in diameter. A **large knot** is a sound knot more than 1-1/2 in. in diameter. A **round knot** is one which is oval or circular in form. A **spike knot** is one sawn in a lengthwise direction.

Knots in timber do most damage when located near the faces or edges of structural pieces. Knots near the center of length of a piece are more injurious than those near the ends.

Detailed rules concerning the grading of timber with knots or other defects are given in the 1927 Standards of the American Society for Testing Materials, Part 11, pp. 581–603.

Pitch Pockets are openings between the grain of the wood containing more or less pitch or bark. These shall be classified as small, standard, and large pitch pockets. A small pitch pocket is one not over 1/8 in. wide. A standard pitch pocket is one not over 3/8 in. wide, or 3 in. in length. A large pitch pocket is one over 3/8 in. wide, or over 3 in. in length. A **pitch streak** is a well-defined accumulation of pitch at one point in the piece. When not sufficient to develop a well-defined streak, or where the fiber between grains, that is, the coarse-grained fiber, usually termed **Spring wood** is not saturated with pitch, it shall not be considered a defect. **Wane** is bark, or the lack of wood from any cause, on edges of timbers.

Shakes are splits or checks in timbers which usually cause a separation of the wood between annual rings. A **ring shake** is an opening between the annual rings. A **through shake** is one which extends between two faces of a timber.

Rot, dote, and red heart are forms of decay which may be evident either as a dark red discoloration not found in the sound wood, or as the presence of white or red rotten spots, and shall be considered as defects.

41. Preservation of Timber

Preservative Processes. The average life of timber used in the United States which is subject to decay, is about 8 years; its life can be extended to 12 years either by a chemical impregnation of the wood cells or by an exterior application of a preservative coating which will penetrate the fibers. Creosote oil is the preservative in most common use.

Preservation. The general method followed in the commercial treatment of timber with creosote involves the following steps: (1) seasoning the timber, (2) steaming the timber in a large cylinder to soften the wood fiber, (3) removal of air and moisture from the wood fibers by means of a vacuum pump, (4) admission of creosote oil to the evacuated chamber—the oil penetrates some distance into the timber, (5) the application of pressure forcing the preservative into the innermost fibers of the timber, and (6) the removal of pressure, after which the excess of creosote is allowed to drip off the timber and run into a tank.

A simpler process for treating small lots of timber consists of soaking the timber pieces in an open tank of hot creosote. This process does not impregnate timber so thoroughly as does the pressure-vacuum process, and it is wasteful of creosote.

Creosote is a rather expensive preservative, and other preservatives have been tried. Zinc chloride is violently poisonous to timber-destroying bacteria, can be forced into the inner fibers of wood, and is cheaper than creosote. However, zinc cloride is soluble in water, whereas creosote is not, and zinc chloride is an effective preservative only in extremely dry regions.

The following table gives approximate weights of creosote required per cubic foot of timber for various services.

Railroad ties:	
Hard wood	6–14 lb. per cu. ft.
Soft wood	13–20 lb. per cu. ft.
Dimension timbers	15–20 lb. per cu. ft.
Piles	20–30 lb. per cu. ft.
Poles and posts, treated by open tank method for a length of 7 ft:	
Chestnut poles	21 lb. per pole
Western pine poles	65 lb. per pole

Properties of Timber

Based mainly on Bulletin 556 of the U. S. Department of Agriculture (Forest Service) by Newlin and Wilson. Values are for wood tested green. Values for green timber are more reliable as a guide for structural use than values for dry timber, since in service the outer fibers of dry timber may readily reabsorb water. For working stresses see Sect. 7, Art. 1.

Kind of timber	Weight, lb. per cu. ft.	Strength in flexure, lb. per sq. in.			Strength in compression, lb. per sq. in.			Ultimate shearing strength, parallel to grain, lb. per sq. in.	Ultimate tensile strength, perpendicular to grain, lb. per sq. in.
		Elastic limit	Modulus of rupture	Modulus of elasticity in flexure	Elastic limit, parallel to grain	Ultimate, parallel to grain	Elastic limit, perpendicular to grain		
Ash	49	5500	9 900	1 490 000	3500	4200	800	1430	700
Cedar (white)	28	2600	4 200	640 000	1400	2000	290	620	240
Cedar (red)	27	3300	5 200	950 000	2500	2800	310	720	210
Chestnut	55	3100	5 600	930 000	2000	2500	380	800	430
Cypress	41	3800	6 500	1 070 000	2700	3200	440	820	270
Elm	52	3600	6 900	1 030 000	2300	2900	390	920	560
Gum (black)	45	4000	7 000	1 030 000	2400	3000	600	1100	570
Gum (blue)	70	7600	11 200	2 010 000	4900	5200	1020	1550	640
Hickory	64	5700	10 500	1 470 000	3500	4400	1270	930	680
Hemlock	45	3700	6 300	1 080 000	2500	3000	420	860	290
Locust	59	7200	12 000	1 570 000	4800	5600	1420	1710	850

Oak (white)	62	4700	8 300	1 250 000	3000	3600	830	1250	770
Oak (chestnut)	62	4600	8 000	1 370 000	2900	3500	660	1210	690
Oak (red and black)	64	3700	7 700	1 290 000	2300	3200	730	1120	740
Pine (white)	39	3400	5 300	1 070 000	2400	2700	310	640	260
Pine (western white)	39	3500	5 700	1 330 000	2800	3100	300	710	250
Pine (red or Norway)	42	3700	6 400	1 380 000	2500	3100	360	780	190
Pine (yellow long leaf)	50	5400	8 700	1 630 000	3800	4400	600	1070	290
Pine (yellow short leaf)	50	4500	8 000	1 450 000	3600	3800	480	890	330
Pine (western yellow)	46	3100	5 200	1 010 000	2100	2500	340	680	280
Pine (Oregon or Douglas fir)	38	5000	7 800	1 580 000	3400	3900	530	910	200
Spruce (red)	34	3400	5 700	1 180 000	2400	2700	350	770	220
Spruce (white)	33	3300	5 400	980 000	2300	2400	270	670	200
Tamarack (or larch)	47	4400	7 300	1 300 000	3100	3600	520	890	240
Walnut	58	5400	9 500	1 420 000	3600	4300	600	1220	570

Kyan's Process.—The timber is steeped in a solution of corrosive sublimate, 1 part of bichloride of mercury to 99 parts of water for a period (at least 5 to 10 days) sufficient to insure thorough penetration of the preservative. Sublimate is comparatively insoluble in water and remains in timber for a longer time than salts like zinc chloride. Great care must be exercised in handling corrosive sublimate as it is a deadly poison. It should not be used as a preservative where domestic animals can lick the treated parts.

Physical Properties.—Strength tests of the U. S. Forest Service in 1907 (H. F. Weiss, American Wood Preservers' Association, 1913) showed that both zinc chloride and creosote reduced the transverse strength of timber, though only to a slight extent in the case of creosote oil. Transverse and compression tests made by H. B. MacFarland (Vol. XIV, American Railway Engineers' Association, 1913) on long leaf pine showed greatly increased strength after one year for creosote treated wood. When tested immediately after treatment the strength was inferior. Thoroughly seasoned timber is stronger than green timber. Some processes tend to increase the moisture content and others to diminish it. If creosote is applied to green wood, the strengthening action of water evaporation is retarded. On the other hand, zinc chloride may cause a chemical dissolution of the wood fiber, thus weakening the structure. Zinc chloride is non-flammable, and wood so preserved is more fire-resisting than non-treated wood. (H. F. Weiss, American Wood Preservers' Association, 1913.) Zinc-treated wood ignited at a temperature of 500° C., 19% of the wood by weight being consumed. Freshly creosoted wood ignited at 225° F., 27% of the wood by weight being consumed. Creosoted wood is adapted for exterior work subject to moisture and is especially effective against marine borers. (See p. 652.)

42. Plywood

Manufacture. Plywood is made by gluing together thin layers of wood. The grain in one layer is at right angles to the grain in the next layer. An odd number of layers is used. It is important that the layers of wood are all split or sawed the same way from a stick of timber, and that the moisture content is approximately the same for all layers. If these precautions are not taken the plywood will tend to warp due to uneven stresses in the different layers.

Strength of Plywood. A limitation of the use of large boards is the difference in strength of wood in various directions. The tensile strength of wood parallel to the grain may be as much as twenty times the strength perpendicular to the grain, and the shearing strength parallel to the grain is much lower than the shearing strength across the grain. In plywood the strength is approximately equal in all directions and is equal, approximately, to the mean of the strength with and the strength across the grain. As plywood is built up of thin layers it becomes feasible to use a high grade of wood in its manufacture.

Woods Available for Plywood. Basswood, redwood, poplar, maple, birch, and red gum are domestic woods which can be cut into the thin sheets necessary for making plywood. Basswood, redwood, and poplar are not often used for the face layers.

Plywood is used mainly in the shape of thin sheets, and is of importance in manufacture of automobiles, street and railway cars, airplanes, and boats.

The strength of glue joints, such as are used in manufacturing plywood, are discussed on page 662.

Tensile Strength of Plywood

Based on test data from the U. S. Forest Products Laboratory, Madison, Wis.

Species	Weight of plywood, kiln-dry, lb. per	Moisture at test, per cent	Tensile strength of 3-ply plywood parallel to grain of faces, lb. per sq. in.	Tensile strength of single-ply veneer, parallel to grain, lb. per sq. in.
Basswood........	28	9.2	6 900	10 300
Yellow birch......	45	8.5	13 200	19 800
Maple, soft.......	38	8.9	8 200	12 300
hard......	46	8.0	10 200	15 300
Yellow poplar.....	34	3.4	7 400	11 100
Red gum.........	36	8.7	7 800	11 800
Redwood........	28	9.7	4 800	7 200

43. Cements and Plasters

For natural and portland cement see Sect. 11. For lime and lime mortar see Sect. 10, Art. 12. **Hydraulic lime** is obtained by burning limestone containing from 10 to 20% of clay. **Magnesian lime** is the term applied to limes containing more than 5% (usually 30% and over) of magnesia. It has the characteristics of being slow slaking or cool, but sets more rapidly and makes a stronger mortar than the high-calcium limes. Lime is never used alone as a binding material, as it shrinks very much in drying. One part of lime paste is combined with 3 or 4 parts of sand, the resulting mortar being about equal in volume to that of the sand.

Grappier Cements are made by grinding lumps of unburned limestone and overburned material which remains when a hydraulic lime is slaked. If lime silicate predominates in the mixture, grappier cement approximates to portland.

Lafarge Cement is a hydraulic grappier cement manufactured at Teil, France. It contains a small percentage of iron and soluble salts and does not stain porous stone masonry.

Plasters are classified by E. C. Eckel as (1) those produced by incomplete dehydration of gypsum ($CaSO_4$), the calcination being carried on at a temperature not exceeding 400° F., and (2) those produced by complete dehydration of calcium sulphate at a temperature exceeding 400° F. **Plaster of paris** is a product of the first class, no foreign material being added to the gypsum during or after calcination. **Cement plaster** is also of the first class, but is manufactured from an impure gypsum, or by the addition of certain impurities during manufacture to act as a " retarder " to the plaster. In the second class are included flooring plaster, commercially known as calcined plaster, being pure calcined gypsum, and also hard-finish plaster, obtained by adding alum or borax during manufacture. Structural gypsum weighs 80 lb. per cu. ft. and cement plaster about 115 lb. per cu. ft.

Common or Lime Plaster is made of quicklime and sand in which hair or fiber is beaten up and thoroughly incorporated with the lime paste. **Wall plasters** are made by the addition of lime and retarder to the calcined plaster.

The Strength of Plaster as determined from tests by Woolson is shown by the following tables (see Proceeding, American Society for Testing Materials, Vol. X, p. 328).

Tensile Strength of Plaster

Values given in pounds per square inch

Kind of lime	1 : 3 lime mortar				1 : 5 lime mortar			
Age	1 mo.	3 mo.	6 mo.	12 mo.	1 mo.	3 mo.	6 mo.	12 mo.
High-calcium (quicklime).....	27	34	47	60	25	36	38	39
High-calcium (hydrated lime).	80	103	113	122	46	62	73	79
Dolomitic (quicklime).......	56	60	74	125	51	72	93	124
Dolomitic (hydrated lime)....	88	90	96	130	27	56	84	122

The Compressive Strength of Gypsum varies from 70 lb. per sq. in. to 3000 lb. per sq. in., depending on the amount of water used in mixing the gypsum paste, the completeness of drying out, the foreign ingredients in the gypsum, and the process of calcination used. For highest strength the least possible amount of water should be used in mixing. From 33 to 38%

Compressive Strength of Plaster

of water is necessary to make the gypsum paste sufficiently plastic to fill molds. From tests by W. A. Slater for the U. S. Gypsum Co. it was found possible to produce regularly gypsum having a compressive strength of 1400 lb. per sq. in. when a few days old. The modulus of elasticity was found to be about 1 000 000 lb. per sq. in.

44. Miscellaneous Materials

Leather as an engineering material is mostly applied in the manufacturing of belting for transmission trains. The best quality of well-tanned oxhide is cut into strips of from 4 to 6 ft. long and usually about 3/16 in. in thickness, which are scarfed, spliced, or cemented end to end to make the desired length of belt. According to the strength required, these are in turn cemented or riveted together in thickness to form " single " or " double " belts. Under light loads, the " single belt " gives the greater adhesion, but under heavy loads the "double belt " proves the more satisfactory. The " flesh side " or inside of the belt is customarily placed next to the pulley, as it gives the best wear, although when placed grain side to the pulley the belt is less liable to slip.

The weight of a hard well-tanned belt leather is about 62-1/2 lb. per cu. ft., whereas the tensile strength of a good quality is about 650 lb. per inch of width of single belt. When spliced or riveted, the tenacity is about one-half of the above figure, and when laced about one-third of the strength is developed. A safe working tension may be taken at about 50 lb. per inch of width.

Rawhide or untanned leather, finds many applications in textile machinery connections, looms, ships' tiller ropes, etc., and also in the manufacture of high speed gear wheels. When sound, it is much stronger than tanned leather and gives greater resistance to violent impact. Its tensile strength may be taken as one-half greater than that of tanned leather.

India Rubber is used for belting, sheets for packing, tires, electrical insulation, hose, etc. The rubber used by the engineer is generally vulcanized by heating and incorporating it with 7 to 30% of sulfur to render it less readily softened by heat and hardened by cold. When vulcanized with 30 to 40% of sulfur, it forms the various qualities of ebonite used in the manufacture of rules, scales, curves, etc. India-rubber belts are made by weaving cotton canvas of the required length and width, which is then coated with the vulcanized rubber. These are made 2, 3, or 4-ply, according as the power to be transmitted requires the strength of 2, 3, or 4 thicknesses of belt. Rubber belts are superior to leather belts in strength, usually run truer and more smoothly, are perfectly impervious to water, and give a higher coefficient of friction. However, when overloaded they are apt to be injured by the tendency to slipping.

The tensile strength of good quality soft rubber varies from 800 to 1200 lb. per sq. in., and the elongation before fracture is about 600%. Under com-

* Waterproofed.

Properties of Various Glues

Technical Note No. 207, U. S. Forest Products Laboratory, Madison, Wis.

Point of comparison	Animal glue	Casein glue	Vegetable glue	Blood glue	Liquid glue
Source of principal ingredient	Animal hides, bones, etc.	Casein from milk.	Starch, generally cassava.	Soluble dried blood.	Animal glue, or skins, bones, etc., of fish.
Spread * Extremes reported / Common range	20 to 50 / 25 to 35	30 to 80 / 35 to 55	35 to 70 / 35 to 55	30 to 100	No data.
Mixing	Soaked in water, then melted.	Mixed cold.	Mixed with alkali and water, with or without heat; can be made without alkali.	Mixed cold.	Requires no preparation.
Application	Applied warm with brush or mechanical spreader.	Applied cold with brush or mechanical spreader.	Applied cold with mechanical spreader.	Applied cold by hand or with mechanical spreader.	Applied cold or warm, usually by hand.
Temperature of press	Cold; hot cauls frequently used.	Cold.	Cold.	Hot or cold, depending on formula used.	Cold.
Strength (block shear test)	High grade; have greater shear strength than strongest American woods; medium grades slightly lower.	Similar to medium grade animal glue.	Similar to medium grade animal glue.	Similar to or slightly less than medium grade animal glue.	Good grades similar to medium grade animal glue; some brands very weak.
Water resistance	Naturally low, but can be increased by chemical treatment.	High or low, as required.	Low.	High.	Low.
Staining	Does not stain.	Stains wood of some species.	If mixed with caustic soda, stains wood of some species.	Does not stain, but the glue is very dark and may show through thin veneer.	Does not stain.
Uses in woodworking	High grade, where a strong joint is desired; low grade sometimes used for veneering, especially where it is desired to prevent staining.	Mainly where water resistance is desired in veneered or joint work.	To some extent for joint work, but mainly in veneered work where good strength at low cost is desired.	Almost entirely for water-resistant plywood for aircraft or automobiles and for articles to be molded after boiling in water.	Mainly for repair work and gluing small articles by hand.

* Expressed in square feet of single glue line per pound of dry glue for veneer work.

pressive load good soft rubber is shortened 50% under a stress of from 500 to 800 lb. per sq. in. The outstanding property of rubber, which makes it unrivaled as the material for automobile tires, is its capacity for absorbing energy. Stressed to a good working stress rubber under tension will absorb about ten times as much energy per cubic inch as will spring steel, and under compression about 3.75 times.

Glass. The tensile strength of common glass varies from 2000 to 3000 lb. per sq. in., and the compressive strength from 6000 to 12 000 lb. per sq. in. A series of transverse tests were undertaken on common glass at the Watertown Arsenal. Sheets of common window glass 2 ft. 6 in. long by about 4.95 in. wide and 0.121 in. thick were subjected to a central load with an unsupported length of 2 ft. The modulus of rupture varied from 3000 to 4000 lb. per sq. in and the modulus of elasticity from 10 000 000 to 11 000 000 lb. per sq. in.

Ice at 32° F. weighs 57.5 lb. per cu. ft., its specific gravity being 0.922 (water at 62° F. = 1). Its volume relative to water is 1.0855. Its melting point decreases from 32° F. at the rate of 0.0133° F. for each additional atmospheric pressure. Its specific heat is 0.504 (water = 1). Some German experiments made in 1885 gave a tensile strength of 142 to 223 lb. per sq. in. Tests made by the U. S. Engineer Corps on 6- and 12-in. cubes, gave crushing strengths varying from 100 to 1000 lb. per sq. in. depending on the structure of the ice and the purity of water from which it was formed. Before crushing, ice in cubes will compress from 6 to 30%. The sustaining capacity of ice is not definitely determined; 2-in. ice is considered safe for infantry, 4-in. ice for cavalry or light guns, 6-in. ice for heavy field guns, and 8-in. ice for loads not over 1000 lb. per sq. ft. on sledges. Railway trains have been run across ice which was 15-in. thick.

The expansive force of ice is given by Trautwine as probably not less than 30 000 lb. per sq. ft. The coefficient of expansion, as given by Ganot, is 0.000 052. By its expansion a sheet of ice 150 ft. in width has been known to tip a masonry bridge pier weighing 1000 tons 2 in. out of plumb, and in another instance to move masonry piers on pile foundations from 2 to 12 in. out of line. The expansive effect in river or lake ice, however, does not make itself felt until the ice is at least 5 in. thick.

Freshly fallen snow weighs from 5 to 12 lb. per cu. ft.; compacted or wet snow weighs from 15 to 50 lb. per cu. ft.

45. Paints and Oils

A Paint consists of a vehicle and a pigment; and many paints have a drier added. The whites, as white lead and zinc white, form the base upon which nearly all tints are made by the addition of colored pigments called stains. Red lead and oxide of iron may also be used as bases for paint without using a white base or they may be used as stains. The usual **vehicle** for the base is linseed oil. Its function is to enable the paint to be spread and also to form a binder for the paint materials after drying. Spirits of turpentine is often used as a paint **thinner.** Its function is to make the paint work more smoothly. The drying of the paint is often hastened by the addition of a **drier,** whose function is to hasten the solidification of the linseed oil by making its oxidation more rapid.

White Lead is a combination of lead carbonate and lead hydrate. The former gives the opacity or body, while the latter gives the saponifying and binding properties. White lead is supplied to the trade ground in linseed oil. It is a good drier of this oil, and very little artificial drier need be added to a white-lead paint.

Zinc White is the oxide of zinc. It is a permanent white pigment, and so is well adapted to interior decoration. Sulfureted hydrogen gases have no discoloring effect upon it, while such gases will darken a white-lead paint.

Red Lead is a double oxide of lead. It is used as a constituent of a priming paint for new woodwork, and its excellent anti-corrosive properties make it the best primer for coating ironwork. It excels all other pigments in withstanding abrasive wear. It is a strong drier of linseed oil, solidifying it in a short time, and it is for this reason that the pigment is sold in the dry powdered state. For the highest grades of red lead the content of lead monoxide (litharge) should not exceed 4%, for a lower grade 13% is allowable.

Raw Linseed Oil is produced by pressing flaxseed. Boiled linseed oil is prepared by heating the raw oil either alone or with a drier such as red lead. Boiled oil dries in about one-half the time that the raw oil does. For this reason the boiled oil is much used for exterior work. For interior work and for grinding up colors the raw oil is used. Linseed oil is subject to adulteration by the addition of cotton-seed, resin, hemp, mineral, and fish oils. As substitutes, fish oil, cotton-seed oil, and Chinese tung oil are used.

Spirits of turpentine is a solvent or diluent used with paints and varnishes. It is also employed for mixing pigments in making flatting colors for interior decoration. It is often adulterated with mineral oil. As substitutes, benzine and naphtha are used.

Staining Colors or Pigments are used for tinting paints which have a white base such as white lead or zinc white. The most common black pigments are the soot and charcoal blacks. The best known red pigments are Venetian red, which is an earth with ferric oxide as the coloring agent, and red lead. The brown pigments are burnt umber, and the raw and burnt siennas, which resemble umber in composition. The green most used is chrome green, a pigment compounded of Prussian blue and chrome yellow. The standard commercial mixture of chrome green contains three parts of base to one of chrome green. Prussian blue is the common blue pigment which has great strength of coloring matter. Another important pigment is the ultramarine blue, an artificial chemical product of complex composition. As this latter pigment has some sulfur, it should not be mixed with white lead but should be used with zinc white as a base.

Graphite Paint is prepared by mixing graphite with boiled linseed oil to which a small percentage of drier has been added. It is an excellent paint for iron. One objection to this paint is that it mars easily under slight abrasion.

Protection of Iron Work under Water. Refined coal tar dissolved in a vehicle makes the most durable paint coating known for iron under water. Asphalt paints made by dissolving asphaltum in some suitable vehicle such as naphtha or benzine is also used for this purpose. Coal tar has been especially effective as a protector for cast iron water pipe.

Varnish is made by dissolving gums or resins in oil, turpentine or alcohol. The primary purpose of varnish is to furnish a smooth, hard, transparent coating for a surface. Hardness and toughness are somewhat contradictory requirements for varnish both of which can be fairly well met in high-grade varnishes. Quick drying and durability are two contradictory requirements which have not been reconciled in any varnish.

For general reference on Paint and Varnish see Sabin, The Technology of Paint and Varnish, 3d Edition, New York, 1927.

STANDARD MARKET SIZES

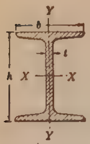
46. Rolled Structural Beams

Structural Beams and Shapes should be ordered by weight per foot or by the thickness wanted. A variation of 2-1/2% either way is allowed in the nominal weight of the shape. Unless otherwise arranged, structural shapes are cut to lengths as ordered with an extreme variation of 3/4 in. For cutting with a less variation, an extra charge is made.

The increase of weight in standard I beams and channels is secured by increasing the web uniformly in thickness for the depth of the beam. This results also in an increased width of flange equal to the increase in web thickness. Increase of weight of Bethlehem beams and girders is secured by increase of both web thickness and depth of beam. In angles the increase is made by increasing uniformly the thickness of the two legs. The effect of the spreading of the rolls to secure this additional thickness is to increase the length of the legs, amounting to about 1/16 in. for each 1/16 in. increase in thickness. As most sizes, however, are rolled in finishing grooves, the exact dimensions are generally maintained for different thicknesses. In Z bars the increase is made by increasing uniformly and by equal amounts the thickness of web and both legs. T shapes do not admit of any variation in weight, and are rolled only to fixed dimensions and weights.

Flanges of standard I beams and channels have a uniform slope of 2 in. per ft., or 16-2/3%. Flanges of Bethlehem I and girder beams have a uniform slope of 12-1/2%. On standard I beams and channels small fillets have a radius of 0.6 of the minimum web thickness, and large fillets a radius of the minimum web thickness plus 0.1.

The Section Modulus of the tables is the moment of inertia of the shape divided by the distance of the center of gravity from the top or bottom of the section. It is used to determine the fiber stress per square inch in a beam or other shape, by dividing it into the bending moment expressed in inch-pounds. It may also be used to guide in the selection of a beam, or other shape, required to sustain a girder load, by dividing the bending moment, in inch-pounds, by the allowable fiber stress per square inch, and finding the required shape in the tables. In those shapes which are not symmetrical about the neutral axis there are, for each case, two section moduli; and in the tables the smaller is always given. The fiber stress calculated from it will be the greater stress and would generally be the one sought.



Properties of Standard I Beams

Dimensions are given in inch units

Depth of beam, h	Lb. per ft.	Area of section, A	Width of flange, b	Thickness of web, t	Axis XX: Moment of inertia, I	Axis XX: Radius of gyration, r	Axis XX: Section modulus I/c	Axis YY: Moment of inertia, I′	Axis YY: Radius of gyration, r′	Shearing stress factor *

* Shearing stress factor multiplied by shear at a section (in pounds) gives the maximum shearing unit stress in the web of the beam (in pounds per square inch).

Comparative Tests on standard I beams and Bethlehem special I beams and girder beams, made at the University of Pennsylvania, gave following values of the modulu- of rupture in pounds per square inch as an average of three specimens in each case. The 15-in. beams were 15 ft. in span, the others were 20 ft. in span.

Standard I,	15-in., 42-lb.,	central loading,	S = 42 200
Standard I,	15-in., 42-lb.,	quarter point loading,	S = 34 700
Standard I,	24-in., 80-lb.,	quarter point loading,	S = 33 000
Bethlehem I,	15-in., 38-lb.,	central loading,	S = 46 100
Bethlehem I,	15-in., 38-lb.,	quarter point loading,	S = 37 900
Bethlehem I,	24-in., 72-lb.,	quarter point loading,	S = 34 600
Girder beam,	15-in., 73-lb.,	central loading,	S = 53 900
Girder beam,	15-in., 73-lb.,	quarter point loading,	S = 41 100
Girder beam,	24-in., 120-lb.,	quarter point loading,	S = 34 300
Girder beam,	30-in., 175-lb.,	quarter point loading,	S = 31 000

The modulus of elasticity for the 31 beams tested was nearly constant, its average value being 26 300 000 lb. per sq. in. This value, deduced from the full-size tests, was somewhat less than that obtained from the tensile tests on specimens cut from the flange, web and root of the several beams; this average was 28 700 000.

The Bethlehem Structural Beams are wide-flange I sections rolled by the Grey universal beam mill. Instead of the horizontal grooved rolls of the ordinary beam mill, the Grey mill has both horizontal and vertical rolls, by which the flanges and web of an I-beam shape are each produced by simultaneous combined rolling operations acting at right angles. This method of rolling makes it possible to obtain wider flanges than can be produced by the ordinary beam mill.

The clear distance between the flange fillets or the depth of the flat surface of the web available for connections, is 6.14 in. for the H 8 sections, 7.67 in. for the H 10 sections, 9.21 in. for the H 12 sections, and 11.06 for the H 14 sections.

All columns having the same section number are from the same rolls. Whenever possible it is advisable to confine the selection of column to the same section number.

The section modulus is needed when the sections are to be used as beams, and also when columns are subject to bending.

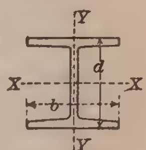

Fig. 69

* Angles marked with an * are listed by some steel makers as special angles, and command a slightly higher price per pound than standard angles, and, in small lots, are not always available to the purchaser.

48. Bars and Plates

Commercial Sizes of Steel Bars commonly kept in stock in warehouses are as follows (values in inches): **Rounds,** 3/16 to 1-1/8 advancing by 16ths; 1/14 to 4-3/4 advancing by 8ths; 5 to 8 advancing by 4ths. **Squares,** 1/4 to 5/8 advancing by 16ths; 3/4 to 2 advancing by 8ths; 2-1/4 to 3-1/2 advancing by 4ths; 4 to 5 advancing by halves. **Flats,** thickness, 3/16 to 1/2 advancing

Square and Round Steel Bars

Approximate rules for computing weights of bars, plates, and prisms: A wrought-iron bar one yard long and one square inch in section weighs 10 lb. Steel is about 2% heavier than wrought iron. Cast iron is about 6% lighter than wrought iron.

Stone is about one-third the weight of wrought iron. Brick is about one-fourth the weight of wrought iron. Timber is about one-twelfth the weight of wrought iron. Concrete is slightly lighter than stone.

49. Bolts and Nuts

Standard Screw Threads

(A. S. M. E.)

National Coarse-thread Series (known also as U. S. Standard)

Recommended for general use in machines and structures.

Upsetting reduces the strength of iron, so that bars having the same diameter at root of thread as that of the bar, invariably break in the screw end, when tested to destruction, without developing the full strength of the bar. It is therefore necessary to make up for this loss in strength by an excess of metal in the upset screw ends over that in the bar. Lengths of upset ends for use with turnbuckles of standard length (6 in. between heads) and with clevises should be 1 in. longer than specified in table, and additions for upset should be correspondingly increased.

Upsets on Square and Round Steel Bars

All dimensions are given in inches

Round bars				Size of upset						Square bars			
Diameter	Area, sq. in.	Addition for upset	Excess of area at root of thread, per cent	Diameter	Length	Diameter at root of thread	Area at root of thread	Number of threads per inch	Weight of one turnbuckle lb.	Side of square	Area, sq. in.	Addition for upset	Excess of area at root of thread, per cent

Standard Cast Washers are proportioned to the bolt as follows: The diameter of the larger or bearing surface is 4 times the diameter of the bolt plus 1/4 in.; the diameter of the smaller surface (against which the bolt head or nut bears) is twice the diameter of the bolt plus 1/4 in.; the thickness is equal to the diameter of the bolt; and the bolt hole is 1/8 in. larger than the diameter of the bolt.

Number of Square Feet of 2-1/2-in. Corrugated Iron, Required to Lay One Square of 100 Sq. Ft. with Side Lap of One Corrugation

Length of sheet, ft.	Length of end lap					
	1 in.	2 in.	3 in.	4 in.	5 in.	6 in.
5	110	112	114	116	118	120
6	110	111	113	115	117	118
7	110	110	112	114	115	117
8	109	110	112	113	114	115
9	109	110	112	113	114	115
10	108	109	110	111	112	113

The United States standard gage, adopted by act of Congress in 1893, is in general use by manufacturers of sheet steel, and the above table gives the thickness and weight of corrugated iron in accordance with that standard. For weight per square, 5% should be added to figures given in the table of weights when sheets are laid with one and one-half laps, and 10% when laid with two laps. If the corrugated iron is to be painted, 2 lb. per sq. ft. should be added to weights given in this table. The 2-1/2-in. corrugation is the one generally employed for roofing and siding, and the regular lengths of sheets are 6, 7, 8, 9, and 10 ft.

The transverse strength of a sheet of corrugated iron is found by the formula $\mathbf{W = 90\,000\ tbd/l}$, in which W = the uniformly distributed load in pounds that will produce failure, t is the thickness of the sheet in inches, b is the width of the sheet in inches, d is the depth of corrugations in inches, and l is the unsupported length of the sheet in inches.

For Roofing and Siding of buildings, corrugated iron is applied directly upon steel purlins or studding by means of clips of hoop iron, placed not more than 12 in. apart,

United States Standard Gage for Sheet Iron and Steel

Adopted as standard by Amer. Rail. Mas. Mechan. Asso. and the Asso. of Amer. Steel Manufacturers

Number of gage	Approximate thickness in fractions of an inch	Approximate thickness in decimal parts of an inch	Approximate thickness in millimeters	Weight per sq. ft. in pounds avoirdupois of iron	Weight per sq. ft. in pounds avoirdupois of steel	Weight per sq. meter in kilograms of steel	Number of gage

This multiplication table is applicable to any kind of material, but it is especially useful in computations on the plates which are used in the beams and members of steel structures for roofs and bridges.

which encircle the purlin or stud. Numbers 20 and 22 are the gages most frequently used for roofs, and numbers 22 and 24 for siding. The sheets are either painted or galvanized, preferably the latter.

A board 1 in. thick, 1 ft. wide, and 1 ft. long contains 1 foot board measure (1.00 ft. b.m.). This table gives feet board measure for lumber of different widths and lengths. For stuff more than 1 in. thick, multiply tabular values by the thickness in inches; thus, for a plank 3 in. thick, 10-1/2 in. wide, and 1 ft. long, $3 \times .875 = 2.625$ ft. b.m. Also, for 418 lin. ft. of such plank, $418 \times 2.625 = 1097$ ft. b.m.

The number of feet board measure in a lot of lumber may also be found by taking 12 times its contents in cubic feet. Or, conversely, the number of cubic feet is one-twelfth of the number of feet board measure.

Boiler Tubes (National Tube Works), of charcoal-iron, lap-welded, come in standard sizes of 1-3/4 in. to 4 in. external diameter, advancing by quarter inches. There is also a 4-1/2-in. size. Above that, beginning at 5 in., they advance by inches to 16 in.

For estimating the effective steam-heating or boiler surface of tubes, the surface in contact with air or gases of combustion (whether internal or external) is to be taken. For heating liquids by steam, superheating steam, or transferring heat from one liquid or gas to another, the mean surface is to be taken. The square feet of surface, S, in a tube of a given L feet long and d inches in diameter may be obtained by the formula $\mathbf{S = 0.2618\ dL}$.

The Standard Pipe Fittings given in the tables were adopted by the American Society of Mechanical Engineers in 1914 after conferences between a committee of that society, a committee representing the manufacturers of pipe fittings, and a committee of the National Association of Master Steam and Hot Water Fitters.

* All 125-lb. flanges have a plain face.

† Sizes 14 in. and larger are to be used with O.D. pipe of the same sizes.

‡ All blind flanges for sizes 12 in. (19 in. O.D.) and larger must be dished, with inside radius equal to the port diameter.

§ This column is the same as column for effective thread (E) in Table I of the American Pipe Thread Standard, published by the American Engineering Standards Committee, except in sizes 1-1/4, 1-1/2, and 2 in.

‖ All weights listed are for flanges faced only, based upon minimum thicknesses given in the table above without allowances for variation. Cast iron is considered to weigh 0.26 lb. per cu. in.

* Drilling templets are in multiples of four, so that fittings may be made to face in any quarter, and bolt holes straddle the center line. For bolts smaller than 1-3/4-in. the bolt holes shall be drilled 1/8 in. larger in diameter than the nominal diameter of the bolt. Holes for bolts 1-3/4 in. and larger shall be drilled 1/4 in. larger than nominal diameter of bolts.

† The bolt holes on cast-iron flanged fittings are not spot-faced for ordinary service. When required, the fittings and flanges in sizes 36 in. and larger can be spot-faced or back-faced, so that standard length bolts can be used.

‡ All 125-lb. cast-iron standard flanges have a plain face.

§ Bolts shall be of steel with standard "Rough Square Heads" and the nuts shall be of steel with standard "Rough Hexagonal" dimensions; all as given in the "Tentative American Standard on Wrench Head Bolts and Nuts, and Wrench Openings." For bolts 1-3/4 in. in diameter and larger, bolt-studs with a nut on each end are recommended. Hexagonal nuts for pipe sizes 1 in. to 48 in. can be conveniently pulled up with open wrenches of minimum design of heads. Hexagonal nuts for pipe sizes 48 in. to 96 in. can be conveniently pulled up with box wrenches.

‖ The stress shown is that of internal pressure only, assumed to act on a circular area equal in diameter to the outside diameter of a ring gasket covering the flange to the inside of bolts.

Standard Pipe Flanges for 250 lb. per sq. in. pressure

Approved by the American Engineering Standards Committee, February, 1928. Sponsor organizations: Heating and Piping Contractors National Association, Manufacturers' Standardization Society of Valve and Fittings Industry, American Society of Mechanical Engineers.

* All 250-lb. cast-iron standard flanges have a 1/16 in. raised face. This raised face is included in the minimum thickness of flange dimensions.

† Sizes 14 in. and larger are to be used with O.D. pipe of the same sizes.

‡ All blind flanges for sizes 10 in. (17-1/2 in. O.D.) and larger must be dished, with inside radius equal to the port diameter.

§ This column is the same as column for effective thread (E) in Table 1 of the American Pipe Thread Standard, published by the American Engineering Standards Committee, except in sizes 1-1/4, 1-1/2 and 2 in.

‖ All weights listed are for flanges faced only, based upon minimum thicknesses given in the table above without allowances for variation. Cast iron is considered to weigh 0.26 lb. per cu. in.

Templets for Drilling 250-lb. Pipe Flanges

All dimensions are given in inches

Nominal pipe size	Diameter of raised face	Diameter of bolt circle	Number of bolts *	Diameter of bolts	Diameter of drilled bolt holes *	Length of bolts † ‡ §	Length of bolt-studs with two nuts §	Total effective area bolt metal	Stress lb. per sq. in. bolt metal ‖	Size of ring gasket

* Drilling templets are in multiples of four, so that fittings may be made to face in any quarter, and bolt holes straddle the center line. For bolts smaller than 1-3/4 in. the bolt holes shall be drilled 1/8 in. larger in diameter than the nominal size of the bolt. Holes for bolts 1-3/4 in. and larger shall be drilled 1/4 in. larger than nominal diameter of bolts.

† The bolt holes on cast iron flanged fittings are not spot-faced for ordinary service. When required, the fittings and flanges in sizes 36 in. and larger can be spot-faced or back-faced, so that standard length bolts can be used.

‡ All 250-lb. cast-iron standard flanges have a 1/16 in. raised face. This raised face is included in the the face to face center to face and the minimum thickness of flange dimensions.

§ Bolts shall be of steel with standard "Rough Square Heads" and the nuts shall be of steel with standard "Rough Hexagonal" dimensions; all as given in the "Tentative American Standard on Wrench Head Bolts and Nuts, and Wrench Openings." For bolts 1-3/4 in. in diameter and larger, bolt-studs with a nut on each end are recommended. Hexagonal nuts for pipe sizes 1 in. to 16 in. can be conveniently pulled up with open wrenches of minimum design of heads. Hexagonal nuts for pipe sizes 18 in. to 48 in. can be conveniently pulled up with box wrenches.

‖ The stress shown is that of internal pressure only assumed to act on a circular area equal in diameter to the outside diameter of the raised face.

Note. For tongue-groove and male-female facings it is recommended that the dimensions given in Table 5 of the Tentative American Standards for Steel Pipe Flanges and Flanged Fittings be used.

52. Ropes and Chains

Weight and Strength of New Manila Rope

Eng. News, Dec. 6, 1890

Diameter, in.	Circumference, in.	Weight of 100 ft. of rope, lb.	Ultimate tensile strength of rope, lb., calculated by the formulas of	
			Hunt	Miller

3-1/4	10	325	72 000	70 000

"Stevedore" Rope is made by lubricating the fibers with plumbago mixed with sufficient tallow to hold it in position, so as to prevent the internal chafing and wear due to the friction between the several strands and the yarns of these strands in passing over sheaves. After running awhile the exterior of the rope becomes compressed and coated with the lubricant. The breaking strength (according to Hunt), in pounds, may be taken at 720 times the square of the circumference in inches; and the weight in pounds per foot at 0.032 times square of circumference in inches.

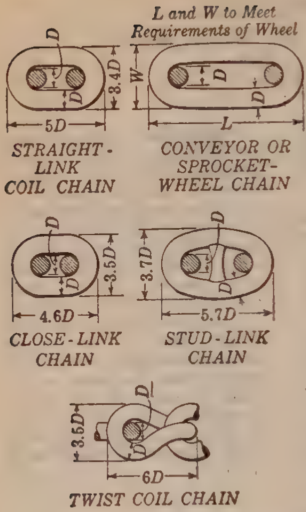

Fig. 69

Chains are classified as follows in the 1927 Standards of the American Society for Testing Materials:

Class AA. Wrought iron chain made from iron free from any admixture of scrap or of steel, for slings, cranes, hoists, steam shovels, and marine uses.

Class A (**Dredge Chain**). Made from puddled iron or a mixture of puddled iron and reworked scrap for the same uses as noted for Class AA.

Class BBB. Wrought iron or open-hearth steel chain for ordinary slings and hoists.

Class BB. Wrought iron or open-hearth steel chain for railroads and construction work.

Class Proof Coil. Wrought iron or open-hearth steel chain for railroad cars, construction, and forestry work.

The tensile strength of chain as determined by tests of lengths not less than 2 ft., cut from the finished chain shall not be less than the values given in the accompanying table. Under a proof load of half the required tensile stength the chain shall not show any defects.

Required Tensile Strength of Chain

1927 Standards of the American Society for Testing Materials. Values are in pounds

Fig. 69 shows the approximate proportions for common types of welded-link chain. Up to about 2 in. diameter chain is made of wrought iron or mild steel with the links forge-welded. Large anchor chains made as steel castings have come into successful use during the past few years, although many large anchor chains are still forged and welded.

53. Wire and Wire Gages

Wire Rope is made of iron, open-hearth steel, crucible steel, or plow steel wires, and accordingly has an ultimate strength per square inch of 45 000 to 100 000 lb. for iron, 50 000 to 130 000 lb. for open-hearth steel, 130 000 to 190 000 lb. for crucible steel, and 190 000 lb. for plow steel.

The wires are either laid parallel to each other as in suspension bridge cables, or twisted together into strands as in smokestack guys or cases where only moderate flexibility is needed. Wire strands consist of 4, 7, 12, 19, or 37 wires, depending on the work intended. The most pliable rope, for hoisting and transmission, contains 19 wires to the strand, while ropes of 12 or 7 wires to the strand are better adapted for use as standing ropes, guys, or rigging.

Wire rope must not be coiled or uncoiled like hemp rope. When mounted on a reel the latter should be so mounted that the rope may be paid off. When furnished in a coil it should be rolled over the ground like a wheel, and the rope run off in that way. All untwisting and kinking must be avoided.

The Flexibility of Wire Rope depends largely on the size of the individual wires used in making up the strands of the rope, the smaller these wires (and consequently the more numerous) the more flexible the rope. For guy wires and other wire ropes not bent around sheaves wire rope is usually made up of 6 strands of 7 wires each. For hoisting rope which is to pass around sheaves the rope in commonest use has 6 strands of 19 wires each. The makeup of two extra flexible hoisting ropes and the approximate ratio of their strength to that of 6 strand 19 wire rope of the same material and the same nominal size is:

8 strand 19 wires	0.87
6 strand 37 wires	0.95

Bending Stresses in Wire Ropes which pass around sheave wheels are sometimes of considerable magnitude. If a straight rod or wire of diameter d is bent into a circle of diameter D there is set up a bending stress S.

$$S = E\,d/D$$

E is the modulus of elasticity of the material.

In a wire rope bent around a sheave each individual wire is bent into the arc of a circle and in the outer fibers of each wire there are set up bending stresses. The extreme fibers on the outer side of each wire must withstand the combined tensile stress due to bending and the direct tensile stress due to the pull on the wire. If a wire breaks, its share of the direct tensile stress is transferred to the remaining wires, but the bending stress in the outer fibers of the other wires is not increased. Owing to the twisting of the strands the length of wire subjected to bending in a wire rope is greater than that of a straight rod bent to the same size circle. This increased length decreases the stiffness of the wire rope and has the same effect on the bending stress as reducing the value of E in the above formula. For 6-strand ropes tests by the American Steel and Wire Co. give for bending stresses in pounds per square inch:

$$S = 12\,000\,000\,D/d$$

D is the diameter in inches of the sheave wheel to the center of the rope, d is the diameter of the largest individual wires in the rope. In determining allowable tensile load on a wire rope passing around a sheave the stress due to bending should be deducted from the allowable working stress for a straight rope, so that no fiber of any wire shall be over-stressed.

The table on p. 703 gives values of tensile load equivalent to bending wire rope around sheaves of various diameters for two common types of hoisting rope. The values are based on tables given in the wire rope handbook of the American Steel & Wire Co., to which reference may be made for a fuller discussion of bending stresses.

Working Loads on Wire Ropes. Since wire ropes are used only in tension the ultimate tensile strength is a good basis for estimating working strength. After making allowance for direct load stresses, bending stresses, and other known stresses the working load should be taken at from 10 to 25% of the estimated breaking load. Factors which tend to reduce the allowable working load are: disastrous results of failure, especially danger to life and limb; high speed of rope travel; difficulty of inspection, length of time between inspection; presence of corroding agencies. A good general rule is to keep the working load below 1/5 of the estimated breaking load. If reasonably effective inspection service is available for a rope the use of a low factor of safety usually means short life of the rope rather than a disastrous failure.

Strength of Wire Rope Fastenings. The best fastenings for a wire rope is a steel socket with the wire rope fastened into it by means of zinc cast around the wire. When such sockets are fitted by skilled workmen under shop conditions their strength may be made equal to the strength of wire rope itself. Made under field conditions the strength of such sockets will hardly be greater than 75% of the values given for wire rope if the work is carefully done, and the strength may fall far below this if the fitting of the rope to sockets is not carefully done. Temporary fastenings for wire rope in the form of clips or clamps are often used. To develop the maximum strength of such a fastening four clips should be used for small-sized ropes and six clips for the larger sizes. The holding power of clips or clamps depends to a large extent on the care with which all the clips are tightened and kept tight. In any event clips or clamps weaken the rope by "crimping" it at the point of application. Carefully made clip or clamp fastenings may develop 60 to 75% of the full strength of a wire rope.

Effect of Bending Wire Ropes Around Sheaves and Drums

(American Steel and Wire Company)

The effect of bending a wire rope around a sheave or drum is equivalent to a pull on the rope of the value (in tons of 2000 lb.) given below.

Diameter of wire rope, in.	Diameter of sheave or drum, in feet

54. Terra Cotta

Terra Cotta is either dense, semi-porous, or porous. The dense tile is very hard and is used for floor arches because of its high crushing strength. Porous and semi-porous terra cotta is made by mixing sawdust with the clay, the sawdust being destroyed during the burning operation. In the porous tile the proportion of sawdust is about 25 to 35%; in the semi-porous tile it is about 20%. Porous terra cotta can be cut with a saw or edge tools, and nails may be easily driven into it.

In a series of tests at Columbia University for the New York Building Department, terra-cotta blocks secured in the open market developed a net crushing stress for dense tile of 5820 lb. per sq. in., and for semi-porous terra-cotta of 3292 lb. per sq. in., the figures in each case being the average results of ten tests. See also p. 645.

16	4	6	600	124	5

Roofing Slate is supplied commercially in thicknesses of 1/8, 3/16, 1/4, increasing by 8ths to 1 in. Slate roofing as laid weighs about 6.5 lb. per sq. ft. for 3/16-in. thickness, and 8.75 lb. for 1/4-in. thickness, the smaller sizes weighing more on account of lap.

Wood Shingles are made from cypress, redwood, cedar, pine, and spruce, this being the order of their durability. Redwood is much less inflammable than any of the others. For hip roofs, 5% should be added to the quantities in the table to allow for cutting, and for irregular roofs with dormer windows 10% should be added.

Common shingles are of random widths, varying from 2 to 14 in. They come in bundles, four of which contain a " thousand " or the equivalent of 1000 shingles 4 in. in width. The above table makes no allowance for waste.

FOUNDATIONS ON LAND

1. Examining the Site

If the nature of the soil has not already been revealed to a considerable depth by excavation it will be necessary to make an examination of the subsoil preparatory to deciding upon the details of the method of constructing the foundation. In the case of simple structures such as dwellings, it is usually sufficient in advance of design and estimates to dig one or two test pits to the depth of the proposed foundation and examine the soil for 4 or 5 ft. below by means of a post auger or iron bar. Generally, however, it is necessary to examine the soil to greater depths, as hereafter described. The examination of the foundation soil other than ledge rock should be extended to a depth at least equal to the width of the largest footing.

Test Pits. The simplest method of examining the soil is by digging open test pits. Test pits, however, are expensive if carried over 10 or 12 ft. in depth, especially if there is much ground-water. The best practice is to sink one or two test pits for each foundation area of a building, dam, or bridge foundation (if the foundation is to be built on land) and then check the remaining area with probings or borings. Test pits have the advantage of permitting the direct examination of the material in place and its degree of compactness and of permitting test loads on the foundation bed.

Soundings can be made in soft soil to a depth of 20 or 30 ft. by driving a rod or sections of gas-pipe with a hammer or maul from a temporary scaffold, the height of which will of course depend upon the length of the rod or of the sections of the pipe. Good judgment is required in interpreting the results of such tests, particularly if the structure is to be a heavy one or a bridge abutment or pier in a stream liable to scour. A layer of compact sand or cemented gravel, which may be scoured away, may be mistaken for a ledge of rock; but the difference can usually be detected by striking the rod or pipe with a hammer, since rock will give a decided rebound, while gravel or sand will not. A boulder may be mistaken for bedrock; but the difference can usually be detected by making one or more additional tests, and accurately noting the depths at which rock is struck. If samples of the soil are desired, use a 2-in. pipe open at the lower end. If much of this kind of work is to be done, it is advisable to fit up a hand piledriving machine, using a block of wood for the dropping weight.

Borings 50 to 100 ft. deep can be made very expeditiously in common soil or clay with a common wood-auger turned by men with levers 3 or 4 ft. long. Or the boring may be made with any one of several earth augers having a spoon-like form for bringing up samples of the soil. An auger will bring up samples sufficient to determine the nature of the soil, but not its compactness, since it will probably be compressed somewhat in being cut off. When the testing must be made through sand or loose soil, it may be necessary to drive down a steel tube to prevent the soil from falling into the hole. The sand may be removed from the inside of this tube with an auger, or with the "sand-pump" used in digging artesian wells.

Water Jet and Wash Borings. In soft soil or clay that can be washed with a stream of water, a hole can be sunk rapidly by driving a pipe, inserting a smaller pipe inside of it, and forcing water down the inside pipe, the débris and water flowing up between the two pipes. See also Sect. 15, Art. 29.

Caution should be used in interpreting the results of wash borings unless suitable undisturbed samples of the soil are secured from the bore hole at intervals. Such samples have generally been secured by driving a pipe into the undisturbed soil beneath the bore hole and withdrawing a sample with this pipe, but this method tends to compact the soil or to alter its condition. No entirely satisfactory means have been developed for securing samples in an undisturbed condition.

Drilling. When the subsoil is composed of various strata, particularly if there are strata of hard soil or rock, it is necessary to use a percussion drill in connection with some form of core drill; and in extreme cases the diamond drill is employed. Great care is needed in interpreting the results of such borings. In using the percussion drill, care must be taken that a stratum sufficiently hard to serve as a foundation is not passed by unnoticed. This can be prevented by taking dry cores at frequent intervals. In using a core drill care must be taken to discriminate between erratic boulders and native ledge rock. See also Sect. 15, Art. 30.

Cost of Explorations. Engineers usually do not spend nearly enough money upon the investigation of foundation conditions in advance of design, making of contracts and actual construction. This often results in (1) change of design after binding estimates of costs or contracts have been entered into, resulting in embarrassing added costs for which funds are not available; (2) lawsuits between the client and contractor; (3) disaster. The engineer usually has difficulty in getting his client or company to provide sufficient funds for such investigation; nevertheless he will be blamed for any added cost resulting from lack of advance explorations. One per cent of the estimated cost of construction may not be excessive to secure in advance sound data upon which to predicate designs, estimates and contracts.

If thorough explorations are not made before preparation of designs, estimates and contracts, the actual cost of foundations may prove to be five or six times as great as the engineer and his client or company were led to expect.

2. Bearing Capacity of Soils

The rational design of the foundation of any structure must be based on an assumed value for the safe bearing power of the underlying soil. For unimportant structures, the bearing power may be estimated from the table (p. 711) after determining the character of the soil by observation. For heavier loads, the soil should be carefully examined and classified, and its bearing power determined by direct test, as explained in Art. 3. If a soil of the same character in some other location has been tested or loaded, and its behavior is already known, this may be used as a guide in selecting a suitable value for the working load.

Ultimate bearing capacity is the maximum load in short tons per square foot which can be applied to a given area of ground without causing sudden or rapid settlement. The **bearing power** of a soil is the load in tons per square foot which may be applied to a given area of ground without causing a total settlement of more than a given amount. The **allowable soil pressure** is the load in tons per square foot which is considered as applied to the ground in designing the foundation, when the maximum assumed loading is transmitted by the structure.

Practical considerations will generally control the allowable soil pressure with reference to the bearing power or ultimate bearing capacity. Inequalities of bearing power cause unequal settlement under a uniform load. Where this would endanger the structure, as in the case of a tall chimney, the foundation pressures should be kept low. In a heavy foundation over a large area, the pressures may be somewhat greater, as unequal settlement would not have such serious results. The pressure per unit of area should be less for a light structure subject to the passage of heavy loads than for a heavy structure subject only to a quiescent load, since the shock and jar of the moving load are far more serious than the heavier quiescent load.

Classification of Soils. In determining the safe bearing power of a soil by comparison with similar soils in other locations, it is essential that the material be accurately classified. As different soils are frequently given the same name in different localities, the following definitions are given to eliminate some of the resulting confusion (see Report of Committee on Soils, Proc. Am. Soc. C. E., Feb., 1921):

Adobe is a sandy, calcareous clay occurring in the southwestern part of the United States.

Alluvium is the finer deposit of earth, sand, gravel and other transported material which has been washed away and deposited by rivers, floods, or other causes on land not permanently submerged.

Bog is a quagmire covered with grass or other plants.

Clay is a general name for cohesive soils, which are firmly coherent, weighty, compact, and hard when dry, but stiff, viscid and ductile when moist, and smooth to the touch. Clay absorbs water greedily but not readily, is diffusible in water and, when mixed, does not readily subside in it. Other characteristics of clay are discussed in Art. 3.

Drift or **glacial drift** is a deposit of loose detrital material, fragments of rocks, boulders, sand, gravel, or clay, or other soil driven together, or a mixture of two or more of these deposits, resting on the surface of the bedrock.

Gravel consists of small stones or fragments of stone or very small pebbles larger than the particles of sand, but often mixed with them.

Grit consists of angular, rough, hard particles of sand or gravel in a loose form.

Gumbo is a dark-colored, very sticky, highly plastic clay, occurring abundantly in the central and southern parts of the United States.

Hardpan is a rather loosely used term, but is most commonly applied to a very dense heterogeneous mass of clay, sand and gravel of glacial drift origin; it is also applied to the hard stratum of consolidated soil underlying the surface soil.

Loam is a mixture of sand and clay with oxide of iron, and generally a varying amount of organic matter.

Peat is a brown soil of vegetable origin consisting of partly decomposed roots and fibers, more or less saturated with water.

Quicksand is a condition rather than a type of soil; it is generally a fine granular soil, supersaturated with water temporarily and when under pressure acting as a fluid.

Sand is any mass or collection of fine particles of stone, particularly of siliceous stone, but not strictly reduced to powder or dust.

Silt is a fluvial sediment of mud or fine soil deposited from running or standing water.

"In classifying soils, it is a decided advantage to the investigator to be able to check his estimates by rubbing samples of the soil between his fingers. As a rule sand feels gritty; silts are velvety, smooth and floury; and clays, which are smooth and plastic, offer considerable resistance to pressure, roll into balls when moist and adhere to the fingers. By the degrees in which they combine these salient characteristics of the primary constituents, soils other than pure sands, silts and clays may be distinguished as sandy loams, silt-loams, sandy clays, clay-loams, silty clay-loams and silty clays." (From "Public Roads," Vol. 6, No. 5, July 1925.)

Allowable Soil Pressure. Where the unit load on the foundation of an unimportant structure is to be assumed, without making any field tests of the soil, the values of allowable soil pressure given in the following table may be used for design. The writer, however, wishes to emphasize that, for any important structure, a thorough examination of the soil is essential, together with suitable loading tests. The accuracy of the allowable pressures given in this table depends entirely upon the proper classification of the soil. Unfortunately soil classification is still too indefinite for accurate use with tabulated allowable soil pressures. In classifying a soil, it should be noted that a dry soil may become wet due to variations in the ground-water level caused by floods, or by leaking or broken water mains.

Allowable Soil Pressure in Short Tons per Square Foot

Kind of material	Minimum	Maximum
1. Quicksand; alluvial soil	0.5	1
2. Soft clay	1	2
3. Wet clay; soft wet sand	1	2
4. Moderately dry sand; fine sand, clean and dry	2	3
5. Clay and sand in alternate layers	2	3
6. Firm and dry loam or clay; hard dry clay or fine sand	2	5
7. Compact coarse sand; stiff gravel	3	6
8. Coarse gravel; stratified stone and clay; rock inferior to best brick masonry	5	8
9. Gravel and sand well cemented	6	10
10. Good hardpan or hard shale	6	10
11. Good hardpan or hard shale unexposed to air, frost or water	10	15
12. Very hard native bedrock	15	25
13. Very hard native bedrock, in thick layers, under caisson	30	

In many cities, the local building codes specify the maximum allowable soil pressures which may be used in foundation design and these must govern.

Rock. Solid rock provides the best foundation. The ultimate compressive strength of good stone, as determined by crushing cubes, is greatly in excess of the strength of stone masonry. The crushing strength of slabs is greater than that of cubes; and the crushing strength of slabs when the pressure is concentrated on only a portion of the upper surface is much greater than for a load uniformly distributed over the entire upper surface. Therefore it is safe to say that any ordinary rock (except the weaker shales) in its native bed will bear any load that can be brought upon it by an artificial structure.

Great care must be taken in limestone areas where the rock may be dissolved by ground waters, and caves may occur close to the surface. In such cases, the engineer should seek advice from persons familiar with local geological conditions and with due appreciation of the engineering problems involved, in deciding on the extent and location of testing or drilling necessary to determine the allowable bearing pressure. Similar precautions should, of course, be taken in mining regions, especially where there is a possibility of abandoned workings extending under the site of the proposed structure.

Even when the engineer has every reason to believe that visible rock is solid ledge, he should sink drill or bore holes from 10 to 30 feet into the rock to verify its soundness.

In preparing a rock foundation, the loose and decayed portions of the rock should be removed, and the surface of the rock should be cut down or stepped if necessary in order to eliminate any possibility of the structure slipping on it. This precaution is particularly important where the rock strata dip at an angle with the horizontal, or the structure is subject to lateral thrust as in a retaining wall or dam.

Engineers who are not experienced geologists should consult a practical geologist concerning the broad foundation problem of important structures such as high dams. The geologist should be able to throw some additional light upon (a) the location of any pre-glacial river beds with relation to ledge rock; (b) the probable dip of the rock at various points; (c) the probable tightness of the reservoir banks; (d) probability of sulfur or other gases being encountered in the excavation.

3. Foundations on Soft Ground

Sand and Gravel. These soils may vary from coarse gravel to fine sand or a mixture of various sizes and proportions of sand and gravel. Coarse gravel when of sufficient thickness forms one of the firmest and best foundations, whereas fine sand when saturated with water is practically a liquid. Sand when dry, or wet sand when prevented from spreading laterally, forms one of the best beds for a foundation. Porous, sandy soils are, as a rule, unaffected by water that is not in motion, but are easily removed by running water, as with water seeping under a dam; in the former case they present no difficulty, but in the latter they require extreme care in the hands of the designer and constructor. Sand and gravel are but little affected by frost unless the water table is near the ground surface. Compact sands and gravels have the advantage of being only slightly compressed under load, this compression occurring when the load is first applied and not being extended over a period of time as with clay soils. Loose gravels and sands may have high ultimate bearing capacity but are compressed under load, causing settlement.

Compact sand or gravel, in beds of considerable thickness and protected against flowing water, and from lateral flow of the sand under pressure, may be loaded with 4 to 10 tons per sq. ft. This statement is given with a warning against the use of such high unit pressures without most thorough study and verification by test loads. Examples of loads on sand and gravel foundations are given below.

	Load, tons per sq. ft.	
Cincinnati, Suspension Bridge:		
Coarse gravel, 12 feet below water.........	4	Disregarding friction on sides of pier.
Brooklyn Bridge, Manhattan pier:		
2 ft. of sand (artificial cushion to reduce injurious vibration) over bedrock, 44 ft. below river bed.	6-3/4	Sand confined within a cup excavated in rock.
Chicago:		
Sand and gravel about 15 ft. below surface.	2 to 2-1/2	
Berlin:		
Sandy soil..................................	2 to 2-1/2	
Washington Monument:		
Gravel.....................................	5.25 to 6	

Vibrations may cause settlement of sand foundations. The same foundation which will sustain 2 tons per sq. ft. static load without any measurable settlement may settle irregularly several inches if the same pressure is exerted by machinery producing violent vibrations. One-half the allowable static pressure is suggested for machinery foundations and two-thirds for railroad bridge and retaining wall foundations.

Clay Soils. The Committee on Soils of the American Society of Civil Engineers (Proc., March, 1922) defines clay as follows: "Clay is an adventitious mixture of inert materials such as sand and a complex compound possessing colloidal properties such as silicates of aluminum, iron, the alkalies and the alkaline soils. Some clays are not wholly colloidal but may resemble a mass of mineral particles partly covered with a colloidal substance. An excessive proportion of sand will produce a sandy clay, and if the colloidol substance is in excess the clay is plastic."

Clay soils vary from slate or shale, which generally will safely support most masonry loads, to a soft wet clay which will squeeze out in every direction when a moderately heavy pressure is brought upon it. Some shale though hard when first exposed becomes soft when exposed to air or water. Whether or not this will occur can usually be determined by observations of short duration and by immersion in water. Foundations on clay should be placed at such depths as to be unaffected by the weather, since clay, at even considerable depths, will gain and lose an appreciable amount of water as the seasons change. The bearing capacity of clay soils can be very much improved by preventing the penetration of water. The drainage of clays is usually a difficult matter and sometimes impossible. The writer has, however, noted in the Province of Ontario clays containing holes or natural pipes which carry water readily and where drainage would be helpful. If the foundation is laid upon wet and undrained clay, care must be taken that excavations made in the immediate vicinity do not allow the clay under pressure to escape by oozing away from under the structure. When the clay occurs in strata which dip toward the excavation, great care is necessary to prevent flow of the soil. There are few foundation problems more difficult than those in which a heavy foundation is placed upon wet or moist layers of clay dipping toward the lower ground. One must consider the possibility of the added pressure causing the upper foundation layers of clay to slide upon the lower ones. A heavy structure built upon moist or wet clay (Fig. 1) might cause, first, the failure of the retaining wall and, second, disaster to the main structure. It also requires an abnormally heavy retaining wall to withstand a wet clay bank. Even a masonry wall with base equal to its height may not suffice.

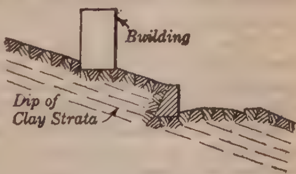

Fig. 1

When coarse sand or gravel is mixed with the clay, its supporting capacity is greatly increased, being greater in proportion as the quantity of these materials is greater. When they are present to such an extent that the clay is just sufficient to bind them together, the combination will bear nearly as heavy loads as the softer rocks. The bearing capacity of soft clays may be increased by the use of "sand piles" (Art. 5).

A proper understanding of the action of clay under load requires a knowledge of its physical properties. Considerable research has been carried out on this subject in recent years. Many investigators have claimed that the properties of clay can be traced to the presence of colloidal substances in the clay. Although the theory of colloids has not been fully developed, perhaps engineers may get some light upon the action of soils, particularly clays, by trying to understand the chemist's idea of "colloidal properties."

A Colloid is a "substance of gelatinous nature, permeable by crystalloid solutions, diffusing not at all or very slowly through animal or vegetable membranes" (Webster's New International Dictionary). A colloidal solution is regarded as a suspension of very fine particles in some liquid. The particles are so small that their total superficial area is very large compared with their mass. There is no sharply defined limit to the size of colloidal particles, but it is generally assumed that particles which are smaller in average diameter than one micron (.001 mm.) are colloidal. A colloidal solution differs from a true solution in that the particles are much larger, though there is no definite line of distinction between the two—a true solution containing particles under 0.001 micron in diameter.

Many of the properties of clay have been explained by assuming the presence of colloidal substances. However, it seems to be quite impossible, with present knowledge, to be certain of the substances to which clays owe their chief characteristics. Many of the properties of clays are closely connected with the colloidal matter present, such matter being in the form of a film of colloidal gel surrounding particles which are of a non-colloidal or a colloidally inert nature. The particular kind and quantity of gelatinous matter present, the size and shape of the grains of non-colloidal material, and the relative proportions of large and small grains are important factors in determining the various physical properties of clays, particularly their binding power, compressive strength, tensile strength and air shrinkage. (For discussion of colloids, see report of Committee on Soils, Proc. Am. Soc. C. E., March, 1922; May, 1925.)

The Physical Characteristics of Clay which are most important in relation to its use as a foundation material are swelling and shrinking with change of water content, compressibility, plasticity, and the relation of these to compressive strength.

(1) Clay will absorb large quantities of water, by direct contact or indirectly from the atmosphere. The amount of water that can be absorbed is apparently controlled by the amount of colloids present in the clay. As the water is absorbed, the clay expands; and if the wet clay is allowed to dry out it will shrink to a smaller volume, and eventually cracks will develop throughout the mass. A clay soil which is likely to have a variable water content may therefore be undesirable as a foundation material.

(2) When a wet clay is subjected to pressure, it is compressed. If the loading is continued for a considerable length of time some of the water in the clay may be forced out and a settlement may occur. If the load is released soon after being applied there will be a "rebound," but this will not be equal to the original compression. The rate of settlement under constant load depends on the rate at which the water can be squeezed out, and this in turn depends on the permeability of the soil. A heavily loaded, impermeable clay may require years to develop its full compressibility, whereas in a more permeable clay the water will be squeezed out more quickly, resulting in a more rapid rate of settlement.

Experiments with mixtures of sand and mica seem to show characteristics under load very similar to clay. It is known that some clays contain a considerable amount of finely divided mica, or similar flat-grained particles, and their presence may have material bearing upon the compressibility of such clays. (See "Compressibility of Sand-Mica Mixtures" by G. Gilboy, Proc. Am. Soc. C. E., Feb., 1928, p. 555.)

(3) An important characteristic of clay is its plasticity, which is supposed to be closely related to the colloidal content. The plasticity increases with the water content. A clay bed which appears hard and sound when examined in a dry state may become highly plastic when saturated with water.

(4) The compressive strength of a clay is closely related to its water content and plasticity. For moderate loads, the clay may undergo elastic deformation, with a "rebound" after the load is released. The limit to which such loading can be applied will be reduced as the water content (and consequently the plasticity) is increased. For a given degree of saturation, this limit will depend on the character of the clay, and apparently is related to the amount of colloids present.

For an exhaustive study of clay soils, see articles by Charles Terzaghi, Eng. News-Rec., Vol. 95, pp. 742, 796, 832, 874, 912, 987, 1026, 1064.

Settlement of Loads on Soft Foundations. Any structure built on a soft foundation will settle. The length of time over which settlement occurs will depend on the nature of the soil. This settlement is in no way serious, provided it is fairly uniform in amount over the entire area of the foundation and is not excessive. The total settlement may be kept within reasonable limits by using moderate unit-pressures in design of the footings, as suggested in the table of Art. 2. It is of vital importance to keep the settlement uniform. This requires careful estimates of the loads that will come upon the footings, and proper proportioning of the footing areas in order to maintain uniform unit-pressure on the soil under all footings. (See Arts. 6 and 7.) If the soil is not uniform under different portions of the structure, particular care will be required in order to secure a reasonably uniform settlement of all parts of the foundation.

In a large flat-slab concrete building upon gravel (column spacing 20 ft. on centers) the writer has observed a difference in settlement in adjacent footings of more than 1 in. without cracks obvious to the eye. If the footings are independent of each other, and one footing settles more than an adjacent one, the floors of the structure will tend to bend as shown in Fig. 2, with maximum bending moments somewhere between the edges of the column and the quarter points. The bending in the floor caused by the direct loads on the floor will produce maximum bending moments at the column and at the middle of the span, with practically no bending at the quarter points. If the floor is adequately designed to carry its dead and live loads, it should also be able to sustain the bending stresses caused by a moderate amount of inequality of settlement of the adjacent footings.

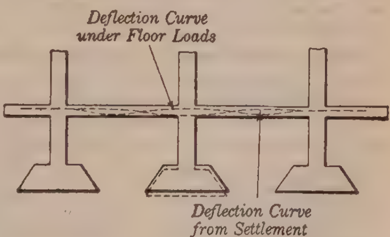

Fig. 2

The question as to whether unequal settlement will be injurious to the structure can be determined only by examination and study of its structural design. It may not be feasible to secure absolute equality of settlement but it should be closely approximated. Special methods may be adopted in the design of the foundations and of the structure itself in order to prevent unequal settlement from causing serious injury to the structure. (See Article by Charles Terzaghi, Trans. Am. Soc. C. E., Vol. 93, p. 270.)

At times uniform pressure upon separate footings based upon assumed dead and live loads is attainable but the bearing "capacity" of the soil is so radically variable that approximate uniform settlement can be obtained only by exhaustive study. Attention is also called to the fact that theoretical live loads and actual ones vary. Certain bays may be heavily loaded at the times others are without live load. The foregoing discussion indicates the wisdom of using conservative "safe bearing capacities" of soils and of studying the subject with more than usual care.

The trained eye may more accurately determine the safe bearing capacity of the soil than the probable settlement under load. Test loads are important for both, particularly the latter; but even test loads over a limited area may be deceptive.

In computing the total load upon a footing, the weight of the backfilled earth should be considered (Fig. 4).

Relation of Settlement to Area of Foundation. For a given soil, the settlement produced by the weight of the structure will not be the same if the footings are spread over a large area as for smaller footings, even if the unit loading on the soil is the same in each case. This is due to the fact that, in soils possessing cohesion, the load of the footing is transmitted to the subsoil both by direct pressure on the loaded area and by friction and shearing stresses into the adjacent soil surrounding the loaded area, and the influence of these shearing forces relative to the direct pressure becomes less as the area increases. Moreover, as shown below, the pressure under the footing is not uniform, and the maximum unit pressure under a large footing is greater than under a smaller area for the same average pressure, causing greater elastic deflection under the larger area. Although no precise formula can be given to describe this feature, it is known that the settlement under a given unit load increases somewhat in proportion to the square root of the loaded area, for soils possessing cohesion. If the soil has little or no cohesive strength the settlement is practically independent of the loaded area.

Relation of Settlement to Depth below Surface. The capacity of a soil to support a load increases with the depth below the surface, probably because the material is more compact due to the weight of covering material that has been removed from it. In general, the settlement produced by a given unit load decreases with the depth. The influence of the depth upon the settlement is less for cohesive soils than for soils without cohesion.

Lateral Flow of Plastic Soils. If the supporting soil possesses considerable plasticity it is liable to be pushed out laterally from under the loaded area. Fig. 3 shows that with such a soil the settlement will be due to two causes: (1) The settlement from aa to a_1a_1 is due to the bulging out or flow of the underlying material, from the straight line ab to the curved line acb; (2) The settlement from a_1a_1 to a_2a_2 is due to direct compression of the soil under the loaded area. The lateral flow may be prevented in whole or in part by driving steel sheet piling around the foundation area. It may also be prevented by the weight of the material surrounding the foundation area. If the footing is placed at some depth below the surface, lateral flow cannot take place without lifting the overlying material surrounding the footing. (See Article by Charles Terzaghi, Trans. Am. Soc. C. E., Vol. 93, 280.)

If the soil contains beds of fine sand, settlement may also be caused by the removal of the sand by flowing water. In New York City one of the large buildings settled because of the pumping of fine sand from an artesian well

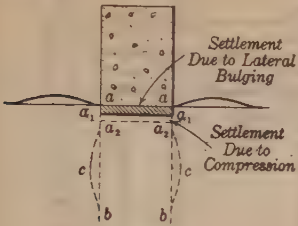

Fig. 3

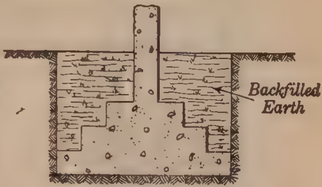

Fig. 4

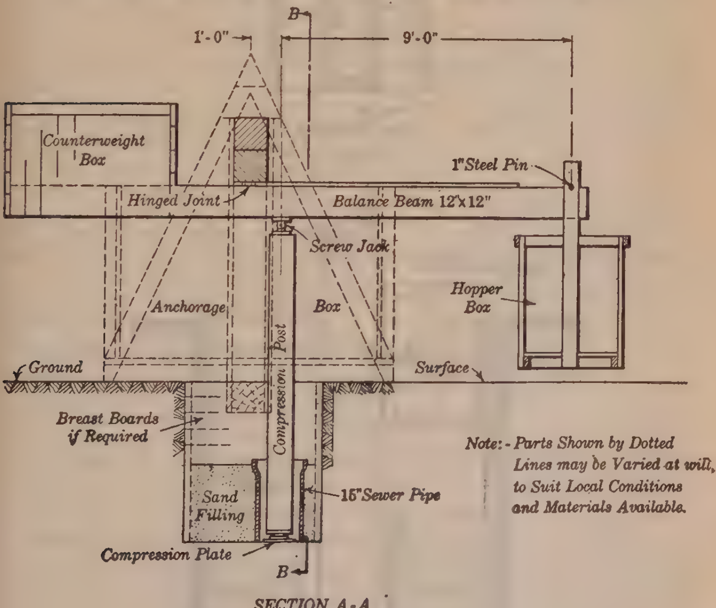
on the site in getting water for the boilers of the building. The removal of large volumes of ground-water may cause settlement.

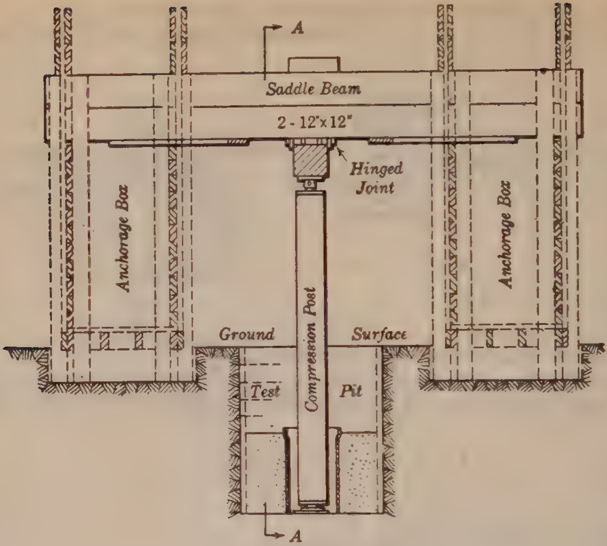
Loading Tests. If the laws of soil mechanics were fully known, it would be possible to compute the bearing power and probable settlement of a soil



SECTION A-A

Fig. 5a

under load. This would require the previous determination of certain physical constants, such as permeability, cohesive strength, etc. The present knowledge of soil mechanics, however, is not sufficient to make such computations of



SECTION B-B

Fig. 5*b*

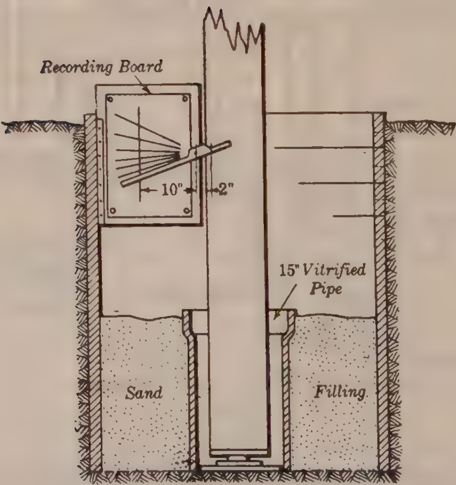


Fig. 5*c*

value. Therefore, the bearing capacity of soils must be determined by test loads. Such tests should be made for the design of important foundations and over as large an area and for as long a period of time as possible.

The Committee on Soils of the American Society of Civil Engineers (Proc. Aug., 1920, p. 907) recommends the apparatus shown in Fig. 5. The load is applied by filling the hopper box with earth or water, this weight being transferred to the compression post by means of the lever or balance beam. The balance beam reacts against the saddle beam which is held down by the anchorage boxes, the latter being also weighted down by earth or other material. The actual compression of the soil is measured by the recording board (Fig. 5-*c*) "on which is tacked a sheet of paper, with a straight-edge of thin material fastened to the board at a certain fixed distance from a nail on the compression post, this nail being against the upper edge of the straight-edge. By drawing a vertical line on the paper, at a definite multiple of the distance between the hinge and nail in the post, a multiplied diagram of the compression for different loads is obtained, reading from a zero line drawn on the paper across the straight-edge before starting the test. At various pressures and compressions, similar lines can be drawn and the time and load noted on the paper. The capacity of this apparatus is limited to about 10 tons, which is sufficient to cover all cases of ordinary soils, and gives a compression diagram exceeding the safe load. In the event that soils of greater or less bearing value are encountered, it would be necessary to substitute other bearing plates under the compression post, of smaller or larger areas."

If this apparatus cannot be made available, use a platform as in Fig. 6, and weight with pig iron or steel, being careful to prevent tipping by wedges marked *w*. If the platform tends to tip adjust the iron or steel and continue loading. In lieu of such apparatus one may get a rough idea of the soil's bearing capacity by standing upon a small block of wood and noting its settlement.

Load tests made by makeshift apparatus, over small areas or of short duration, must be conservatively interpreted.

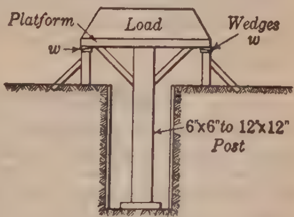

Fig. 6

Existing Structures a Guide. If the designer has not had experience with the terrain under consideration, the opinions of experienced engineers and builders, and perhaps geologists who have had such experience, should be obtained and existing structures and their foundations should be studied. One should at least avoid the obvious mistakes of others. Structures with settlement cracks are very instructive.

Semi-Liquid Soils like mud, silt, alluvium, or quicksand, have little or no supporting power; and with any of these soils it usually is necessary (1) to remove it entirely, or (2) to sink piles, tubes or caissons through it to a solid substratum, or (3) to consolidate the soil by adding earth, sand, stone, etc. The method of performing these operations will be described later. It is impossible to give useful results of the bearing power of soils of this class.

Effect of Frost on Foundation. If foundations are not carried down below the frost line in soils which retain moisture, which is the case with most soils, they may be lifted several inches during the winter. The writer's knowledge of such action is limited to concrete roadways, sidewalks and small building piers. Although the weight of heavy structures may be too great to be "lifted by frost," all foundations should be carried below the frost line.

The following discussion is taken from the paper by Charles Terzaghi, Trans. Am. Soc. C. E., Vol 93, p. 291. The freezing starts at the surface of the ground and gradually proceeds downward. At the same time the soil freezes to the masonry, the adhesion being practically equal to the shearing strength of the frozen soil. Suppose that at some intermediate state freezing has proceeded from the surface, *s–s*, (Fig. 7), to the level, *aa*, the frozen soil being cemented to the pier along the faces *as*. If the freezing process continues still farther, causing expansion of the soil within the space *aabb*, there are then three possibilities:

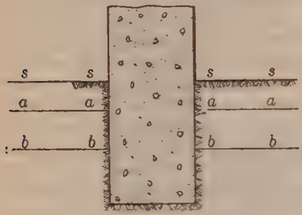

Fig. 7

(1) The ground beneath the freezing layer is only slightly compressible, and the adhesion between the faces, *as*, and the soil may be greater than the weight of the pier. In this case the pier may be lifted bodily as freezing continues, leaving an empty space beneath the pier. (2) The ground is easily compressible, in which case the expanding soil in the area *aabb* may compress the soil below *bb* without raising the pier. Then when the ground thaws, the pier will settle. (3) The ground is slightly compressible but the weight of the pier is greater than the adhesion. In this case the expansion of the soil, *aabb*, will cause a slow upward creep of the soil, *ssaa*, along the outside of the pier.

Reference has already been made to the paper by Charles Terzaghi, "The Science of Foundations," Trans. Am. Soc. C. E., Vol. 93, p. 270. See also Eng. News-Rec., Vol. 100, pp. 520 and 629. The reports of the Committee on Soils of the American Society of Civil Engineers also contain much valuable material; see Proc., Am. Soc. C. E., Aug., 1920, p. 905; Feb., 1921, p. 11; March, 1922, p. 523; May, 1925, p. 884.

4. Distribution of Pressure in Soils

In the design of foundations, it has generally been assumed that the pressure of the soil against the bottom of the footing is uniformly distributed over the foundation area, when the resultant load on the footing coincides with the center of gravity of the loaded area. This assumption is probably closely correct for loads on hard ground or on rock but it has been proved incorrect for compressible soils. It is thought that further study along the lines of Terzaghi and Paaswell will develop information that will enable more correct footing designs. In the interim it is suggested to assume a uniform distribution and conservative soil bearing capacities.

Experiments made by the U. S. Bureau of Public Roads show that the soil unit pressure is a maximum under the center of the load, and is less than the average under the edges. The maximum unit pressure under the center of the load also increases as the bearing area increases for the same average unit loading. Fig. 8 shows the pressure distribution measured at a depth of 54 in. in damp sand, loaded with circular bearing blocks of various sizes and with 5,000 lb. per sq. ft. average load. (See Proc. Am. Soc. C. E., May, 1925, p. 896; also paper by A. T. Goldbeck, Trans. Am. Soc. C. E., Vol. 88, p. 264.)

So far as the computed stresses in an isolated footing are concerned, the assumption of uniform distribution of the load is on the safe side. The stresses computed under this assumption will be greater than if a non-uniform distribution of the loading were adopted. With a footing carrying several concentrated loads, the assumption of uniform distribution may result in lower computed stresses than would result from a non-uniform distribution. For this condition more than ordinary conservatism must be used or it may be best to assume a parabolic distribution of the loading upon the soil, having a maximum value under the center of the footing-area of 1.5 times the average unit-pressure, and zero unit-pressure at the edges of the footing area. (See paper by Charles Terzaghi, Trans. Am. Soc. C. E., Vol. 93, p. 277.)

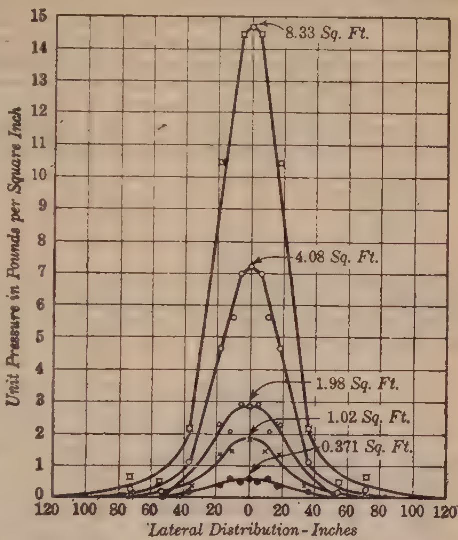

Fig. 8

The distribution of the pressure into the subsoil has been discussed in an interesting and valuable way by George Paaswell (Trans. Am. Soc. C. E., Vol. 85, 1922, p. 1563). He shows that, in any type of foundation material, the pressure from a load is transmitted both downward and outward through the soil, in the manner of a "bulb of pressure." At any given depth below the footing, the load is spread out to an indefinite distance in all directions. However, the limiting zone of pressure influence is contained within a slope of 1 vertical to 2 horizontal from the bottom edge of the footing (see Fig. 9). There is such great variation in the character of soil that further scientific soil classification and further experiments and study are needed before discarding the obvious approximate and probably inaccurate assumption of 1 to 1 distribution. In other words, although the actual distribution may more nearly follow the curve marked "pressure distribution" in Fig. 9, the average pressure based on a 1 : 1 slope limit is recommended. This gives the average distribution shown by the rectangle of "average pressure."

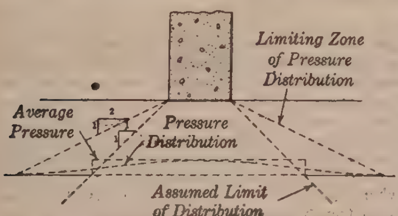

Fig. 9

Soil Pressure on Trench Sheeting. The pressure of earth placed back of a retaining wall is discussed in Sect. 10, Art. 19. An entirely different problem is involved in the calculation of the pressure that must be sustained by trench sheeting. Soils which possess a large amount of cohesion may not require sheeting for trenches of moderate depth, as such material will stand up with vertical faces for some length of time. If sheeting is not used the engineer must watch the banks with care to guard against ultimate sloughing. If the cohesiveness of the soil is not great, sheeting is of course necessary. Experiments have shown that the unit pressure on the sheeting generally reaches a maximum at or slightly above a point half way between the top of the trench and the bottom, and the total pressure in the upper half of the cut is greater than the total pressure in the lower half. Measurements at the Flatbush Avenue subway cut in Brooklyn (1916) showed the following results:

Depth in feet	Actual pressure, lb. per sq. ft.
15	900
45	900
55	300

The actual line of rupture of an earth bank *in situ* is approximately a curved line, roughly described by a quarter-circle meeting the bottom of the cut and tangent to a vertical line distant $d/2$ from the top edge of the cut (Fig. 10). (See Trans. Am. Soc. C. E., Vol. 60, p. 27.) This rule applies to cohesive materials. Therefore no pressure should be exerted upon the trench sheeting from any material lying behind the line of rupture. Experience has shown that when earth or sand is left in place over the top of a timbered excavation, the overlying material arches over, relieving the roof timbering of a large portion of the superimposed load. In a similar way, it is probable that the pressures in a sheeted trench are produced by the arching action of the soil lying between the sheeting and the line of rupture. The material at the bottom of the trench may exert little pressure but it must be prevented from running into the trench, which would destroy the arch action and permit the full pressure of the soil to come upon the lower portion of the sheeting.

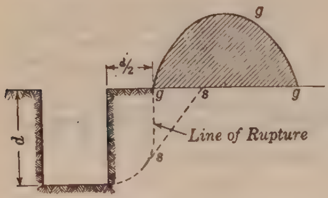

Fig. 10

Experience in subway excavation has shown that the line of break of the soil reaches the surface at a distance from the trench equal to about one-half the depth of the cut. It has been contended that some buildings adjacent to subway work would probably have been safe without underpinning, whereas they have been badly cracked and injured after underpinning because the work incident to underpinning weakened the bank near its critical line. This is possible; but attention is called to the fact that buildings or excavated material adjacent to a trench (*ggg*, Fig. 10) and within a slope *ss*, which varies with different soils and with the extent of soil disturbances as a result of excavating, may exert great pressures upon the sheeting. This is especially true in moist or wet clays where heaving of the bottom may also be caused by such surcharge. (For pressures on trench sheeting, see "Earth and Rock Pressures" by H. G. Moulton, Trans. Am. Inst. Mining and Metallurgical Engineers, Vol. 68, p. 327; also discussion by E. G. Haines and J. C. Meem.)

5. Improvement of Bearing Capacity

Increasing the Depth. The simplest method of increasing the bearing capacity is to dig deeper. Ordinary soils will bear more weight the greater the depth reached, owing to their becoming more condensed from the superincumbent weight. Depth is especially important with clay and saturated fine sands, since it is then less liable to be displaced laterally owing to other excavations in the immediate vicinity, and also because at greater depths the amount of moisture in it will not vary so much. However, occasionally the soil grows more moist as the depth increases beyond a moderate distance, in which case increasing the depth is undesirable. For example, in Chicago the clay grows softer after a depth of about 12 to 14 ft. below the sidewalk is reached.

Drainage. Another simple method is to drain the soil. The water may find its way to the bed of the foundation down the side of the wall, or by percolation through the soil, or through a seam of sand. In most cases the bed can be sufficiently drained by surrounding the building with a tile drain laid a little below the foundation. This drain must have an outlet to permit accumulated water to flow off. In more difficult cases, the expedient is employed of covering the site with a layer of gravel, the thickness depending upon the plasticity of the soil, the gravel serving the double purpose of distributing the concentrated loads of the footings to a larger area of the native soil and of improving the drainage of the bed of the foundation. In extreme cases, it is necessary to enclose the entire site with a puddle-wall to cut off drainage water from a higher area.

Adding Sand. A simple method of improving the bearing capacity of a compressible soil is to spread sand or gravel or broken stone over the bed of the foundation, and pound it into the soil, thus forming a comparatively compact stratum upon which to found the structure. This method is not very effective, since at best the effect of the blow cannot extend very deep, whereas the heavy masses of the masonry make themselves felt at great depths. A more efficient way is to make an excavation a little larger than the proposed structure and cover the bed of the foundation with a layer of sand or gravel. The sand should be deposited in successive layers, each of which should be thoroughly tamped before laying the next. The sand should be moist, so it will pack well. Sand when used in this way possesses the valuable property of assuming a new position of equilibrium and stability should the soil on which it is laid yield at any of its points; and not only does this take place along the base of the sand bed, but also along its edges or sides. The bed of sand or gravel must be thick enough to distribute the pressure on its upper surface over the entire base of the trench.

Short Piles. If the soil is very soft, it can be consolidated to a considerable depth by driving short wood piles, for which purpose many small ones are preferable to fewer but larger ones. It is customary to employ wood piles about 6 ft. long and about 6 in. in diameter, since this size can be driven with a hand maul or by dropping a heavy block of wood with a tackle attached to any simple frame, or by a hand piledriver. They may be driven as close together as necessary, although 2 to 4 ft. in the clear is usually sufficient. Clay is compressible, whereas sand is not; hence this method of consolidating soils is not applicable to sand, and is not very efficient in soils largely composed of sand.

When the piles are driven primarily to compact the soil, it is customary to load them and also the soil between them, by depositing a bed of concrete between and over the heads of the piles. For further discussion of piles, see Articles 9 and 10.

Sand Piles. Experiments show that in compacting the soil by driving wood piles it is better to withdraw them and immediately fill the holes with sand, than to allow the wooden piles to remain. This advantage is independent of the question of the durability of the wood. When the wooden pile is driven, it compresses the soil an amount nearly or quite equal to the volume of the pile, and when the latter is withdrawn this consolidation remains, at least temporarily. If the hole is immediately filled with sand this compression is retained permanently, and the consolidation may be still further increased by ramming in the sand in thin layers, owing to the ability of the latter to transmit pressure laterally. Further, the sand pile will support a greater load than the wooden pile; for, since the sand acts like innumerable small arches reaching from one side of the hole to the other, more of the load is transmitted to the soil on the sides of the hole. To secure the best results, the sand should be fine, sharp, clean, and of uniform size.

Sand piles are not suitable where liable to be disturbed by nearby excavations, which may not be possible to foresee.

6. Loads for Designing Foundations

Spread Foundations are those in which the width is increased until the load can be safely carried, and for soft or compressible soils the loads must be accurately determined. The structures requiring the most careful consideration are buildings, since usually they give a greater unit pressure upon the soil and are more likely to settle unevenly and crack. The load consists of three parts, that of the building itself, the movable loads on the floors, and the part of the load that may be transferred from one part of the foundation to the other by the wind.

Dead Load. The weight of the building is ascertained by calculating the cubical contents of all the various materials in the structure. If the weight is not equally distributed, care must be taken to ascertain the proportion to be carried by each part of the foundation. For example, if one vertical section of the wall is to contain a number of large windows while another will consist entirely of solid masonry, it is evident that the pressure on the foundation under the first section will be less than that under the second. In this connection it must be borne in mind that concentrated pressures are not transmitted, undiminished, through a solid mass of masonry in the line of application, but spread out in successively radiating lines; and hence, if any considerable distance intervenes between the foundation and the point of application of this concentrated load, the pressure will be nearly or quite uniformly distributed over the entire area of the base.

For final design, the actual weights of the various parts of the structure as designed should be computed. Weights of partitions are given in Sect. 12, Art. 6, and weights of fireproof floors in the same section, Art. 5. Weights of different kinds of masonry are given in Sect. 10, Art. 17. For preliminary design the following approximate loads may be assumed: For ordinary dwellings, weight of floor including framing is about 15 lb. per sq. ft. exclusive of plastered ceiling; fireproof floors including framing should be taken at not less than 75 lb. per sq. ft. for large public buildings, and will be from 135 to 200 lb. per sq. ft. for reinforced concrete warehouses.

Live Load. The movable load on the floors depends on the nature of the building. For dwellings it is usually taken at 40 lb. per sq. ft. but is probably considerably less; for office buildings it is usually taken at 50 lb. per sq. ft. For theaters and other public places of congregation the assumed live load is usually 100 lb. per sq. ft. Actually to approximate this load people must be crowded like sardines within a closed area. However, in public places the possibility of rhythmic stamping justifies conservatism. For stores, warehouses and factories, the live load should be from 100 to 400 lb. per sq. ft., according to the purposes for which they are used. (See also Sect. 12, Art. 6.) In designing a structure to be built in a city, the minimum live loads specified in the local building code must be considered.

The above live loads are generally reduced in the designing of columns and foundations. The New York City code states that, in computing the column loads "in buildings more than five stories in height, the live load on the floor next below the top floor may be assumed at 95% of the allowable live load, on the next lower floor 90%, and at each succeeding lower floor at correspondingly decreasing percentages, provided that in no case shall less than 50% of the allowable live loads be assumed" at any one floor. The footing loads are taken the same as the reduced column loads. Wind loads are generally not considered in the design of footings except for high, narrow buildings; and where used, they are usually reduced to 50% of their theoretical value.

On a compressible soil it is very important that the live load assumed as reaching the footings be neither greatly over- nor under-estimated. The dead load can be estimated with accuracy, and as the load on the footings under the walls is mostly dead load, it can be computed readily and with accuracy. But the possible maximum load on the footings of interior columns may be made up largely of live load (as in the case of a warehouse). The assumed live loads upon the interior footings may be a large percentage of the dead load or may even equal or be three times the dead load. Further, the actual live loads on adjacent footings may vary so radically that one must anticipate unequal settlement. This being an operating necessity, one should be conservative in the unit pressures allowed upon compressible soils.

D. E. Moran suggests the following procedure: The footing receiving the largest ratio of live to dead load is proportioned for the combined live and dead loads. The dead plus one-half probable live load on this footing is then divided by the area of the footing, and this value is then divided into the dead plus one-half probable live load of the other footings to get their areas. (See Eng. News, Vol. 69, p. 463; Eng. News-Record, Vol. 85, p. 219.)

Experience in Chicago in founding on a compressible soil shows that the settlements of the columns and walls of eight- and ten-story office buildings, hotels and retail stores are almost exactly the same when designed on the assumption that no live load reaches the footings. In other words, the live load apparently caused no settlement. This, however, is believed to be the exception and not the rule.

Attention must be given to the manner in which the weight of the roof and floors is transferred to the walls. For example, if the floor joists of a warehouse run from back to front, it is evident that the back and front walls alone will carry the weight of the floors and the goods placed upon them, and this will make the pressure upon the foundation under them considerably greater than under the other walls. Again, if a stone-front is to be carried on an arch or on a girder having its bearings on piers at each side of the building, it is manifest that the weight of the whole superincumbent structure, instead of being distributed equally on the foundation under the front, will be concentrated on that part of the foundation immediately under the piers.

7. Unit Pressure on Foundations

Area of Foundation. This is determined by dividing the load on the foundation by the pressure which may safely be brought upon the soil. Then having found the area of foundation, the base of the structure must be extended by footings of masonry, concrete or timber, so as to cover that area and distribute the pressure uniformly over it. The object is not so much to secure an absolutely unyielding base as to secure one that will settle as little as possible, and uniformly. All soils will yield somewhat under the pressure of any building, and even masonry itself is compressed by the weight of the load above it. If the foundation bed is uniform, the pressure per square foot should be the same for all parts of the building, so that the settlement may be uniform. This can be secured only when the axis of the load (a vertical line through the center of gravity of the weight) passes through the center of the area of the foundation. If the axis of pressure does not coincide exactly with the axis of the base, the ground will yield most on the side which is pressed most; and, as the ground yields, the base assumes an inclined position, and carries the lower part of the structure with it, thus producing unsightly cracks, if nothing more.

The coincidence of the axis of pressure with the axis of resistance is of the greatest importance. The principle is almost self-evident, and yet the neglect to observe it is the most frequent cause of failure in the foundations of buildings. Fig. 11 is an ex-

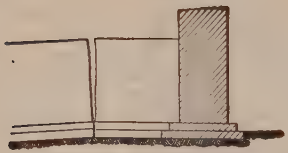

Fig. 11

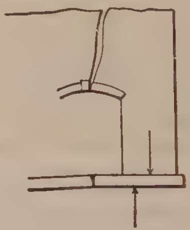

Fig. 12

ample of one way in which this principle is violated. The shaded portion represents a heavily loaded exterior wall, and the unshaded portion a lightly loaded interior wall. The foundations of the two walls are rigidly connected at their intersection. The center of the load is under the shaded section, and the center of the supporting area is at some point farther to the left; consequently the exterior wall is caused to incline outward producing cracks at or near the corners of the building. The two foundations are connected in the belief that an increase of the bearing surface is of advantage; but the true principle is that the coincidence of the axis of pressure with the axis of resistance is of more importance. Fig. 12 is another illustration of the same principle. The foundation is continuous under the opening, and hence the center of the foundation is to the left of the center of pressure; consequently the wall inclines to the right, producing cracks, usually over the opening.

One conclusion to be drawn from the above examples is that the foundation of a wall should never be connected with that of another wall either much heavier or much lighter than itself, as both are equally objectionable. Large brick or concrete chimneys should not be firmly connected to a building. A second conclusion is that the axis of the load should strike a little inside of the center of the area of the base, to make sure that it will not be outside. Any inward inclination of the wall is rendered impossible by the interior walls of the building, the floor beams, etc.; whereas an outward inclination can be counteracted only by the bond of the masonry and by anchors. A slight deviation of the axis of the load outward from the center of the base has a marked effect, and is not easily counteracted by anchors.

The center of the load can be made to fall inside of the center of foundation by extending the footings outward, or by curtailing the foundations on the inside. The latter finds exemplification in the properly constructed foundation of a wall containing a number of openings. For example, in Fig. 13, if the foundation is uniform under the entire front, the center of pressure must be outside of the center of the base; and consequently the two side walls will incline outward, and show cracks over the openings. If the width of the foundation under the openings is decreased, or if this part of the foundation is omitted entirely, the center of pressure will fall inside of the center of base and the walls will tend to incline inward, and hence be stable.

The bearing capacity of the soil may vary greatly over the area of a single building. In a glacial district a small area may contain clay, fine sand, coarse sand and gravel, with mixtures of these, and a bearing capacity varying between 2 and 5 tons. In this event each footing must be especially designed with an effort to keep the settlements uniform.

Where horizontal loads must be considered with vertical loads, as in bearing walls subject to earth or water pressure, the distribution of pressure upon the soil involves the principles contained in Sect. 10, Arts. 19 and 26.

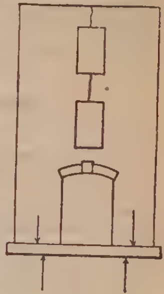

Fig. 13

An Important Principle derived from the above conclusions is the following: Foundations should be so constructed as to compress the ground slightly concave upward, rather than convex upward. On even slightly compressible soils, a small difference in the pressure on the foundation will be sufficient to cause the bed to become convex upward. At Chicago, in buildings founded upon soft clay an omission of 1 to 2 per cent of the weight (by leaving openings) usually causes sufficient convexity to produce unsightly cracks. With very slight differences of pressure on the foundation, it is sufficient to tie the building together by careful bonding, by hoop-iron built in over openings, and by heavy bars built in where one wall joins another.

The art of constructing foundations on a compressible soil was brought to a high degree of development by the architects of Chicago between 1870 and 1890, when the principal buildings were founded upon a bed of soft clay. The special feature of the practice in that city, is what is called " the method of independent piers "; that is, each tier of columns, each pier, and each wall has its own independent foundation, the area of which is proportioned to the load on that part. The interior walls are fastened to the exterior ones by anchors which slide in slots.

The opposite extreme is to rest the structure upon a platform of concrete, timber, or steel beams so strong as to resist local settlement. This method has not always been successful; and when it is successful, it is usually expensive.

The post-office building erected in Chicago in 1875 rested upon a bed of concrete 3 feet thick over the entire site; but the concrete was insufficient to resist the unequal loading, and the building settled so badly and so unevenly that it was necessary to demolish it after it had stood only seventeen years. It is said that some noted buildings in Europe rest upon beds of concrete 8 or 10 feet thick. With a properly designed reinforced-concrete slab, it is thought that similar difficulties may be overcome. In fact, in soft ground this may be the best solution.

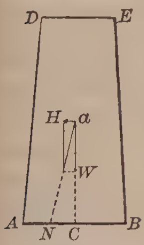

Fig. 14

Effect of Wind. On chimneys and other tall narrow structures the action of wind increases the pressure on one side and decreases it on the other. The maximum horizontal pressure of the wind is usually taken as 40 lb. per sq. ft. on a flat surface perpendicular to the wind (in regions of recorded cyclones, 50 lb. should be used) and on a cylinder at about 25 lb. per sq. ft. of the projection of the surface. In Fig. 14 let $ABED$ represent a vertical section of the chimney; a is a point horizontally opposite the center of the surface exposed to the pressure of the wind and vertically above the center of gravity of the chimney; C is the position of the center of pressure when there is no wind; N is the center when the wind is acting. Let $H =$ the total pressure of the wind against the exposed surface,

W = the weight of the structure above the section considered, L = the distance AB, h = the distance aC, d = the distance NC found from $d = hH/W$. When there is no horizontal force acting, the load on AB is uniform; but when the wind blows from the right, the pressure is greatest near A and decreases towards B. The maximum pressure at A will be that due to the weight of the chimney plus the compression due to overturning moment and the pressure at B will be the compression due to the weight minus the tension due to the overturning moment. For a rectangular base with length L normal to the width b the average pressure is W/Lb, and

$$\textbf{Maximum unit-pressure at A} = \frac{W}{Lb}\left(1 + 6\,\frac{d}{L}\right)$$

$$\textbf{Minimum unit-pressure at B} = \frac{W}{Lb}\left(1 - 6\,\frac{d}{L}\right)$$

These equations show that when $d = NC = 1/6\ L$, the maximum pressure at A is twice the average, and that the pressure at B is zero. This is equivalent to what is known, in the theory of arches, as the principle of the middle-third. It shows that as long as the center of pressure lies in the middle-third, the maximum pressure is not more than twice the average pressure, and that there is no tendency to produce tension at B. The average pressure per unit on AB is supposed to have been adjusted to the safe bearing power of the soil, and if the maximum pressure at A does not exceed the ultimate bearing power, the occasional maximum pressure due to the wind will do no harm; but if this maximum exceeds or is dangerously near the ultimate strength of the soil, the base must be widened. (See Sect. 10, Art. 22.)

8. Footings

The footing is the bottom course or courses of masonry, timber, or steel beams employed to increase the area of the foundation. Whatever the character of the soil, footings should extend beyond the face of the wall (1) to add to the stability of the structure and lessen the danger of the work being thrown out of plumb, and (2) to distribute the weight of the structure over a larger area and thus decrease the settlement due to the compression of the ground. To serve the first purpose, footings must be securely bonded to the body of the wall; and to produce the second effect, they must have sufficient strength to resist the transverse strain to which they are exposed.

In Masonry Footings that part of the footing that projects beyond the portion above it acts as a cantilever beam uniformly loaded by the reaction of the soil or of the footing below. To determine the safe offset, let P equal the pressure in pounds per square foot at the bottom of the footing course under consideration, S = the working tensile stress of the material in pounds per square inch (Sect. 10, Art. 16), o = the greatest possible offset or projection of the footing course in inches, t = thickness of the footing course in inches. Then with sufficient accuracy $\mathbf{o = 7\,t\,\sqrt{S/P}}$. The accompanying table gives values of o/t for three values of **P**. For example, if **P** is 4000 lb. per sq. ft., then for granite $o/t = 1.4$, and hence if t is 12 in. the offset o would be 16.8 inches.

The table is strictly correct only for the lower offset, because flexure of the short projecting cantilevers brings indeterminate concentrations upon the edges of the upper courses. Attention is called to the necessity of keeping the outside vertical joints well within the outer edges of the upper stones. (See Fig. 15). The values in the table are applicable to any of the several projecting courses, provided no stone projects more than half its length beyond

Safe Offset for Masonry Footings

Kind of stone	S in lb. per sq. in.	Ratio of offset to thickness P = 1000	P = 2000	P = 4000
North River bluestone	200	3.1	2.2	1.6
Granite	150	2.7	1.9	1.4
Limestone	125	2.5	1.8	1.2
Sandstone	75	1.9	1.4	1.0
Good quality clay brick, 1 : 3 portland cement mortar age 90 days	25	1.1	0.8	0.6

the end of the next course above. The proper projection for rubble masonry lies somewhere between the values for stone and for concrete. If the rubble consists of large stones well bedded in good strong portland-cement mortar, then the values for this class of masonry will be but little less than those given for stone; but if the rubble consists of small irregular stones laid with portland-cement mortar, the projection should not exceed that given for concrete. Footing courses should not be laid of small stones in either natural-cement or lime mortar.

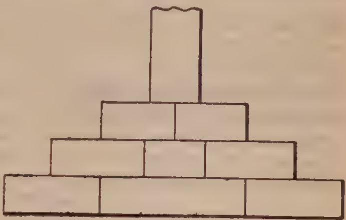

Fig. 15

After the safe length of the offset of the footing has been determined, it should be examined to see if it is safe against failure by shearing. Since footings are subject to heavy loads and consequently to great shearing stress, and since the allowable shearing stress for stone and brick is much less than the crushing strength, the allowable shearing stress should be considered, as given in Sect. 10, Art. 16.

Timber Footings were formerly much used but are not as efficient as reinforced-concrete footings. They should be used only in places where the ground is always wet and where it will not subsequently become dry by the lowering of the ground-water. They may be desirable: (1) for temporary construction; (2) where disintegration of concrete might be probable due to the chemical condition of the water; (3) since timber has much greater flexural strength than masonry, the timber footing requires less thickness, with less depth of excavation and lower cost; (4) where concrete materials are not readily available.

The safe projection, as computed by the formula under masonry footings, is given in the table on page 730. On account of the flexure of the timbers, the pressures on such footings will not be uniformly distributed. The soil pressure under the footing will be greater near the center, so that the stress in the timber may be less than assumed in the table.

Steel-Beam Footings are specially useful in the foundations (particularly of the columns) of a heavy building supported upon a compressive soil. The footing consists of a row of steel beams placed side by side and embedded in rich concrete; on top of this and at right angles to it is a shorter row; and above this, one and sometimes two other rows. The advantages of such footings are that they decrease the area of the foundation and at the same time decrease the weight of the footing and increase the usable space in the cellar.

Safe Offset for Timber Footings

Kind of timber	S in lb. per sq. in.	Ratio of offset to thickness		
		P = 1000	P = 2000	P = 4000
Chestnut	760	6.1	4.3	3.1
Southern yellow pine	1200	7.7	5.4	3.8
Oak	1120	7.4	5.2	3.7
Douglas fir—Coast region	1200	7.7	5.4	3.8
Rocky Mountain	800	6.6	4.6	3.3
Hemlock—West Coast	1040	7.1	5.0	3.6
Eastern	880	6.6	4.6	3.3
Spruce—red, white	880	6.6	4.6	3.3

These values are for best-grade timber. For common grade, use two-thirds of the projections given in the table.

Steel-beam footings were first used in Chicago in 1878. For design of steel beam grillages, see "Foundations of Bridges and Buildings," by Jacoby and Davis, 2nd Ed., p. 510.

Reinforced-Concrete Footings are sometimes more economical than steel-beam footings. See Sect. 11, Art. 40.

Inverted Arches were formerly sometimes built under and between the bases of piers, as shown in Fig. 16. Employed in this way, the arch simply distributes the pressure over a greater area; but it is not well adapted to this use, for it is nearly impossible to prevent the end piers of a series from being pushed outward by the thrust of the arch, and it is generally impossible, with inverted arches, to make the areas of the different parts of the foundation proportional to the load to be supported. The only advantage the inverted arch has over masonry footings is in the shallower foundations obtained. This construction is used now only in reinforced concrete.

Fig. 16

9. Piles and Piledriving

Timber Piles are widely used for foundations, the softer varieties for easy driving and the harder varieties for difficult driving. Piles should never be less than 6 in. and preferably not less than 8 in. in diameter at the small end; never more than 18 in. and preferably not more than 14 in. at the large end. To prevent bruising and splitting in driving, 2 or 3 in. of the head is usually chamfered off. As an additional means of preventing splitting, the head is often hooped with a strong iron band, 2 to 3 in. wide and 1/2 to 1 in. thick. The expense of removing these bands and of replacing the broken ones, and the consequent delays, led to the introduction of a hood or cap for the protection of the head of the pile. The hood consists of a cast-iron block with a tapered recess above and below, the chamfered head of the pile fitting into the lower recess and a cushion piece of hard wood, upon which the hammer falls, fitting into the upper one. The hood preserves the head of the pile, adds to the effectiveness of the blows, and keeps the pile head in place to receive the blows of the hammer.

A further advantage of the pile hood is that it saves the piles by preventing brooming and consequently the necessity of successively cutting off the pile when the driving is hard. Sometimes, particularly in stony ground, the point is protected by an iron shoe.

The shoe may be only two V-shaped loops of bar iron placed over the point, in planes at right angles to each other, and spiked to the piles; or it may be a wrought- or cast-iron socket.

Piles for permanent construction should be cut from sound trees, should be close-grained and solid and free from defects and sharp bends. A line drawn from the center of the butt to the center of the tip should lie within the body of the pile. Piles should be peeled soon after cutting, especially when they are cut in the summer, in order to avoid decay due to fungi and the ravages of worms; if not done at this time, the bark must be removed before driving.

The bearing power of wood piles in soft ground has sometimes been increased by bolting lagging pieces on the sides of the piles. This increases the area of cross-section and also the surface area, thereby providing a greater surface for supporting the pile by friction on the surrounding ground. (See Trans. Am. Soc. C. E., Vol. 54, F, pp. 8, 27.)

Concrete Piles are of two types, precast piles which are molded and cured before driving, and various types of cast-in-place piles. Precast piles are generally required in docks, wharves or piers, where a portion of the pile is left standing above the surface of the firm supporting ground, and is subject to bending stresses from transverse loads on the structure. In certain soils, such as plastic clay, or fine wet sand, the soil may react against the soft concrete of a cast-in-place pile and cause great damage. Under such conditions, the precast pile is preferable. Cast-in-place piles are well suited to compressible soils which have sufficient stability to prevent damage to the soft concrete when it is first placed in the pile form.

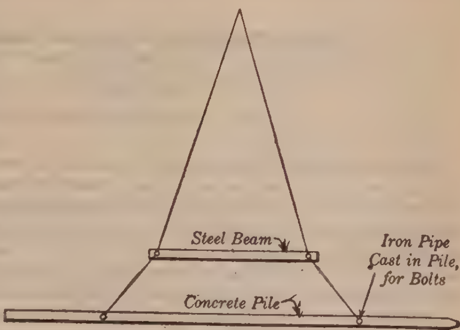

Fig. 17

A Precast Pile is a reinforced-concrete pile which is molded in a form, and after hardening and curing is handled and driven like a timber pile. All precast piles are reinforced, since appreciable bending stresses are developed in the pile during handling. Before the pile is designed, the method of handling to and from the storage piles and piledriver must be determined in order that the pile may be properly reinforced for such handling. Fig. 17 shows a common method of handling. The pile may need extra reinforcement to take care of the resulting bending strains. The head of the pile is often provided with additional reinforcement to withstand the impact of the piledriver. The general design of premolded piles is similar to that of concrete columns. (Sect. 11, Art. 39.) The reinforcing steel is generally made up in units. The foot of the pile is sometimes provided with a metal cap, for protection during driving; more frequently the foot is strengthened by additional reinforcing steel. The foot of the pile is pointed. Several types of precast piles in use are unpatented, though there are a number of patented designs. Precast piles are constructed either with taper or without it. Tapering adds to the cost of manufacture but probably increases the carrying capacity. If the piles are to be driven with a water jet, they are constructed with a hole in the center, either by casting a jet pipe in the pile, or by leaving a tapered wooden core or collapsible form in the center of the pile. The reinforcing steel should have a cover of concrete of at least 3 in. to protect against rusting. Precast piles are generally molded in horizontal forms, but sometimes vertically. They must be thoroughly cured after removal from the forms, and therefore they should be molded at least thirty days before driving. As soon as they are driven, they are ready to receive their load, which is an advantage that they hold over the cast-in-place piles. Fig. 18 shows precast piles used in a pier at Havana, the maximum length of these piles being 85 ft.

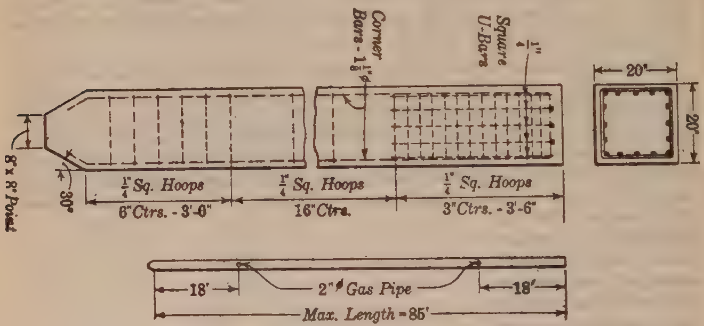

Fig. 18. Concrete Piles in Havana Piers

Cast-in-Place Piles are generally patented. There are a number of types available which may be grouped in two classes: (1) piles in which a permanent shell or protection is allowed to remain in the ground to protect the newly placed and unset concrete from the action of the surrounding soil and water and to prevent distortion of the shaft by natural earth pressure or from the pressure caused by driving adjacent piles; (2) piles in which no permanent protection remains around the concrete after it has been placed in the ground.

The best-known pile of the first class is the **Raymond** pile, which is made by driving a tapering reinforced steel shell into the ground to refusal, by means of a collapsible steel core, withdrawing the core and then filling the shell with concrete. The concrete within the shell may be reinforced or not, as may be desired. Raymond piles are 8 in. in diameter at the point and the diameter increases at the rate of 0.4 in. per ft. The shell is made of sheet steel of a thickness suited to local conditions, and is reinforced by means of steel wire spirally wound on the interior of the shell on a 3-in. pitch and held in place by grooving the shell around the wire. No. 24 gage steel in the shell and No. 3 wire are most commonly used. A " boot " or point of pressed steel is placed on the end of the core or mandrel, and completely encloses the bottom of the shell. Due to the weight of the mandrel, a strongly constructed piledriver is required. The Raymond piles have the following advantages: (1) The form can be inspected before placing the concrete; (2) the bearing power of every pile is tested by the average penetration of the steel core under the final blows of the hammer; (3) the steel core permits driving through very hard material; (4) due to the large taper, the surface friction is increased, which enables them to support under ordinary conditions about twice the working load which would be used on wood piles of the same length.

Simplex and MacArthur piles are of the class which has no permanent shell. The **Simplex** pile is made by driving a cylindrical steel pipe, usually 16 in. in diameter and about 3/4 in. thick, which is sealed at the bottom by a conical cast-iron point. After the pipe has been driven to the desired depth it is filled with concrete and withdrawn, leaving the cast-iron point at the bottom of the concrete shaft. A ram is often used to force each batch of concrete into place against the surrounding soil as the pipe is withdrawn. Occasionally a precast pile is inserted in the pipe after it has been driven, the space around this pile is filled with grout, and the pipe is then withdrawn. The Simplex type of pile is adapted to stiff, non-water-bearing, or clay soils, which are not plastic.

The **MacArthur** or "pedestal pile" is placed by driving a steel pipe through which extends a steel ram. After the pipe has been driven to the required depth, the ram is withdrawn and is then used to force concrete out of the bottom of the pipe to form an enlarged base. When this operation has been completed, the ram is removed, the pipe is filled with concrete, and finally the pipe itself is pulled out, leaving the concrete shaft superimposed on the base. This pile permits taking advantage of the larger bearing power of a lower stratum of soil, by means of the pedestal base. The ramming process also compacts and strengthens the concrete. If for any reason the earth at the base of the pile should present unequal resistance to pressure, the pedestal is likely to assume an eccentric shape.

The Pretest Pile is a patented method, well adapted to underpinning of existing foundations on sand or clay soil. It consists in forcing a hollow steel pipe or tube, 12 in. to 16 in. in diameter, into the soil by means of jacks which react against the bottom of the existing footing. The pipe is in sections of relatively short length, and as the sinking progresses additional sections are added, being joined together by special collars. As the pipe is forced down, the material inside is removed, generally by a water jet and pump. And finally the pipe is filled with concrete.

Precautions for Cast-in-Place Piles. All such piles may be subject to injury to the green concrete by driving forms for adjacent piles, either by displacement of the concrete by the earth pressure, or by vibration of the fresh concrete after the initial set of the cement has taken place. This difficulty may be avoided by providing that no pile shall be driven within a distance of 5 to 10 ft. from a freshly placed pile until 3 to 7 days after the latter has been driven, in order to permit the green concrete in the pile to attain a strength adequate to withstand injury. The construction of cast-in-place piles often requires more careful supervision than is needed for driving precast concrete piles.

Composite Piles have been used successfully in water-bearing ground, to eliminate the great cost of placing extremely long concrete piles. A long wood pile is driven to such a depth that its top is below the permanent water level. A concrete pile is then placed on top of the wood pile, and properly doweled to it, the concrete extending up above the water level to the required elevation. A similar construction is by driving a hollow reinforced-concrete pile over the wood pile, removing the water and mud from the hollow pile and filling the latter with concrete. In clay care should be taken to be sure that the concrete "tops" first built are not shoved off the wooden piles by the displacement of the clay by the piles subsequently driven.

Concrete vs. Wood Piles. Advantages of concrete piles are: (1) Can extend above permanent water level without decaying and can be used in water infested with borers. (2) Are not subject to decay through unforeseen changes in ground-water level. (3) Greater bearing capacity; timber piles are generally restricted to 20 tons, whereas concrete piles (depending upon their size and the soil through which and to which they are driven) may be safely loaded up to 50 tons. (4) As foundation may be above ground-water level, there is a saving in excavation and in foundation masonry, with a possible reduction in time of construction. (5) They can be readily bonded into a grillage or capping of concrete. (6) They may save time where it is necessary to wait for delivery of timber piles. (7) When properly designed they have great flexural strength.

Advantages of wood piles are: (1) Less expensive than concrete. (2) They can be driven more quickly and with lighter equipment and often can be obtained in less time. Precast concrete piles usually require thirty days to cure. (3) Where the length of pile cannot be accurately determined in advance the wood pile has a decided advantage. Five or six feet of additional pile may be purchased at relatively small cost and if necessary cut off with little additional cost.

The Drop-hammer Piledriver consists of a heavy block of iron, called a ram, monkey, or hammer, which is carried by a rope or cable passing over a pulley fixed at the top of an upright frame and allowed to fall freely on the head of the pile. The machine is generally placed upon rollers or on a car or scow. The frame consists of two uprights, called leaders or leads, from 10 to 60 ft. long, placed about 2 ft. apart, which guide the falling weight in its descent. The leaders are either wooden beams or steel channel-beams, usually the former. The hammer is generally a mass of iron weighing from 500 to 7600 lb. (usually about 2000), with grooves in its sides to fit the guides and a staple or pin in the top by which it is raised. The rope employed in raising the hammer is usually wound up by a steam engine placed on the end of the scow or car, opposite the leaders.

The hammer is operated by attaching the rope permanently to the staple in the top of the hammer, and dropping the hammer by setting free the winding drum by the use of a friction clutch. In this way the hammer can be dropped from any height, thus securing a light or heavy blow at pleasure.

Steam-Hammer Piledrivers are of two types—single-acting and double-acting. The **single-acting steam-hammer** consists essentially of a steam cylinder (stroke about 3 ft.) the piston-rod of which carries a striking weight of 3000 to 5000 lb. The steam cylinder is fastened to and between the tops of two I-beams 8 to 10 ft. long, the beams being united at the bottom by a piece of iron in the shape of a frustum of a cone, which has a hole through it. The under side of this connecting piece is cut out so as to fit the top of the pile. The striking weight, which works up and down between the two I-beams as guides, has a cylindrical projection on the bottom which passes through the hole in the piece connecting the feet of the guides and strikes the pile. The steam to operate the hammer is conveyed from the boiler through a flexible tube. In principle the single-acting steam hammer does not differ from the drop-hammer.

The whole mechanism can be raised and lowered by a rope passing over a pulley in the top of the leaders. After a pile has been placed in position for driving, the machine is lowered upon the top of it and entirely let go, the pile being its only support. When steam is admitted below the piston, it rises, carrying the striking weight with it, until it strikes a trip, which cuts off the steam, and the hammer falls. At the end of the down stroke the valves are again automatically reversed, and the stroke repeated. By altering the adjustment of the trip-piece, the length of stroke (and thus the force of the blows) can be increased or diminished. The admission and escape of steam to and from the cylinder can also be controlled directly by the attendant, and the number of blows per minute is increased or diminished by regulating the supply of steam. The machine can give 60 to 80 blows per minute.

The Double-Acting Steam-hammer not only lifts the ram by steam pressure, but also uses the steam to drive the ram down. This action increases the energy of the blow exerted by the hammer, and permits the use of a lighter hammer. The double-acting hammers are made in various sizes, with piston-stroke ranging from 2 1/4 in. to 20 in., and weight of ram varying from 5 1/2 lb. to 2 tons, and running at speeds of from approximately 1500 to 120 strokes per minute. The lighter hammers are used for driving wood sheeting, and the heavier machines can be used to drive all sizes of wood or concrete piles. The advantages of the double-acting over the single-acting or the drop-hammer are: (1) The lighter weight permits use of lighter handling equipment; (2) The shorter hammer lessens the headroom required in the leads. (3) The increased frequency of blows gives easier driving, as the motion of the pile never actually ceases between blows. This also permits driving with less injury to the pile, especially in the case of large concrete piles.

When a pile is to be driven in water, and the top of the pile must be below the water surface, a "follower" is commonly used, especially with the drop-hammer. This is a round stick of hard timber about 20 ft. long, banded with steel at either end, and placed upon the top of the pile as the latter is driven into the water. The need of a follower may be avoided by using a special type of double-acting steam-hammer which is adapted to driving under water. For this purpose, telescopic leads are used, the inner leads being lowered through the water to the bottom, then the pile with the hammer is let down within the lower leads and driving begins. Other advantages of the submarine driving are: shorter piles, full force of blow delivered to the pile, bearing power determined in the same way as for driving at the surface, piles can be driven straight and accurately spaced, no delays on account of high water, divers not required except for inspection and occasional sawing. An important use of submarine driving is for driving piles within a cofferdam. If the cofferdam is pumped out before the piles are driven, the driving of the piles may open up "sand boils," with the result that some of the piles may be lifted up after they are driven. By driving the piles before unwatering the cofferdam, such troubles are avoided. (See article by E. R. Evans in "The Florida Engineer and Contractor," Aug., 1927.)

Another special use for steam hammers is in pulling piles, and particularly steel sheet piling. For this purpose, the hammer is suspended from a derrick in an inverted position and attached to the pile by wire rope. The derrick pulls on the hammer, which transmits this pull to the pile; in addition the blows of the hammer, acting upward, are transmitted to the pile.

The size of hammer required will depend on the weight of the pile, and on the difficulty of driving. The McKiernan–Terry Drill Co. recommends for concrete piles that a double-acting steam hammer be used exerting an energy of not less than 5500 ft-lb. per cubic yard of concrete in the pile, and that in no case should the total energy per blow be less than 6000 ft-lb. Any of the steam hammers may be operated with compressed air.

Cost of Driving Piles. It is impossible to give any general costs that will be applicable to most conditions. The actual cost is a function of locality, varying soil conditions, length of pile, the number of piles that are to be driven and the time in which they are to be driven. In small work the cost of getting the piledriving equipment to and from the job may be the major item of cost, whereas in the larger work this is a negligible factor. The cost of wooden piles varies from 20 to 40 cents per lin. ft., depending upon the locality and the length. The cost of driving varies between

15 and 30 cents per lin. ft., depending upon the above-mentioned conditions. Precast concrete piles cost from $1.50 to $4.00 per lin. ft. in place, including the cost of driving. The reasons for variations are given above for wood piles. In addition, some of the longer precast piles may be as large in cross-section as 24 in. × 24 in. and are therefore expensive. The cost of manufacturing piles having a cross-section of 12 × 12 in. to 16 × 16 in., including all materials, is about $1.00 per lin. ft. The remaining portion of the above cost is the cost of handling and driving, including the rental of plant. Raymond Concrete Pile Company states that the cost of their cast-in-place pile is approximately $2.00 per ft. in place.

In Water-jet Piledriving a jet of water is discharged below the point of the pile, thus loosening the soil and allowing the pile to sink by its own weight or with very light blows of a drop-hammer. The water may be conveyed to the point through a hose or pipe loosely tied or stapled to the pile, or, if the pile is a concrete one, through a hole molded in the center for that purpose. It makes very little difference, either in the rapidity of the sinking or in the accuracy with which the pile preserves its position, whether the nozzle is exactly under the middle of the pile or not. The efficiency of the jet is greatest

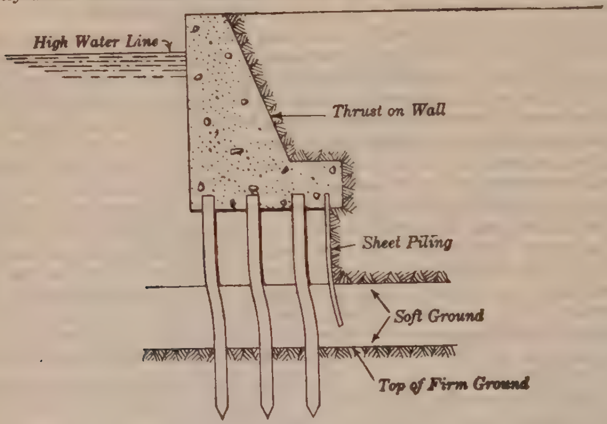

Fig. 19

in clear sand, mud or soft clay; and it is almost useless in gravel, or in sand containing a large percentage of gravel, or in hard clay. The use of the water jet is practically indispensable for driving large piles in sand. The rate of jetting piles in sand that does not contain clay or silt may be much increased by raising the water pressure of the jet, and without decreasing the bearing capacity of the pile.

Lateral Stiffness of Piles. The lack of stiffness of a pile supporting a structure subject to horizontal or lateral pressures is not generally understood. If a pile is placed in a horizontal position, the unsupported projecting ends will bend from 3 in. to 1 ft., depending upon the length unsupported. The same pile in a vertical position will be no stiffer. This may be observed, in the case of piles extending 20 to 40 ft. above firm ground, by a person standing on the pile and working it back and forth by swaying the body. Such piles can often be pushed apart with the hand. When they are framed together with a top platform the piles will work together, but the flexure under lateral or horizontal thrust will be approximately the same.

Attention is also called to the fact that the point of flexure in soft ground may be far below the top surface of the ground (see Fig. 19). The lateral stiffness of vertical piles should be considered only where the piles are driven in firm ground such as coarse sand, and do not extend much above the surface

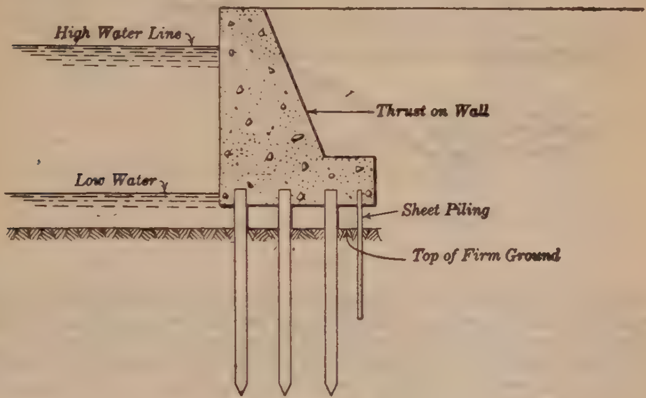

Fig. 20

of this ground, as in Fig. 20. To prevent a retaining wall from moving, as in Fig. 19, either the wall must be carried down into firm ground or riprap, shore anchors or batter piles must be used, as in Fig. 21.

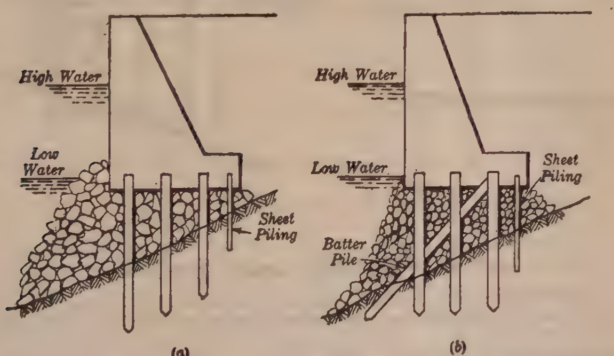

Fig. 21

Attention is called to the fact that a pile bent with a vertical and a batter pile framed as in Fig. 22 is not stable unless there is sufficient length of vertical pile, *a*, below the ground level to act as an anchor through skin friction. If this is not the case a vertical load such as the earth fill above a platform, Fig. 23, must be placed on the vertical piles to give the necessary weight to hold the structure down. This is one reason for the so-called "platform type" of wall shown in Fig. 23.

Attention is also called to the fact that sometimes the stresses at the connection of the vertical and batter pile of Fig. 23 are not given sufficient con-

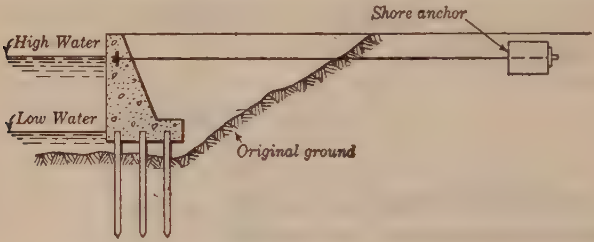

Fig. 21c

sideration. The writer knows of one wall of this type 1000 or more feet in length which gives serious trouble because one bolt was used at this joint instead of three, although the rest of this structure was well designed.

Further comments on the design of such connections are given in Sect. 19, Art. 13. The detail of the joint should be in accordance with the principles of timber detailing given in Sect. 9.

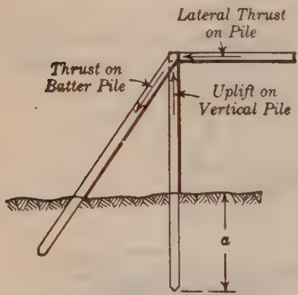

Fig. 22

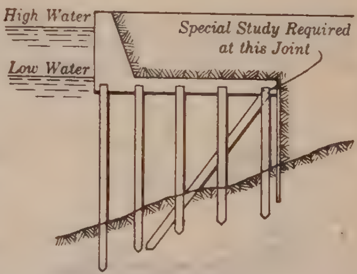

Fig. 23

10. Safe Bearing Loads for Piles

(The following discussion of safe bearing loads for piles is based largely on the paper on "The Science of Foundations" by Charles Terzaghi, published in Trans. Am. Soc. C. E., Vol. 93, p. 288.)

Bearing Capacity of Individual Piles. Piles can be grouped in two general classes: (1) The lower end of the pile rests upon a hard stratum, and the body of the pile receives little or no support from the earth above. In this case the pile must be designed as a column, and its bearing capacity will depend upon its strength as a column rather than upon the bearing capacity of the supporting ground. (2) The pile transmits its load largely by friction along its sides into the adjacent ground. This is the condition most frequently encountered, and to which the following discussion mainly applies.

In attempting to determine the bearing capacity of a pile as based on the effect of the blows of the piledriver, the soil into which the pile is driven must be considered under two general classes:

Class I. In certain materials (particularly in sand, gravel, and permeable artificial fills) the resistances acting while the pile is being driven are practically identical with those acting on the pile under static load. Under such conditions the piledriving formulas can be expected to furnish accurate results. The formulas most commonly in use are the "Engineering News formulas," which are as follows:

For a pile driven with a drop-hammer, $$\mathbf{P} = \frac{2\,\mathbf{Wh}}{\mathbf{s}+1}$$

For a pile driven with a single-acting steam-hammer, $$\mathbf{P} = \frac{2\,\mathbf{Wh}}{\mathbf{s}+0.1}$$

For a pile driven with a double-acting steam-hammer, $$\mathbf{P} = \frac{2\,\mathbf{h}\,(\mathbf{W}+\mathbf{ap})}{\mathbf{s}+0.1}$$

In these, **P** is the safe load in pounds, **W** is the weight of the hammer in pounds, **h** is the free fall of the hammer in feet, **a** is the effective area of the piston in square inches, **p** is the mean effective steam pressure in pounds per square inch, and **s** is the penetration of sinking in inches. **s** is generally measured as the average penetration under the last 5 or 10 blows under a drop-hammer or as the average of the last 20 blows under a steam-hammer, and is assumed to be at an approximately uniform rate; it should not be less than 1 in. under a drop-hammer or 1/4 in. under a steam-hammer, for consistent results with this formula. These formulas are based on an assumed factor of safety of 6.

The Engineering News formula was developed for use with wood piles; it is not as satisfactory for concrete piles, since their great weight influences the amount of penetration under the hammer. For concrete piles, Eytelwein's formula is frequently used:

For a concrete pile driven with a drop-hammer, $$\mathbf{P} = \frac{2\,\mathbf{Wh}}{\mathbf{s}\,(1+\mathbf{W_p}/\mathbf{W})}$$

For a pile driven with a single-acting steam-hammer, $$\mathbf{P} = \frac{2\,\mathbf{Wh}}{\mathbf{s}+0.1\,\mathbf{W_p}/\mathbf{W}}$$

For a pile driven with a double-acting steam-hammer, $$\mathbf{P} = \frac{2\,(\mathbf{W}+\mathbf{aP})}{\mathbf{s}+0.1\,\mathbf{W_p}/\mathbf{W}}$$

in which W_p is weight of pile in pounds and the other symbols are as given above.

For piles sunk with a water jet or those cast in place, the formulas do not apply, except when the pile is tested by driving some time after it has been placed. For these conditions, a static loading test is more satisfactory.

Class II. In very fine-grained silts, soft clays and saturated fine sands and similar fine water-bearing materials, the friction acting on the pile during the driving (hydrodynamic pile friction) is very much less than that which develops after a couple of days' rest (static pile friction), whereas the resistance of the point of the pile under impact (dynamic point resistance) is very much greater than its resistance under static load (static point resistance). The difference between the dynamic and the static resistance is thought to be caused by the squeezing of a certain quantity of water out of the soil beneath the point of the pile in the driving. The water escapes toward the surface through the space between the pile and the ground and forms a film acting as a lubricant, which greatly reduces the friction along the sides of the pile. The force required to squeeze the water rapidly out of the soil beneath the pile is greater than that required to compress the soil slowly. During a period of rest, the film of water is gradually absorbed by the soil and the full static pile friction develops. When piledriving is resumed, both the static friction and the dynamic point resistance must be overcome. For such materials, the pile formulas based on resistance under the hammer give only an approximate indication of the static bearing power of the pile. The safe load is probably far in excess of that given by the formula.

The best way to distinguish whether a material belongs to Class I or Class II is by comparing the penetration per blow immediately before and after a period of rest of at least 24 hours. If these two penetrations are approximately the same, it is evident that the material belongs in the first class, and that the piledriving formulas can be expected to furnish reliable results. If after 24 hours the penetration is two-thirds or less of that previously noted, the material belongs to the second class, and the only satisfactory way to determine the bearing capacity of the pile is by a static load test.

Test Piles. Before designing a structure or ordering piles for a structure, test piles should be driven over the area to determine the total number and requisite lengths. If the behavior of the pile in driving definitely indicates the safe applicability of the foregoing formulas, test loads may be omitted. If in doubt, test several of the piles, framing a platform upon three adjacent piles, and load with pig iron or other heavy material.

In making a driving test there should be little or no bouncing of the hammer. If the hammer bounces to any considerable extent, the fall is too great, or the pile has struck a solid obstacle, or the hammer is too light. Frequently, decreasing the fall will decrease the bouncing and also increase the effectiveness of the blow. If the pile has struck an impenetrable stratum, and the driving is continued, it is probable that there will be a small and continuous apparent penetration due to the mashing of the foot of the pile, which may be followed by a sudden drop of several inches, showing that the pile is broken. Not infrequently when a pile is pulled the bottom is found badly bruised, and sometimes the body of the pile is shattered.

Unless the observed penetration is uniform or at a uniformly decreasing rate, it should not be used in the formulas. If the penetration is practically zero, it is probable that the pile is against an impenetrable stratum and further driving will crush the point. When the penetration has reached as small an amount as 1/4 or 1/2 in. per blow and the hammer rebounds, it is safe to conclude that the limit of safe driving of that pile has been reached. Care should be taken that the test blow is struck on sound wood, otherwise the observed penetration may be much too small and the computed supporting power much too great.

Static Load Tests should be made on piles driven in soils belonging to Class II described above. In such a test, the pile is allowed to stand at least 24 hours after driving. It is then loaded by placing weights on a platform constructed upon a pile (or three piles), keeping the load symmetrical. Careful records of the settlement should be taken, as the load is increased. After a load of 20 or 30 tons per pile has been reached, the pile should be allowed to stand for one or two days, after which the load should be still further increased. The allowable load must not exceed one-half the ultimate load and preferably should not exceed one-third. A record should also be made of the distance which the top of the pile rises after the load is removed, to serve as an indication of the elasticity of the supporting ground.

Bearing Capacity of Pile Foundation. Tests of a few piles in advance of design may be misleading as to the number of piles that are needed. If the piles are driven through soft ground to very hard ground or rock, practically to refusal, it is safe to assume that the bearing capacity of the entire foundation is equal to the safe load as determined by the test pile multiplied by the number of piles used. On the other hand, the test load on a few piles may be misleading when (a) the test pile is driven into spongy ground such as clay which is more disturbed than compacted by the driving of piles, or (b) short piles are driven into ground which is uniform for the full length of pile. These tests may indicate a larger safe bearing capacity than will be true for a group of piles. In the case of (a) the single pile might not disturb the ground sufficiently to injure the skin friction, whereas a group of piles in the same ground may make the skin friction negligible. The writer has observed clay which rose from 5 in. to 5 ft. when piles were driven on 3-ft. centers. The disturbance of the ground was so great that large numbers of the piles first driven rose several feet as a result of subsequent driving of piles in the adjacent area. In the case of (b) the load will be merely transferred from the bottom of the foundation slab to a point a short distance below it, say 25 or 30 ft.; and unless the soil at or near the bottom of the piles is much firmer than the upper layers it is probable that the total resistance of the piles will be materially less than would be indicated by a test load upon a single pile. See discussion of this subject by C. Terzaghi, Trans. Am. Soc. C. E., Vol. 93, p. 290.

11. Deep Foundations*

When an earth or rock stratum suitable for the foundation of a structure can be reached by excavation, by unwatering the site, or by unwatering and subsequent excavation, a number of methods are available, the choice of which must be determined by the particular conditions which may exist.

Open Excavation. When the excavation will be above water level and the ground is cohesive as well as dry, it may be practical to excavate to the desired depth without supporting the sides of the excavation. Usually such excavation does not safely exceed 10 or 15 ft. in depth but, in very dry materials, such pits can be carried down to considerable depths. The foundations for the Nebraska State Capitol, at Lincoln, are concrete piers, belled out at the bottom and resting upon Dakota sandstone, at depths of 25 to 45 ft. below the surface. The excavations for these pits were made through the dry loess and cemented sand and gravel, without sheeting or bracing.

Wood Sheet Piles. The ground below the surface is generally moist, water-bearing, or it may be non-cohesive, and the sides of the excavations must then be supported. For this purpose braced planks are used in ordinary excavations. In all except dry and cohesive ground, the planks are driven vertically and close together, and are called sheet piles. The plank should be 2 to 12 in. thick, depending upon the earth pressures to be resisted and the spacing of the bracing. Except in dry materials the plank should be tongued and grooved, or splined; or Wakefield sheet piling should be used. Tongued-and-grooved sheeting is made or milled so that on one edge of each plank there is a projecting tongue and on the opposite edge a groove into which the tongue of the adjoining plank engages when driven. Splined sheeting has a groove cut into both edges of each plank. A narrow wood strip is then nailed in one of these grooves, projecting beyond the edge of the plank, so that it

* Most of this article was written by Ralph H. Chambers.

will engage with the groove in the adjoining plank in the same manner as tongued-and-grooved sheeting. The connection between the planks is stronger when splined sheeting is used as the splines can be made wider and thicker than the tongues of tongued-and-grooved sheeting. Also, the width of splined sheeting is not reduced by the milling as is the case with tongued-and-grooved sheeting. The tongues and grooves are sometimes made by spiking strips of wood to ordinary dimension lumber.

Wakefield sheeting (Fig. 24) is made of three layers of plank which are nailed or bolted together to form each sheet pile, so that the middle plank projects beyond the edges of the planks on each side of it, thus forming a tongue on one edge of each sheet pile and a groove on the other edge. This form of sheeting is not as strong as solid sheeting of equal total thickness of either of the other two forms mentioned. On the whole splined sheeting is preferable.

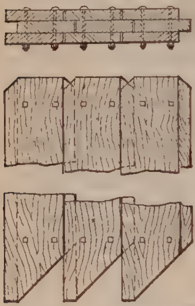

Fig. 24. Wakefield Sheet Pile

Wood sheet piles should be beveled at the bottom on one side and one edge to facilitate driving and to cause each succeeding sheet pile to drive close against the adjacent sheet pile and tight against the bracing. In general, wood sheeting should be driven as the excavation proceeds and the bottom of the sheeting should never at any time be driven more than a few feet below the bottom of the excavation. Wood sheeting may be driven by wooden mauls, the tops of the sheet piles being protected by an iron cap, or may be driven by steam- or air-hammers.

In large open excavations the sheeting is braced by one or more sets of horizontal timber rangers or wales supported by braces which slope down to the bottom of the excavation, or by horizontal braces across the excavation. Rangers, wales or sets are usually spaced 6 or 7 ft. apart vertically at the top, and closer together near the bottom. In deep excavation, especially if there is a large hydrostatic head, it may be necessary to place them almost touching each other near the bottom. Both sheeting and bracing must be proportioned to resist the lateral pressure of the earth and water (see Sect. 10, Art. 19). In pits of small horizontal dimensions, the computed pressure should be modified in accordance with Art. 4. When the ground is very unstable or is water-bearing, hydrostatic pressure should be used as a measure of the forces to be resisted.

The excavation may be made by hand tools, casting the excavated material to the top of the excavation, or to successive benches and so to the top; or the excavation may be loaded into buckets and hoisted by windlass or derrick. Clamshell or orangepeel buckets, operated by derrick or crane, may also be used Water in the excavation must be removed, as will be later described. When the headroom over the site of a foundation is restricted, as under an existing building, the sheeting may be placed horizontally. It is then put in, plank by plank, in horizontal sets, notched and butted together at the corners. After four or five of these sets have been placed, vertical breast pieces and horizontal braces must be placed, if needed.

In comparatively dry ground, excavation by the use of wood sheet piles may be carried to a depth of 60 or 70 ft. When the depth is more than 20 ft., it is usual to make the horizontal dimensions of the first pit (i.e., the upper 20 ft.) sufficient so that, when a depth of 18 to 20 ft. is reached, a second set of sheeting can be started inside the rangers of the upper pit, and thus a pit of smaller dimensions can be carried another 20 ft. If the excavation is to be carried still deeper a third set of sheeting may be driven inside the second set.

In order to obviate the necessity of enlarging the excavation in the upper section, the so-called "poling board" method may be used. Fig. 25 shows the details of this method, which is similar to that already described except that the sheeting, in each successive drive, is only 4 or 5 ft. long and is driven slanting outward, so that the average horizontal dimensions of the pit are kept constant. It is obvious that this method cannot be used in wet or very unstable materials. This method is more generally used when the great depth to which the excavation must be carried has not been anticipated. When the material to be excavated is very soft or is water-bearing to the extent that the ground rises inside the excavation, or is carried up into the excavation by water, wood sheeting cannot be used advantageously and steel sheet piling driven at all times 10 or 15 ft. below the bottom of the pit excavation works better (Art. 12).

Fig. 25. Poling Board Method

Chicago Method. When the material to be excavated is a fairly stiff clay, as that which underlies the city of Chicago, the excavation may be carried down to comparatively great depths by the Chicago Method. In this method the excavation is carried down in a circular well 3 to 8 ft. in diameter in successive sections of 5 ft. each. The sides of these sections are lagged with 6-in. tongued-and-grooved staves, usually maple, 2 or 3 in. thick and 5 ft. long Each 5-ft. section of lagging is held in place by two steel rings 3 × 3/4 in., each ring consisting of two semicircles flanged at the ends and connected by bolts. The rings are usually removed as the wells are filled with concrete but the lagging remains in place. It is usual to bell out the bottoms of these wells to a frustum of a cone, having a bottom diameter twice the diameter of the well. These wells are excavated to rock to depths of 100 ft. or more.

Gow Method. In material similar to the Chicago clay, or even in a softer and more water-bearing material, a method somewhat similar to the Chicago method is sometimes used. In this method a single cylindrical concrete shaft of sufficient cross-sectional area (generally not less than 3 ft. in diameter) is sunk through any unsuitable upper layers of soil to a satisfactory bearing material. The method consists of sinking a series of short steel cylinders varying slightly in their several diameters so as to telescope into one another, the largest size being used as a starter and the others inserted successively through those already in place. When the cylindrical excavation has reached the desired depth the bottom of the opening is enlarged in the form of a truncated cone having a base of sufficient area upon which to impose the entire load carried by the particular column without danger of overloading the underlying soil. Concrete is then deposited in the opening thus prepared so as to fill it entirely, the several steel cylinders being successively withdrawn as the concreting work progresses. The excavation is done by hand tools.

Drop Shafts. Another method which can be used in ground which is not too soft or too water-bearing is similar to the dredging caisson method (Art 14). This consists of the sinking of a "well curb" which is a hollow cylinder built of reinforced concrete or brick, often sheathed on the outside with wood plank, and provided with a steel cutting edge at the bottom and which is constructed to a convenient height at the site and sunk by excavating inside and under it. The well curb will sink of its own weight until the friction of the ground against the sides becomes sufficient to support the weight. The well shaft must then be weighted until the friction is overcome. The intensity of the friction on the sides of the shaft is equivalent to that on dredging caissons (Art. 15). Sometimes the shafts are built in two sections, the lower telescoping within the upper. This method was used in the construction of a mine shaft for the St. Albert Collieries, near Calgary, Alberta, Canada. The object of using two sections of shaft is the reduction of the amount of weight which must be used at one time. It will be obvious, however, that the use of two sections greatly increases the quantity of excavation and concrete.

Well-Drilling Method. Recently, large pipes or steel cylinders have been sunk to rock by well-drilling methods. It is believed that cylinders up to 48 in. in diameter can be sunk by such means. This cannot, however, be done when many boulders are encountered, because the boulders force the drilling apparatus and the cylinders out of line. The method consists of driving a steel pipe into a hole in the ground which is drilled out ahead of the pipe. The drilling is done by a heavy "bit" which is lowered into the pipe on the end of a cable, and is churned up and down in the soil below the pipe. The loosened soil is removed by a "bailing" bucket, which is lowered into the pipe after the bit is hoisted out. After the hole is drilled out for some distance below the end of the pipe, the latter is driven down to the bottom of the hole by a special drop-hammer.

This method was used to construct the foundations for the west ventilating shaft of the Holland Vehicular Tunnel, under the Hudson River, between New York and Jersey City, N. J. Two groups of 24-in. diameter pipes, forty-two in each group, were driven to support two rectangular foundations. The pipes were spaced around the peripheries of the two proposed foundations. The pipes were driven to rock from a temporary platform of piles and timber through 30 ft. of water and 220 ft. of silt. They were cleaned out by pumping water into the pipe, then reinforced with hooped reinforcing bars, concreted to a level about 100 ft. below water level and cut off (from inside the pipes) at that point, 70 ft. below the surface of the silt. Two pneumatic caissons were then sunk until they rested upon the two groups of pipes. Each of these pipes supports a load of 97 tons which may become 126 tons under wind pressure. (See Eng. News-Rec., Vol. 90, p. 242.)

The Well-Point Method consists of sinking a row of pipes vertically into the ground around the excavation, at intervals of a few feet, to a depth somewhat greater than that of the proposed excavation. The lower end of each pipe is provided with a "well-point," which is a metal tube with a solid pointed end, the sides of the tube containing a large number of small holes. After the pipes are placed, their tops are connected with mains leading to the pumps, which draw the ground-water through the well-points and thus lower the ground-water level. The length of time required to lower the water to the desired level will depend upon the degree of fineness of the sand. This method has been much used in the construction of the New York City subways and was used to excavate portions of the Cape Cod Canal by steam shovels working "in the dry."

An example of its use on a large scale is given in the report of the construction of the lock for the inner Harbor Navigation Canal at New Orleans, La. The subsurface materials were alternate strata of clay and quicksand. The unwatering and excavation were accomplished by using driven pipe wells and sheet piling to cut off the quicksand strata. The site (1625 ft. by 650 ft.) was surrounded by an enclosure of wood sheet piles, 48 ft. long, within which the excavation was done by suction dredges. Then a second enclosure of wood sheet piles 55 ft. long was driven within the first enclosure. This second enclosure was 1285 ft. long and 280 ft. wide. Inside the second enclosure a third enclosure of 50-ft.-long Lackawanna (Bethlehem) steel sheet piles was driven. Thirty-two pipe wells were driven just outside of the second sheet pile enclosure and 24 pipe wells were driven outside and close to the innermost enclosure of steel sheet piling. Both of these lines of wells were driven to a level about 40 ft. below original ground surface. Just inside the enclosure of steel sheet piling 126 pipe wells were driven and 5 pipe wells were driven in a line at the middle of the proposed excavation. The two latter groups were driven to a level about 60 ft. below the original ground surface. All pipe wells were 10 in. in diameter. The inner enclosure of sheet piling and the several lines of pipe wells were driven successively as the water level was lowered. The innermost enclosure of steel sheet piling was braced by horizontal timbers running across the enclosure. After months of pumping the water level within the innermost enclosure was lowered to a depth of 47 ft. below the level of the original ground surface and the lock floor was built.

See also account of this method as used at Lynn, Mass., by Charles Terzaghi, Journal Boston Soc. Civ. Eng., Sept., 1927.

Freezing Method. This method, invented by F. H. Poetsch of Prussia, in 1883, has been much used in Germany and has also been used in Belgium and England but has been used in this country in only a few instances. It was used in the construction of the Chapin mine shaft, Iron Mountain, Mich., and it was also used for stopping a leak in a cofferdam for the Detroit–Superior Bridge at Cleveland, Ohio. It is used where the subsurface materials are fine sands and quicksands which cannot be successfully handled by ordinary methods. The extensive installation necessary makes this method expensive, but it is invaluable in very deep shafts and it will doubtless be increasingly used for such shafts. Shafts more than 2000 ft. deep have been so sunk. The site was surrounded by pipes driven to a depth somewhat greater than that of the proposed excavation. These pipes were closed at the bottom and inclosed smaller pipes which were open at the bottom. A brine freezing mixture was pumped through the inside pipes and, issuing from the bottoms of these pipes, rose through the larger driven pipes. After many days' operation of the freezing apparatus, the ground within the circle of driven pipes was frozen and was excavated as solid material.

Costs. The cost per cubic yard of excavation for foundations must include not only the cost of the excavation itself but also the cost of supporting the sides of the excavation, as well as the costs of pumping, an allowance for plant and the cost of operating the plant. By the Chicago method, at present prices and labor rates, the cost per cubic yard, of an excavation 6 or 7 ft. in diameter, including lagging and pumping, as well as overhead charges, will be about $15.00. The cost of excavation by the Gow method will be about the same.

FOUNDATIONS UNDER WATER

12. The Cofferdam Process *

When the site of a proposed foundation is covered by water it must first be unwatered, unless caissons are used, before the excavation work can be done and the foundation built. Recourse may then be had to one of the following methods.

* Most of this article was written by Ralph H. Chambers.

Earth Dikes. When the site is covered by comparatively quiet water 4 or 5 ft. deep, or even more, and the bottom is rock or firm and impervious material, the unwatering can be done by constructing an enclosing dike composed of sand- or clay-filled bags, or a bank consisting of two walls of sand-bags with a clay filling between. The dike should be at least as thick as its height and usually the clay puddle between the sand-bags should be 3 ft. or more in thickness.

Puddle Cofferdams. When the bottom is a stiff impervious material into which sheeting can be driven, puddle cofferdams are built by driving two lines of sheeting to retain the clay puddle (Fig. 26). Temporary timber piles, at intervals of 10 ft. or more, are first driven in two lines around the site. To these, timber wales, *w* and *g*, are bolted above water level. Within these timber rangers are driven an inner and an outer enclosure of wood sheet piling, of one of the forms that have been described. The space between the two lines of sheet piling is filled with clay puddle. The innermost sheet piling and the supporting rangers or wales should be designed to support the clay puddle. The outer ring of sheet piling, which will always have the water pressure against it, may be comparatively thin. The whole cofferdam may depend for its support, after the site has been unwatered, upon the temporary timber piles, or the inside wales may be braced across the site. The puddle in a cofferdam of this form should never be less than 3 ft. thick and should be at least one-half as thick as the height of the cofferdam.

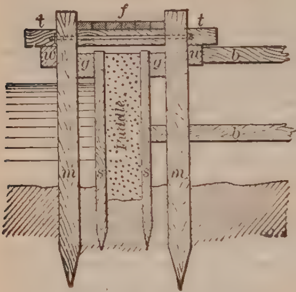

Fig. 26. Puddle-Wall Cofferdams

Steel Sheet-Pile Cofferdams. Except when the bottom is bare rock, it is now usual to build a cofferdam consisting of a single wall of steel sheet piling rather than any of the foregoing types. (Rock-filled cribs with sheet piling, as in Figs. 27 or 28, are used if the width of excavation is too great to be braced.) Even on bare rock if the rock is soft enough to get a toe-hold steel piling may be used. On some of the piers of the Arlington Memorial Bridge at Washington, D. C., steel piling about 50 ft. long was used successfully, the rock being usually a hard gneiss and the overlying material of little value either for a toe-hold or as a water stop (Fig. 29). Such cofferdams consisting of wood sheet piles have already been described. When the water is more than 20 ft. deep or when it is necessary to drive the sheet piles to a depth below the bottom to cut off the water, steel sheet piling is used. There have been many sections of steel sheet piling designed but only a few of these have been found satisfactory and some of the forms formerly used are now obsolete. The sections now used in this country for cofferdams are Bethlehem sections D P 165 and SPE 14, and the Larssen section II which is imported from

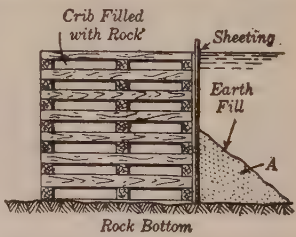

Fig. 27

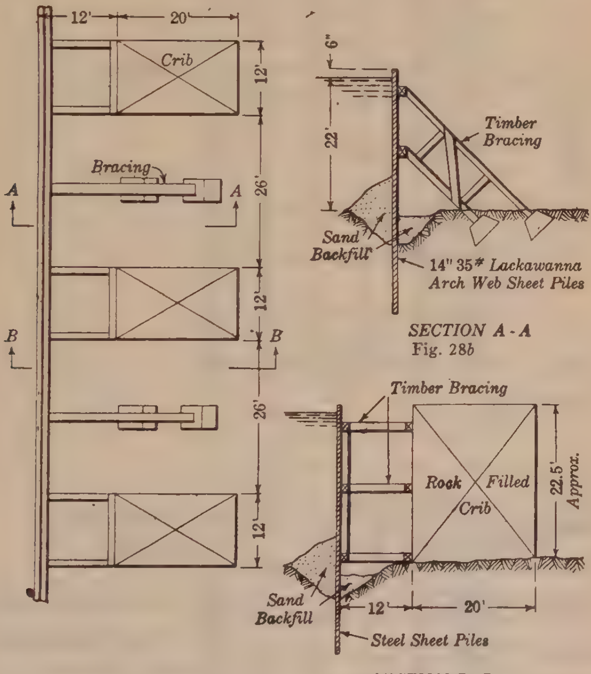
Germany. These sections are shown in Fig. 30. Fig. 30a shows a new section introduced in 1928 by Jones & Laughlin Co., which is also suitable for cofferdams and deep foundations. Steel sheet piling is also often used in excavations for foundations where the site is not covered by water. The advantage in using steel sheet piling is that it can be driven far below the bottom of the excavation, to cut off a flow of water or to retain soft and unstable materials. It can be pulled after the work is done and can be used again. In



SECTION A - A
Fig. 28b

SECTION B - B

Fig. 28a Fig. 28c

Cofferdam Sherman Island Dam

excavations of small dimensions, on land, the sections most used are the Carnegie section M 104 and the Bethlehem sections SPB 12 and SPE 14.

When steel sheet piling is used for a cofferdam, at a site covered by water, a guide frame should first be constructed around which the piling is driven. When the water is not over 12 ft. deep, such a frame may be constructed by driving a line of timber piles around the site and bolting timber wales to these piles, usually outside and inside of the proposed line of sheet piling. When water is deeper it is usual to build a framework which will serve to brace the sheet piling after the cofferdam is pumped out. This frame is built at the site and lowered by weighting into an excavation which has been dredged for it;

or the frame may be built elsewhere, towed to the site and sunk into place. Timber piles are usually driven to hold the bracing frame in place. The wales may be braced across the cofferdam, above the water.

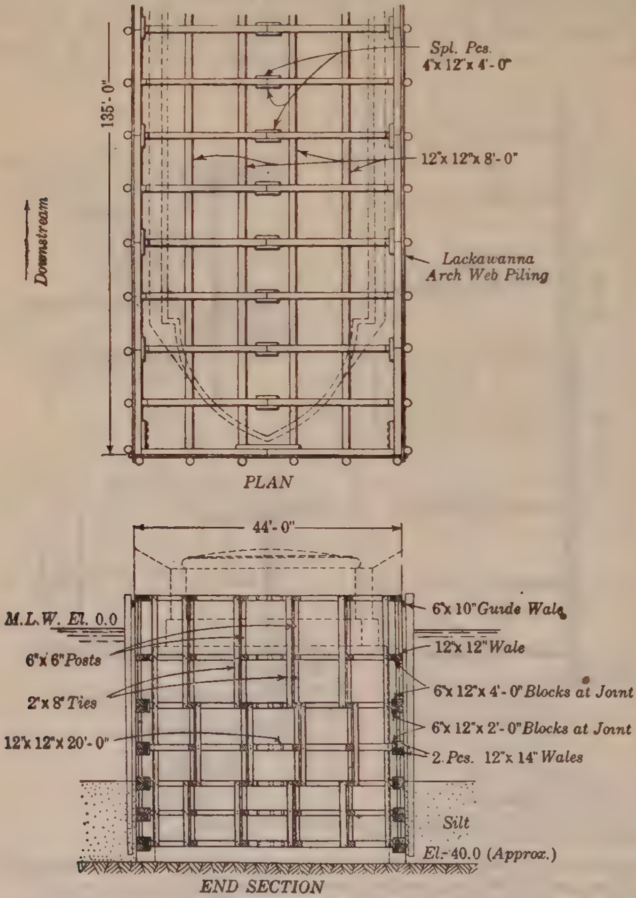


Fig. 29. Cofferdam for Arlington Memorial Bridge Piers

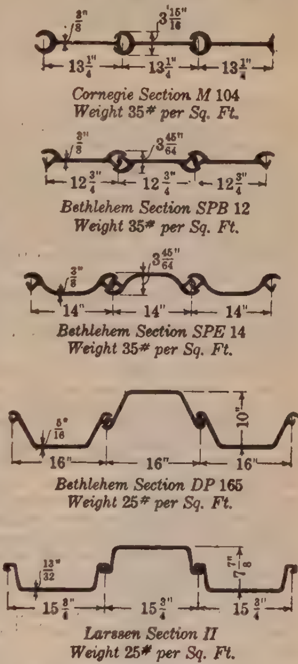
Steel sheet piling is usually driven by a double-acting steam- or air-hammer. Such a hammer, suspended from a derrick or frame, is also used to pull the sheeting by reversing the direction of the blows (Art. 9). Steel sheet piling will usually leak when first driven. After the pumping in the cofferdam has been started, cinders dumped into the water outside of the sheet piling will be drawn into the interlocks of the piling by the currents induced by the pumping and will effectually calk these joints. The vertical spacing of the wales and the size and spacing of the bracing should be determined by computation, considering the water and earth pressure upon the piling and the strength and stiffness of the piling. Excavation inside cofferdams is usually done by clamshell or orangepeel buckets, operated by derrick or crane, or by hand labor and dump buckets.

Steel sheet-pile cofferdams have been built of very large horizontal dimensions and it is common to build such cofferdams to depths of 45 ft. or more.



SECTIONS OF STEEL SHEET PILING

Fig. 30

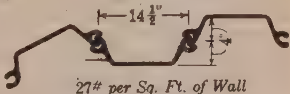


Fig. 30

No discussion of this subject would now be complete without mention of the cofferdams which were used for the construction of the foundations of the western tower of the Hudson River Bridge from 178th Street, New York City, to Fort Lee, New Jersey, which is now in course of construction (1928). Two cofferdams, each about 100 ft. square, were built for this foundation near the west bank of the Hudson River. The rock surface, at the west side of these cofferdams, was about 45 ft. below the water surface. From the west side to the middle of the cofferdams the rock sloped gradually down and from the middle the slope was steep down to the east side where the depth below surface was about 85 ft. The site was first dredged down almost to the level of the rock at the west side. Bracing frames, consisting of 30-in. Bethlehem beam rangers and timber braces and posts, were built in place and sunk. Larssen steel sheet piling, Section II, was then driven around the frame, down to rock. On the west side and about half-way on the north and south sides, a single wall of sheet piling was driven. Along the balance of the north and south sides and along the east side two lines of sheet piling, about 8 ft. apart, were driven and connected together by steel sheet piling at intervals to form pockets. These pockets were dredged out to rock and were filled with concrete, placed under water, up to a level about 50 ft. below the water surface. The balance of the height of the pockets was then filled with sand. These cofferdams were unwatered without difficulty and the excavation to the full depth was made without mishap, except for one accident at the northeast corner of the north cofferdam where the rock berm under the sheet piling failed suddenly, causing the flooding of this cofferdam. The sheet piling at this point was pulled and replaced and the work was successfully completed.

These are, by far, the deepest cofferdams that have been constructed Their successful completion was undoubtedly due to the use of concrete-filled double walls on the deep sides.

The essential feature for the success of any cofferdam is that the stratum into which the sheet piling is driven shall be practically impervious to water for a considerable depth below the proposed bottom of the cofferdam. If there appears to be any doubt of this, the method described in Art. 14 should be adopted.

Driving Sheet Piles. The Bethlehem Steel Company gives the following recommendations for driving steel sheet piling: "A drop-hammer or steam-hammer mounted on a suitable rig are the more common. The latter is preferable as it puts a constant weight on the pile, delivers quick, short blows which keep the pile moving, is less apt to batter the piling tops unless the hammer selected is too light, and as a rule does the most satisfactory work. The use of a cap over the end of the pile while being driven is not essential, but is recommended wherever hard driving is encountered, to save the top of the pile from being battered. Piles which are to be pulled and re-used should invariably be protected in this way, and as occasional piles must usually be withdrawn and re-driven in any work, the use of the driving cap is advisable. Good types of caps, each consisting of a steel casting, slotted to fit the piledriver leads and the top of the pile, and containing a recess in which a wooden block on end can be placed to cushion the blows of the hammer, can be secured from the manufacturers of pile-driving hammers.

"Driving piling under water or below the piledriver leads is facilitated by using a follower, consisting of another pile fitted with projecting plates that conform with the section below. (See also under Double-Acting Steam Hammers, Art. 9.)

"Care should be observed in driving to keep each pile plumb. If the first pile driven is vertical, maintaining a wall straight or in true form and making closures will not prove difficult. Piling that deflects badly or refuses to penetrate on account of serious buried obstructions should never be forced, otherwise it may separate at the interlock and be twisted out of usable shape. Where the decreased movement of the piling under the hammer blows indicates serious obstruction, it is often advisable to continue the line, leaving the obstinate piles projecting above the rest until after excavation, when the obstruction may be removed and all parts of the piling wall properly set.

"The cost of driving steel sheet piling must necessarily depend so much upon the size, length and type of section used, the nature of the soil, the amount of piling used, local labor conditions, the method of driving, etc., that general figures are not practical."

In driving the sheet piles it is usually best to place them around the entire cofferdam and then work them down gradually (this is called "gang driving") rather than to drive each one down as it is placed. The latter method is more liable to result in getting them out of plumb. In this case it is necessary to use tapered piles which have to be specially made, are expensive, and require time to manufacture. In the construction of the cofferdams of the Sherman Island hydroelectric development and in driving the permanent sheet steel piling cutoff, much trouble was found in keeping the piling plumb when each pile was driven down as placed. These piles were driven into sand containing occasional small boulders. In some cases additional sheet piling was driven back of and in contact with the original sheeting because the interlock opened up when the piles encountered boulders.

Reinforced-Concrete Sheet Piles are used where the piles are to form a permanent part of the structure, as in piers and wharves. These are designed as beams to carry the lateral pressure of the material which they support, though they may also carry vertical loads. The thickness is generally 8 in. or more. They may be tongue-and-grooved; or a semicircular groove may be cast in each edge, leaving a cylindrical space where the adjacent pile is driven, this space being later cleaned out and filled with mortar. Combination concrete and steel sheet piles have also been used, in which the steel pile is cut longitudinally along its web, and the two pieces are cast into a concrete pile on opposite edges, leaving the interlocking portions of the steel pile exposed.

Cost. A statement of the cost of construction work, unless all the conditions are taken into account, is likely to be misleading. However, to give some idea of the cost of such work as has been described the following are the approximate labor costs of the cofferdam for the screen well for the Narraganset Electric Light Co. built at Providence, Rhode Island, in 1925:

Driving steel sheet piling, 24 cents per square foot.
Pulling steel sheet piling, 14 cents per square foot.
Timber bracing, placing and removing, $97.00 per M. b. m.
Excavation, $2.00 per cubic yard.
Placing concrete under water, $2.65 per cubic yard.
These costs do not include plant, power, insurance and general overhead expenses.

Miscellaneous Types of Cofferdams. It is sometimes expedient to construct the foundation for a structure upon a base of concrete, deposited under water. To confine this concrete a crib with sheeted sides but open at the top and bottom is sunk at the site, upon a bottom which has previously been dredged out and leveled. Such a method was used for the construction of the river wall of the lock at the Scotia dam, on the Mohawk River near Schenectady, New York, for the New York State Barge Canal. Eight cribs, 26 ft. wide and 44 to 51 ft. long, were sunk in a continuous line upon a previously dredged gravel bottom about 30 ft. below the water surface. Concrete to a depth of 12 ft. was placed in the bottom of these cribs by bottom-dump buckets. After the concrete had set and the sides of the cribs had been connected by divers, the cribs were pumped out and the concrete wall was constructed in the cofferdam.

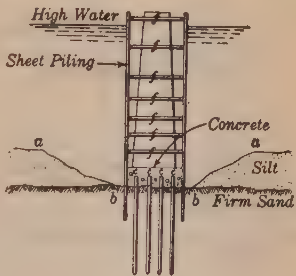

Fig. 31

This method was also successfully used in the construction of three piers in the Niagara River between Buffalo, New York, and Fort Erie, Ontario, Canada. Each of the cribs used was built of timber in skeleton form. The current in the river has a velocity of 6 to 8 miles per hour and it was impossible to tow the cribs to site by ordinary means. Therefore heavy anchors were set in the river about 1500 ft. above the site and each of the cribs was towed to site by a winding drum, mounted upon a barge and pulling against the anchors previously set above the site. After the cribs had been anchored in place and sunk in 16 to 19 ft. of water, steel sheet piling was set around the frame and driven tight into the rock. The joint between the piling and the rock was then calked by concrete in bags, placed by divers. In the quiet water within the sheet piling, concrete was placed through the water to a depth of 8 ft. When this concrete had set the space above was pumped out and the masonry of the piers was completed.

In soft ground the method used is as follows (Fig. 31): (1) Excavate to line *a b b a*. (2) Drive wooden piles and cut off as at *c c c c*. (3) Drive wood or steel sheet piling to form cofferdam. (4) Cap piles with concrete to seal against water coming up through bottom when unwatered. (5) Float in bracing frames and force them into positions *f f f*, by weighting or otherwise. (6) Unwater the cofferdam. (7) Build pier on concrete cap in the dry. (8) Pull sheet piling.

Rock-filled cribs are adapted to either hard or soft bottoms, using wood sheeting if the cribs rest on rock, or wood or steel sheeting if built to act as a water stop upon a soft bottom. Cribs generally should have a width at any point equal to the probable height of the water above the point. These crib coffers may be used for dams or piers and obviously without a sealed bottom.

On rock it may be desirable to fill in an earth cut-off as at *A*, Fig. 27. Fig. 28 shows the cribs used for the cofferdam of Sherman Island dam on the Hudson River.

13. Leakage and Pumping

Leakage. A serious objection to the use of a cofferdam is the difficulty of preventing leakage through or under it. It is nearly impossible to prevent considerable leakage, unless the bottom of the crib rests upon an impervious stratum or the sheet piles are driven into such stratum. Water will find its way through nearly any depth or distance of gravelly or sandy bottom, and seams of sand are very troublesome. Logs or stones under the edge of the dam are also a cause of considerable annoyance. The object of a cofferdam is not to prevent all infiltration, but only to reduce it to the extent that a moderate amount of pumping will keep the water out of the way.

Large leaks in a sand bottom often carry fine particles of soil. Sometimes this water appears clear to the eye, but if a glassful of such water is held up to the light, particles may be seen in it. If particles are being transported,

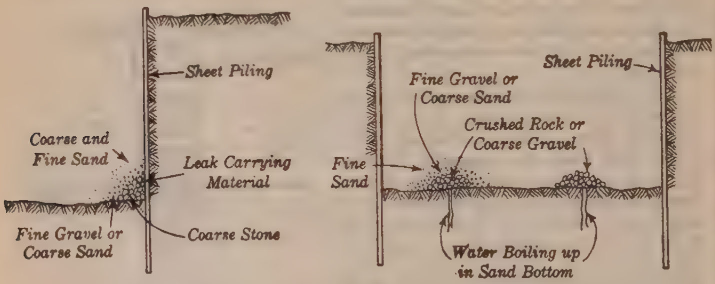

Fig. 32

settlement may take place in the structures outside of and adjacent to the excavation and subsequently it may take place in the foundation which is being built, but to a less degree. The following methods may be used to decrease the flow of water into the cofferdam and to reduce the amount of material that is being carried by the water coming into the bottom of the excavation by reducing its velocity:

(1) Leaks or boils at the bottom of the sheet piling may be prevented from carrying material by checking the velocity of flow, as in Fig. 32.

(2) Similarly, the flow of material carried by water " backing up " in the foundation bottom may often be prevented, as in Fig. 32.

(3) If there are bubbling springs all over the foundation area with sufficient velocity either to carry material or to wash out the cement or mortar of the concrete, cover the whole area with a thin and preferably a porous fabric which will stand the weight of a light layer of stone or gravel (5 to 8 in. thick) and then place the concrete. A sump outside the concrete forms is desirable

to permit the concrete above the first 2 or 3 ft. to be placed in the dry (see Fig. 33).

(4) With steel or wood sheet piling driven through water, leaks in the sheeting may be stopped by depositing, outside of the sheeting, cinders, sawdust, manure, or fine sand. This fine material will be drawn into the joints of the piling and stop a surprisingly large quantity of water.

The method to be employed in removing the water will vary greatly with the amount present, the depth of the excavation, the appliances at hand, etc. If the excavation is shallow and the amount of water small, it can be bailed out; but usually some form of pump must be employed. The pumps generally used for this kind of work are the direct hand-lift foundation-pump, the diaphragm pump, the steam siphon, the pulsometer, and the centrifugal pump.

The Direct Hand-lift Foundation-pump consists of a straight tube at the bottom of which is fixed a common flap valve, and in which works a piston carrying another flap valve. The tube is either a square wooden box or a sheet-iron cylinder, usually the latter, since it is lighter and more durable. The pump is operated by applying the power directly to the upper end of the piston-rod, the pump being held in position by wooden stays or ropes. The only advantage of the wood-box hand-lift pump is that it may be improvised on the job; and the disadvantage for foundation work of all pumps having flap valves is the danger that straw, sticks, mud, etc., will interfere with the action of the valves.

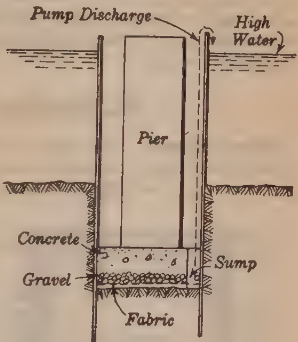

Fig. 33

The Diaphragm Pump is the usual form of hand pump for foundation work. This pump consists of a short cast-iron cylinder having a rubber hose connected to its lower end, and being divided about midway of its height by a flexible horizontal rubber diaphragm. The central portion of the diaphragm is connected to a bent-lever handle, and there is a valve in the center of the rubber disk. The rise and fall of the center of the disk acts as a piston. A pump of this form throws a large amount of water, allows sand and gravel to pass without choking, is not easily clogged by straw, leaves, etc., and is easily unclogged. Various forms of diaphragm pumps are also driven by a gasoline engine and are much superior to the hand pump.

The Steam Siphon is the simplest of all pumps, since it has no movable parts whatever. It consists essentially of a discharge pipe, open at both ends, through the side of which enters a smaller pipe having its end bent up. The lower end of the discharge pipe dips into the water; and the small pipe connects with a steam boiler. The steam, in rushing out of the small pipe, carries with it the air in the upper end of the discharge pipe, thus tending to form a vacuum in the lower end of that pipe; the water then rises in the discharge pipe and is carried out with the steam. The steam siphon is limited practically to lifting water only a few feet; its cheapness and simplicity are recommendations in its favor, and its efficiency is not much less than that of other forms of pumps. One of the advantages of the steam siphon is that frequently it can be improvised on the work from ordinary pipe and fittings. Several forms and sizes are upon the market, ranging in capacity from 5 to 200 gal. per minute, and are much better than one made from pipe. They are usually called jet-pumps by the manufacturers.

The Pulsometer is an improved form of the steam siphon. It may be properly called a steam pump which dispenses with all movable parts except the valves. The height to which it can lift water is practically unlimited, and it is in very common use for pumping out cofferdams.

A Centrifugal Pump must be used when very large quantities of water must be handled. The distance from the water to the pump is limited by the height to which the ordinary pressure of the air will raise the water and is generally not over 18 or 20 ft. vertically; but the height to which a centrifugal pump can lift the water is limited only by the velocity of the outer ends of the revolving blades. Since there are no valves in action while the pump is at work, the centrifugal pump will allow sand and large gravel to pass. Pumps having a 6-in. to 10-in. discharge pipe are the sizes most frequently used in foundation work.

14. Floating Caisson Process *

Open Caissons. This method, which is very old, is still used and, under some conditions, is very reliable and practical. It consists of the sinking of a floating box in which the masonry is built as the box sinks (Fig. 34). The

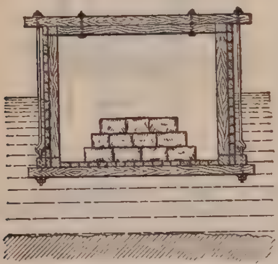

Fig. 34 Open Caisson and Pier

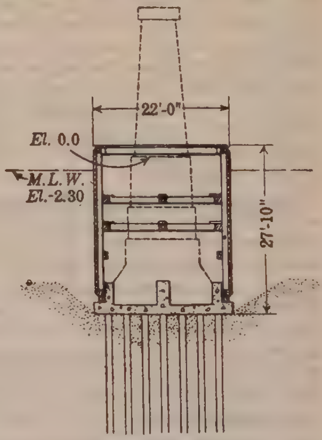

Fig. 35. Pier Caissons, Newark Bay Bridge, C.R.R. of N. J.

sides are then detached, leaving the masonry resting upon the bottom of the box which in turn rests upon a previously prepared foundation. In its modern adaptation the bottom of the box is usually made of reinforced concrete and the sides of braced timber.

The subway and highway bridge over Flushing Creek at Flushing, Long Island, is an example of its use (1927). Two piers, one on each side of the creek, were built for a large bascule span. Each of these piers was 93 ft. wide and 118 ft. long and the bottom of the masonry was placed at an elevation 36 ft. 9 in. below mean high water on a foundation of timber piles which had been previously driven and

* In part by Ralph H. Chambers.

cut off under water. An enclosure of 12-in.-thick wood sheet piles was built around the site, before the piles were driven. The purpose of this sheeting, which was only braced above water level and was never pumped out, was simply to keep out the mud which had previously been dredged down only part way to the level of the top of the proposed pile foundation. After the balance of the mud was dredged out by clamshell bucket and the piles had been driven, which was done by a steam-hammer working under water, the tops of the piles were cut off to an exact level. A comparatively thin wooden floor was built in sections, assembled and connected together within the area enclosed by the sheet piling. To this floor wooden sides were connected and braced. A thick slab of concrete was then placed on the floor, the box formed by the floor and sides sinking as the concrete was placed. This concrete slab or base was reinforced by steel, longitudinally and transversely. Upon the concrete base the concrete and masonry of the pier above were built up as the box sank, until finally it rested upon the pile foundation. The sides of the box were then detached and used again on the second pier.

The same method was used in the construction of a large number of piers for the Central Railway of New Jersey Bridge over Newark Bay, New Jersey (Fig. 35).

15. Dredging through Wells*

Dredging Caissons. When it is necessary to excavate to great depths to obtain a satisfactory foundation, particularly when the site is under water, dredging caissons are used. This method has the advantage that it can be carried to great depths, far below the limit that is possible with pneumatic caissons (Art. 17). A dredging caisson is simply a large box or shaft, built of timber or steel and filled with concrete, or it may be built of reinforced concrete. It is provided with a well, or wells, through which the material below may be dredged. The caisson sinks as the material below is dredged and as the compartments of the caisson are filled with concrete. It may be of the form of a hollow cylinder or may be rectangular in section. In the circular form there is only one central dredging well; in the rectangular form there are usually several wells. The bottom edge of the caisson, called the "cutting edge," is usually V-shaped in section and shod with steel to prevent distortion or damage in sinking. The caisson is built up, as it sinks, and the dimensions are usually such that the weight of the caisson will overcome its buoyancy and the friction of the sides against the surrounding materials, without the use of the additional weight which is usually necessary in sinking drop shafts and many pneumatic caissons.

The friction to be overcome in sinking these caissons is usually of greater intensity than that encountered in sinking pneumatic caissons, as the air escaping from the latter somewhat relieves the friction. This friction may be 400 to 1500 lb. or more per square foot of surface. Probably the average friction encountered is 500 to 700 lb. per sq. ft. Dredging caissons are often provided with jetting pipes, running from the top down to the cutting edge and discharging around it, to relieve the friction. Dynamite sunk down into the bottom at the cutting edge and exploded will often start the movement of a caisson. Another difficulty encountered is the proper guiding of the caisson, particularly when the caisson has a number of dredging wells and when obstacles, such as sunken logs or boulders, are encountered. This

* By Ralph H. Chambers.

method is not as sure and definite as sinking by the pneumatic method, but has been successful in the many years of its use, though only after the surmounting of many difficulties.

This method was used to sink the piers of the Poughkeepsie Bridge, New York, to a depth of 134 ft. below mean high water (Eng. News, Oct. 29, 1887); of the Hawks-

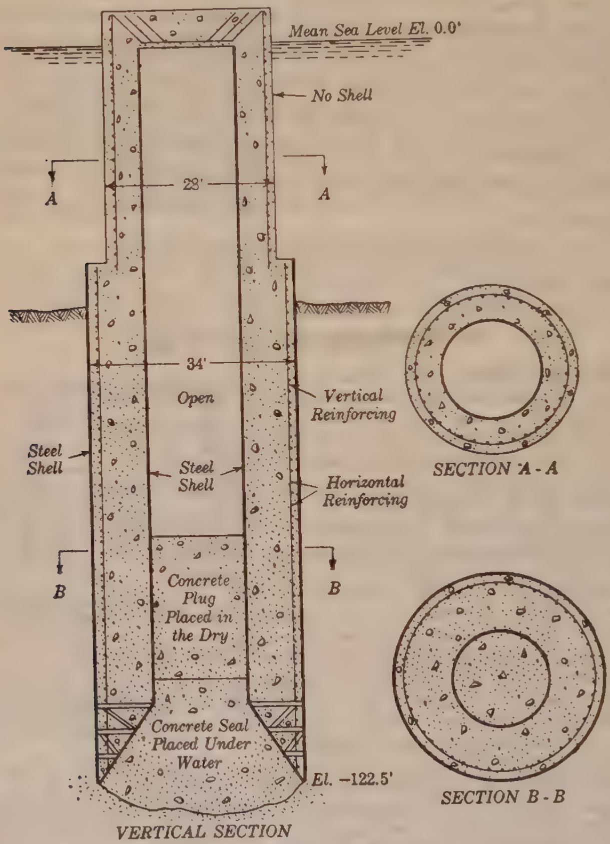

Fig. 36

bury River Bridge, Australia, to a depth of 162 ft. below high water; and of the Morgan City Bridge over the Atchafalaya River in Louisiana, to a depth of 120 ft. The greatest depth ever attained was at the bridge over the Ganges River at Sara, India, where one pier was dredged to 185 ft. below high water. The bridges over Chef Menteur and Rigolets Passes between Lake Borgne and Lake Pontchartrain, in Louisiana, for the Louisville and Nashville Railroad, are recent illustrations (1925) of this method. One of the piers at Chef Menteur reached a depth of 122.5 ft. below mean sea level.

The piers for these bridges were sunk as hollow concrete cylinders surrounded, inside and out, by a steel-plate shell. The diameter of the piers was 34 ft. These were sunk through gray sand. The maximum friction amounted to 765 lb. per sq. ft. Fig. 36 shows some of the features of these piers.

16. Divers and Diving

In laying foundations under water it is sometimes necessary to employ a diver to examine the site, to prepare the bed, or to lay the masonry. A diver is also sometimes required in other engineering operations, as in tunneling to erect or remove a bulkhead; in water-supply engineering to inspect and repair a conduit, clear an inlet, or take out pumps; in wrecking operations, etc. With the best modern apparatus it is possible for any able-bodied man to prosecute any ordinary kind of work under a moderate head of water without serious risk of personal injury. No man suffering from chronic disease, alcoholic excess, ear or heart troubles, having a sluggish circulation or a great excess of fat, should attempt the work of a diver; and if the work is to be carried on at a greater depth than 35 to 40 ft. the man should undergo a thorough examination by a physician before attempting diving.

A Diver's Outfit consists of a metal helmet or head-covering, a breast-plate which rests upon the chest and back, and an airtight flexible diving suit which envelops the body from the breast down. The helmet is provided with at least one window in front, and usually also one on each side, and sometimes one above the face; and is also provided with a valve in either the head-piece or the breast-plate for receiving air, and also a safety valve and a regulating valve. The diving suit is closed at the feet, but is open at the hands, which are provided with rubber bands that fit closely around the wrists. The helmet is connected by a hose to an air pump above the water. A rope, called the life line, passing around the diver's waist and reaching to the surface, is used in raising and lowering him. To overcome buoyancy weights are hung to the diver's waist, and his shoes have lead or iron soles. The weights upon the feet are more particularly intended to prevent the diver from losing his upright position by undue buoyancy of the lower portion of his diving suit, caused by an excessive air pressure on the inside. The air pressure in the diving dress may be controlled by the diver by means of the regulating valve. To prevent the possibility of the diver being blown to the surface by the inflation of the lower part of his diving dress, a new type of suit has been developed which has the legs tightly laced up, thus preventing the air from getting into the legs when the diver suddenly stoops over or if he falls down; and consequently if he loses his upright position, he is able to right himself. The air pump is always operated by hand power, and may be any one of several forms, according to the amount of work or the depth: one, two, or three cylinders; single- or double-acting; lever or fly-wheel type; with or without a water-jacketed cylinder. The diver communicates with his attendant by jerks upon the life line through a code of signals, or by a telephone the wires of which are embedded in the life line or in the air hose. Except in very clear water, the surface light does not penetrate very deep, and hence the diver usually works in the dark, although sometimes he is provided with an electric light.

To Prepare for Diving the diver takes off all his own clothing, puts on a heavy flannel shirt, a pair of drawers which must be carefully adjusted outside of the shirt and be well secured to prevent slipping down, and then a pair of heavy stockings. If the water is cold, he may put on two or more of each of these articles. He also puts on a woolen cap, drawing it well down over his ears. Usually a shoulder pad is put on and tied under the arms. The diver then gets into the diving suit and draws it well up to the waist; he next puts his arms into the sleeves, and an assistant opens the cuffs, by means of the cuff expander provided with the apparatus, so that the diver can push his hand through the cuff. Sometimes the diver wears rubber mittens; and if so, they are next put on by first inserting a ring into the cuffs, and then each mitten is fastened in place by a clamp. Canvas overalls are usually next put on over the diving suit to preserve it from injury. The diver now sits down, and the shoes are put on. Next the inner cape is drawn up around his neck and tied loosely with a yarn string. The breast-plate is then put on, and the rubber collar of the diving suit is put over the projecting screws of the breast-plate; and the sectional clamping piece is put over the projecting screws and fastened with the thumb nuts. The helmet, with the front plate or window removed, is next put on and screwed fast to the breast-plate; but before putting the helmet over the diver's head, the attendant should place it over his own head and place his mouth over the place where the air escapes and blow, to see whether the safety valve is in working order. The life line is looped around the diver's waist, brought up in front of the man's body, and secured with a small rope passing around his neck or is fastened to the stud on the helmet. The waist belt is then buckled on with the knife pocket at the left. The end of the air hose is passed through the ring on the belt on the diver's left and up to the inlet valve of the helmet, and secured to it, and then the upper part of the hose is made fast by lashing it to the loop on the helmet. A ladder or a rope must be provided which reaches from the surface to the bottom, for the use of the diver in descending and ascending; and must be heavily weighted at the bottom. The ladder, usually a rope one, is the better for the inexperienced man although an expert diver prefers a single rope. The diver steps on the ladder, and weights are hung to his waist and fastened in place. Two men take their places at the pump. When the attendant is sure that everything is right and the diver understands the code of signals, he gives orders for the pump to start, screws the front plate into place, takes hold of the life line, and gives the signal for the diver to descend. While the diver is under water, an attendant should give constant attention to air hose and life line, keeping the former free and clear of kinks and the latter just taut enough that any signals by the diver can be easily felt; no talking, laughing or distracting noise should be allowed on the surface.

The diver should descend slowly, and as soon as his head is under water should stop to see that everything is satisfactory, particularly the escape valve. The valve is kept closed by a spring, and the farther the valve is screwed up the less air escapes. If too much air escapes, breathing is difficult; and if too little escapes, the diving dress may become inflated to such an extent that the diver will rise. The proper adjustment is that which just takes the pressure of the weights from the diver's shoulders. As he descends, if he feels any pain in his ears, he should shut his mouth and inflate his cheeks, or blow through his nose, or swallow several times, to equalize the pressure on the inside of the drum of his ear. He should continue his descent slowly, and not demand too much air. If the pain is not relieved or if he feels oppressed, he should slowly rise a yard or two, and remain at that point a minute or two, and inflate his cheeks or swallow or do both; and if the oppression, or the singing in the ears, or the headache should continue, he should slowly return to the surface. However, unless there is some serious physical defect a man with a cool head and good judgment is not likely to have any trouble in diving. Arriving at the bottom, the diver signals his attendant, usually by one jerk on the life line to indicate "all-right." The diver takes down in his hand a coil of small rope, one end of which is fastened to his waist, and the other end of which he attaches to the bottom of the ladder or rope down which he descended, so that he can always find his way back to the ladder when he wishes to return to the surface.

If the diver has been down some time, particularly in deep water, the liquids and tissues of his body have gradually become saturated with compressed air and other gases, and consequently when he ascends it should be slowly to allow time for desaturation. Remaining down too long or ascending too rapidly is likely to cause a form of paralysis, which in pneumatic caisson work (Art. 18) is called by the physicians caisson disease and by the workmen "bends." It occurs only after returning to the normal atmosphere; and in ordinary cases in diving can be prevented by care in ascending. The desaturation is more rapid and less harmful if the diver ascends say halfway and then stops for a time (the exact time depending upon the depth and the time under pressure), and then continues the ascent, again stopping when halfway up. This is what is known in the British navy as stage decompression, and an elaborate series of tables has been established for that service which give the time to be consumed in the ascent for different depths and for various times down. For a depth of 36 ft. and unlimited time down, the time of ascent is 1 minute; for a depth of 60 ft. the time of ascent after being down 20 minutes is 2 minutes, and after being down 2 or 3 hours it is 32 minutes; and for a depth of 120 ft. after being down 15 minutes the time of ascent is 15 minutes, and after being down 30 minutes it is 33 minutes.

The Nominal Maximum Depth for a diver is 100 ft. and the ordinary maximum for a strong and expert diver is 150 ft., although the maximum reached is over 300 ft. Strong and experienced divers can stay under 2 hours at 100 ft. and 5 or 6 hours at 90 ft., but the maximum depth at which a diver can do any considerable work is 60 to 80 ft. It must not be forgotten that the work of a diver is much less efficient than that of a man above water, owing to restraint of his diving apparatus, the resistance of the water, the seeming tendency of his tools to rise, etc. The catalog price of a diving outfit varies from $350 to $1300, the former being for an outfit for a brief examination in shallow water and the latter for the best apparatus suitable for the deepest work.

Skin Divers. In emergency work, naked expert divers, working in water not over 25 ft. deep, can do certain kinds of simple work. Hartley Rowe successfully repaired a sea wall in Colon, C. Z., during a storm, by underpinning with concrete in bags placed by skin divers.

17. The Pneumatic Method*

When Expedient. The pneumatic method offers a certain and dependable solution when a foundation cannot be carried down to a satisfactory stratum by means of piles or by open methods. Such a situation arises (1) when the intensity of load upon a foundation is too great to permit the use of piles; (2) when subsurface conditions, such as boulders or buried obstructions, would prevent the penetration of piles to the desired stratum; (3) when the depth of the proposed bearing stratum and the hydrostatic head would make the driving of sheet piling and the bracing of an open cofferdam difficult and expensive; (4) when it is desirable or necessary to build a deep foundation adjacent to an existing structure and such a foundation must be carried down through unstable and water-bearing materials, the pneumatic method provides a means which will reduce to a minimum the possible settlement and hazard to the adjoining structure; (5) even when an open dredging caisson might be used, it may be desirable to unwater and explore the proposed foundation stratum and to avoid the placing of concrete through water. These considerations have led to the wide use of this method for the construction of the foundations of bridges, dams, and piers, and for the foundations of heavy buildings, especially in congested districts.

Referring to the use of this method for building foundations it should be understood that, even by its use, the settlement of nearby wall footings and piers cannot be entirely prevented. The friction of the sides of caissons upon the surrounding materials induces some settlement; and the excavation of material from space outside of the limits of the caissons, which cannot always be prevented, leaves voids which are later filled by a movement of the surrounding ground with some consequent settlement. Nevertheless, this method does furnish the safest means for constructing deep foundations under such conditions, and possible settlement of adjacent structures must be guarded against by preliminary shoring and underpinning of these structures.

On the other hand, on account of its usually greater cost, the pneumatic method should not be used when some other method is possible, provided the

* Most of this article was written by Ralph H. Chambers.

work could be done by such other method with certainty and without hazard to adjoining structures or to the success of the undertaking.

Limits. Foundations may be constructed by the pneumatic method to a depth of about 110 ft. below water or ground-water level. Even this depth has been exceeded; but usually, because of the rapidly increasing costs at the greater depths it is not advisable to use this method to a depth of more than 90 ft.

Essentials of the Method. The essential feature of the pneumatic method is the use of compressed air to drive the water out of the space in which the

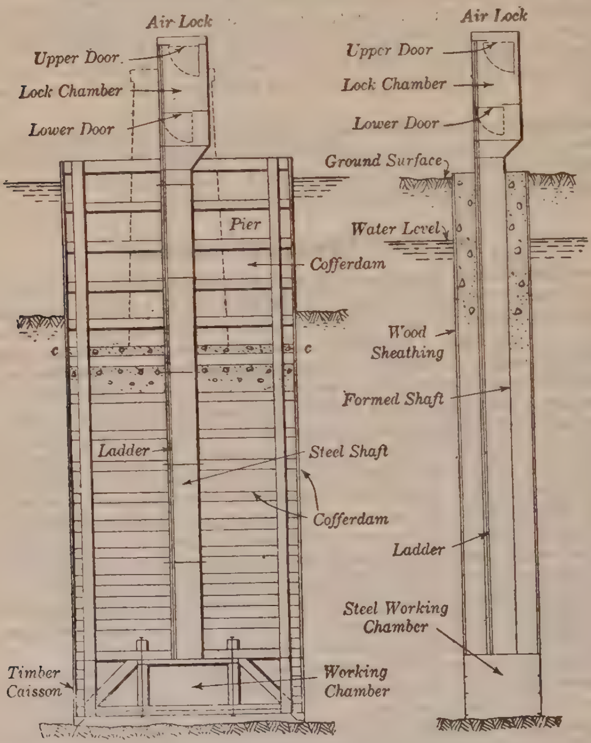

Fig. 37

men are working and out of the voids in the material which is being excavated, so that this material becomes comparatively dry and easy to handle, will not rise in the bottom of the excavation, and will stand to a considerable height without other lateral support. Excavation is done within a suitable box or chamber (Fig. 37) closed on the sides and top but open on the bottom, into which compressed air is fed. Men working upon the ground in this chamber remove the material under the chamber and cause the chamber and the construction above it to sink as the excavation proceeds. When the bottom of the working chamber reaches the desired stratum, the chamber is filled with concrete. It is evident that the excavators working in a dry, well-aired and well-lighted space can work advantageously in the removal of the excavation, including sunken logs or boulders, in leveling or stepping up the foundation, and in concretng the foundations within the chamber. This method is therefore dependable for use in foundation work.

It is necessary to provide means of access to the working chamber, from the surface of the ground or water above, so that men may go into and out of the working chamber and so that excavated materials may be removed and concrete and other materials may be lowered into it. This is accomplished by means of a cylindrical well or shaft (Fig. 37) leading from the working chamber to a point above water level. The shaft is provided with a valve or air lock which permits ingress and egress to and from the shaft, without appreciable loss of air pressure in the working chamber.

Working-Chamber Details. The form and horizontal dimensions of the working chamber are usually determined by the form of foundation required and by the required bearing area upon the foundation stratum, although in very small caissons the size is sometimes determined by the minimum space required in the working chamber. The smallest working chamber now used is about 3 ft. in diameter and 6 ft. high. This is used in the underpinning of heavy buildings. A caisson of this form and size was called a "pneumatic pile" in the older treatises upon the subject but this term is no longer used. When it is possible to use them, caissons of circular cross-section can be sunk with greater ease and less disturbance to the surroundings than other forms.

The exterior sides of the working chamber are now invariably made plumb. Formerly it was customary to batter the sides so that the working chamber at the bottom would be larger than at the top. This was done with the idea that a working chamber of this form would, in sinking, leave a space all around and thus the friction of the sides of the caisson upon the surrounding ground would be relieved. Experience has shown that the result hoped for was not obtained and that such caissons were more difficult to keep in alignment. Further, when it is necessary to guard against the settlement of adjacent structures, it is necessary to prevent the removal of any material which will not be replaced by the sinking caisson.

The bottom edges of the working chamber, known as the "cutting edge," were formerly made sharp or V-shaped in section. This is no longer regarded as necessary and the cutting edge is now often 12 in. or more in width. It is usual to protect the bottom edges of the working chamber by a steel or hardwood curb to prevent damage due to blasting or to the landing of a portion of the cutting edge upon a boulder or other hard obstruction. The inside height of the working chamber should be 6-1/2 to 7 ft. The inside faces of the side walls are often battered so that the thickness of the walls increases above the cutting edge.

Formerly, working chambers and a portion of the pier above, known as the "crib," were always made of timber, although some of the largest caissons such as those used in the Forth Bridge (Scotland) were built of steel. Timber is still used, especially when the working chamber must be built on shore and launched; but, when it is possible, reinforced concrete is a much better material except in small caissons where lack of space requires the use of steel. The risk of fire in the working chamber which, before the now invariable use of electric lights, was a constant danger, is eliminated by the use of incombustible materials. These fires were especially bad on account of the large amount of oxygen due to air compression. Timber working chambers must be thoroughly calked, inside and out. Fig. 38 shows a large timber pneumatic caisson used for the new Memphis Bridge (1915).

The sides of the working chamber should be designed for a load equal to the hydrostatic pressure, at the greatest depth to which the caisson is to be sunk, so that, in case of a blow-out and the sudden loss of pressure in the working

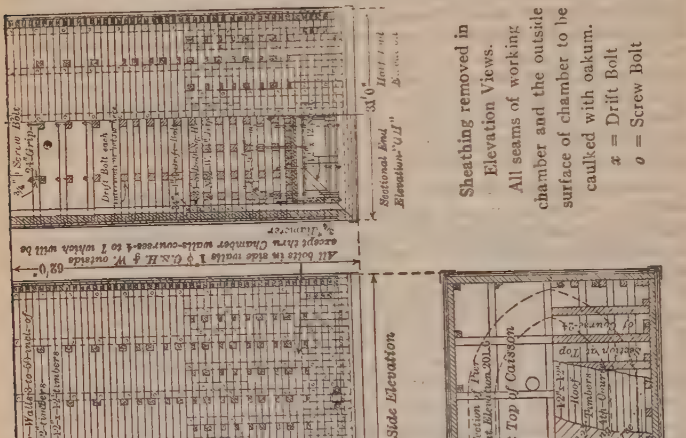

Fig. 38. Pneumatic Caisson and Crib for Second Memphis Bridge

chamber, the walls will not collapse. It is also usual to design the walls to resist a bursting pressure of about one-half the hydrostatic pressure. The roof of the working chamber must be made sufficiently strong to support the load of the pier upon it. This, however, does not mean that it must support the whole weight of the pier above, but only so much of it as is not carried directly to the side walls of the working chamber, due allowance being also made for the supporting effect of the friction of the sides of the pier against the adjacent soil.

Cofferdam or Pier Shaft. In large caissons where the top of the masonry built upon the roof of the working chamber may, at times, be below the water surface or when the pier shaft above the working chamber will cover less area than the top of the working chamber, a cofferdam is constructed above this working chamber (Fig. 37). This is usually built of timber and calked. It is built up as the caisson sinks. This cofferdam is filled with concrete or the pier masonry is built inside of it, as shown above $c-c$, Fig. 37. The amount of concrete or masonry in the cofferdam while the caisson is sinking should be regulated so that its weight will only slightly overbalance the buoyancy of the caisson and the friction on the sides. Provision must be made to prevent the pulling apart of the cofferdam or its separation from the working chamber because of the friction.

When caissons are built upon dry ground, as in the case of building foundations, the foundation above the working chamber is built up of concrete as the caisson sinks and without a cofferdam. The method of operation when building on land is to build the working chamber and then build upon it a small amount of concrete masonry, sinking the working chamber into the ground always to such a depth that the masonry pier above it will not be in danger of tipping. The preliminary sinking may be done without air if there is no ground-water. When the top of the concrete sinks to about the level of the ground the sinking is interrupted until another concrete section can be built up 10 or 15 ft., the air pressure being maintained in the meanwhile.

Caisson Shafts. Access to the working chamber is provided by one or more vertical shafts, depending upon the size of the caisson, extending up through the masonry in the cofferdam from the top of the working chamber to a level above the water surface. These shafts may be of steel or may be formed in the concrete. They are usually 3 to 4 ft. in diameter, but may be as small as 30 in. in diameter in small caissons. Steel caisson shafts are usually built in 10-ft. lengths with outside angle flanges bolted together and having yarn or rubber gaskets. The caisson shafts are provided with iron ladders and furnish a passage for men and for buckets. In large caissons, separate shafts for men and for materials are provided. In smaller caissons only one shaft is used, this being for both men and materials. In some cases a single shaft has been used with separate passages for men and for materials. Upon the completion of the caisson the shafts are filled with concrete. If made collapsible they can be removed and the space filled with concrete.

Air Locks. The air lock (Fig. 37) is a device used to allow the men to enter or leave a working chamber without appreciable loss of air pressure through the shaft and to allow the introduction of materials into the working chamber and the removal of excavated materials from it. The air lock is simply a chamber, usually 4 to 6 ft. in diameter and 7 ft. high, having doors at each end. These doors both open in a direction against the air pressure. By closing the lower door and opening the upper, men can enter the lock chamber. The upper door being then closed and the air pressure in the lock chamber being gradually made equal to that in the working chamber, the lower door can be opened and the men can proceed down the caisson shaft into the working chamber. The air lock should always be placed above water level so that in case of a blow-out, or sudden loss of pressure in the working chamber, the men may take refuge in the lock and then be passed out. Fig. 37 shows the general air lock, diagrammatically.

In order that excavated materials may be removed from the working chamber by buckets, the cable carrying the bucket must pass through the top of the air lock or through the upper door. In the first locks the upper door was located in the side of the lock chamber and the lower door in the bottom. The bucket cable then passed through the top of the lock. This arrangement is still used in one form of lock but it necessitates the dumping of the contents of the bucket from the side of the lock chamber and its rehandling, or the releasing of the cable from the bail of the bucket in the lock, and the connection of another cable, outside the lock, by which the bucket can be hoisted and dumped. This disadvantage led to an arrangement of details of the upper door which would permit a bucket to pass out of the top of the lock without disconnecting the cable. This is accomplished by making the upper door in two sections which will close around the cable, or by entering the bucket into the lock and then moving it sidewise so that the cable enters a slot in the edge of the upper door as it is closed. The upper doors, of locks now most used, are simply hinged or hinged and provided with a connecting lever so that they will swing laterally as they swing open. The lower doors are simply hinged. Both doors are usually counterbalanced and provided with outside operating levers.

Air locks must be provided with piping and valves to permit the equalization of the air pressure in the lock and the discharge of air from it, and the discharge should be located so that it can be operated by men in the lock.

Air Connections. Connections for the supply of compressed air must be made to the air lock and to the caisson shaft below the lower door of the lock. A connection must be carried down to the working chamber itself in order to supply fresh air direct to the working chamber. This is done by a pipe leading down through the caisson shaft or by a pipe buried in the concrete and leading down to the working chamber. All these connections should be of 3-in. pipe except in very large caissons when they are made of 4-in. To the top of the connection to the working chamber and to the connection to the air lock, two lines of hose lead to a manifold which in turn is connected to the main air line from the receivers and compressors. At the manifold, each line leading to the hose is provided with a gage and these gages are attended by a gage tender who regulates the pressure and supply of air to the caisson.

Connections are made for electric light, high-pressure air for drilling, and for a signal whistle to the working chamber, through the shaft or by pipes buried in the concrete. Ordinary signals are made by the men in the working chamber rapping upon air pipes or caisson shafting, answered by men rapping upon the air lock above.

Compressors and Air Mains. To maintain a constant supply of compressed air, suitable low-pressure compressors must be provided. High-pressure compressors might be used on small jobs by dropping the pressure the required amount at the caissons, but this would be uneconomical. Usually a high-pressure compressor with a separate air line is also installed to supply air for drilling. Compressors may be driven by steam, oil, gasoline or electricity, but when electric power is available, at equivalent cost, it is the most convenient. Air receivers, of adequate capacity, are required to equalize the pressure. When the work is done in warm weather, provision for cooling the air should be made just before it reaches the caissons as the air is likely to be highly heated by long supply mains lying in the sun. The mains should be 4 to 8 in. in diameter, depending upon the amount of air used and the lengths of mains. The quantity of air which will be required will depend upon the size of the caissons, the number being sunk simultaneously and the character of the ground through which the caissons are being sunk. A supply of 1500 cu. ft. of free air per minute may be enough for a small number of small caissons sinking in tight ground whereas large caissons and porous ground may require several times as much. Usually 2500 to 3000 cu. ft. per minute will be sufficient for fair-sized works in ordinary ground. At least two compressors should be provided or, better, a stand-by compressor should be installed, in case of trouble with the compressors.

Launching and Placing. The working chambers of caissons which are to be sunk through open water before reaching ground are usually built on land, launched on sliding ways similar to shipbuilding ways, and towed to site. Or the working chambers may be built on a submersible barge. False bottoms in working chambers are sometimes necessary when the depth of water is otherwise insufficient for launching. These false bottoms are removed after air pressure has been applied, or by weighting them off in deep water with sand. Provision is usually made for anchoring, holding and guiding such caissons, by driving clusters of piles around the site and by current breakers and anchors. For caissons to be sunk from the ground surface, the working chambers are built upon the site.

Sinking. Caissons are usually sunk a little below water level before compressed air is applied, except those which are placed in open water. When air is applied, the organization for each caisson consists of a working gang foreman and as many men as can conveniently work in the working chamber, two lock tenders on the air lock and a gage tender. A general caisson foreman is in charge of all the caissons. Besides this there are required sufficient derricks with their operators to handle the excavating buckets, and a complement of men to build up the caissons and to supply mixed concrete to the air locks, also operators for the compressors and a general works organization.

The material excavated in the working chambers is handled into buckets and hoisted through the air locks. When the excavated material is sand, gravel, or silt, it may be advantageously handled out of the caissons by blow pipes, except in foundation work in city districts. These consist of pipes, usually 4 in. in diameter, running up through the roof of the working chamber to the top of the caisson and terminating in an elbow. The lower end of the pipe extends down into a shallow, water-filled pit just below the level of the cutting edge. At a point about 4 ft. above the cutting-edge level, the blow pipe is fitted with a full-way valve. Excavated material is shoveled into the pit at the bottom of the blow-pipe and from time to time the valve is opened for short periods. The air pressure in the working chamber blows the material through and out of the pipe at the top of the caisson. It is necessary to protect the bend in the elbow at the top of the pipe, by chilled cast iron, to prevent rapid wear. This apparatus is an expeditious means of raising excavated materials, when used with proper material and when the air pressure exceeds 10 lb.

Men working under compressed air are exhilarated and usually work energetically. Each man in the working chamber should handle 2 or 3 cu. yd. per eight hours of working time. Boulders or rocks may be drilled and blasted in the working chamber in the ordinary manner but the men must be taken out of the working chamber at each blast.

In sinking a caisson care must be taken to keep it in correct position and plumb. Improper handling of caissons has caused them to turn over. In order to keep the caisson plumb and in alinement it may be necessary to excavate ahead of whichever side is lagging behind in the sinking, or to use shores above the ground if the caisson is sunk from the ground or in shallow water, or by using shores within the working chamber and also sliding blocks. Sliding blocks are heavy timbers placed under the cutting edge and sloping in the direction in which it is desired to shift the caisson.

As the sinking proceeds and the pressure increases, the length of time during which men can safely work in the caisson rapidly decreases and the time required for decompression in the air lock increases. These periods are sometimes regulated, as in New York State, by law (see Art. 18) and by union rules.

It will be noted in Art. 18 that the higher the air pressure and therefore the deeper the caisson the shorter the day's work. The following tabulation shows also that the higher the air pressure the higher the per diem wages: For pressures up to and including 17 lb., $12.00 per shift (two working periods).

	Per shift
For pressures of 18 to 25 lb.	$12.50
For pressures of 26 to 32 lb.	13.00
For pressures of 33 to 37 lb.	13.50
For pressures of 38 to 42 lb.	14.00
For pressures of 43 to 48 lb.	14.50

From the foregoing it will be seen that under pressures of less than 18 lb. the cost of labor is $1.50 per hour of actual working time, whereas, at 34 lb. pressure the labor cost per hour is $3.38 and at 48 lb. pressure the cost per hour is $9.67.

Friction and Weighting. Only very large caissons will sink of their own weight as the material under them is excavated, overcoming the friction of the surrounding ground against the sides of the caissons. This friction varies with the character of the ground materials, from 150 to 1500 lb. per sq. ft. of surface or even more. The usual friction is 350 to 500 lb. per sq. ft. Loam, silt and sand cause the least friction, clay often causes more, and strata of boulders and loose rock sometimes raise the friction to an amount which cannot be overcome. The air escaping from the working chamber tends to reduce the friction. Water jets around the sides are sometimes effective. Dynamite exploded in the ground below the working chamber will sometimes start the movement of a caisson. When it can be done without risk of settlement of adjacent structures, the sudden release of air pressure in the working chamber will often cause a sinking of the caisson. Caissons of steel or timber will sink with less friction than concrete caissons. In fact it is advisable to sheath concrete caissons with 2- or 3-in. wood plank to reduce the friction.

To overcome the friction and the buoyancy of the air pressure, which is equivalent to the hydrostatic pressure at the bottom, it is usually necessary to add to the weight of the caisson by loading it with sand or gravel, concrete blocks, or iron. The weight usually used is pig iron, loose or in boxes, or cast-iron blocks (about 2 tons each). A load of 300 to 1000 tons of added weight on a caisson is not unusual.

Concreting Working Chambers. When a caisson has reached the desired foundation stratum and the bottom has been cleaned, the working chamber is filled with concrete. The concrete is either lowered in buckets through the air lock, or is dumped into the lock chamber and dropped by opening the lower door, either free or through a pipe. The concrete should be spaded and packed tight against the roof of the working chamber and should then be grouted, through the air pipes, or through the caisson shaft. The workmen usually receive additional pay for concreting under air pressure.

Rate of Sinking. When the sinking of a pneumatic caisson has been begun it is usual to continue the sinking night and day without interruption, although this is not absolutely necessary provided air pressure is constantly maintained. The rate at which a caisson can be sunk depends upon its size, upon the character of the material through which it is sinking, and the number of men working in the working chamber. Small caissons, 5 to 7 ft. in diameter, sinking through silt, sand or light clay, may be sunk 5 to 7 ft. per eight hours of working time. Larger caissons, 20 by 50 ft. or more in horizontal dimensions, may be sunk 1.5 ft. or more in eight hours.

Costs. From the foregoing it will be evident that there are so many variable factors entering into the cost of pneumatic caisson work that any statement of costs would probably be misleading. The cost of any particular work, per cubic yard of caisson, might vary within limits as wide as $35 to $100, depending largely upon the magnitude of the work. Before such work is undertaken, careful borings should be made, also a thorough study of the costs of materials and labor, power, equipment and liability insurance. This having been done, it is generally possible to estimate very closely the cost of pneumatic caisson work and, as has already been stated, the results which can be obtained by the use of this method can usually be more definitely forecast than can be done with any other method.

Other Hazards. The danger of fire in the working chamber has already been mentioned. This in the past has been the cause of a number of serious accidents, but by the use of electric lighting and the increasing use of incombustible materials this danger has been largely eliminated. There is always, in ground of certain character, a possibility of a blow-out or sudden loss of air pressure in the working chamber, the subsequent inrush of water and mud drowning the men before they have had a chance to escape. Similar accidents have been caused by the dropping of a loaded bucket through the lower door of the lock, causing it to open and suddenly releasing all the pressure in the working chamber. This can be guarded against only by constant vigilance on the part of the experienced men who are usually employed in this work. Marsh gas and other inflammable, explosive, or suffocating gases may be encountered in some localities and means must be adopted to recognize immediately the presence of such gases.

18. Physiological Effect of Compressed Air

After entering the air lock, as the pressure increases, the first sensation experienced is one of great heat. As the pressure is still further increased a pain is felt in the ear, arising from the abnormal pressure upon the ear-drum. The tubes extending from the back of the mouth to the bony cavities over which this membrane is stretched are so very minute that compressed air cannot pass through them with a rapidity sufficient to keep up the equilibrium of pressure on both sides of the drum (for which purpose the tubes were designed by nature), and the excess of pressure on the outside causes the pain. These tubes can be distended, thus relieving the pain, (1) by the act of swallowing, or (2) by closing the nostrils with the thumb and finger, shutting the lips tightly, and inflating the cheeks. Either action facilitates the passage of the air through these tubes, and establishes the equilibrium desired. The relief is only momentary, and the act must be repeated from time to time as the pressure in the air lock increases. This pain is felt only while the air in the lock is being "equalized," and is most severe the first time compressed air is encountered, a little experience generally removing all unpleasant sensations.

The Rate of Entering the compressed air, or of "locking in," should be as rapid as possible, the only limitation being the ability of the individual to equalize the air pressure in his head cavities. For this reason the novice should go in slowly, but an experienced workman may enter as quickly as the valve will admit the air.

When the lungs and whole system are filled thoroughly with the denser air, the general effect is rather bracing and exhilarating. The increased amount of oxygen breathed in compressed air very much accelerates the organic functions of the body, and hence labor in the caisson is more exhaustive than in the open air; and on getting outside again a reaction with a general feeling of prostration sets in. At moderate depths, however, the laborers in the caisson, after a little experience, feel no bad effects from the compressed air, either while at work or afterward. In passing through the air lock on leaving the air chamber, the workman experiences a great loss of heat owing (1) to the expansion of the atmosphere in the lock, (2) to the expansion of the free gases in the cavities of the body, and (3) to the liberation of the gases held in solution by the liquids of the body. Hence, on coming out the men should be protected from currents of air, should drink a cup of hot strong coffee, or preferably hot beef extract, take a warm shower, dress warmly, and lie down for a short time.

The Cause of Compressed Air Sickness, which is known as caisson disease or the "bends," is the release of free gas bubbles in the blood. The blood dissolves both oxygen and nitrogen in passing through the lungs, and if exposed to compressed air the amount of gas dissolved will increase proportionally to the pressure. The oxygen gas thus dissolved will generally be absorbed by the bodily functions, but the nitrogen remains in solution. If the air pressure is reduced too rapidly when "locking out," this dissolved nitrogen is not able to escape through the lungs, and some of it will form bubbles in the blood which will be carried to the various tissues. In most cases this will cause pain in the joints of the limbs, which is the form of the disease known as the "bends," this symptom being generally of a non-dangerous type. More dangerous forms are the "chokes" caused by the pressure of gas bubbles in the lungs, and the "staggers" or vertigo caused by bubbles in the brain or the middle ear. Very severe cases may result in collapse, followed by death. Caisson disease is more likely to occur where the men remain too long under heavy pressure, and when the decompression is too rapid.

Precautions to be taken to limit the occurrence of the disease are as follows:

(1) Each workman should be examined by a physician before being employed and at intervals not exceeding two months. The men should be young, of spare build, and with low blood pressure.

(2) The hours of work should be limited, and should be less at the higher pressures. The New York State regulations (1921) specify hours of labor per man in any 24 hours as follows:

Gage pressure lb. per sq. in.	1st period of work in compressed air—hours	Period of rest—normal air—hours	2nd period of work in compressed air—hours
0–20	4.0	0.5	4.0
21–29	3.0	1.0	3.0
30–34	2.0	2.0	2.0
35–39	1.5	3.0	1.5
40–44	1.0	4.0	1.0
45–49	0.75	5.0	0.75

(3) Decompression should be at a slow rate, and the time allowed for decompression should be increased with higher pressures. The time required may be reduced by adopting "stage-decompression," in which the pressure is first reduced to half its original amount at a rate not exceeding 5 lb. per

minute and then reduced to normal at a much slower rate. For pressures under 20 lb. per sq. in. the rate of decompression may be fairly rapid. For higher pressures, the total time required should be about one minute for each pound of gage pressure.

(4) Care should be taken to avoid chill during and after decompression as noted above.

(5) The men should be required to remain near the work for at least one hour after decompression, as it has been found that a large proportion of cases of the disease occur within that time. The men should also be advised not to go to work with an empty stomach.

The Cure for Caisson Disease is recompression to the same pressure as that at which the man had been working, followed by decompression at a much slower rate than prescribed for actual work. For this purpose, a "hospital lock" should be required on all compressed-air work. This is a chamber arranged to receive the required air pressure, and provided with necessary facilities for the comfort and treatment of the patient. The treatment is generally effective after one recompression, but in more serious cases it may have to be repeated several times to obtain permanent relief.

The comfort and safety of the workmen will be greatly increased by keeping the air supplied to the compressed-air chambers as clean as possible, and properly cooled. The air lock should also be heated during decompression in cold weather. If proper precautions are taken, the pneumatic process can be applied at depths of 80 to 90 ft. without serious consequences, but it is generally considered to be limited to depths of 110 ft.

EARTHWORK

19. Loosening and Shoveling

Loosening. If the earth is not to be handled by steam power, it must first be loosened, unless it is sand or sandy loam. The loosening is done with a pick, a mattock, or a plow. The **pick** is used in trenches and other confined positions, and the plow elsewhere. The pick is much more economical than a mattock; and the latter should be used only in trimming a surface. The amount that a man can loosen in a given time with a pick varies greatly with the man, the supervision, the character of the soil, the depth of breast, etc.; but is usually about as follows: hardpan or cemented gravel, 0.5 to 1.0 cu. yd. per hour, and ordinary loam 3.0 to 5.0. The **plow** is usually drawn by two horses or mules in ordinary loam, four in stiff clay and gravel, and six in hardpan. In each case there is a driver and a plowman, and in the last also one or two men to ride the plow-beam to keep the plow in the ground. Gasoline tractors may often be more economical than horses or mules. The amount loosened is in ordinary loam 40 to 50 cu. yd. per hour, in stiff clay 25 to 30, and in hardpan 15 to 20. If the plow worked continuously and straight along, it could loosen a great deal more than this; but the plowing must usually be done in short sections, and for various reasons much time is lost.

Shoveling. The shovel employed may be either square-end or round-end, and may have either a long or a short handle. Pointed shovels are generally used except for handling loose material from a platform or other smooth surface. The long-handled shovel is usually more economical, unless the shovelers are crowded closely together. A man will shovel well-loosened earth into a wagon at the rate of 1.2 to 1.5 cu. yd. per hour; if the wagon is comparatively low the larger amount can be realized, and if the wagon is high the smaller amount is a good output. If the man shovels earth from a platform he can handle 2 or 2.5 cu. yd. per hour. In soil that can be spaded easily, a man can dig and load more solid earth with a spade than of loose earth with a shovel. Ordinary men can spade and load as task work 20 cu. yd. of brick clay per day; and experienced and skilful men have spaded and loaded month after month 40 cu. yd. in 8 to 9 hours, and occasionally 56 cu. yd. A man can pick and load about 1 cu. yd. of loam per hour, about 3/4 cu. yd. of stiff clay, and 1/3 to 1/2 cu. yd. of hardpan.*

The Pneumatic Spade, operating on the same principle as the percussion drill (Sect. 10, Art. 4), is efficient for excavating stiff clay.

20. Scrapers

Scrapers are useful on small jobs which do not warrant the use of extensive mechanical equipment. There are three kinds of drag scrapers commonly in use: the drag, the Fresno, and the flat-bottomed tongue scraper. They are efficient in sand or gravel with or without clay which is not indurated and does not contain a large percentage of heavy cobbles or boulders. If the soil is very fine the output is decreased by the miring of the horses. Large cobbles are hard on the horses and upset or block the scrapers.

The Drag Scraper, the form of scraper most frequently used, consists of a solid steel bowl with two handles by which to load and dump it, and of a bail to which to hitch the team. It is made in three sizes, which vary a little with the maker. The smallest, for one horse, has a rated capacity of about 3 cu. ft., and the larger sizes, for two horses, have nominal capacities of about 5 and 7 cu. ft. respectively. Under working conditions they will carry only about 70% of these capacities. The drag scraper is admirable for borrowing at the sides of embankments and for wasting from cuts or ditches, and also for opening the mouths of large cuts; but is not economical except for short distances. There is no danger of the scraper getting out of order until it is worn out and unfit for use, and the manner of using it is quickly learned by any one.

Drag scrapers, in the usual short hauls, are operated in gangs of three, each with a man to load the scrapers; and the teams, even on the shortest hauls, travel in a circuit of about 150 ft. Usually the driver dumps the scraper; but when an embankment is being built, there is sometimes a man to keep the dump level, who also aids in dumping the scrapers. If the earth is sand or sandy loam and unobstructed with grass or tree roots, it may be scraped without plowing; but usually it is economical to plow before scraping, since then the scrapers are filled more nearly full. Sometimes a man is required to grub roots, etc. The " drag " is not economical to move earth more than about 200 ft. and generally at more than 100 ft. the wheel scraper is more economical than the drag.

The output on a drag scraper job depends very much upon the experience and constant supervision of the foreman. Rough average outputs for various lengths of haul are as follows:

* Although the rates given in this paragraph are possible, under average conditions they should be reduced 50%.

Haul distance, feet	Cu. yd. per 10-hr. day
25	70
50	60
100	50

These figures are for loose material.

The Fresno Scraper differs from the ordinary drag scraper in the form of the bowl and in having adjustable runners upon which the bowl is carried in dumping and returning and which permit the scraper to distribute its load in dumping and to level off the fill. The Fresno scraper is made in three sizes, the cutting edge being 3 1/2, 4 and 5 ft., and having nominal capacities of 10, 12 and 15 cu. ft. respectively. The working loads are about 75% of these capacities, except on downhill work. The distance from the cutting edge to the rear of the scoop is comparatively small, which enables it to be easily loaded to its full capacity; and the runners enable it to deposit its load in layers. It is usually drawn by three or four horses abreast.

The Fresno scraper is very efficient in easily dug material, especially on downhill work, where large loads can be pushed along in front of it. The greatest loss in Fresno work is found in short loading, which under proper supervision can be largely eliminated. Hauls may be made economically up to 300 ft. The following table gives the output for a standard 4-ft. Fresno for various lengths of haul and for average management. Good management will increase these outputs about 30%. This table was compiled by J. L. Harrison of the U. S. Bureau of Public Roads.

Haul distance, feet	Loads per Fresno per 10-hr. day, cu. yd.
50	380
100	270
150	220
200	190
250	160
300	140
350	130
400	115

The Flat-Bottomed Tongue scraper is an iron-shod wood or solid-metal scoop employed in filling ditches and leveling off the bottom of an excavation, particularly in pavement and macadam road construction, and is made in two sizes, 36 and 48 in. wide.

The Power Scraper, described in detail in Art. 26, is found useful in all types of earth-moving operations. It is particularly useful in removing overburden and in making the smaller cuts and fills.

The Wheel Scraper consists of a steel box mounted on wheels and furnished with levers for raising, lowering, and dumping. All of the movements may be made without stopping the team. There are two forms, the two-wheel and the four-wheel. The former has long been in use; the latter was first made in 1909 but is not used to any extent at present.

The **two-wheel scraper** is made in five sizes, Nos. 0, 1, 2, 2 1/2 and 3, having a rated capacity of 7, 9, 12, 14 and 16 cu. ft., respectively. Some manufacturers make an automatic front end-gate which adds materially to the load the scraper will carry, particularly on a rough or downhill road, and is useful in preventing sand and gravel loads from spilling. The two-wheel scraper is drawn by two horses; but it is usually necessary with the larger sizes to hitch another team, called a snatch team, ahead to aid in loading. One man, and in tough soil two, in addition to the driver is required in loading the largest scraper.

Except under the most favorable conditions the wheel scraper is not entirely filled owing to the difficulty of forcing the earth to the back of the bowl, hence it is not usually safe to count upon the scraper placing in the dump more than 60 to 75% of its nominal capacity. Sometimes when the haul is long, the bowl is filled heaping full by men with shovels as the scraper leaves the pit. The smallest wheel scraper is used when the haul is short and the rise is steep. It is usually more economical than the drag scraper, but where there are many stones the latter is the better.

The wheel scraper is used largely on excavation jobs where the hauls are from 200 to 800 ft. and in conjunction with Fresno or drag scrapers, the change from these to the wheelers being made at about 300 ft. J. L. Harrison of the U. S. Bureau of Public Roads found that there cannot be any generalization made as to the point at which one should change from Fresnos to wheelers. The wheeler generally requires a snatch team which is not required by the Fresno. For a short haul the Fresno output is large, but it decreases with the increase in length. For a short haul, the wheeler uses a large percentage of time loading with the snatch team but becomes increasingly efficient as the length of haul increases. It is therefore of greatest importance that the change point be considered carefully in order to save losses which would be caused by an error of even 50 ft. in the slection of the change point.

The wheelers can carry 8 cu. yd. per wheeler per hour for a 100-ft. haul, and about 4 cu. yd. per wheeler per hour for a 500-ft. haul. It has also been found that in some cases a tractor can be used instead of teams with savings in labor of more than 25%.

In constructing the Chicago Sanitary Canal, the average output for 300 000 cu. yd. having a cut ranging from 4 to 8 ft. deep, a vertical lift of 10 to 20 ft. and a horizontal haul of 400 ft., ranged from 39 to 50 cu. yd. per scraper per 10 hours, and from 27 to 35 cu. yd. per team; on another section the average output per 10 hours was 46 cu. yd. per scraper, and 30 cu. yd. per team.

The Four-Wheel Scraper is a steel box or scoop suspended from a frame supported on four wheels. It is made in two sizes, 3/4 yd. and 1 1/4 yd. capacity. It is economical because it is self-loading and self-dumping, and on long hauls also because of the larger load carried. It is usually tractor-drawn, in trains of 2 to 6, and with this type of operation will move 350 to 500 cu. yd. a day.

In excavating a channel 800 ft. long, 200 ft. wide, and up to 4 ft. deep for a temporary dam on Schoharie Creek for the Board of Water Supply of New York City, two men operated one 5-ton tractor pulling 3 scrapers of 1 cu. yd. rated capacity and excavated 8000 cu. yd. in two months, working 8 hours per day (1924). The material was mostly light loam, with gravel for about one foot at the bottom that required plowing.

See also article in "Contractors' and Engineers' Monthly," June, 1928, p. 395.

21. Grading Machines

The Scraping Grader is a machine primarily for smoothing a roadway, and incidentally for moving small quantities of earthtoward the crown. It consists of a cutting blade sliding upon the ground or of a cutting blade, adjustable in height and direction, supported upon two wheels or suspended from a frame carried by four wheels. In addition to its use in smoothing the trackway and restoring the crown of an earth road, the scraping grader is used in pavement and macadam-road construction in smoothing up the surface of an excavation, and also in backfilling trenches.

The Elevating Grader is a combined digging and loading machine and consists of a frame resting upon four wheels, from which are suspended the plow and a frame carrying a wide traveling belt. The plow loosens the soil and throws it upon the traveling inclined belt, which delivers it upon the embankment direct or into wagons. The carrier is built in sections and its height is adjustable. The machine can be had in three sizes, small, standard and large. The standard is the size best adapted for general use. The small size is recommended for use where space is limited. The large size is used on embankment work and will deliver earth 30 ft. from the plow. The machine has loaded an average of 650 to 1000 cu. yd. per 10-hour day.

The elevating grader is an effective machine for grading roads and building open ditches and earth embankment, or filling wagons. It works best in light loam, and when hauled by a tractor. Large wagons or trucks should be used to remove the excavated material. The elevating grader cannot be used in coarse sand or gravel, since the plow will not throw this material upon the elevator; and it is not suitable for use where there are roots or stones enough to interfere with the work of the plow. On an average road-grading job the usual output for the grader is about 700 cu. yd. per 10-hour day. Theoretically this should be much greater, but losses on the job cut down the output. The elevating grader is most efficient in cutting out shallow road ditches. It can be operated by one man. (See " Public Roads," 1925, for much detailed information on the elevating grader.)

The Shuart Grader consists of a scraping steel blade attached to a frame borne upon four low wheels, having at each side a guard that enables the blade to push considerable earth along in front of it. The height of the blade may be adjusted by levers. It is used in the West in preparing the ground for irrigation. If the guards are removed, this machine can be used as a grader, that is, to smooth off a surface and to push small quantities of earth horizontally sidewise.

22. Loading and Hauling

Wheelbarrows are never economical where teams can be used. A man will pick and load into a wheelbarrow 1 cu. yd. of ordinary loam per hour. A wheelbarrow load will make about 1/15 cu. yd. (or about 2 cu. ft.) in the settled embankment. The time consumed in going and returning is about 1 1/3 minutes per 100 ft., since the load is usually taken up a rather steep grade; or say 20 minutes per cu. yd. per 100 ft. For each load the time lost in dumping, fixing runway, and changing the position of the barrow is 1/2 minute per load, or 7 1/2 minutes per cu. yd.

Carts drawn by one horse are used in some parts of the country for transporting earth. They are not economical except where the haul is so short that a driver can tend two carts by taking one to the dump while the other is being loaded. The loading is usually done by four men casting in at the back end of the cart. The chief advantage of the cart is the ease with which it is dumped, especially into hoppers or scows; but usually either the wheeled scraper or the wagon is preferred. A load is 1/2 cu. yd. for level hauls, and 1/4 for steep ascents, or say 1/3 cu. yd. per load on the average; and the speed is 200 ft. per minute, or 3 minutes to transport 1 cu. yd. 100 ft. It requires about 3 minutes for 4 men to load a cart, and about 1 minute to dump it; or the lost time is 4 minutes per load, equivalent to 12 minutes per cu. yd.

Wagons. There are two general forms of wagons made especially to transport earth: the bottom-dump and the end-dump wagon. The ordinary farm wagon is unsuitable for the purpose, because the box or bed is so light as soon to be knocked to pieces by being struck with the shovels, and also because the load must be shoveled out of it.

Of the **Bottom-Dump Wagons** there are two forms: a box which is placed upon the running gears of an ordinary wagon, and a wagon made especially for hauling earth. In each the bottom of the box consists of two doors, usually hinged at the sides, which drop down to discharge the load. The doors are kept in place by chains which are wound around a spool by means of a lever operated by the driver; and when the chains are released the load drops. The load can be dumped almost instantly by the driver without stopping the team, and the bottom can be closed while the wagon is returning for another load. The drop-bottom box holds 1-1/2 to 2 cu. yd. of loose earth, and the bottom-dump wagon 1 to 5 cu. yd., although 1-1/2 to 2-1/2 are the most common. The larger sizes of bottom-dump wagons are made of steel, and are drawn by three horses and sometimes by four. The bottom-dump wagon is better than the drop-bottom box on ordinary running gears, since (1) it has larger capacity, (2) there is no coupling pole to interfere with the dumping device, (3) the front wheels go under the bed, thus greatly facilitating the turning of the wagon, and (4) it has wider tires and hence draws easier.

The **end-dump** wagon is used only where it is necessary to dump into hoppers, or onto barges, or into railroad cars. This form of wagon is too heavy and too high for use in ordinary earthwork construction.

Loading Wagons by Hand. If the haul is comparatively short, a wagon is left to be loaded while the team takes another to dump, whereby the team and driver are kept busy, and besides this gives an opportunity to fix the responsibility for the amount of output. The number of shovelers and extra wagons will depend upon the length of haul. If no extra wagons are used, and the haul is short, it is important that the team be kept on the road as much as possible, which requires that as many men as possible should be employed in loading. If the haul is extremely long, it is not important that the wagon be loaded quickly, since the team then needs a little rest. Ordinarily ten men, four on each side and two at the rear, are as many as can profitably be used. The height of the wagon materially affects the cost of loading by hand. The top of the box of a dump wagon is about 4 1/2 or 5 ft. high, and at this height a man can load 15 cu. yd. per day; but for greater heights the amount will be decreased about 10% for each 6 in. of additional height. The loading of wagons can be greatly facilitated by first excavating narrow cuts 5 or 6 ft. deep, and then placing the wagons in these trenches while being loaded. The earth at the sides of the trenches can be shoveled into the wagons much more rapidly than if the men stood on the same level as the wagon. As the sides are shoveled off, the trench can be deepened. The slopes of the material at the sides of the wagon should not be steeper than about 2 to 1, or it will be difficult to operate the plow on them or for the men to stand on them. If the wagon must be loaded from only one side, and particularly if the haul is long, an extra side-board should be placed upon the opposite side of the box to increase the size of the load.

Wagons are also loaded with a steam shovel, in which case the earth should preferably be first dumped into a hopper under which the wagon is driven to load, as otherwise there is time lost in centering the wagon under the shovel and there is much dribbling around the wagon, and besides the shovel is likely to strike and damage the wagon. The hopper should rest upon a trestle which is mounted upon wheels so that it may move forward as the shovel advances. Wagons are also loaded with an orange-peel excavator or grab bucket swung from a derrick.

Motor Trucks are now being used extensively on earthwork jobs, particularly on large jobs and on work in the large cities. For small jobs and in locations where the truck would be hard to handle, the wagon is still used. The motor truck has greater power and capacity than team-drawn wagons and makes better speed, but it cannot get into some places that are accessible to wagons. Waits for loading and dumping are more expensive for trucks than for wagons, so that trucks are most economical for long-haul work. Trucks are obtainable with power dump and hoist equipment. Trucks are available of the sizes and capacities following:

Tons	Cubic yards
1-1/4	1-1/2
1-1/2	1-1/2
2	2
2-1/2	2-1/2 to 3
3-1/2	4 to 5
5 to 7-1/2	5

The capacities of course are nominal and vary with conditions. In some cases they may require under-loading, and in others would permit over-loading.

Belt Conveyors have been used with success on a few large jobs for the transportation of excavated materials. Due to the cost of installation, they are limited to cases where the amount of earth to be moved is very great, and where mechanical means are available for loading the excavated earth. They are not practical unless the material is of fairly uniform character, and does not contain any large stones. They can be successfully used on grades as high as 25 or 30%. For description of belt conveyors in construction of the earth dam at Wanaque, N. J., see Eng. News-Rec., Vol. 95, p. 252.

23. Power Shovel Work

Where very large quantities of earth are to be moved the power shovel is generally economical. The dragline excavator competes with the power shovel in excavating large volumes of material, but is not effective in hard ground.

There are two types of power shovel: the boom-swinging or railroad type, and the revolving. The railroad type has a boom with its main bearing and swing circle at its base. The total swing of the boom is from 180 to 200 deg. The dipper handle passes through the struts of the boom and is operated by a rack and pinion. The boom and dipper are at one end of the machine and the engines and boiler at the other. All are mounted on a two-truck car body and generally operate on standard-gage railroad tracks. The size of this type ranges from 3/4- to 6-yd. dipper, the largest size having a rated capacity of 300 to 500 cu. yd. per hour. The maximum depth of through cut which this type will make is about 16 to 18 ft. It can dig from 4 to 6 ft. below track level. For loading into dump cars it will lift to a height of 14 to 18 ft.

The revolving shovel has its boom fixed to a revolving frame which forms the base for the engines, boilers, and other machinery. The frame rotates on several large rollers. This type is well balanced and does not need jack arms or struts to keep it from overturning, as with the railroad type. The revolving shovels are made with dipper sizes of 1/2 to 8 cu. yd. They can rotate in a full circle in either direction. The smaller shovels can lift 11 to 18 ft. for loading. The larger shovels can lift from 20 to 70 ft.

Some of the newer boom-swinging type shovels are mounted on caterpillar or crawler tractors. The ease and rapidity with which this type can be moved around the excavation make it a very efficient machine. It not only saves in time but also in the number of laborers needed whenever it is shifted in the process of excavating. The small and medium sized revolving shovels are mounted on wide flat-tread wheels, or on caterpillar traction. Economy of operation is causing the wheel types to be abandoned in favor of the caterpillar type. Caterpillar traction is now generally used for all but the very large shovels and the tendency is to use this type on the larger sizes. Power is furnished the shovels by either steam or electric motors, the smaller sizes sometimes using gasoline engines. Gasoline shovels are more compact and can be used in close quarters. Diesel oil engines are used on some of the large machines.

Besides the operator, who is the only man required on the smaller revolving shovels, there is sometimes a fireman. From one to three groundmen are needed to do the labor jobs around the machine. On the railroad type it is usual to have a man to operate the boom as well as a dipper operator.

The revolving type has some advantages over the boom-swinging in that it can revolve completely and can dig at any point in its swing, is more compact and can work in closer quarters, and can be converted very easily and quickly into dragline, trenching machine or crane. Caterpillar mounted, and steam- or gasoline-driven revolving shovels of 1/2-yd. to 1-yd. capacity are best for small contracting jobs. The large revolving shovel is used on large-scale mining operations.

The boom-swinging type is still best for large capacity requirements where standard railroad equipment is available. However, because of its limited digging range, considerable benching is required for it in deep cuts.

The power shovel will excavate almost any material, except solid rock, without blasting. The output of the smaller shovels varies but they will do from 400 to 600 cu. yd. per 10-hour day. Working time is usually from 50 to 65% of total time. The larger shovels (such as 70 tons, with 2 1/2-yd. dipper) will do from 1000 to 1600 cu. yd. per 10-hour shift, depending upon their actual size and the materials handled.

In general, the commonest sizes are 60- to 80-ton shovels for the usual railroad work. For light grading, up to 25,000 cu. yd. per mile, where a shovel can be used economically, a light revolving shovel is desirable. For 25,000 to 40,000 yd. per mile, a shovel of 50 tons is a good size. For 40,000 to 60,000 cu. yd. per mile, a shovel of 60 to 80 tons is well suited. For anything over 60,000 cu. yd. per mile, the shovel may run up to well over 100 tons economically if its transportation is not too expensive, and if the ground is fit to carry its weight during excavation.

The greatest cause of delay in shovel work is in the removal of the excavated material. Too great attention cannot be given to securing proper and ample equipment in the matter of cars and locomotives, transportation and disposal. A shovel or a dredge can theoretically dig three or four times as much material as can be transported and disposed of, for the following reasons.

1. Shovels are usually not adapted in size and character to the material in which they are used. Contractors buy shovels for specific work for which they are suitable and then use them for all kinds of work almost regardless of conditions. On large work it would often pay them to sell their existing equipment and buy new plant of size and kind best adapted to the work.

2. Old shovels and poorly maintained equipment cause daily losses. It pays to have only the best equipment, thoroughly maintained. The master mechanic is an important factor in output. Second-hand plant is rarely economical. When the shovel is broken down the contractor loses the time not only of the shovel but of all collateral equipment, and the efficiency and enthusiasm of the whole organization suffer.

3. Excavation is usually more of a transportation problem than one of digging; therefore:

(a) Lay out the plan of excavation and your track plan and dump locations months in advance of the work. Be sure the tracks are not only properly located but ample for the transportation requirements.

(b) Use heavy and good rails and plenty of ties, and keep the trackwork in repair.

(c) On large work use large-size cars and locomotives and keep them in good condition. Assume that at least 15% of the cars and one locomotive will always be in the shop.

(d) Select dump sites requiring a minimum haul. A high dump saves delays in "jacking dump track."

(e) Note that in northern latitudes winter work is slow and expensive.

As the plant charge against shovel work is always an important item, either three 8-hour shifts or two 10-hour shifts are recommended. Continuous work for a long period is not practicable without spare plant because of the impossibility of adequate maintenance.

An excellent study of power-shovel operation is given in "Public Roads," Feb., March and April, 1928. See also report of Committee on Roadway of the American Railway Engineering Association, 1921 Manual.

24. Shrinkage and Settlement

Shrinkage and Settlement. In all operations involving the moving of earth, it should not be forgotten that the act of excavation so breaks up the earth that it occupies more space after excavation than before; but when the material has been placed in an embankment, it will usually occupy less space than in its original position. The expansion due to excavation is usually 8 to 12% of the volume, and in extreme cases may be 40%; but in placing the material in the embankment, it is compacted by the weight of the embankment itself, by the pounding of the hoofs, and by the action of the wheels, until usually the final volume is less than the original. Ordinary earth in its original position is more or less porous owing to its soluble portions having been carried away by the percolating water, to the penetration of vegetable roots which subsequently decay, and to the continued action of frost. There is usually also more or less earth lost in transporting it from cut to fill. The amount of shrinkage depends chiefly upon the character of the material and the means by which it is put into the embankment, and somewhat upon the moisture of the soil, the rainfall conditions while the work is in progress and soon afterwards, and the depth to which frost usually penetrates. If the soil is moist when placed in the bank, it will become more compact than if it were dry. Rain greatly affects the shrinkage; and embankments put up during a rainy season will be more compact than those built during a dry time. Soil from above the usual frost line is more porous than that not subject to the heaving effect of alternating freezing and thawing, and consequently shrinks more when put into an embankment. The shrinkage of the ordinary soils is in the following order: (1) sand and sandy gravel least, (2) clay and clayey soil intermediate; and (3) loams most. The shrinkage according to the method of handling is in the following order, beginning with the greatest: (1) wheelbarrows, (2) cars, (3) wagons, (4) wheel scrapers, (5) drag scrapers, and (6) caterpillar traction equipment. The usual allowance for shrinkage for drag scraper work is as follows: gravel 8%, gravel and sand 9%, clay and clayey earth 10%, loam and light sandy earth 12%, loose vegetable surface soil 15%. The above results are for ordinary earth, and do not apply to such unusual materials as "buck-shot," gumbo, very fibrous soil, etc., which have a much greater shrinkage.

Broken rock placed in an embankment will occupy a volume 40 to 50% greater than in its original solid state.

The shrinkage of earthwork referred to above takes place chiefly during construction; but the continued action of the weight of the embankment and the effect of rain and traffic will usually cause a comparatively small settlement after completion. Sand or gravel embankments built with wheel scrapers will usually settle 1 to 2% after completion, and clay or loam embankments about 2 to 3%. With drag scrapers the settlement will usually be a little less than the above; and with dump carts or wagons a little more. With wheelbarrows the settlement is usually about 10%, but may be as much as 25%. A sand and gravel embankment on which caterpillar traction equipment was used was found to have practically no settlement. The settlement of steam-shovel work depends upon the method of dumping, the length of time the work is in progress, the season and the soil.

The Manual of the American Railway Engineering Association (1921) states that because it is easier to add to the height of a fill than to decrease it, little or no allowance should be made for vertical shrinkage after construction. Allowance in width should be from about 5% to 20% of the height of the fill depending on the materials and conditions. For estimating, figure a shrinkage of 10% measured in excavation, on earth removed from excavation to embankment.

Subsidence is due to compression or displacement of the strata of earth under the embankment. Some subsidence occurs under all embankments, built on any ground but rock. It must always be anticipated in bogs or swamps, or any land on which there is standing water. Serious subsidence is local and it is impossible to fix any rule as a guide in estimating it.

Fig. 39

For the above reason, culverts in compressible soil should be built with a camber; and if of concrete, additional reinforcement should be used to prevent cracks. Fig. 39 shows the effect of building a culvert with camber.

25. Levee Construction

A Levee is a bank of earth thrown up along the side of a stream to prevent the flooding of the adjoining land. The cross-section of a levee depends upon the material of which it is constructed and the length of time it will be subjected to the flood. To prevent the levee from being overtopped by waves, the crown should be 3 ft. above the highest water for the smaller levees and 5 ft. for the larger. A levee usually has a top width of 3 to 12 ft., a slope on the water side of 1 to 3 or 4, and a slope on the land side of 1 to 2 or 3. A 1 : 4 slope on the water side is more desirable because it facilitates maintenance and increases resistance to wave action. A 1 : 3 slope is satisfactory if the surface is paved soon after construction. If the material of the levee is very light, the slopes should be flatter than the above. The above slopes are easily constructed, are readily kept clear of weeds and brush by the use of a mowing machine, do not slide when tramped over by stock when wet, are not difficult to get set in grass, and resist wave action reasonably well. It is important to avoid sharp corners, and flat curves should be used even if arable land is thereby lost; and on the curves the levee should be thicker and have flatter slopes than on the straight portions.

The slopes are determined also by the lines of seepage of water through the levee, and it is desirable to keep the line of seepage below the toe of the levee. Some seepage is unobjectionable when the levee is built on good foundation and is of good construction. H. St. L. Coppee in a paper in the Transactions of the American Society of Civil Engineers, Vol. 39, p. 229, shows as a result of tests made that the slope of the line of seepage for small sections is about 8 : 1 and large sections 5 : 1. He also estimated the relative strength of various levees to resist deformation due to seepage in the following order: (1) Clay and gravel tamped in shallow layers, (2) clay mixed with sharp sand in shallow layers, (3) clay, (4) heavy strong soils, (5) coarse sharp sand, (6) light soils, (7) fine sandy rounded particles. The Mississippi River Commission has adopted a minimum line of seepage of 7 : 1 in the landside slope for its new sections. (See Eng. News-Rec., Vol. 100, p. 398). Figs. 40*a* and 40*b* show the old and the proposed new levee sections of the Mississippi River Commission. In the old section, a banquette (reinforcing bank) was constructed where the foundation was weak and the height more than 10 or 12

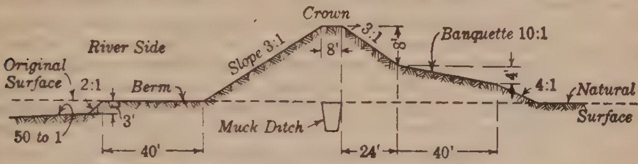

Fig. 40*a*. Standard Levee of Mississippi River Commission

ft. The chief object of the banquette is to keep the levee from sloughing off when saturated with water, which it does by keeping the surface of saturation well within the embankment. In the proposed new section, the banquette has been eliminated.

In order to help maintain equilibrium of the bank during high water, the Mississippi river levees are provided with iron pipe siphons, 10 or 12 in. in diameter, running up the face of the levee, over the top and down the back.

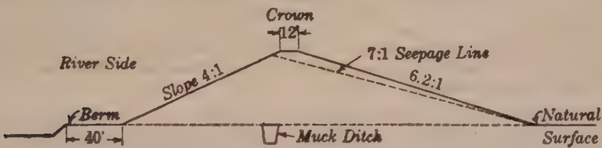

Fig. 40*b*. Proposed New Levee Section

The siphons are started by exhausting the air from the pipe with a hand pump, and are used to flood the borrow pits at the rear of the levee.

After the alignment is fixed, the surface should be freed from trees, logs, brush, and débris; and all buried logs, stumps, and roots of any considerable size should be removed. For the Mississippi river levee all logs, stumps, and roots are removed down to a diameter of 4 in. and for a width extending 5 ft. each side of the base of the levee. After clearing the foundation the ground is plowed deeply, and any unsuitable soil is removed. If the soil is not reasonably uniform, the foundation is tested by sinking pits at various points, and any defects are remedied as far as practicable. A muck ditch is usually cut on the river side of the center line, to explore the foundation and to aid in preventing the seepage of water along the plane of the base of the levee. It should extend through the porous surface soil; and should be filled with the best soil available, preferably clay or clayed gravel, which is thoroughly tamped into place. The standard dimensions of the muck ditch of the Mississippi river levees are 12 ft. wide on top, 8 ft. wide at the bottom, and 8 ft. deep, these dimensions being selected so that the muck ditch can be dug and filled with wheel scrapers. The width of the muck ditch may vary with the quality of the soil used for filling; if pure clay is employed, the width need not be more than 1 or 2 ft. except for the highest levees. Where the muck ditch will not efficiently cut off seepage, sheet piling is used. This is very expensive, but is sometimes necessary.

The smaller levees are constructed in layers not more than 2 ft. thick extending over the entire base, usually with drag or wheel scrapers. For the very large levees, draglines, steam shovels with long booms, and tower machines are used. Only unfrozen earth free from sticks, leaves, and straw should be used. The earth is taken when practicable from borrow pits on the stream side of the levee. For the Mississippi river levees the borrow pits on the river side must be at least 40 ft. from the toe of the levee, the side slope of the pit must not be steeper than 1 on 2, the depth next to the levee must not exceed 3 ft., the bottom of the pit must have a uniform slope toward the river of about 1 : 50, the depth on the farther side must not exceed 6 ft., and traverses (tongues of undisturbed earth) must be left at intervals of 300 to 400 ft. The traverses are to prevent destructive currents along the base of the levee; and should be pierced at the river end by drainage ditches, since standing water affords refuge for crawfish, muskrats, etc., which endanger the levee. The berm between the borrow pit and the levee should be kept intact, and any depressions in it should be filled to the level of the natural surface. Ditches and borrow pits on the inside are very objectionable; and, if the earth is borrowed from the land side, the pit should be well back from the levee. On the Mississippi the distance from the toe of the levee to the edge of a borrow pit on the land side must be at least 100 ft.

When the levee has been carried to the proper height and the crown and side slopes have been dressed to planes, tufts of Bermuda grass 2 to 4 in. square are planted at intervals of about 2 ft., which soon spread over the entire embankment and effectually protect it from the wash of the rain and to a considerable extent from the wash of waves and the current. Weeds and bushes should not be permitted to grow on levees, since weeds die and blow over, thereby loosening the soil, and bushes by shading the ground kill the grass and their roots loosen the earth. The injurious effect of wave action is greatly increased by the presence of weeds and bushes, as their roots break the surface and cause erosion to begin. Large trees should not be permitted to grow near the levee, as their roots will penetrate the base of the levee and give an opportunity for seepage, and when the tree is cut or dies its roots will decay and leave large openings which may cause a crevasse.

The smaller levees are built with drag or wheel scrapers, elevating graders and wagons, and the large ones with power shovels, dragline excavators and cableway excavators. The use of the elevating grader discharging directly on the embankment is unsatisfactory because it brings the pit too close to the levee. The same is true for the power shovel and dragline. They all are very useful for loading cars and trucks where the material has to be hauled. The grapple-dredge with an orangepeel bucket and a long boom is recommended by C. W. Okey of the U. S. Bureau of Public Roads for use in wet or marshy lands. It is superior to the dipper dredge for this use. The hydraulic dredges are used where the site is favorable for them, namely, where large quantities of material are present suitable for hydraulic dredging and where there are facilities for carrying off excess water, etc. They have been used on the Mississippi to transfer materials at high water to points within range of other type of equipment.

The Tower Machine has been used with very much success on the new larger sections of Mississippi levee. It is essentially a dragline or cableway excavator with the main tower on the land side of the levee, and the tail tower on the farther or river side of the borrow pit, usually up to 1000 ft. from the main tower. The two are connected by a cable which carries a 5-cu. ft. bucket. Both towers are traction mounted and can be moved parallel to the direction of the work. They eliminate the need of a haul, but the cost is considerable for moving the plant.

Drains are sometimes constructed through levees to carry away storm water during a low stage of the stream, but such openings are always a menace to the stability of the levee. If used at all, they should have substantial and adequate walls of concrete at both ends and the barrel should be of iron or vitrified pipe so laid that the joints will not leak. The lower end should be provided with a substantial automatic gate, usually a flap valve, for closing at the time of high water in the stream; and the inner end should be provided with a sliding gate to be moved by hand, for use in case the outer valve fails to work at the time of high water.

Roads along or across the top of levees are objectionable since ruts and holes result, and the edges of the crown are cut off by the wheels. Further, water collects in ruts and flows down the slope where it does considerable damage. If the crown is to be used as a roadway, the levee should be given an additional top width of at least 12 ft., and the completed structure should be carefully and frequently inspected. As better practice, it is recommended that the road be put on a shoulder on the landside slope, about 5 ft. below the crown.

26. Dredges and Dredging

Classification. Dredges may be classified according to the method of handling the material, as (1) dipper dredges, (2) elevator or ladder dredges, (3) hydraulic or suction dredges, (4) the grapple or grab-bucket dredges, and (5) scraper or dragline bucket dredges. Dredges may be classified according to the way in which they are moved forward while working, as (1) floating dredges, (2) traction dredges, (3) roller dredges, (4) drag dredges, and (5) walking dredges, of which the last four are used chiefly in ditch work. In harbor work the dredge usually discharges into a scow moored alongside; but sometimes the barge carrying the dredging machinery is provided with pockets large enough to hold several hours' output, and when these are filled the dredge steams out to sea and dumps its load. The latter type of dredge is called a **sea-going** or **hopper dredge**; and is used where the water is too rough to fasten scows alongside of the dredge. The hopper dredge is advantageous to use wherever the material is suitable and the excavation is deep enough to permit its use, and where the dump is not too remote. It is well adapted to sand and gravel when the latter is not too coarse, but cannot operate in mud because this will not settle in the bins. The Ambrose Channel at New York Harbor is maintained by such dredges, the material being all sand and the distance to the dump about 15 miles. Excavation by this method costs about 9 cents per cu. yd., bin measurement.

A Dipper Dredge is simply a steam shovel of the railroad type (see Art. 23) mounted upon a scow; and differs from an ordinary steam shovel chiefly in having a longer dipper-handle and a longer boom. In extreme cases, for ditch and levee work, the dredge can dig as deep as 60 ft. at low water. The dipper ranges in size from 1/3 to 15 cu. yd. It is better adapted to all kinds of work than any of the other types, since it can handle any material any other type can, and it can excavate material too tough for any of the other forms; but when large quantities of earth are to be moved and when other conditions are favorable, some of the other types are more economical.

The dipper dredge is excellent for hard digging, in which it has no competitor excepting the ladder dredge and that is rarely a serious competitor. A great deal of soft or stratified rock is dug by dipper dredges without blasting. They are the only machine adapted to removing old cribs and docks. In operation, the dipper dredge is not afloat, but is hoisted or " pinned up " on the " spuds." In soft ground these spuds have wide shoes to spread the pressure upon the bottom. These are adjustable steel posts or legs which are forced down into the bottom and hold the dredge rigidly in place. A modern

15-yd. dipper dredge costs from $700,000 to $1,000,000. Dipper dredges are much used for harbor and ditch work. (See Bull. 300, Bureau of Public Roads, U. S. Dept. of Agriculture.)

The Elevator Dredge, also called a ladder dredge and a chain-and-bucket dredge, consists of a series of scraper buckets attached to a chain, which scoop up the material and deliver it at the top of the ladder, where it is discharged into a chute or onto a belt conveyor. The tower which carries the upper end of the ladder is usually 20 to 25 ft. high. One " high tower " type has towers 75 to 80 ft. in height. The buckets have capacities of 1/2 to 15 cu. ft., are spaced from 3 to 6 ft. apart, and travel at a speed of 40 to 60 ft. per minute. The first machine of this type was made in France in 1859 for use on the Suez Canal. This type is more common in Europe than in the United States. For certain types of work where the material is free from roots and stones, it is rapid and economical of power. It can work in deeper water than the dipper dredge, and has continuous operation and large capacity; but it is more complicated and more likely to get out of repair. It is used in placer mining and for sand and gravel digging. On canal work in New Orleans a small ladder dredge having 32 buckets of 6-ft. capacity and working in swampy muck averaged 24,000 cu. yd. per month (Eng. News, Aug. 14, 1913).

Hydraulic Dredge. The essential feature of the hydraulic or suction dredge is a centrifugal pump which draws water and suspended earth through a suction pipe and discharges them through a line of pipe floated on buoys or pontoons. With light alluvium or fine sand, a reasonable amount of solid material is drawn up with the water, if the lower end of the suction pipe is nearly in contact with the soil; but in any other soil some form of agitator must be employed to loosen and stir up the material to be excavated. With medium soils the material can be stirred up sufficiently with one or more water jets; but in tough material a mechanical agitator, usually in the form of a hollow rotary cutter, is required. The agitator and the suction head are mounted on a ladder which, in the forward-feeding type of dredge, swings in a vertical plane. For lateral motion the whole dredge must be moved. In the radial feeding type, the ladder is designed to permit horizontal as well as vertical movement. The dredge may be either steam-, electric-, or Diesel-driven. Some smaller ones are gasoline-driven. The hydraulic dredge is used principally for construction and maintenance of rivers and harbors, for filling in and reclaiming land, and for canals and ditches, provided the material to be handled is of a nature which lends itself to hydraulic dredge handling. There must be a large spoil area available for dumping and it must not be too far away, although there are dredges which will transport material economically 10,000 ft. The following table taken from Bulletin 300, Bureau of Public

Diameter of suction and discharge pipes, in.	Normal capacity, gal. per min.	Cubic yards solids pumped per hr. Per cent of solids			Approximate horsepower required for each foot of total head
		10%	15%	20%	
4	450	12	18	24	0.4
6	1 000	30	45	60	0.8
8	1 800	50	75	100	1.5
10	2 800	90	135	180	2.5
12	4 000	130	195	260	3.0
18	9 000	300	450	600	7.0
24	17 000	500	750	1000	10.0

Roads, U. S. Department of Agriculture, gives an indication of what these dredges can do; but it should be considered as giving only a very approximate idea of the output, which is a function of the kind of material, the length of discharge pipe, and the height to which the material is lifted.

Material pumped by a hydraulic dredge and used for fill will take slopes approximately as follows: Sand pumped into place under water, 1 : 8 to 1 : 15; sand pumped into fill on land, 1 : 20 to 1 : 60; clay pumped into place on land, 1 : 4 or 1 : 5 if the clay forms balls in passing through the delivery pipe, and practically horizontal if the material comes out as liquid mud.

A Grapple or Grab-Bucket Dredge consists of a self-filling bucket suspended from a swinging or rotary boom; and is often called a **clamshell dredge** from the former form of the two halves of the bucket. At present there are only two forms of bucket in use, the orangepeel and the grab-bucket. The former consists of three or more curved triangular spades which when closed form a hemisphere; and the latter consists of two quadrants of a cylinder, which when closed form half of a short cylinder. These buckets are suspended by two chains or wire cables, one to close the bucket in loading it and one to open it in discharging. Both forms of buckets are made of rated capacities varying from 1/2 to 12 cu. yd. loose measurement. The great advantage of the grapple dredge over the dipper form is the greater length of boom permissible and the fact that there is practically no limit to its digging depth. A grapple dredge has done excellent work with a boom 240 ft. long. (Eng. Rec., Vol. 74, p. 360.) A long boom is sometimes of great advantage in ditch or levee work. The orangepeel bucket fills itself only in comparatively soft ground; and consequently the grab-bucket must be employed in hard or tough ground, for which work it is sometimes provided with teeth on the cutting edge and with extra power for closing. This form of dredge is peculiarly adapted to very deep dredging or to work in confined places like the inside of a cofferdam or even a pier cylinder. The grapple excavator is sometimes economical in excavating trenches, and can be used to load wagons or cars in dry excavation. It is particularly advantageous in cellar excavation, since the wagons can remain on the natural surface. In good material it can deliver a bucket load every minute. A 10-yd, 15-ton 2-part bucket working in water 65 ft. deep with 10 men and 5 tons of coal averaged 4000 cu. yd. in 10 hours, and in another case 2300 cu. yd. in 10 hours (Eng. News, 1899, vol. xli, p. 66).

Grapple dredges can be operated very cheaply due to their rapidity. Where the material is favorable, such as mud and sand or soft clay, it can be put into a scow lying alongside by a grapple dredge more cheaply than by any other method.

A Dragline Bucket Dredge is a form in which material is handled with a scoop roughly resembling the ordinary drag scraper suspended from a swinging boom, the scoop being drawn toward the machine by a line attached to the front and a second line at the rear holding it at the proper angle to slice the earth away as it is moved forward. When the scoop is filled, it is lifted to the point of the boom, both lines being kept taut, and is then swung around; when on slacking the drag or hauling line, the scoop dumps automatically. The bucket or scoop is lighter than an orangepeel or grab-bucket of equal size, and hence the whole machine may be lighter. It will excavate either soft or fairly hard material. There are several slightly different forms of bucket on the market. An important advantage of the dragline excavator is the wide reach possible by the use of a long boom. The dragline excavator is at present the favorite machine for widening and deepening small streams and ditches and for building levees and earth dams.

The dragline machine may be used for excavating either under water or in the dry. It is best adapted for jobs where the excavated material does not have to be removed from the site, but may be piled up temporarily by the dragline and later backfilled or spread out on the "dump" by the same machine. In cut-and-fill work, it is sometimes economical to handle the material as many as four times, the dragline being used first to scrape the soil from the cut to the beginning of the fill, and afterwards being moved to the fill and used again to scrape the excavated material still farther onto the fill.

The engineers of the Miami Conservancy District, Dayton, Ohio, under the direction of Arthur E. Morgan, Chief Engineer, made an elaborate investigation of different earth-excavating machines, and adopted the dragline excavator for that mammoth work, and had extensive experience in the use of this machine in excavating channels, and in building levees and earth dams. The District had nineteen dragline excavators at work, ranging from a 40-ft. boom and a 1 1/2-yd. bucket to a 160-ft. boom and a 5-yd. bucket. The following are the advantages, as stated by C. A. Bock, Division Engineer, which led to the adoption of the dragline excavator on this work almost to the exclusion of other devices.

Advantages. 1. The shape of the bucket and the method of loading make it possible to excavate boulders and also to pull stumps and large roots. The capacity of the buckets in use ranges from 3/4 to 5 cu. yd. Clamshell and orangepeel buckets may also be used, in which case the machine operates like an ordinary grab-bucket dredge. 2. The dragline has greater reach than steam shovels or any type of dredge. The horizontal radius for excavating or dumping may be 20 to 30 ft. beyond the end of the boom; and the vertical reach may be as low as 50 ft. below the machine bed and as high as 30 ft. above. 3. While the dragline ordinarily digs toward itself, with comparatively simple rigging it may be arranged to dig away from itself. 4. It is efficient in loading cars, in some cases even surpassing the steam shovel. 5. The dragline excavator may often be used to advantage as a movable revolving derrick for lifting track and equipment in conjunction with its own operation, which frees it from many interruptions to which other types are subject. 6. The lighter dragline machines may be mounted on caterpillar traction, or may be provided with walking devices, which give greater speed and more freedom of movement than any other type of excavating machine. 7. The heavier types are usually mounted on skids and rollers or on wheels and track, in which case they have greater range of action and require less track shifting than steam shovels or other types of dredges. 8. The dragline picks up, moves ahead, and relays, its own track.

Disadvantages. The disadvantages of the dragline excavator are: 1. In narrow cuts there is not sufficient dragging distance to fill the bucket properly and hence under this condition the dragline is not as efficient as the steam shovel or the dipper dredge. 2. The dragline ordinarily leaves the bottom of cuts and borrow pits quite rough, although a skillful operator can secure fairly satisfactory results.

The Cableway Excavator consists of an excavating self-loading bucket carried on a cable which is supported by towers at its two ends. One tower is high and usually is the one at which the operating machinery is located. The other tower is lower and is at the other side of the work. The commonest type of cableway excavator is the slackline cableway. The track cable in the slackline type can be loosened and tightened to permit raising and lowering of the bucket. The tightline type has a fixed track cable and the bucket is raised and lowered by mechanical attachments. The slackline can excavate up to one-third its span, which may be from 200 to 1200 ft. It can lift excavated material about 150 ft. It is used mainly for gravel pit operations, but has been found very useful on Mississippi river levee construction. The towers may be fixed or may be mounted to travel along the work. The power may be steam, electric, or gasoline. In gravel pit operation the material is dumped usually into a screening and handling structure. In levee work the material is dumped into the embankment. The accompanying table indicates roughly what may be expected from this type of excavator. The variations are due to differences in materials and other local conditions.

Capacities in Cubic Yards per Hour on Average Hauls for Various Lengths of Span

(Data furnished by Sauerman Bros., Inc.)

Size of bucket, cu. yd.	300-ft. span, 200-ft. av. haul	500-ft. span, 300-ft. av. haul	700-ft. span, 400-ft. av. haul	1000-ft. span, 550-ft. av. haul
1/2	19 to 26	18 to 24	....	....
1	38 to 52	36 to 48	30 to 40	....
2	78 to 104	72 to 96	60 to 80	50 to 68
3	114 to 156	108 to 144	90 to 120	75 to 102

The Power Scraper is a bottomless drag scraper which is pulled back and forth across the job by cables by means of a steam-, gasoline-, or electric-driven hoist. It may be crescent-shaped or V-shaped and the bottom or cutting edge may be equipped with teeth. The scraper is dragged through the material by the front cable, gets its load, and deposits it at the load point. It is then dragged by the rear cable back to the digging point. Towers are needed at the head and tail points to carry the sheaves over which the cables operate.

The scrapers come in 1/3- to 6-cu. yd. capacity sizes. They are used for stripping operations, for moving large quantities of materials in storage operations, and for highway construction. They are often used in conjunction with slackline cable operations. The power drag scraper is found most economical on hauls of 200 to 400 ft.

Estimated Hourly Capacities in Cubic Yards

(Data from Sauerman Bros., Inc.)

Length of haul, ft.	Size of scraper, cu. yd.							
	1/3	1/2	3/4	1	1-1/2	2	4	6
100	22	34	51	80	120	160	320	480
200	12	18	27	42	63	84	168	254
300	8	12	19	28	42	56	112	168
400	6	10	14	21	32	43	86	126
500	5	7	11	17	26	34	68	104

27. Ditching Machinery

It has been estimated that there are still in this country something like 100,000,000 acres, or over 150,000 square miles, of swamps and wet lands. This area is about two and a half times as large as all the New England States. A considerable part of the redemption of this vast tract will consist of building levees and dredging main drainage channels. The building of levees and the construction and operation of dredges have been described in Arts. 25 and 26, and the principles of drainage are discussed in Sect. 16. It is proposed to briefly consider here some of the machines employed in constructing medium-sized drainage and irrigation ditches.

The **dipper dredge** (see Art. 26) is an important machine in the drainage of swamp or overflowed land. There are four forms of this machine specially adapted to ditch work, namely, the floating type, the land type, the walking dredge, and the drag boat.

The **floating type** is a steam shovel mounted upon a wooden or steel hull. It may work either up or down stream, but the latter is much the more common, since then dams are not necessary behind the dredge to retain water in which to float it. The capacity of the dipper varies from 0.5 to 5 cu. yd. The maximum size of ditch that can be dug economically with this type varies from 100 to 1200 sq. ft. and the minimum is 10 ft. wide and 5 ft. deep.

The **land type** of dipper dredge consists of a boom, a dipper, and the necessary machinery mounted upon a frame which straddles the ditch and runs upon wheels resting directly on the banks or upon a track. Some machines have caterpillar traction. The capacity of the dipper varies from 1/2 to 1-1/2 cu. yd., and the span from 15 to 50 ft. The land type can be dismantled and moved more easily than the floating form; but in stumpy ground it is not as good as the latter, since it lacks power to uproot large stumps. The land type is objectionable unless the ditch is narrow and the banks of the ditch are firm. With soft banks the caterpillar traction is better than either broad wheels or a track. The chief advantage of the land dredge is that all of the excavation is in sight, and hence a better ditch can be dug than when the excavation is done under water as with the floating type.

The **walking dredge** straddles the ditch. Its distinguishing characteristic is that each corner of the frame rests upon a built-up foot of which the horizontal cross-section is about 6 × 8 ft., and in the middle of each side of the frame is a similar foot about 6 × 12 ft. When the machine is to be moved forward, it raises itself and also the four corner feet until it is entirely supported on the two center feet; and then the machine slides itself about 6 ft. forward on the middle supports. The corner feet are then lowered, and the weight of the frame thrown upon them; and next the center supports are raised, and brought forward ready for another move. "Walking Speed" is about 500 to 800 ft. per hour. The chief advantage of the walking device is that it enables the whole machine to move itself across country without dismantling, thus saving much time and also the cost of dismantling and rebuilding.

The **drag-boat ditching machine** is mounted on a hull whose transverse cross-section is somewhat like that of the ditch to be dug. The whole machine is moved forward by winding up a cable anchored ahead. This type has booms from 25 to 30 ft. long, and dippers of 1/2- to 3/4-cu. yd. capacity; and will excavate a ditch having a bottom width of 4 to 6 ft. It cannot be used if the banks of the ditch will not stand without caving, since that may wedge the hull fast.

The **drag-line excavator** (see Art. 26) is in many ways the most developed type of machine for ditch work. It may follow the center line of the ditch, backing away from the completed work, or it may travel on one side of the ditch. The first method is usual for small ditches, and the second for large ditches; and sometimes for large ditches the machine travels down one side and back on the other, excavating half of the channel each trip. Dragline excavators have been made with booms 40 to 150 ft. long and buckets holding from 1 to 5 cu. yd.; but the longer booms and larger buckets are not very common. The comparatively wide reach of the dragline excavator fits it for excavating channels wider than can be dug economically with the floating dipper dredge, but the cost of ditch work with a dragline excavator is usually more than with a dipper dredge. The dragline can cut the side slopes of the ditch more accurately and more economically than the dipper dredge and also can leave a wider berm, both of which are important advantages.

When arranged specially for ditch work, the dragline excavator may be mounted upon traction wheels, or on skids and rollers, or on car wheels on a track; or it may be mounted as a walking machine like the walking dipper dredge previously described. It may also be mounted on a tractor, and is then specially adapted to ditches of small cross-section.

A form of dragline scraper is called the **templet excavator.** It has two buckets, back to back, working on a frame transverse to the ditch in such a manner that one bucket shaves off a thin slice down one slope and across the bottom and up the other slope, and then dumps. One scraper does the excavating one way and the other in the opposite direction. The frame carrying the buckets is lowered automatically as the ditch increases in depth, so that the slopes and the bottom are cut accurately to specifications. When the desired depth is reached, the frame is raised and the machine moved forward or backward, as the case may be, for a new cut.

28. Hydraulic Sluicing

Hydraulic Sluicing has been used successfully for the excavation of large volumes of material, and notably on the Panama Canal and by the Miami Conservancy District in Ohio. The method consists in breaking down the material in the " borrow pit " by means of a powerful water jet which is discharged from a large nozzle or monitor commonly called a " giant." The nozzle diameter varies from 2 1/2 to 5 in., and the jet or " muzzle " velocity of the stream varies up to 150 ft. per sec. The working pressure for a 5-in. nozzle may be as high as 150 lb. per sq. in.

The water is supplied by centrifugal pumps, which must have the required water capacity and must exert a head sufficient to overcome the suction and the friction losses in the pipe line and to develop the necessary head at the monitor. The pipe line from the pump to the monitor should be 12 to 15 in. in diameter in order to reduce friction losses, but is reduced in size near the monitor where the pipe requires frequent handling.

In operation, the water jet is directed against the base of the bank which is being excavated, and washes out the material. This causes caving of the bank and furnishes loosened material which is readily washed away by the jet. The water, with its burden of excavated soil, flows out of the borrow pit and is conducted to the site of the fill in a " sluiceway " which generally is merely the natural channel formed by the flowing water. As a rule, the supply of water from the jet is not sufficient to carry off the excavated soil properly, and an additional stream of water is provided for this purpose by low-pressure pumps. The sluice will generally require a slope of about 4 per cent. Where the ground is particularly hard, especially with some types of clay, it may be necessary to loosen the bank partially by blasting. Gravel and sand are the easiest material to excavate by this method, if there are not too many cobblestones or small boulders scattered through the bank. Clay is more difficult to handle; some kinds of clay will not entirely break down, but will pass through the sluice in round balls several inches in diameter.

The monitor should be placed as close to the pit face as possible in order to take advantage of the full force of the jet, but this distance will be limited by the danger of caving of the bank. The slope of the sluice should be as flat as possible in order to keep the elevation of the monitor at a minimum, as this will give a higher pit face and increase the quantity of material available for excavation.

The hydraulic sluicing method is well adapted to excavating jobs which have suitable material for breaking down, where there is an ample water supply, and where the borrow pit is at a high enough elevation so that a sufficient grade may be obtained for the sluiceway. The method is particularly adapted to the construction of hydraulic-fill earth dams. It has also been used on large street grading work in Seattle, Wash., in 1912 (Eng. Rec., Vol. 65, p. 480), and in highway grading near Vancouver, Wash., in 1926 (Eng. News-Rec., Vol. 97, p. 776). In the Miami Conservancy District large quantities of material were handled by this method, at costs ranging from 21 to 65 cents per cu. yd., the lower costs being for gravel handled under favorable conditions. On this work, however, the cost was higher than should be expected on an ordinary excavation job, due to the necessity of securing the requisite amount of fine material for the core of the dam. The output ranged from 12,000 to 50,000 cu. yd. per month, the latter being accomplished with two giants having nozzles of 5-in. and 2 1/2-in. diameters. The contract price for the work at Seattle was 10 cents per cu. yd. for excavation and 15 cents per cu. yd. for embankment.

See "Methods and Plant for Excavation and Embankment" by C. H. Paul and C. S. Bennett; also "Construction Plant, Methods and Cost," Technical Reports, Part X, Miami Conservancy District.

For sluicing of hydraulic fill dams, see Sect. 15, Art. 6.

29. Excavation Classification

There is probably no single problem in the interpretation of contracts that is more difficult than the classification of excavation into rock, loose rock, and earth. No specifications have yet been evolved that will be interpreted by two men precisely alike. Wide variations of interpretation are possible by those of opposing interest. It is the duty of the engineer to write them as clearly as he can and to interpret them as broadly and definitely as he can to prospective bidders, especially to the contractor to whom the contract is to be awarded. The following specification is in part from the Reading Railroad company.

Excavation is classified as: solid rock, loose rock, and earth—dry or in water.

(1) **"Solid Rock"** shall include all rock which is found in ledges or detached masses, exceeding 1 cu. yd. each, and which may be best removed by blasting.

(2) **"Loose Rock"** shall include all other rock and cemented gravel which may be removed without blasting, although blasting may occasionally be resorted to; also detached stones less than 1 cu. yd. and more than 1 cu. ft. in volume.

(3) **"Earth"** shall include all materials of whatever name or character not unquestionably rock, as above defined.

(4) **Excavation in Water**: (a) This term shall apply to the removal of all materials in water, or materials thoroughly saturated or impregnated with water, except surface water which can be drained away.

(b) It shall include drainage, bailing, pumping and all labor and other expenses connected with such excavation.

(c) In changing, deepening, or making water courses, all materials above the water level and materials that can be removed without becoming saturated with water shall be classified as dry.

(5) **Payment for Excavation.** Excavations in all the several classes thereof shall be estimated and paid for by the cubic yard of material removed, measured in its original undisturbed state. Estimates shall be based on cross-sections, made by the engineer, of the undisturbed surface before the work is started, of the uncovered surfaces as the work progresses (when different classes of material are uncovered), and of the completed surfaces. Specifications for dredging should state whether or not excavated material is to be paid for in its original undisturbed state or on basis of scow measurement.

(6) **Payment for Embankment.** Embankments shall not be estimated or paid for when made from excavations; but in special cases when made from material furnished by the owner to the contractor they shall be estimated and paid for by the cubic yard of material placed in the embankment measured in its finished state. Estimates shall be based on cross-sections, made by the engineer, of the surface before the filling is started and of the finished surfaces.

(7) **Haul.** The prices paid for the several classes of excavation shall be understood to cover the entire cost of removal and disposal in the manner and at the location prescribed, it being understood that no allowance will be made for over-haul.

Comments on Specifications: There often arises a question whether or not shale, soft sandstone, or hardpan belong under solid rock or loose rock. In justice to the contractor and in the interests of all parties to the contract, an interpretation of this should be made in advance of the signing of the contract. Even then the final line of demarkation is usually a matter of judgment.

It is extremely difficult at times to determine with justice the difference between earth and loose rock. For instance, if the work consists of ordinary sand and gravel and it is understood that it is to be removed by scrapers, nests of small boulders of 1 or 2 cubic feet make the operation of scrapers impossible. If such nests could not be foreseen by observation or from the borings that were taken in advance of the contract, the contractor has some equity in his contention that such material is not earth.

It is also difficult to specify accurately what is not rock. It has been classified by some as that which cannot be plowed and by others that which cannot be loosened with an ordinary pick. However, a very heavy plow and tractor can loosen ground which would not normally be classified as earth unless this was clearly explained to the contractor in advance of signing the contract. In other words, standard specifications without a specific interpretation, applicable to the particular work to be undertaken, are dangerous.

Referring to paragraphs 5 and 6, the common expression is that "excavation shall be measured and paid for in cut and not in fill."

If item 7 is included in the specification the contractor must be careful to determine, in advance of signing the contract, where the fill is to be spoiled; or in some way the haul must be predetermined.

In some specifications slate, coal, shale and soft friable sandstone and soft soapstone are not classified as solid rock but as loose rock. It should also usually be stated that the prices agreed upon for excavation include the cost of all clearing and grubbing and for the removal and disposing of all materials covered by the contract; if not so stated, separate prices should be given for clearing and for grubbing. These terms should be defined by the contract substantially as follows: **Clearing** is the disposal of all trees, brush and other perishable material, which shall be removed or destroyed by burning. Large trees shall be cut not more than 2-1/2 ft. from the ground; and in embankments less than 4 ft. and more than 2-1/2 ft. high, they shall be cut even with the ground. **Grubbing** is the removal of stumps and roots. Clearing and grubbing are paid for on the basis of the area involved.

Overcutting or excess excavation is not usually paid for unless due to causes beyond the control of the contractor. Rock excavation is generally carried 6 in. below subgrade.

SECTION 9

TIMBER STRUCTURES

BY

WALTER J. DOUGLAS *

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

* H. A. Foster and W. H. Correale assisted in the revision of this section.
Acknowledgment is made for valuable criticism and suggestions by C. E. Paul.

SIMPLE TIMBER CONSTRUCTION

1. Working Unit Stresses

The recommended unit stresses for material complying with structural grades of the American Society for Testing Materials, as determined by Forest Products Laboratory, U. S. Forest Service, 1926, are given in the following table:

Safe Allowable Working Unit Stresses in Pounds per Square Inch

Dry Location—Common Grade Timber

Kind of timber	Allowable stress: Bending: In extreme fiber (tension with grain)	Allowable stress: Bending: Horizontal shear (with grain)	Allowable stress: Compression: Perpendicular to grain	Allowable stress: Compression: Parallel to grain; short columns	Intermediate columns, value of K: Select grade	Intermediate columns, value of K: Common grade	Modulus of elasticity, E
Cedar, western red	720	64	200	560	24.2	27.1	1 000 000
Northern and southern white	600	56	175	440	24.5	27.3	800 000
Port Orford	880	72	250	720	23.4	26.2	1 200 C00
Alaska	880	72	250	640	24.8	27.8	1 200 000
Chestnut	760	72	300	640	22.7	25.3	1 000 000
Cypress, southern	1040	80	350	880	21.2	23.7	1 200 000
Douglas fir, Coast region	1200	72	325	880	23.7	27.3	1 600 000
Rocky Mountain region	880	68	275	640	24.8	27.8	1 200 000
Fir, balsam	720	56	150	560	24.2	27.1	1 000 000
Golden, noble, silver, white	880	56	300	560	25.4	28.4	1 100 000
Hemlock, West Coast	1040	60	300	720	25.3	28.3	1 400 000
Eastern	880	56	300	560	25.4	28.4	1 100 000
Larch, western	960	80	325	880	22.0	24.6	1 300 000
Oak, red and white	1120	100	500	800	24.8	27.8	1 500 000
Pine, southern yellow	1200	88	325	880	23.7	27.3	1 600 000
White, sugar, western white, western yellow	720	68	250	600	23.4	26.2	1 000 000
Norway	880	68	300	640	24.8	27.8	1 200 000
Redwood	960	56	250	800	22.2	24.8	1 200 000
Spruce, red, white, Sitka	880	68	250	640	24.8	27.8	1 200 000
Englemann	600	56	175	480	23.4	26.2	800 000
Tamarack, eastern	960	76	300	800	23.1	25.8	1 300 000

(See A. S. T. M. Standard Specifications D 245–27; Dept. of Commerce Report on "Recommended Building Code Requirements for Working Stresses in Building Materials," 1926; also Trans. Am. Soc. C. E., Vol. 91, p. 400.)

The following comments on the use of this table are based on the authorities quoted.

The allowable stresses given are for **Common Grade** timber, which contains many knots and blemishes but which is suitable for general utility and construction purposes. For **Select Grade** timber, which is generally clear and limited in defects both in size and number, these stresses may be increased 33-1/3% for Douglas fir (Coast) and Southern pine, and 25% for all others, excepting compression perpendicular to the grain and modulus of elasticity which are the same for both grades.

The stresses also are given for dry locations. In locations where the timber will be exposed to the weather, the allowable stresses shall be reduced 25%, excepting horizontal shear and modulus of elasticity which, in designing, are assumed not to vary with conditions of exposure.

In joints, the shearing stress with the grain may be taken as twice the value given in the table, for both grades of timber.

Stress due to dead and live loads acting singly or in combination, without wind load, shall not exceed the allowable stress given above. For stresses produced by wind loads or by a combination of wind loads and dead and live loads, the working unit stresses may be increased by 50% provided the resulting sections are not less than those required for dead and live loads alone. The recommended working stresses may be used without any increase of live loads to allow for impact.

Stress in compression perpendicular to the grain may be increased by 50% above that given in the table in the case of joists supported on a ribbon board and thoroughly spiked to the studding rather than resting upon or in masonry.

The unit stresses for columns whose ratio of unbraced length to least width l/d is 11 or under are those given in the table for short columns. The unit stresses for columns whose ratio l/d is 12 or greater must be reduced by column formulas (Art. 3). The values for modulus of elasticity are average for the several kinds of timber and not safe working values. They are for use in computing average deflections of beams. When it is desired to prevent or limit sag in a beam, one-half the values given in the table should be used. For instance, in a building, beams supporting an ornate plastered ceiling should be figured using the value $E/2$. E cannot be used to determine the shortening of timber when the pressure is applied to side grain, such as the pressure of a post upon a cap or sill.

For continuous heavy loading, or loading causing reversal of stress in a member, 80% of the table stresses is suggested. The strength of timbers in old exposed structures should not be assumed higher than 80% of the table stresses, after deducting for timber exposed to weather as noted above, and only the section exclusive of rotted or partly rotted portions should be considered as effective. Old timbers should be bored at numerous points, in order to determine the effective sections. For timber to be immersed in water deduct 33%, except for side grain impression for which deduct 50%.

In the design of structures to be built in cities, the unit stresses permitted by the building codes must be considered.

In designing, only the net section of dressed timber should be considered. Undressed seasoned timber is generally a little scant of the listed or nominal cross-sectional dimensions. Ordinary differences between nominal and actual standard dimensions of dressed timbers are:

Timber	Nominal	Standard
Joists, rafters, plank, flooring.	Thickness, 2 to 4 in.	3/8 in. less
	Depth, 4 to 7 in.	3/8 in. less
	Depth, 8 in. and over	1/2 in. less
Beams, girders, stringers.	Thickness, 6 in. and over	1/2 in. less
	Depth, 8 in. and over	1/2 in. less
Posts, caps, sills, timbers.	Size 6 × 6 in. and over	1/2 in. less

Standard lengths are in multiples of 2 ft.

The constructor should inspect important timbers to be sure that the actual dimensions equal those assumed in the design.

2. Properties of Timber

Unit Weights of various kinds of timber are given in the table herewith. In designing, an average value of 40 lb. per cu. ft. or 3.3 lb. per ft. board measure may be used; this is closely the actual weight of commercially seasoned southern pine.

Kind of timber	Weight per cu. ft. air-dry	Kind of timber	Weight per cu. ft. air-dry
Cedar, Western red	23	Hemlock, West Coast	28
Northern and Southern white	23	Eastern	28
Port Orford	29	Larch, Western	36
Alaska	29	Oak, red	44
Chestnut	30	White	48
Cypress, Southern	32	Pine, Southern	41
Douglas, fir, Coast region	34	White, sugar, Western white, western yellow	27
Rocky Mountain	30	Redwood	30
Fir, Balsam	26	Spruce, red, white, Sitka	27
Golden, noble, silver, white	27	Engelmann	23
		Tamarack, Eastern	37

These are average values, as determined by the U. S. Forest Products Laboratory.

Sizes and Specifications. In designing small structures, standard sizes and lengths should be used, as special sizes and long lengths are expensive. Standard lengths are in multiples of two feet, and usually do not exceed 20 ft. In many cases, considerable saving can be made by using "short-length lumber," less than 8 ft. long. (See "Marketing of Short-Length Lumber," published by U. S. Dept. of Commerce, 1926.) Nominal cross-sectional sizes of undressed timber are in multiples of 1 or 2 in.

"Simplified Practice Recommendation No. 16," on Lumber, published in 1926 by the U. S. Department of Commerce through the Bureau of Standards, gives a recommended set of standards and specifications for sizing, classifying or grading timbers which was generally accepted by the lumber interests throughout the country and was adopted by the American Railway Engineering Association and the American Society for Testing Materials.

Indentation under Side Grain Compression. The safety of structures is seldom endangered by crushing across the grain. The indentation made, however, is important in some structures and allowance for it should be made in design. It is suggested that in computing the amount of side grain indentation or compression, 0.05 in. be used for all exposed timbers under the safe load unit pressures and 0.10 in. for double these unit pressures. If timber is to be immersed in water, double the above allowances. In rough carpentry work where joints are not well made, double the above allowances; if such joints are to be saturated, use four times the above values. In the construction of the Arlington Memorial Bridge, Washington, D. C., white and red oak wedges, which carried the arch load although subjected to the weather, failed when saturated for three days by flood waters. It is thought that if these wedges had been thoroughly oiled or greased (which is good practice for such wedges subjected to weather or flood) failure would not have occurred.

For thoroughly seasoned timber in a housed structure and for first-class carpentry work, it is suggested that the indentation be computed as 0.01 in. for the allowable compressive stress given in Art. 1.

Non-Uniform Distribution of Pressure on timber requires special consideration, and the excess pressure caused by such distribution should be considered in designing. Such a condition commonly occurs at the end of a roof-truss or arch centering, where the center of the support is not directly in line with the resultant load of the structure. Fig. 1 shows this condition under arch-

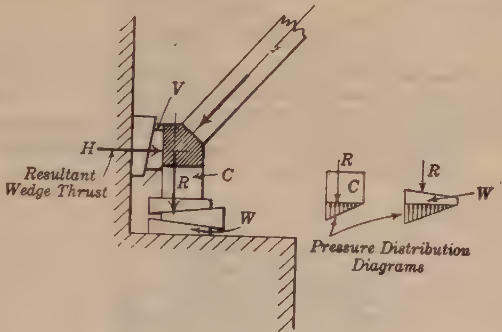

Fig. 1

centering, where the resultant thrust from the timber framing and the wedges which take the horizontal thrust falls outside the center of the supporting timber. This causes non-uniform stress distribution in the latter as indicated by the pressure diagram.

Attention is also called to the fact that the point of application of *H* depends upon the care with which the wedges are made and driven. It may vary by one-fourth the length of the wedge *V*. Therefore the unit side-grain compression should be conservative in both the vertical and horizontal wedges and in the cap *C*.

In a study made in 1917 by the Forest Service of the U. S. Department of Agriculture, hardness of air-dried timbers was tested by measuring the load required to embed a 0.444-in.-diameter ball to one-half its diameter in the wood. Hardness across the grain may then be determined from the accompanying table.

Kind of timber	Load required to imbed ball, lb.	Relative hardness	Kind of timber	Load required to imbed ball, lb.	Relative hardness
Cedar, Western red..	380	.28	Hemlock, Eastern...	490	.36

Hemlock, Western...	620	.46			

Compressive Stress on Surfaces Inclined to the Fibers. Many formulas exist for determining the compressive strength of wood on surfaces at an angle to the fiber. One of the more recently developed ones, known as the Hankinson formula, is recommended by the U. S. Forest Products Laboratory for general use in timber framing. The equation for the formula is

$$N = \frac{PQ}{P \sin^2 \theta + Q \cos^2 \theta}$$

in which N = allowable unit stress on the inclined surface;
P = unit stress in compression parallel to the grain;
Q = unit stress in compression across the grain;
θ = angle between the direction of the load and the direction of the grain. It is equal to 90° minus the angle between the inclined surface and the direction of the grain. (See Fig. 1*a*.)

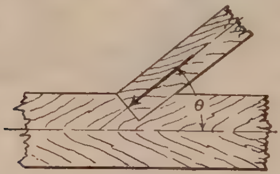

Fig. 1*a*

The table given here is based on this equation

Safe Loads in Pounds per Square Inch

Common Grade Timber—Dry Location

Kind of timber	Angle θ, degrees						
	7-1/2	15	30	45	60	75	82-1/2
Cedar, Western red	540	500	390	295	240	210	200
Cypress, Southern	860	800	640	500	410	370	355
Douglas fir, Coast	860	790	615	470	390	340	330
Fir, Balsam	535	470	330	240	180	160	150
Hemlock, Western	705	660	535	425	355	315	305
Oak, red and white	790	770	695	615	550	515	505
Pine, Southern yellow	855	790	620	470	390	340	330
Redwood	770	695	515	380	300	260	255

Select Grade Timber—Dry Location

Kind of timber	Angle θ, degrees						
	7-1/2	15	30	45	60	75	82-1/2
Cedar, Western red	670	600	430	310	245	210	205
Cypress, Southern	1060	965	715	530	420	365	355
Douglas fir, Coast	1125	1000	710	510	395	340	330
Fir, Balsam	660	560	365	250	185	160	155
Hemlock, Western	870	790	600	450	360	315	305
Oak, red and white	985	940	800	665	570	515	505
Pine, Southern yellow	1125	1000	710	510	395	340	330
Redwood	950	830	570	400	310	265	255

For timber in locations exposed to the weather, the safe loads in these tables should be reduced by 25%. If timber is to be saturated, reduce by 50%.

Coefficients and Angles of Friction

Kind of surface. Position of fibers with reference to direction of sliding	Coefficient of friction	Angle of friction
Wood on wood, undressed, side grain, fibers parallel	0.45	24° 10′
Wood on wood, undressed, side grain, fibers at right angles	0.35	19 20
Wood on wood, undressed, end grain on side grain	0.30	16 40
Wood, undressed, on rough metal	0.45	24 10
Wood, undressed, on smooth metal	0.30	16 40
Wood on wood, dressed smooth	0.35	19 20
Wood dressed smooth on smooth metal	0.25	14 00
Wood on masonry. See Sect. 10, Art. 18	....	....

These coefficients are average values for dry seasoned wood as determined by comparison of published data. "Fundamental Ideas of Mechanics" by Morin contains good data on this subject. Soft, wet or unseasoned timber usually gives higher coefficients, although very green timber under small loads gives lower values.

When very heavy loads are applied, the fibers interlock and give higher values. End grain timber on side grain and metal on wood under heavy loads bite into the wood, tearing the fibers (Fig. 2) and causing mechanical restraint against sliding.

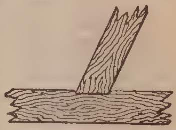

Fig. 2

If lubricants are used and the pressures are small, the coefficients of friction may be reduced 50 or 70% of the tabulated ones. If the pressures are as great as those given in Art. 1, the lubricant is squeezed out, the fibers bite into each other and the coefficient of friction will not be reduced.

Friction should not generally be regarded in the design of framed structures except as an added factor of safety. For temporary structures or simple members of permanent ones, such as battered posts of a highway trestle, it may properly be considered, but it is suggested that not more than 50% of the tabulated coefficients be used.

3. Beams and Columns

Wooden Beams are generally of rectangular section and of uniform depth, and only such beams are considered in what follows. A beam should be designed so that the extreme fiber stress due to bending, the maximum horizontal shear, and the compression across the grain, at the end bearings, do not exceed the allowed unit stresses, and so that the maximum deflection does not exceed a limit which is fixed by the use to which the structure is to be put. For highway bridges and trestles this limit is generally 1/200 of the span, for railway bridges and trestles 1/300, for plastered ceilings 1/360 and for ceilings supporting shafting 1/700. When the ratio of length to width in a beam exceeds 20, it should be laterally braced, cross-bridging being commonly used. If not braced, the safe extreme fiber stress in Art. 1 should be reduced as follows:

Ratio of length to width	20 to 30	30 to 40	40 to 50	50 to 60
Percentage of reduction	25	34	42	50

In the case of a beam used without a floor (which acts partly as lateral bracing) the ratio of length to least width should not exceed 30.

Wooden beams are often continuous over several supports and may be so figured, but most designers compute all timber beams as simple beams.

To design a beam for any loading, the depth d should be assumed, consistent with the general governing conditions and the fact that beams over 12 in. deep cost more per board foot than shallower ones. Having selected d, the width of beam can be determined by the proper formulas, selecting values for the unit stresses from Art. 1. For long and shallow beams the flexure formula will generally govern, for short and deep beams the shear formula. The designer must be careful to consider only the actual or standard cross-sectional dimensions of lumber and not the nominal ones. The safe loads given in the tables are based upon the standard or actual depths, although the depths given are nominal ones.

If the amount of deflection is important, formulas for depth in terms of deflection and unit stress should be used. The end-bearing area A should not be less than V/S_a, in which S_a is one-half of the allowed unit stress across the grain; this is recommended because flexure of the beam makes the pressure upon the front of the bearing greater than that at the back.

Safe Loads in Pounds Uniformly Distributed for Rectangular Beams One Inch Wide

For an allowable fiber stress of 1000 lb. per sq. in.

Span, ft.	Nominal depth of beam, in.										
	4	6	8	10	12	14	16	18	20	22	24

22	.....	160	280	460	670	920	1210	1540	1920	2340	2790
24	.....	150	260	420	610	840	1110	1420	1760	2140	2560
26	.....	140	240	390	560	780	1030	1310	1620	1980	2360
28	.....	130	220	360	530	720	950	1210	1510	1830	2190
30	.....	120	210	330	490	670	890	1130	1410	1710	2040
32	.....	110	200	310	460	630	830	1060	1320	1610	1920
34	.....	100	180	290	430	590	780	1000	1240	1510	1810

The weight of the beam need be considered only when the ratio of span to depth of beam is large. For concentrated loads at the middle of a beam, divide table safe loads by 2. For allowable fiber stresses other than 1000 lb., multiply safe loads of table by the (allowable fiber stress) ÷ 1000.

Safe Loads Based on Horizontal Shear. Safe loads uniformly distributed, for rectangular beams one inch wide, with assumed allowable horizontal shearing stress along the grain = 100 lb. per sq. in., are given in the following table:

Nominal depth, in.	4	6	8	10	12	14	16	18	20	22	24
Safe load, lb.	480	750	1000	1260	1530	1800	2060	2330	2600	2870	3130

The weight of the beam need not be considered, because when the shearing strength of a beam governs the design the weight of the beam is negligible. For short and deep beams these values will generally govern rather than those in the preceding table.

For allowable horizontal shearing stress other than 100 lb., multiply safe loads of table by (allowable shearing stress) ÷ 100.

Depths given in these tables are nominal (i.e., they are the sizes used for ordering timbers in the lumber trade), but the safe loads are computed for the corresponding standard depths (i.e., the probable actual depths). The total safe load is found by multiplying the load for a beam one inch wide by the standard or actual width in inches.

Notched Beams. Beams are frequently notched at their ends in order to cut down clearance and to bring the top surfaces of adjacent beams to the same level. They are also occasionally notched at intermediate points to clear other parts of a structure, such as the top lateral rods of a highway deck bridge. When notched at the ends, the strength of the beam is materially decreased if the depth of the notch is a large percentage of the depth. For beams whose depth is great compared to their length, the effect of notching is greatest because such beams fail in horizontal shear. It is suggested that in designing beams with end notches the actual end depth be used to determine the horizontal shearing stresses, or the safe load based upon horizontal shear, and that only 80% of the allowed horizontal shearing stresses given in Art. 1 be used.

When the notches are at or near the middle of the beam, the depth of the beam, in determining the extreme fiber stresses or the safe loads based on same, should be regarded as the net depth. It is further recommended that only 80% of the allowed fiber stresses and the safe loads based thereon be used. Report of the Chief of Engineers, U. S. A., 1883, p. 1496, contains valuable tests upon the subject of notches.

Knots. Beams containing large or loose knots should not be used, unless an allowance is made for the knots. Beams containing knots should be placed with the knots in the compression side of the beam, that is, for simple beams the knots should be at the top.

The Deflection formula for a beam 1 in. wide under uniform load may be written $f = 270\ (l/d)^3W/E$. The following table gives values of $C = 270\ (l/d)^3$ for various spans and widths. In this formula, l is expressed in feet, f and d in inches, W in pounds of total load on beam divided by standard or actual width in inches.

Values of C in the Formula, Deflection = CW/E for Beams One Inch Wide and Uniformly Loaded

36	......	......	......	......	......	......	3380	2350	1700	1270	970

The depths given in this table are nominal, but the tabulated values are computed for the corresponding standard sizes.

For a concentrated load at the middle of a beam, multiply the tabulated value of C by 1.6.

To Design a Beam for a span of 15 ft. under a uniform load of 4000 lb., deflection not to exceed 1/200 × span, the beam to be of southern pine, common grade. Art. 1 gives an extreme allowable fiber stress of 1200 lb. per sq. in. for southern pine. Using the first table of this article, assuming a nominal depth of 12 in., the safe load is 980 lb., but as this table is for a fiber stress of 1000 lb. per sq. in. the safe load for a pine beam 1 in. wide = 980 × 1200/1000 = 1180 lb. As beams come in widths which are generally in multiples of 1 in., select a beam 4 in. wide, nominal, or 3-5/8 in. standard.

The allowable horizontal shearing stress, with the grain, for southern pine is 88 lb. per sq. in. The preceding tabulation, based on shear, gives for a pine beam 1 in. wide and 12 in. nominal depth 1530 × 88/100 = 1350 lb. For a beam 4 in. wide, nominal size, the safe load = 3-5/8 × 1350 = 4900 lb. Therefore the dimensions of the beam are governed by flexure rather than by shear.

From Art. 1, $E = 1\,600\,000$. For the given span and depth $C = 600$, $W = 4000/3.625 = 1100$, and $f = 600 \times 1100/1\,600\,000 = 0.41$ in., which is less than 1/200 × span, and hence satisfactory. The safe compression across the grain is 325 lb. per sq. in. and using one-half of 325 lb. the area of the end bearing must be at least 4000/(2 × 163) = 12.3 sq. in. Since the beam is 4 in. wide nominal, or 3-5/8 in. actual, the length of bearing required is 3-1/2 in.

If the ratio of length of unbraced span to width exceeds 20, the safe loads of the table must be reduced by the percentages given in the first part of this article. For example, the ratio = 180/3.625 = 50. Therefore, if there is no lateral support, the safe load = 1180 × 0.50 × 3-5/8 = 2140. If this beam is detached so that it has no lateral support in its length, the nominal width should be increased to 8 in. (actual width 7-1/2 in.). If the beam supports joists or stringers or a floor fastened to it, it may be regarded as braced laterally and the 4-in. width may be used. A timber beam which is not braced at one or more points very seldom occurs in practice.

Columns. The following formula adopted by the American Railway Engineering Association, 1926, is recommended for columns whose ratio of unsupported length to least dimension is greater than 11 and less than K:

$$\frac{P}{A} = S\left[1 - \frac{1}{3}\left(\frac{l}{Kd}\right)^4\right]$$

in which P/A = safe working stress for the column, S = safe compressive stress parallel to the grain (Art. 1), l = unsupported length of column in inches, d = least side of column in inches. K is a constant which varies with the variety of timber, and is given in the table of Art. 1.

The above formula is used for intermediate columns whose l/d is greater than 11. When l/d is 11 or less, the safe load may be found by multiplying the column area by the allowable stress for short columns given in Art. 1. When l/d is greater than K, the following formula (based on Euler's formula for long columns) is used:

$$\frac{P}{A} = \frac{0.274\,E}{(l/d)^2}$$

Column **slenderness** should be limited to $l/d = 50$.

Columns abutting against side-grain lumber, at top or bottom, must usually be provided with caps or shoes of hardwood or metal, otherwise the pressure upon the side-grain will be excessive.

Columns may be designed by the above formulas, or by the following table which is based on them.

Safe Stresses for Square and Rectangular Columns

Select Grade Timber

(Working stresses in pounds per square inch)

The heavy line marks the division between intermediate and long columns.

The table can be used for other than rectangular columns, the l/d being equivalent to 0.289 l/r, where r is the least radius of gyration of the section.

The stresses are given for dry locations. In locations where the timbers will be exposed to the weather, these stresses should be reduced 25%.

For columns with l/d intermediate between those given in the table the safe load may be found by interpolation.

Example. Design a Douglas fir (Coast region) column (common grade) 13 ft. long to support a load of 50 000 lb. To get an approximate size, assume that the column is a short one. The allowable stress from Art. 1 is 880 lb. per sq. in. for common grade, dry location, so that the section needed is 50 000/880 = 56.8 sq. in., or a 7.5 × 7.5-in. square column. The l/d for this trial section is 13 × 12/7.5 = 20.8 which, being greater than 11, indicates that the reduced stresses of the column table must be used. From the above table, we find for Douglas fir (Coast) and an l/d = 20.8, a safe stress allowed of 775 lb. per sq. in. The area of the section needed is then 50 000/775 = 65 sq. in. The nearest commercial size which will satisfy this requirement is an 8 × 10-in. nominal or 7-1/2 × 9-1/2 actual, giving 71 sq. in. of section.

4. Fastenings

Nails for ordinary structural work are of two general types, cut nails of rectangular cross-section tapering from head to point and wire nails of circular cross-section without taper. Both types are usually of steel. Cut and wire nails of larger cross-section than common nails are called spikes. Boat spikes, used for very heavy timber work, have larger cross-sections than ordinary spikes. A clinch nail is similar to a cut nail, but is so made that it may be clinched or bent down, so as better to withstand shock or vibration.

Screws are preferable to nails for permanent work and work subject to vibration or shock, when a joint or connection of great strength is desired, and for lumber which splits readily under the driving of nails.

The common sizes of cut and wire nails and spikes and the approximate number per pound are given in the following tables. The numbers per pound are approximate, as different manufacturers use slightly different standards of cross-section, taper, and head. Nails are usually designated in size by the "penny" system. For instance, a 3-in. nail is called a ten-penny nail (written 10d.), probably because such nails once were sold at ten pence per 100. A keg of nails or spikes weighs 100 lb.

Square Steel Boat Spikes

Approximate number in a keg of 200 lb.

1/4	3400	2600	2040	1748	1456	1294	.....	.....	.....	.....	.....	.....

Screws for structural work are divided into two general types, wood screws and lag screws. Lag screws (Fig. 10q, p. 808) are used for heavy timber work. Lag screws are often used instead of bolts where it is difficult or impossible to place through bolts. They are also used for trestles, especially to attach guard-rails to ties, as they require less maintenance than bolts and render dapping of the guard-rails unnecessary.

For a wood screw, a hole should be bored smaller than the diameter of the shank and about one-half its depth, before inserting the screw. For a lag screw, a hole should be bored slightly smaller than the diameter of the shank. Wood screws and lag screws should not be hammer-driven.

Strength of Nails. Nails are seldom used in permanent structural work where the strain is parallel to the length of the nail, but for scaffolding such a fastening is not uncommon. The following formulas for safe loads on a nail

Nails and Spikes

Size	Steel cut nails and spikes: Length, in.	Approximate number per pound: Common nails	Spikes	Clinch nails	Size	Steel wire nails and spikes: Length, in.	Approximate number per pound: Common nails	Spikes	Clinch nails

12	9/16 to 1-1/2

* Flat heads are commonly used.

† Other gages may be approximated by proportion.

‡ Lag screws may be obtained with hexagonal or square heads.

were determined from a comparison of tests on the resistance to pulling out. When one piece of timber is nailed to another, the penetration of the nail into the second timber should not be less than one-half the length of the nail. The formulas are given for a penetration of one-half the length of the nail, when driven across the grain.

	Cut nails	Wire nails
In Southern pine............	$P = 6\text{-}1/2 \times$ d.	$P = 4 \times$ d.
In Douglas fir...............	$P = 6\text{-}1/2 \times$ d.	$P = 4 \times$ d.
In White pine...............	$P = 4 \times$ d.	$P = 2\text{-}1/2 \times$ d.
In White oak...............	$P = 13 \times$ d.	$P = 8 \times$ d.

In this table, d. is the number of penny weight of nail, and P is safe load in pounds. For example, a 60d. wire nail in Southern pine, if driven perpendicular to the grain, has a safe resistance to pulling out of $4 \times 60 = 240$ lb.

If driven parallel to the grain use 60% of the above values. If subject to shock, the resistance of the nail to pulling out is very low as was shown by W. C. Riddick in 1890 and as may be observed when a nailed plank is struck by a sledge in the demolition of timber structures. Nails should never be depended upon for important joints, in either temporary or permanent structures.

The Safe Lateral Resistance of Nails driven across the grain may be approximated by the following formulas, in which P is in pounds when d. is the penny weight.

Cut nails in oak, $P = 12$ d.
Wire nails in oak, $P = 10\text{-}1/2$ d.
Cut nails in Southern pine and Douglas fir, $P = 7\text{-}1/2$ d.
Wire nails in Southern pine and Douglas fir, $P = 7$ d.

Nails should be driven at right angles to the contact surfaces. When nails are driven parallel to the grain, use 60% of the tabulated values. For shock see preceding paragraph. The nails should not be driven closer to each other than about one-half their length nor closer to the edge of the timber than about one-quarter their length. It is generally impractical to develop the full strength of timber by the use of nails.

Safe Resistance to Pulling Out, in Pounds per Linear Inch of Threaded Length of Wood Screws when Inserted across the Grain

Kind of wood	Gage number								
	4	8	10	12	14	16	18	20	24
Cypress................	40	50	60	70	80	90	100	100	100
Southern pine...........	90	120	150	165	180	195	210	220	220
White oak..............	100	140	180	210	240	250	260	260	260

For wood screws inserted with the grain, use 75% of the values in the table.

Large diameters should be avoided for screws 3 in. and under in length. The screw with the greater length and smaller diameter should be chosen when practicable. For wood screws holes should be bored about 70% of the core diameter of the screw in soft woods and 90% in hard woods. Lubricants may be used with screws without any great loss in holding power.

The Lateral Resistance of Screws is much higher than that of nails. The accompanying table gives safe working values for lateral resistance of common wood screws, assuming that the screw is imbedded in the main piece of timber

Safe Lateral Resistance of Wood Screws in Southern Pine and Douglas Fir

Gage of screw	Safe lateral resistance in pounds	Gage of screw	Safe lateral resistance in pounds	Gage of screw	Safe lateral resistance in pounds
6	82	14	256	22	527
8	116	16	314	24	612
10	156	18	381	26	700
12	204	20	451		

approximately 6/10 the length of the screw. (See Cornell Civil Engineer, Nov., 1913.)

Safe Resistance to Pulling Out of Lag Screws when Inserted across the Grain

In pounds per linear inch of thread

Kind of wood	Diameter of lag screw in inches				
	1/2	5/8	3/4	7/8	1
Southern pine	315	390	470	550	630
Douglas fir	315	390	470	550	630
White pine	195	245	295	345	390
White oak	470	590	700	825	940

The Lateral Resistance of Lag Screws was determined in a series of tests by H. D. Dewell, which are described in *Engineering News*, Vol. 76. He recommends an allowance for a 7/8 × 5-in. lag screw of 1050 lb. for all-timber joints and 1200 lb. for a joint in which a metal plate is fastened to timber, and 900 lb. and 1030 lb. for a 3/4 × 4-1/2-in. lag screw under similar conditions.

A Dowel or dowel pin is a pin of wood or steel extending into adjacent parts of a structure (Figs. 3 and 4) to keep them from being displaced. Wood

Fig. 3

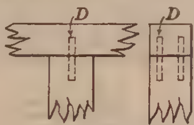

Fig. 4

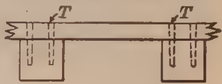

Fig. 5

dowels are also called tree nails. Steel dowels are troublesome in renewals. Dowel pins are usually not computed to transmit stress. They should be made a tight fit and extend at least 4 diameters into side-grain and 6 diameters into end-grain timbers. It is better to use two rather than one to a joint. Tree nails are occasionally computed to transmit stress, the strength of the connection being regarded as 1/2 the shearing strength of the cross-section of the nail. They are often substituted for bolts in lumber work below high water. In Figs. 3 and 4 the dowels or tree nails are marked *D*. In Fig. 5, the tree nails fastening grillage planks are marked *T*.

Drift Pins or drift bolts are long pins of steel or wood, usually the former, driven through the timber and into an adjacent timber to hold them together

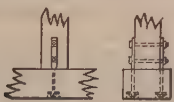

Fig. 6

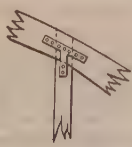

Fig. 7

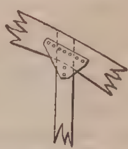

Fig. 8

and to transmit stress. Drift pins are made with or without heads. Round pins are preferable and whether round or square, a hole should be driven having a diameter from 1/16 to 1/8 in. less than the diameter of the bolt and for the full length of the bolt. Boat spikes may be used for drift pins.

Safe Resistance to Pulling Out, in Pounds per Linear Inch, of Drift Bolts when Driven across the Grain

Kind of wood	Diameter in inches				
	1/2	5/8	3/4	7/8	1
Southern pine	160	200	240	275	315
Douglas fir	160	200	240	275	315
White pine	95	120	140	170	195
White oak	240	300	350	410	470

For drift bolts driven with the grain, use 50% of the tabular values.

Common Bolts (see Sect. 7, Art. 49) are generally preferable to nails, screws or drift pins. For holding power of bolts see Art. 6. **Strap Bolts** are bolts with a strap at one end. They are used for the purpose of fastening the end of one timber to the side of another timber, Fig. 6. Common bolts are often used with steel straps as in Fig. 7, and steel gussets or plates as in Fig. 8.

Washers are metal disks placed under the heads and nuts of bolts to distribute the pressure upon the wood over such an area that the unit compression will not exceed a safe limit. Five types of washers are used in timber construction: (1) cast-iron ogee (Fig. 9*a*), (2) cast-iron ribbed (Fig. 9*d*), (3) malleable iron (Fig. 9*g*), (4) circular pressed steel (Fig. 9*b*), and (5) square plate washers (Fig. 9*c*). Washers of standard sizes and shapes may be bought

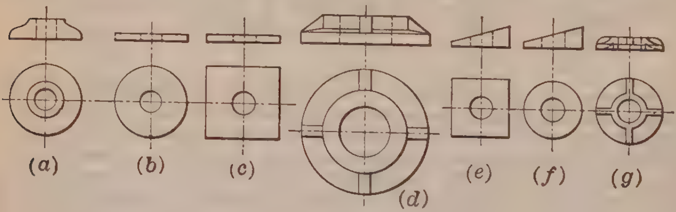

Fig. 9. Types of Metal Washers

from the manufacturers. For bolts over 2 in. in diameter, special cast-iron washers (Fig. 9*d*) are often used, though this type is very expensive unless a large number of the same size are required. Beveled cast-iron washers (Fig. 9*e*, *f*), for cases in which the axis of the bolt makes an angle with the bearing surface, may also be purchased from the manufacturers.

When the tension in a bolt is at right angles to the base of the washer, the washer should be designed so that the compression upon the wood, due to tension in the bolt, will not exceed by more than 50% the allowable compressive unit stresses of Art. 1. The malleable iron washer does not have its full area of base available for bearing; therefore when used with a bolt in tension 60% of its nominal area should be taken. In joints where the bolt acts only in shear and bending, smaller washers, such as the malleable washer, may be used. However, if there is any chance that the bolt may be brought into tension by washer tightening in maintenance work, square plate washers or special cast-iron washers should be used. The circular cut or pressed steel washer should not generally be used except between metal and metal.

Wrought-iron or Steel-plate Round Washers

Diameter in inches	Size of hole in inches	Approximate number in a pound	Area of washer, sq. in.
1-3/8	9/16	27.0	1.3
1-1/2	5/8	22.0	1.5
1-3/4	11/16	13.0	2.0
2	13/16	10.0	2.6
2-1/4	15/16	8.6	3.3
2-1/2	1-1/16	6.2	4.0
2-3/4	1-1/4	5.2	4.5
3	1-3/8	4.0	5.6
3-1/4	1-1/2	2.8	6.5
3-1/2	1-5/8	2.5	7.6
3-3/4	1-3/4	2.4	8.6
4	1-7/8	2.2	9.8
4-1/4	2	1.9	11.0
4-1/2	2-1/8	1.7	12.4
4-3/4	2-3/8	1.0	13.3
5	2-5/8	1.0	14.2

The size of hole in washer is 1/16 in. larger than the diameter of the bolt up to and including bolts 1 in. in diameter. For larger bolts the hole is 1/8 in. larger.

Wrought-iron or Steel-plate Square Washers

Width in inches	Size of hole in inches	Approximate number in a pound	Area of washer, sq. in.
2	9/16	5.0	3.8
2-1/4	3/4	3.2	4.6
2-1/2	7/8	2.5	5.7
3	1	1.7	8.2
3-1/2	1-1/8	.9	11.3
4	1-1/8	.7	15.0
4-1/2	1-1/4	.5	19.0
5	1-1/2	.4	23.2
6	1-5/8	.3	34.0

For size of bolts see round plate washers.

Cast-iron Washers

Diameter in inches	Size of hole in inches	Approximate number in a pound	Area of washer, sq. in.
2-1/4	5/8	3.3	3.8
2-3/4	3/4	2.5	5.5
3-1/4	7/8	1.4	7.9
3-3/4	1	1.0	10.1
4	1-1/8	.5	11.6
4-1/2	1-1/4	.4	14.7
5	1-3/8	.3	18.2
6	1-3/4	.2	25.9

The size of hole in washer is 1/8 in. larger than the diameter of the bolt up to and including bolts 1-1/4 in. in diameter. For larger bolts the hole is 1/4 in. larger.

Where the bolt makes an angle with the bearing surface, thetimber may be notched instead of using a beveled washer, provided the notch does not reduce the timber section beyond a safe limit. Bearing in this case would be inclined to the direction of the fiber, and greater unit stresses can be taken advantage of (see Art. 2). Where notching is impracticable, especially if large washers are required, a combination of a large flat washer and a small beveled washer may be economical.

To determine the size of washer required, divide the tension in the bolt by the safe unit compression of the wood and add the area of the hole of the washer, which gives the gross area required. From this the outside dimensions are computed. Its thickness, if of wrought iron or steel, should be at least 1/8 its width or diameter. If of cast iron (Fig. 9*a*), the thickness should be not less than about 1/4 its diameter. The square plate washer should have a thickness of 1/2 the diameter of the bolt plus 1/16 in. If of the type shown in Fig. 9*d*, it may be designed similar to cast-iron shoes, the unit pressure upon the bottom of the washer being the allowable compression upon the wood. If the tension in the bolt is small use standard washers.

If the washer is bevelled (Fig. 10*n*), the pull on the washer should be resolved into the components shown by the arrows and the pressure upon the wood in either direction P or N should not exceed the allowed safe limits of Art. 1. The washer should be so designed that the line of pull and the line of resistance P and N meet in a point.

Common Joints are shown in Fig. 10. *a* is a butt joint. *b* is a bevel joint. *c* is housing. *d* is single notching. *e* is double notching. *f* is halving. *g* is beveled halving. *h* is cogging. *i* is dovetail halving. *j* is a dapped joint. *k* is a double-step dapped joint. *l* is a head block. *m* is a lap joint. *p* is a bird's-mouth joint. *q* is a lag screw.

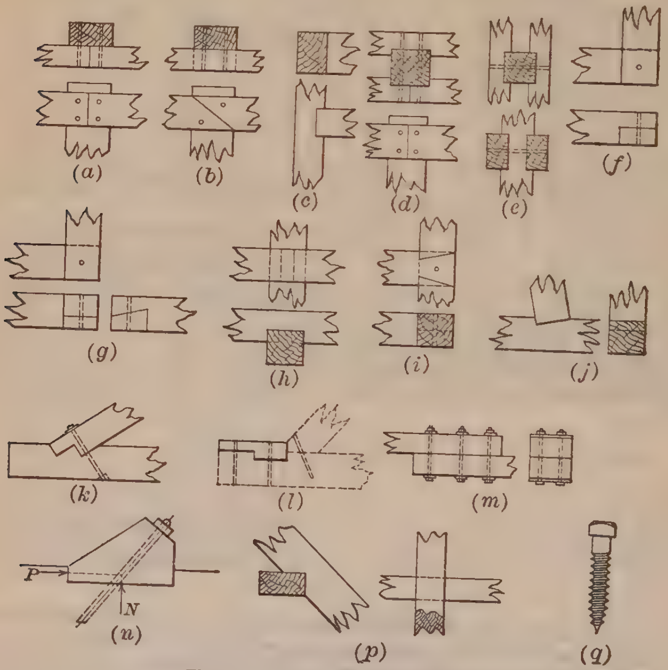

Fig. 10. Common Timber Joints

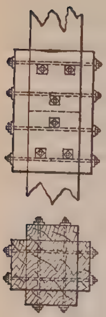

Fig. 11

5. Compression Joints

The Butt Joint, shown in Fig. 11, is used to splice columns and struts. The ends of adjacent sections should be sawed at right angles, and in important work the ends should be dressed to an even surface. If the contact surfaces or ends are not flush and true, the column is loaded eccentrically. This joint need not be computed, but braces should hold the lower or upper section of the joint to correct alinement, so as to prevent buckling of the column at the joint.

A Column with beams framed into its sides (Fig. 12*a*) must not be reduced at section *A*, to such an extent that the unit compression exceeds the safe end-bearing compression. The beveled dap may not give sufficient end bearing for the beams, in which case the beam bearings may be increased as in Fig.

12a, by use of angles, by bolted side blocks (Fig. 12b) or by use of side and bent plates (Fig. 12c).

Example. (Fig. 12a) Girder 10 × 10 in., columns 10 × 12 in., both Southern pine, common grade. Location is dry. Load on upper column = 70 000 lb. End-beam reactions each = 9500 lb. The allowed compression across the grain = 325 lb. per sq. in. It is suggested that only 50% of the allowed unit compression be used, as the flexure of the beam causes greater compression at the front of the support than at the back. The minimum bearing area of the beams = 9500/163 = 58.2 sq. in. As the beam is 10 in. wide, the length of bearing should be 6 in. As the load on the upper

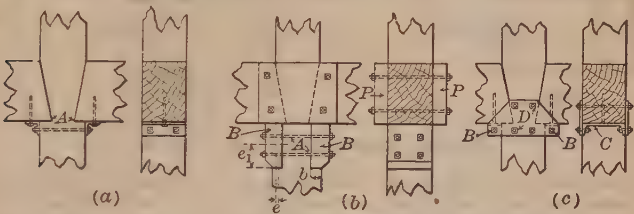

Fig. 12. Struts Framed into Beams

section of column is 70 000 lb. and the safe bearing on end grain for short columns is 880 lb. per sq. in., the minimum reduced area of the column = 70 000/880 = 80 sq. in. Therefore the length of bearing on the column for each beam may be 2 in. The additional length of end bearing needed for each beam = 6 − 2 = 4 in. This may be provided by using 4 × 4 × 3/8-in. angles as in Fig. 12a. The load on each angle will be 9500 × 4/6 = 6350 lb. The bolts are in single shear.

Bolts should be selected of such diameter that the shear will not exceed safe limits and so that the compression brought upon the wood by the bolts will not exceed the allowed stresses of Art. 1. At least two bolts should be used. The shear on the ends of each bolt = 6350/2 = 3175 lb. 3/4-in. bolts will be safe against shearing and bearing of the angles on the bolts. As the bolts bear on the end grain of the wood, the safe bearing for the two bolts = 2 × 3/4 × 12 × 880 = 15 850 lb., which is more than the total load on the two angles.

The joint of Fig. 12b should be designed similarly to Fig. 12a. The load on block B is transmitted to its end b. The lines of action of the pressure at the top and bottom of the block B are not coincident. The eccentricity e causes a couple whose moment equals the load multiplied by e. This couple is resisted by a couple consisting of the bolts acting in tension and the adjacent wood acting in compression parallel to the length of the bolts. The arm of this resisting couple may be considered as equal to 2/3 e_1 in which e_1 equals the distance from a point halfway between the bolts to the shoulder b. The washers should be designed to develop the tension in the bolts without stressing the timber higher than allowed in Art. 1.

In the joint of Fig. 12c, the end-bearing area of the beams is increased by bent plates or channels marked C. The load on these bent plates is transmitted to the side plates through bolts B, and the load on the side plates is transmitted to the post by bolts D.

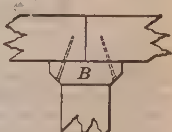

Fig. 13

Joints at Top and Bottom of Columns. When beams rest upon the top of a column, a hardwood bolster marked B, Fig. 13, may be used to decrease the side-grain compression upon the ends of the beams. In this case the unit side-grain compression may be excessive upon the bottom of the bolster. To decrease this compression, the tops of the columns may be widened as in Fig. 12b. Cast-iron caps of the type shown in Fig. 14, a, b, are often used at the tops of columns of buildings. The compression upon the side grain of caps and sills, at the top and bottom of columns, will generally be excessive if the columns be designed to take the maximum safe loads and the top and bottom of the columns are not

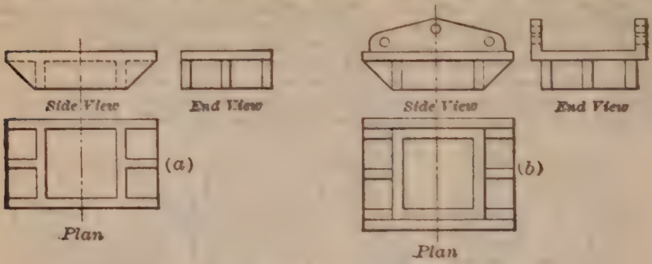

Fig. 14. Metal Caps for Timber Columns

widened similar to Figs. 12, 13. In trestles it is often cheaper to design the columns for loads which, without widening the top and bottom, do not produce excessive side-grain compression upon the caps and sills. Joints like Fig. 12*b* exposed to the elements hold water and rot quickly.

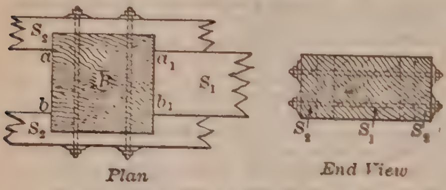

Fig. 15. Dapped Compression Joint

Dapped Compression Joints (Fig. 15) may be designed as follows: Assume that a load of 80 000 lb. is to be transferred from the middle 12-in. × 12-in. Douglas fir (common grade) timber, marked S_1, to two outside Douglas fir timbers, marked S_2. The length of the block *B* should be such that it will not shear along the lines aa_1 and bb_1. Using a white oak block which has a shearing value with the grain of 200 lb. per sq. in. (for joints), and assuming that the depth of the side pieces S_2 will be 12 in. to correspond with the middle piece S_1, the length of the block must be at least $80\,000/(2 \times 12 \times 200) = 17$ in. The length of bearing in each side timber, with the safe end-bearing compression on Douglas fir = 880 lb. per sq. in., must be at least

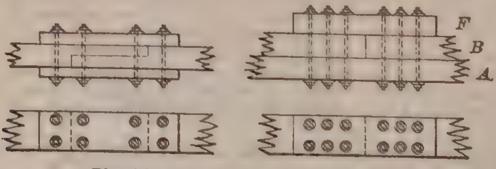

Fig. 16 Fig. 17

$80\,000/(2 \times 12 \times 880) = 3.8$ in. A sufficient number of bolts with standard washers should be used to clamp the wood closely together and prevent displacement of the block. The outside timbers S_2 may have the same combined cross-section as the middle timber S_1, unless l/d for S_2 is greater than l/d for S_1, in which l/d is the ratio of the length of the timbers to their least width.

Fig. 16 shows a half-lap compression joint with side or fishplates. Fig. 17 shows a compression joint in which the timber *A* is continuous and timber *B* is spliced. *F* is a fishplate and *A* acts as a fishplate in splicing *B*.

6. Tension Joints

Plain Fishplate Joints (Figs. 19 and 20) can be economically used for small timbers or large timbers under small unit stresses. The fishplates marked *F* may be of wood or steel. The design of a joint with metal plates (Fig. 20) is similar to that for wood plates, excepting that the strength of the bolts in shear and bearing on the metal must be carefully considered. Round bolts are generally used and are the only ones considered in what follows. When planks less than 3 in. thick are joined by bolts they may be designed without considering the bending of the bolt.

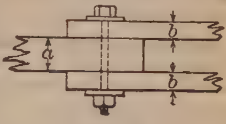

Fig. 18

The following table may be used in determining the safe loads upon bolts of plain timber fishplated joints. In this class of joints, the bolts are not in tension, and therefore standard washers, preferably of cast iron, may be used. The bolts should be taut so as to bring the pieces tightly together, to prevent

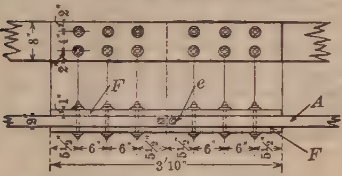

Fig. 19

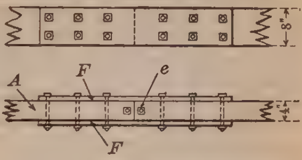

Fig 20

buckling of the side plates and to exclude moisture. Both values given by the table should be considered and the lesser safe load be used.

Safe Bearings and Uniform Loads for Bolts

Diameter of bolt in inches	Safe bearing load, lb. per lin. in.		Safe load in pounds on bolt for dimension in inches as shown in Fig. 18					
	End grain	Side grain	a = 2 b = 1	a = 3 b = 1-1/2	a = 4 b = 2	a = 6 b = 3	a = 8 b = 4	a = 10 b = 5

1-1/4	1250	125	17 250	11 500	8640	5750	4300	3450

The safe loads per linear inch of bolt shown in the second and third columns are based on a safe compressive stress parallel to grain of 1000 lb. per sq. in., and a safe compressive stress across the grain of 100 lb. per sq. in. For other allowed unit stresses the safe loads may be obtained by proportion.

In a tension joint such as Fig. 18, it is often assumed that the pressure of the bolt against the timber is uniformly distributed along the length of the bolt. However, this is not correct, as the unit pressure will be greatest at the point of contact between the center timber and the outside timbers. It is therefore recommended for design that the safe compressive stress of the bolt against the timber be taken as 75% of the working stresses given in table of Art. 1, where the pressure of the bolt on the timber is assumed as uniformly distributed.

The safe loads on the bolt in the table are for the entire bolt, based upon an extreme fiber stress in bending in the bolt of 22 500 lb. per sq. in. For higher or lower assumed safe fiber stresses the safe load can be obtained by proportion.

Design of a Plain Fishplate Joint with wooden fishplates (Fig. 19). The timber *A* to be spliced is a 2-in. × 8-in. southern pine (common grade) tension member, stressed to 1200 lb. per sq. in. of net section (see Art. 1). It will be assumed, in order to get the approximate net section, that two bolts will be necessary in the same plane at right angles to the length of the member and that the diameter of each hole equals 1 in. Therefore the approximate net section equals 16 − 4 = 12 sq. in. The total tension in the member = 1200 × 12 = 14 400 lb. Using the same kind of wood for the fishplates, as for timber, *A*, their gross area must be 16 sq. in. Therefore use two 1-in. × 8-in. fishplates.

The Number of Bolts required may be obtained by assuming any convenient diameter of bolt and finding the safe load on the bolt as a restrained beam, taking the length of the beam as the distance between the center lines of fishplates, and finding also the safe load upon the end grain of the timbers against which the bolts bear. The smaller safe load should be used. Dividing the smaller safe load upon the bolt into the total stress, 14 400 lb., the number of bolts necessary may be obtained. This work is much simplified by using the table on p. 811.

Assuming that a 3/4-in. bolt will be used, the table shows that the safe bearing value is 750 lb. per lin. in., with 1000 lb. per sq. in. working stress. Two inches of the length of the bolt will bear upon the end grain of the tension member, and also of the fishplates. The safe compression with the grain for Southern pine is 880 lb. per sq. in., which should be reduced to 660 lb. per sq. in. as recommended above. Therefore the safe load upon a 3/4-in. bolt, determined by bearing on the timber, is 2 × 750 × 660/1000 = 990 lb.

From the table, the safe load on the bolt as determined by bending is 3720 lb. The strength of the bolt is, therefore, limited by bearing on the timber, and the number of bolts required = 14 400/990 = 14-1/2. As the fishplates are wide, there should be two lines of bolts; if one line were used the splice plates might buckle and the splice would be very long. In order to cut down the number of bolts, use 12 1-in. bolts, which are safe in bearing for a load of 12 × 2 × 660 = 15 800 lb.

The distance between adjacent holes of the same line from each other, and from the end of the tension member and the fishplates, must be such that the unit shearing stress with the grain will not exceed 80% of that allowed in Art. 1. The reduction of 20% is made on account of a splitting action transverse to the line of tension when round bolts are used; for square bolts this reduction need not be made. Bolts tend to shear the wood in two planes tangent to the top and bottom of the bolt. There are 12 1-in. bolts on either side of the joint and the length of the bolt in the tension member and the fishplates is 2 in. The safe shear with the grain is 176 lb. per sq. in. (twice the value in table of allowable stress). Therefore the distance between the bolts must be not less than 14 400/(12 × 2 × 2 × 176 × 0.8) = 2.1 in. Add 1-1/8 in. for the bolt hole, which is assumed as 1/8 in. larger than the bolt, and the spacing of bolts will be not less than 3-1/2 in. The distance from the ends may be 1/2 in. less than between bolt holes, as only half of the bolt hole need be added. (The splice as here computed differs in details from that shown in Fig. 19.)

The bolts marked *e* in Figs. 19 and 20 are inserted in the ends of the main timbers for the purpose of overcoming the tendency of the wood to split under the pressure of the round bolts.

Tabled fishplate joints are commonly used for heavy timber work. They offer the best type of tension joints and should be used in permanent work where practicable.

Design of a tabled plate joint with wooden fishplates (Fig. 21). Southern pine (common grade) will be used in both the tension member, *A*, which is to be spliced and the fishplates. From Art. 1, the safe stresses per square inch for Southern pine are: for tension with the grain, 1200 lb.; for compression with the grain, 880 lb.; for compression across the grain, 325 lb.; and for shear with the grain, 176 lb. The fishplates *F* are to transmit the full tension of the member across the joint, which in this example is 56 000 lb. The size of the tension member is 8 × 10 in.

The tension to be transferred to and carried by one fishplate = 56 000/2 = 28 000 lb. The net area therefore must be 28 000/1200 = 23.3 sq. in. A bolt should be placed at *h*, the end of each timber *A*, to hold it firmly and to keep the fishplates from buckling. Assume all of the bolts in the joint to be 3/4 in. and their holes 7/8 in. The net width of the fishplate is then 10 − 7/8 = 9-1/8 in. Dividing the net area by this net width gives the net depth, thus 23.3/9.125 = 2 56 in. This should be made the same at *f* and *g*. The fishplate receives its tension through the bearing of the shoulders of the tables *TTTT*, which bear against the end grain of the tables of the main tension member *A*. Assume 4 tables in each fishplate, 2 either side of the middle of the joint. Two tables should be used only for small timbers. The net area of each shoulder should therefore be 28 000/(2 × 880) = 15.9 sq. in. Since the tables are the same width as the depth of timber *A*, or 10 in., the depth of the tables should be 15.9/10 = 1.59 in. The total depth of the fishplates must therefore be 2.56 + 1.59 = 4.15 in. The nearest standard size timber is 5 in., which should be used.

The length of the tables on the fishplates is determined by the necessary shearing strength, with the grain, along lines *bb*. Since there are two tables on either side of the

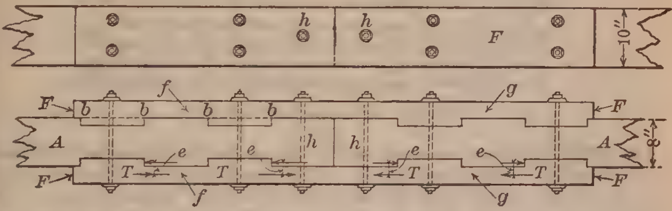

Fig. 21. Tabled Fishplate Joint

joint, the required area for each table is 28 000/(2 × 176) = 79.6 sq. in. If *x* is the length of the table, then 10 *x* is the gross area, from which must be deducted 2 × 0.60, the area of two bolt holes, since two lines of bolts are necessary because of the great width of the fishplates, which might buckle if only one line were used. Then 10 *x* − (2 × 0.60) = 79.6 from which *x* = 8.08 in. The tables of the main timbers *A* are generally made the same length as those of the fishplates. When no bolts go through the tables of the timber, they may be made shorter than those of the fishplates.

The bolts do not transmit the stresses by bending as in the plain fishplate joint, but by tension. The tension in the fishplate and the compression upon the shoulders, shown by arrows in Fig. 21, do not act in the same plane, thus causing a couple, = (28 000/2) *e* for each table, where *e* = one-half the net thickness of the fishplate plus one-half the depth of the shoulder, or 1-3/4 + 3/4 = 2.5 in, using nominal thickness of timber. The moment of the couple for each table = (28 000/2) × 25 = 35 000 in-lb. This moment must be resisted by a couple consisting of tension in the adjacent bolts and compression in the adjacent portion of the fishplate and timber *A* acting in a direction parallel to the bolt. The arm of this couple may be taken at one-half the length of the table, or 4.04 in. The stress in each bolt hence = 35 000/(2 × 4.04) = 4330 lb. A 3/4-in. bolt has a net area of 0.302 sq in., and therefore, based on the allowed tension of 16 000 lb. per sq. in., the strength of the bolt = 4830 lb.; hence 3/4-in. bolts can be used. The bolts should be tightened to their full working strength when constructed, and as this is difficult to determine in practice, an excess of strength is desirable. For the same reason it is suggested that for this type of joint the unit compression across the grain under the washers should not exceed that allowed in Art. 1.

The washers must have a net area of 4330/325 = 13.3 sq. in. A standard cast-iron washer may therefore be used. If a standard washer cannot be used, the gross area should be determined by adding the area of the hole in the washer, and from this gross area the diameter or width of the washer computed.

Fig. 22 shows a modified type of Fig. 21. This joint is costly, but as the bolts are not located at the minimum section of the main timber or fishplates, the area of the bolts need not be deducted in figuring its strength. Fig. 23 shows a common eccentric tabled splice. Timber *A* is continuous in this joint, while *B* is spliced by *C*.

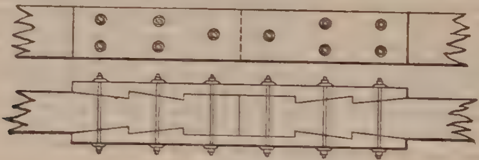

Fig. 22. Scarf Tabled Joint

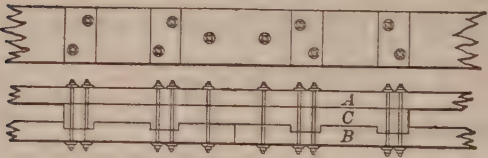

Fig. 23. Eccentric Tabled Joint

Lap Joints (Fig. 24*a*) are often used in temporary work; they are inefficient but quickly and inexpensively made. To compute this joint either in tension or compression assume that the bolts take a bending moment equal to the tension or compression times the distance *e*. The shear in the bolts and the compression on the timber brought by the bolts must also be computed. The table given herewith is convenient in finding the safe resisting moment and

Safe Stresses for Bolts when Used in Timber Connections

Bolt	Area in gross inches	Net area in inches	For tension	For single shear	For resisting moment
1/2	0.196	0.126	2 020	1 960	275
5/8	0.307	0.202	3 230	3 073	540
3/4	0.442	0.302	4 830	4 420	930
7/8	0.601	0.420	6 720	6 010	1 480
1	0.785	0.550	8 800	7 850	2 205
1-1/8	0.994	0.694	11 100	9 940	3 145
1-1/4	1.227	0.893	14 290	12 300	4 310
1-3/8	1.485	1.057	16 910	14 800	5 745
1-1/2	1.767	1.295	20 720	17 700	7 460
1-3/4	2.405	1.746	27 940	24 000	11 835
2	3.142	2.302	36 830	31 400	17 670
2-1/4	3.976	3.023	48 370	39 800	25 155
2-1/2	4.909	3.719	59 510	49 100	34 475
2-3/4	5.940	4.620	73 920	59 400	45 935
3	7.069	5.428	86 850	70 700	59 635

Unit stresses used in this table are: for tension 16 000, for single shear 10 000, and for resisting moment 22 500 lb. per sq. in.

Values for tension are for net area; values for shear for gross area.

safe shear in the bolt, while the safe bearing on the bolts may be obtained from the table on p. 811. The shearing resistance may be increased by the use of hardwood or iron keys, shown in the figure.

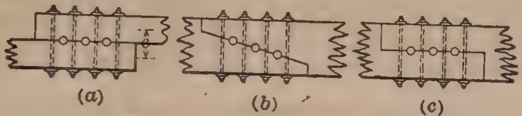

Fig. 24. Scarf Joints

Scarf Joints (Figs. 24, *b*, *c*) are used to transmit tension or compression and sometimes flexure. They are less efficient for tension than fishplated joints, but may be used when the tension is small. They are more generally used to transmit compression stresses with possible small reversal of stress.

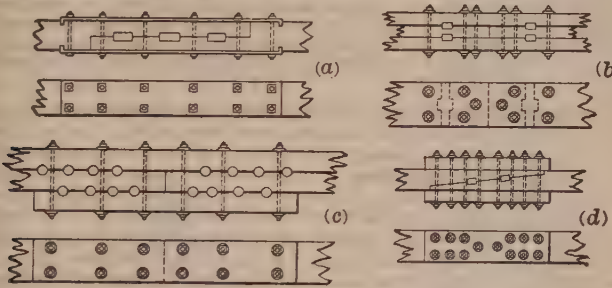

Fig. 25. Four Types of Tension Joints

7. Joints in Flexure

Built-Up Truss Members are occasionally designed for both compression and flexure. Cases of this kind can usually be avoided and should be whenever possible. Compound beams built of two pieces of timber, one above the other (Figs. 26, 27), have been used, but in present practice trussed beams are generally employed if beams of single timbers cannot be obtained of large enough dimensions. The general method of designing a compound beam is given below. When such a beam is in compression, as the top chord of a Howe truss, directly supporting floor beams intermediate between panel points, the direct compression stresses must be considered in determining the cross-sections.

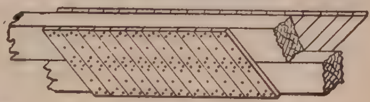

Fig. 26

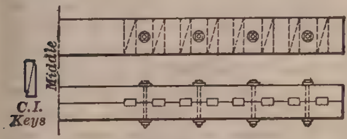

Fig. 27

A Compound Beam should be designed so that the horizontal shear between the adjacent timbers is properly taken care of, so that when the beams bend under the applied loads they will not slide upon each other. If no such provision were made, the strength of the beam would be equal only to the sum of the strengths of each timber acting independently. Compound beams cannot in practice be made as strong as those of single timbers of equal dimensions, and the deflection of the former exceeds the deflection of the latter. For properly designed compound beams of well-seasoned timber carefully framed together and keyed with metal wedges the difference will not be material.

For temporary structures the two timbers may be fastened together by a continuous sheeting of planks, well spiked to the main timbers as in Fig. 26. The thickness of each side piece should be at least 1/8 of the width of the main timbers and the nails should extend at least 1/2 their length into the timbers. On the basis of Kidwell's tests (Trans. Am. Inst. M. E., vol. 27) it is recommended that the strength of this type of compound beam be taken at 70% of a solid beam of equal dimensions.

For permanent work, keys of hardwood or metal should be used and the pieces fastened together by bolts as in Fig. 27. The efficiency of keyed beams on the basis of Kidwell's test will be taken at 75% for hardwood keys and 80% for metal keys. The keys are generally made of wedges or tapered pieces so that they may be made a driving fit; they are also made of flat plates or cast-iron blocks without taper. It is thought that a stronger and stiffer beam will result by the use of wedged or tapered keys.

To Design a Compound Beam with iron keys, since the efficiency is taken at 80% of that of a solid beam of the same dimensions, multiply the load upon the beam by 1.25, adding the weight of the beam, determined by approximate design, and use this increased load to determine the stresses and necessary dimensions. From the bending moment determine the necessary dimensions of the beam, making the width of beam approximately 4/10 its depth. Compute the vertical external shears at governing points and draw the vertical shear diagram. Determine the total horizontal shear between the point of zero shear and the ends of the beam. If d is the total depth of the beam, and V is the total vertical shear between the point of zero shear and the end of the beam, the total horizontal shear will be $3V/2d$. The number of keys in each half of the beam may be assumed, and five is a desirable number. Making all keys of the same size, the compression to be resisted by each key equals the total horizontal shear in the left or right portion of the beam divided by the number of keys. As the horizontal shear will be different to the right and left of the point of zero shear, in an eccentrically loaded beam, the compression to be resisted, per key, or the number of keys, may be different in the right and left portions of the beam.

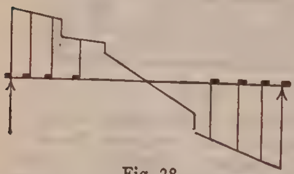

Fig. 28

To find the positions of the keys, divide the right and left areas of the shear diagram by vertical lines into as many equal areas as there are keys to the right and left of the point of zero shear. This may be done graphically or by trial. Fig. 28 shows a shear diagram for an eccentrically loaded beam divided by vertical lines into equal areas. The position of each key is fixed by the vertical lines of division. The keys should be placed back toward the ends, and not in front of the vertical lines. They are shown on the horizontal axis of the diagram. The dimensions of the keys must be such that the safe end compression on the wood is not exceeded. The distance between keys must be such that the safe horizontal shearing stresses are not exceeded. The end keys may be moved back of the point of support to decrease the unit horizontal shear between the first and second keys from the end.

Stresses in the bolts and their sizes may be determined as in the design of a tabled fishplate joint. Additional bolts should be used to bind the timbers together. The friction resulting from the tightening of the bolts increases the strength of the beam, but to an indeterminate amount, and should not be depended upon in design.

If the keys are of wood, the bearing of the end grain of the timbers against the side grain of the keys will govern their cross-sectional dimensions. If the keys are inclined the stress in the bolts and also the available shearing area between keys will be increased. For inclined keys, the shearing area of the timber for any key may be regarded as extending from its outer end to the middle of the next key. The breadth of a key should not be less than twice and preferably not less than 2-1/2 times its thickness.

8. Trussed Beams

For Spans Exceeding 20 ft. or when the loads are unusually large and where head room permits, trussed beams may economically be used. For economy the trusses should be generally as deep as head room permits. Trussed beams are of two types (Fig. 29). Type 1 is used when available head room is below the beam seats and type 2 when the head room is above. The member *aba* of both types may be of a single timber or of two or more timbers placed side by side. Usually each timber *aba* is a single unspliced piece extending from end support to end support. When it is of a single timber, the tie rod or rods of type 1 pass through oblique holes bored through the ends

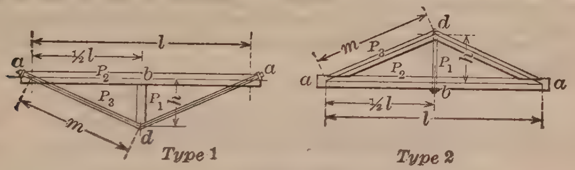

Fig. 29. King Types of Trussed Beams

of the piece. If it is of two or more pieces, they are separated so as to allow the tie rod or rods to pass between them. Type 1 should be designed with ends of tie rods made adjustable, or with an intermediate portion of rods, made adjustable by turn-buckles, or preferably with both adjustments. The adjustable tie rods should be made taut when erected, which causes initial stresses in the beam, and if the tightening is not carefully done, the strut *bd* may be pulled out of the vertical. The base of *bd* in type 1 should be made wide to better withstand unequal tightening of adjacent tie rods.

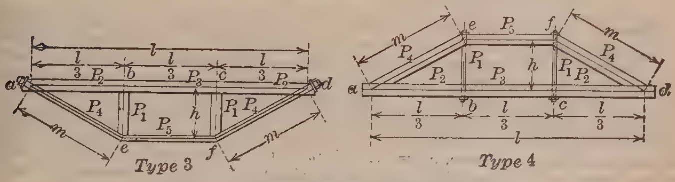

Fig. 30. Queen Types of Trussed Beams

For Spans over 25 ft., or when the head room is small or when loads are concentrated at two intermediate points, types 3 and 4 (Fig. 30) are preferable to types 1 and 2. The struts *be* and *cf* are generally placed vertical in these types, but they would be more efficient if placed so as to bisect the angle between the horizontal and inclined portions of the rods. In the design of all beams, the line of action of all pieces intersecting in a joint should meet in a point, or secondary stresses must be considered.

Type 1 (Fig. 29) may be designed by the following approximate formulas, in which W in pounds = total load on beam. (1) When **W is uniformly distributed** over the length of beam, $\mathbf{P_1}$ = compression in bd = $\mathbf{5/8\,W}$; $\mathbf{P_2}$ = compression in ab = $\mathbf{5\,Wl/32\,h}$; $\mathbf{P_3}$ = tension in ad = $\mathbf{5\,Wm/16\,h}$; and $\mathbf{S_2 = P_2/bd}$ = unit compression in ab, due to direct compression. To find the maximum unit compression in ab, add to S_2 the flexural or bending unit extreme fiber stress, due to the load acting upon ab as a beam. The extreme fiber stress due to bending $\mathbf{S_3 = 2.25\,Wl/bd^2}$. To find the maximum unit fiber stress add S_2 to S_3, or use the formula $\mathbf{S = Wl\,(5/h+72/d)/32\,bd}$. All lengths are expressed in feet, except that b and d, the width and depth of the chord aba, are expressed in inches. P_1, P_2 and P_3 are expressed in pounds, and S_2, S_3 and S in pounds per square inch. (2) When **W is concentrated** at the middle of the beam, $\mathbf{P_1}$ = compression in bd = $\mathbf{W}$; $\mathbf{P_2}$ = compression in ab = $\mathbf{Wl/4\,h}$; $\mathbf{P_3}$ = tension in ad = $\mathbf{Wm/2\,h}$. For this loading there are no flexural stresses except those due to dead load of the beam, which, excepting in long spans, under small loads, may usually be ignored.

Type 2. The stresses will be of the same intensity as in type 1, but the character of the stresses will be reversed. Members bd and ab will be in tension, and ad in compression. If the load is uniformly distributed, the foregoing flexural formulas may be used, but the maximum unit stress in ab will be tension.

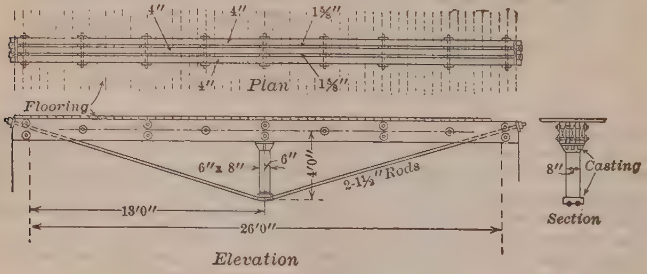

Fig. 31. Beam Trussed with Steel Rods.

Example, Fig. 31. To design a trussed beam, type 1, span 26 ft., depth of truss 4 ft.; load, exclusive of weight of truss, 1500 lb. per lin. ft., using Southern yellow pine, common grade, for top chord and vertical post. The compression in $bd = 5/8 \times 1500 \times 26 = 5/8 \times 39\,000 = 24\,375$ lb. Assuming that the ratio of length of bd to its least width will be less than 11, the cross-sectional area of $bd = 24\,375/880 = 27.7$ sq. in. The direct compression in $ab = 5\,Wl/32\,h = 39\,600$ lb. The necessary cross-sectional area of ab therefore $= 39\,600/880 = 45.0$ sq. in. The extreme fiber stress in ab acting as a beam, $S_3 = 2.25\,Wl/bd^2$. Use a safe extreme fiber stress 80% of that given in Art. 1 in order to allow approximately for direct compression. From the above formula $d = \sqrt{2.25\,Wl/bS_3}$. Assume $b = 12$ in., and for S_3 substitute eight-tenths of the allowed extreme fiber stress or $1200 \times 0.8 = 960$ lb. per sq. in. Then $d = \sqrt{2.25 \times 39\,000 \times 26/12 \times 960} = 14.1$ in. The maximum fiber stress per square inch, due to direct compression and flexure, is $S = Wl\,(5/h + 72/d)/32\,bd = 1190$ lb. per sq. in. The weight of the truss per lineal foot = approximately 1.3 of the weight per lineal foot of the top chord aba or $1.3 \times 12 \times 14/12 \times 3.3 = 60$ lb., where

12 × 14/12 equals the number of board feet, and 3.3 equals weight of a board foot of timber. As this weight is only 4% of the load, it may be ignored. Instead of using 80% of the allowed extreme fiber stress, the necessary size of *ab* due to bending may be found by formula, using the allowed extreme fiber stress and adding the necessary area for direct compression.

For the top chord 3 planks 4 × 14 in. will be used, separated so as to allow two steel rods to pass between them. This chord will be assumed to be stiffened laterally by a plank floor. Allowing 16 000 lb. per sq. in. in the tie rods, the net section A in square inches for $S = 16\ 000$ and $P_2 = 5\ Wm/16\ h = 41\ 450$, is $A = 2.6$ sq. in., or the two rods having a diameter of 1-1/2 in. may be used if the ends are not upset. If the ends are upset, two rods of 1-3/8-in. diameter may be used, as they have a combined area slightly in excess of 2.6 sq. in. The pieces of the top chord should be separated, so as to permit the insertion of the rods and their upset ends.

As the necessary cross-sectional area of *bd* based on end compression is 27.7 sq. in. a timber 6 × 6 in. might be used if the columnar reduction is not too great. The safe stress for a 6 × 6 Southern pine column 4 ft. long with $l/d = 8$ is 880 lb. per sq. in. Therefore the safe load for a 6 × 6 column 4 ft. long = 5-1/2 × 5-1/2 × 880 = 26 600 lb. For stiffness and simplicity of end connections, 6 × 8-in. timber will be used.

A cast-iron cap may be advantageously used at the top of the vertical strut to transmit the pressure to the side grain of the top chord. The width of the top must be sufficient to engage the top timbers, and its length must be sufficient to reduce the unit compression across the grain to that allowed in Art. 1. A metal foot of cast iron or steel should be used to reduce the unit compression with the grain of *bd* within a safe limit. The width of *bd* was, in this case, increased to 8 in. in order to receive the rods, which, on account of the top chord construction, are 5-1/2 in. apart on centers. The washer at the ends of the tie rods must be of such size that the compression on the surfaces inclined to the grain will not exceed the assigned safe limits. (Art. 2.)

The Design of Type 3 (Fig. 30), when the three panel lengths are all equal, may be made as follows. W = total load on beam in pounds. (1) **W uniformly distributed.** The end reactions brought by *ab* and *cd* acting as beams = $(4/30)W$. The stresses in the various members acting as a truss may be determined graphically or analytically. To the stresses so determined the flexural beam stresses in the top chord of type 3 and in the bottom chord of type 4 should be added. The following approximate formulas are easily applied when the panels are of equal lengths. They are sufficiently accurate for practical purposes. $\mathbf{P_1}$ = compression in *be* or *cf* = $\mathbf{1/3\ W}$; $\mathbf{P_2 = P_3}$ = compression in *ad* = $\mathbf{P_5}$ = tension in *ef* = $\mathbf{W\mathit{l}/9\ h}$; $\mathbf{P_4}$ = tension in *ae* and *fd* = $\mathbf{Wm/3\ h}$. The extreme fiber stress per square inch in the top chord panels acting as beams = $S_3 = \mathbf{W\mathit{l}/bd^2}$. The maximum extreme fiber stress $S = \mathbf{W\mathit{l}(h/9 + 1/d)/bd}$. All lengths are expressed in feet except that b and d are expressed in inches. (2) For **1/2 W on each vertical strut.** Let P_1 = compression in *be* or *cf* = $\mathbf{1/2\ W}$; $\mathbf{P_2 = P_3}$ = compression in *ad* = $\mathbf{P_5}$ = tension in *ef* = $\mathbf{W\mathit{l}/6\ h}$; $\mathbf{P_4}$ = tension in *ae* and *fd* = $\mathbf{Wm/2\ h}$. For this loading there are no flexural stresses except those due to dead load of beam, which may be usually ignored.

Type 4. The stresses will be of the same intensity as in type 3, but the character of the stresses will be reversed. *be*, *cf* and *ad* will be in tension and *ae*, *ef* and *fd* in compression. If the load is uniformly distributed, the flexural formulas of type 3 may be used, but in this case the maximum stress in *ad* will be tension.

9. Grillages and Wharves

Grillages of Timber are used on the tops of piles or upon foundation beds to support masonry. Fig. 32 shows a design of a grillage supporting a masonry retaining wall. The top of the grillage blocks B should not be higher than about 18 in. above low tide and the bottom timbers should not be so low that they must be laid by divers. The sizes of timbers may be computed by means of the beam formulas and tables. As the timber is under water the unit side-grain compression should be taken at 50% of that given in the table of Art. 1. The caps *C* and blocks *B*, which help prevent the masonry from sliding on top of the grillage, should be drift-bolted or lag-screwed, using long special screws, to the top of the piles. The grillage plank *A* should be fastened to the caps with boat spikes.

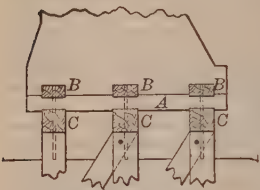

Fig. 32.

Grillages Supporting Building Bearing Walls are of the type shown in Fig. 33. These grillages should not be used except where they will be permanently wet. The bottom course of plank should be at least 2 in. thick and the top course at least 3 in. thick, provided that the clear spacing of the middle timber does not exceed 18 in. This middle timber must be designed so that the extreme fiber stresses do not exceed those specified in Art. 1. The bearing of the top plank upon the middle timber will not need to be investigated, except for soft wood. As in the preceding design, only 50% of the compression across the grain specified in the table of Art. 1 should be used.

The middle timber should be figured as a cantilever beam whose length is the portion extending beyond the outer edge of the wall. The load upon this cantilever beam equals the allowed safe load on the foundation bed $\times\, l_1 \times c$ (Fig. 33). If the depth of the middle timber is assumed, its width may be determined by

$$\mathbf{b_1 = 36\, w\mathit{l}_1^2/Sd^2}$$

and

$$\mathbf{b = 3\, w\mathit{l}_1c/2\, S_h d}$$

where b = width of timber in inches, based on extreme fiber stress, b_1 = width of timber in inches, based on horizontal shearing stress; l_1 = portion of middle timber extending beyond the edge of wall in feet; d = depth of beam in inches; c = distance between consecutive middle timbers in feet; w = safe load on foundation in pounds per square foot; S = safe extreme fiber stress in pounds per square inch; S_h = safe horizontal shearing stress in pounds per square inch. For shallow beams the width b will generally govern, and for deep beams the width b_1; the greater width should be used.

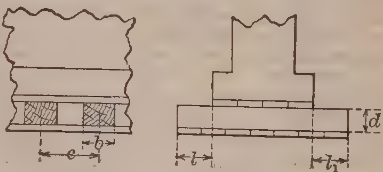

Fig. 33. Grillage for Wall

Wharves. The width of a wharf or pier is usually governed by local and commercial conditions, and its length by conditions and regulations of the United States government. The direction of the length of a wharf, as a rule, should be perpendicular to the bulkhead wall or shore line. In narrow rivers this direction may be made oblique to the shore line, the outer end being farther downstream than the shore end. This arrangement facilitates the entrance of vessels into slips between adjacent wharves. Timber wharves are of two general types: (1) having the floor system or deck supported on piles; (2) having the floor system or deck supported upon timber cribs. The first type is generally the better and cheaper and should be built wherever conditions permit. It cannot be built where the bottom of the river is too hard for pile penetration. When a small penetration, from 4 to 10 ft., may be gotten, the requisite stiffness and holding power of the piles may be obtained by using riprap. The riprap, if of small stones, may be placed, in whole or part, in advance of the piledriving. This is unusual practice and, if adopted, the pile points should be shod with iron.

The top of the deck of a wharf must be above high water, but low enough to permit the economical loading of vessels at low tide. The wharf should be designed with the greatest practical free waterway, so as not to obstruct the flow of water, sewage or ice. Pile piers are usually built with piles in transverse rows 8 to 12 ft. on centers, the piles in the rows being 3 to 10 ft. on centers. The close spacing is for heavy loads or where the pile resistance is small. When timber cribs are used they extend for the transverse width of the wharf and are usually spaced 15 to 35 ft. on centers. Where cost of cribs and their foundations is high, trussed spans may be found economical for distances much over 25 ft. A wharf need not, as a rule, be braced longitudinally, as the impact of vessels in this direction may be taken care of by the bulkhead wall or the earth at the shore end; and as the length of a wharf is generally much greater than its width, the force of impact is distributed over a greater number of piles than when the force acts in a transverse direction.

The lines of transverse piles should be placed as nearly as possible parallel to the thread of the current. They should be strongly sway-braced, the braces being carried down at least as low as low tide. If the piles are to be driven into soft bottom or deep water or in a rapid current, riprap or batter piles should be used to stiffen the wharf against the impact of vessels. A horizontal stick of 12×12-in. timber, 20 ft. long, neglecting its weight, acting as a cantilever, will deflect 1/4 in. under a load of 100 lb. applied at its end; if 40 ft. long, the deflection will be about 2 in. Wharf piles, if unbraced and under the impact of vessels, are cantilever beams whose length equals the distance from their top to firm river bottom. If the upper portion of the piles is sway-braced sufficiently, the length of pile, acting as a cantilever under vessel impact, is the portion below the bottom of the sway bracing. As the deflection under a given load varies as the cube of the length, it is evident that the sway bracing should be carried down as low as possible.

Guard or fender piles should be used to protect the structure from abrasion of vessels lying alongside, and clusters of piles should be placed near corners to protect them. In deep water, or where the river mud is deep and for large vessels, the clusters should consist of from 10 to 50 piles. The corners of wharves for large vessels should be rounded and strongly reinforced. The rounded corner makes it easier for boats to enter slips between the adjacent wharves.

A timber wharf in fresh water, or in salt water where marine wood borers do not exist, lasts about 30 years, with minor repairs and floor renewals. To increase the life of a wharf all joints and bearings should be treated with a preservative; drift bolts should be driven below the tops of the timber, and the hole thus formed filled with tar or asphaltic cement. Large washers should be used under all bolt heads and nuts, and the bolts should not be tightened so as to break the outer wood fibers. When wood pieces are in contact and it is possible to force them into closer contact with bolts in order to exclude water, this should generally be done. Beams built up of two or more pieces and all joints should be packed at least 1 in. apart, using metal packing pieces or separators. The timber should, in general, be so designed as to permit as much circulation of air around each piece as is possible. Wooden floors should be built so as to drain the rain water to outlets. Leaving open joints between adjacent floor planks in order to get rid of rain water decreases the life of a floor subject to vehicular travel, due to the pounding of the wheels across the joints and the abrasion of the edges. Exposed timbers will last longer if beveled so as to shed water freely. Creosoting lumber, if well done, increases the life of the structure. (See Sect. 7, Art. 41.)

In fresh water the portion of the pile between about 1 ft. above low water and high water usually rots before the rest of the structure. By making the caps continuous over several piles, the rotted pile tops may be removed and replaced without removing the top timbers. In fresh water, piles generally last longer with bark removed above low tide. In salt water, piles in warm climates are attacked by marine borers which generally enter the piles between high tide and a point about 4 ft. below low tide.

They may continue their destructive work above high tide and many feet below low tide. They never enter the wood below the mud line. Wood borers are classified by the Forest Service as Teredo, Xylotrya and Limnoria, Chelura and Sphaeroma. The first two are commonly called Teredo and the latter three Limnoria. These borers do not live in fresh water nor in salt water containing much sewage, but may exist in brackish water. The average length of time in which the Teredo and Xylotrya have destroyed barked and unprotected piles in the Gulf of Mexico ranges from 1 to 5 years, the minimum time being sometimes only a few months. Circular 128, U. S. Forest Service, gives methods of protection. (Ref. Sect. 7, Art. 41.)

Live Loads for Wharves range between 75 and 1200 lb. per sq. ft. for concentrated loads of wagons, unloading apparatus, trains, and posts of wharf buildings. The lighter loads are used for excursion boat landings. For ordinary commercial wharves 600 lb. per sq. ft. should be used. The necessary sizes of timbers are determined from the preceding beam formulas and tables. All the parts of the structure should be well bolted, drift-bolted, spiked or lag-screwed together, so that the wharf will act as a unit under the impact of vessels. As the piles between high and low water decay before the other portions, except the floor plank, the unit stresses in the piles should be taken at about 50% of those recommended in Art. 1. This will usually be taken care of by the proper application of pile formulas.

The cost of pile wharves varies, depending upon the depth of water, nature of foundation, necessity of batter piles or riprap, and the loads to be carried. Wharves of the crib bridge type cost one and one-half to twice as much as the pile wharves, depending upon similar conditions.

For additional data on wharves, see Sect. 19.

FALSEWORK AND TRUSSES

10. Trestles

Timber Trestles are generally used for semi-permanent work when their first cost is less than an earth fill or an earth fill and culvert, if a stream of water is to be taken care of. When permanent work is desirable, there is usually no sound reason for timber trestle construction, other than the lack of funds, because, due to the high cost of lumber and timber maintenance, an earth fill or steel structure will be cheaper in the end. Trestles usually consist of a series of bents spanned by beams or stringers. Each bent generally consists of two or more vertical posts, depending upon the width of roadway and the load to be carried, two outside battered posts, a cap and sill, and sway bracing. The outside posts are given a batter of from 1 1/2 to 3 in. in 12 in. and the bent is sway-braced to resist lateral force such as wind or rack of a locomotive. The roadway or track is carried upon stringers, which should be continuous over two spans. Fig. 34 shows a common form of trestle less than 30 ft. in height as used in 1906 on the Baltimore & Ohio R.R. Trestles over 30 ft. high are generally built in stories of from 15 to 30 ft. in height, as in Fig. 35, which shows the 1908 standard of the New York, New Haven & Hartford R.R. In this design the bent is framed into two separate stories, the second story being erected upon the cap of the completed story below. This is the more common design and is easy to erect, but occasionally the vertical and batter posts are made continuous from top to bottom of trestle. The latter method reduces to a minimum the number of joints where end grain bears upon side grain. This is desirable, as the side grain is often injured by such compression, and in the case of sills dampness is retained by the broken fibers and rot takes place rapidly. Trestles over 50 ft. high are sometimes built with pairs of bents framed into towers at intervals of 20 to 30 ft., the stringers being compound or trussed beams.

Longitudinal bracing for railway bridges must be designed to take the thrust of a braking train, which may amount to 75 000 to 100 000 lb. It is generally assumed as 20% of the live load. The longitudinal bracing should not only consist of horizontal struts between bents to take compression, but the bents should also be X-braced as shown in Fig. 34. For highway trestles the bracing may be of smaller cross-section and the X-bracing at less frequent intervals. Where the trestle is of short length and there are abutments of earth, timber or masonry at either end, the X-bracing may be safely reduced in cross-section.

Trestle Design. The sizes of the stringers and posts can be obtained from the timber tables and formulas, using the specified loads given in Sect. 12, but it is advisable to increase the dimensions so determined, to allow for decay. Stringers rot quickest where the ties or flooring rest upon them and where they rest upon the caps, as dampness lodges in such joints. The stringers of railway bridges should be packed 1 to 2 in. apart, to permit circulation of air, using metal separators or packing spools, as in Fig. 34. Bolts should pass through the spools, having large washers at their ends to permit the bolts to be tightened without injury to the fibers. The sizes of the posts depend upon the safe allowable compression upon the side grain of the caps and sills, see Art. 1. It is therefore desirable to use hardwood caps and sills when possible. The caps and sills should have about the same dimensions as the posts. As a rule the posts can be so placed with reference to the stringers that there will be practically no bending stress in the caps, and similarly there will be none in the sills, the function of caps and sills being to hold the posts in position and transmit shear.

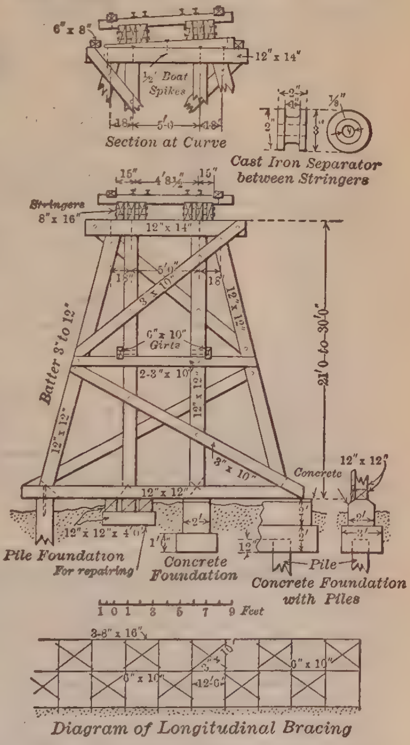

Fig. 34. Trestle, Baltimore & Ohio R.R.

The posts may be drift-bolted or mortised to the caps and sills.

The bottoms of sills should be supported by masonry so as to be at least 12 in. above the ground. If the trestle consists of piles driven into dry ground, the piles at ground level will rot badly in 5 or 6 years, and as the life of a trestle is from 10 to 14 years, it is advisable to double, or nearly double, the number of piles per bent, in order to allow for decay, or cap the piles with masonry, as in the extreme right footing of Fig. 34.

Bracing. Good examples of sway bracing are given in Figs. 34 and 35. For highway bridges the sways may be lighter. Use 3/4- or preferably 1-in bolts for fastening sways. The design of this bracing for trestles under 30 ft. high is generally made on the basis of precedent, the effect of wind being small and the other stresses indeterminate. For higher trestles the wind

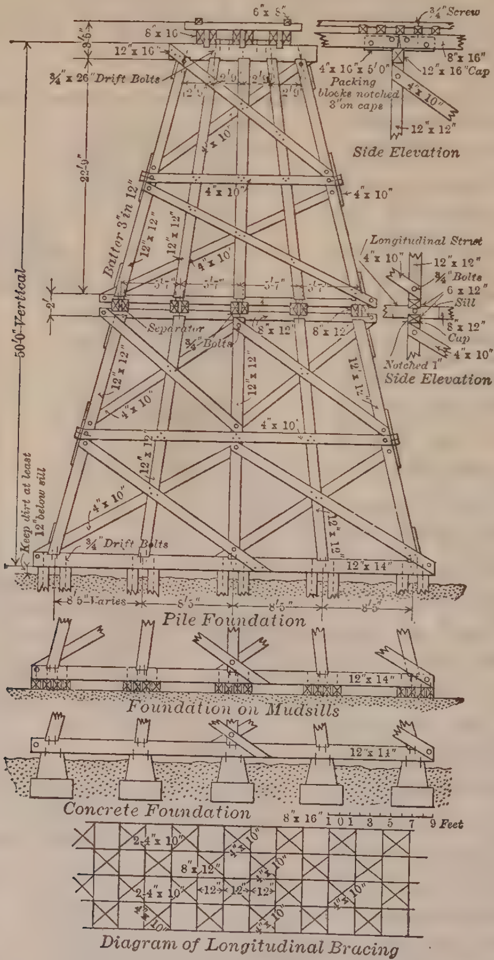

Fig. 35. High Trestle, New York, New Haven & Hartford R. R.

stresses should be computed as guide in the selection of proper size and in the design of joints. The horizontal struts or girts of the longitudinal bracing should not, for railway work, depend upon a single bolt for the transmittal of stress, but such stress should be transmitted by end bearing. For railway trestles the struts should be from 6 by 8 to 8 by 12 in. For highway trestles, the span being longer, the size should not generally be less than 6 by 6 in. The longitudinal X-bracing need not be used in every panel, except for railway trestles on curves over 7°. In high railway trestles on curves over 8°, the centrifugal force of the moving train should be further guarded against by additional braces on the convex side of the trestle. The sizes of the X-braces cannot be determined by computation, but should be selected from existing designs. The details of all trestle work should be simple. When pieces are in contact they should be drawn tight, to exclude water, and where possible they should be separated at least 1 in. and preferably 2 in. to allow circulation of air. In the design of high trestles, in order to decrease the number of bents the span of the beams is reduced by means of corbels and A-frames as shown in Fig. 36, thereby permitting a greater distance center to center of columns.

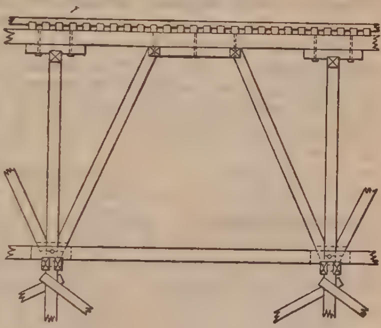

Fig. 36

Life of Trestles may be increased by the use of wood preservatives, such as creosote, and all surfaces in contact or which have been disturbed by ax or adze, all screw and bolt holes and the tops of all drift bolts should be thoroughly coated with similar preservatives. The tops of caps and stringers are often covered with sheet zinc or iron to protect them from water and hot cinders. These coverings are unquestionably of value as fire protection, but as they decrease the circulation of air, it is doubtful if the life of the caps and stringers is prolonged thereby.

Construction Trestles are for temporary use, and therefore in selecting the sizes for posts the compression across the grain may be taken 50% higher than allowed in Art. 1, and no allowance need be made for rot. Trestles for light industrial tracks and narrow-gage construction tracks require only light transverse and longitudinal bracing. In making earth fills from temporary trestles constructed therefor and from old trestles constructed for semi-permanent use, as railway trestles, the lateral and longitudinal bracing, and in high fills even the caps and sills, may be broken by the fall or weight of the material or its settlement. Such fills should be brought up evenly on either side of the axis of the trestle to diminish the possibility of large and sudden movements of the fill, which occur most frequently in fills made upon side hills. It is often advantageous to remove the bracing when it is reached by the fill to prevent the pull in the bracing, under the load of the fill, from distorting the posts and even breaking them. This is a matter which can be determined only after the character of the fill and contours of the ground are known. If the bracing is old and rotted it is often best to put on a new and substantial bracing before starting the fill.

When eath fills are made from trestles of piles driven into 15 to 20 ft. of mud, sudden movements of the mud and newly made fill frequently not only break the bracing but snap off the piles and demolish the entire structure. Such trestles should be built of piles of large diameter, driven to hardpan and heavily sway-braced, and the sway bracing removed when reached by the fill. But even with these precautions sudden failure may take place.

11. Floors for Trestles and Bridges

Floors for Steel Highway Bridges are illustrated in Fig. 27 of Sect. 12. In designing the roadway joists concentrated wheel loads may be regarded as distributed over two joists, when the distance center to center of joists does not exceed 2 1/2 ft. and the flooring is at least 3 in. thick. In maintenance work, when the center distances do not exceed 2 ft. and the wheel load is not applied near the outer line of stringers, it may be regarded as distributed over three joists, provided the flooring is at least 3 in. thick. The front roller of a steam roller may be computed as equally distributed over all joists which it can cover or partially cover. The wheel loads upon cross-ties of electric railways may be regarded as distributed over three ties.

Roadway Flooring may consist of a single thickness of 3- or 4-in. plank, the distance between centers of stringers not exceeding 9 times this thickness; 3-in. flooring should be used for light and infrequent travel and 4-in. where it is heavy and continuous. Roadway plank should be laid with a transverse grade of from 1 to 1 3/4 in. in 10 ft., to drain the water to the sides of the roadway. In bridges over 16 ft. wide, the plank may be cut in two lengths and the level of the roadway raised at the middle. **Floor plank** should be laid snug, as the planks at open joints are easily torn, and the floor is made very rough and wears quickly. They may be laid transverse to the bridge or oblique; the former method is slightly cheaper and appears equally satisfactory. Planks need be dressed on only one side, but all joints should be adzed smooth when the floor is laid. Roadway plank should have a uniform width of 12 in., although if ordered in variable widths of 8, 10 and 12 in., a substantial saving results. When variable widths are used it is necessary in making repairs to select particular widths of plank for each defective one replaced, which is troublesome. For bridges having little travel the life of the flooring depends upon the rotting of the timber, and therefore timber which rots slowly, such as Southern pine, is desirable. For bridges carrying heavy and continuous travel the floor does not rot but is worn out, and therefore the harder and tougher woods such as white oak or chestnut oak are best.

Three-inch flooring should be fastened to the joists with 6-in. nails and four-inch with 7-in. nails. Flat-head wire nails are more easily driven than round-head nails. Well-seasoned hardwood floors often require holes to be bored in advance of driving nails, but most commercially seasoned oak and all pine flooring may be nailed down without such holes. All flooring should have a one-heart face. The heart face should be laid down for light travel and up for heavy. The general rule is to put the heart face down, but experience with bridges in Washington, D. C., shows that as a rule it should be up.

The life of the flooring under light travel is from 4 to 5 years, and under heavy travel 3-1/2 to 4 years. In the latter case probably 10% of the plank will have to be replaced before a general replacement is made, using a low grade of timber.

Double floors consisting of a 3- or 4-in. creosoted subfloor, laid with 1/2- to 2-in. open joints and having a wearing floor of from 1-1/2 to 2 in., are sometimes used. They should never be used with untreated plank in the subfloor. A creosoted subfloor lasts 12 or 15 years. The lower planks are laid transverse or oblique to the bridge and the upper ones at an angle of from 45° to 60° with the ones below. The subfloors should be nailed to the joists with 60d. nails, using two per joist, and the top planks nailed to the lower floor with two 40d. nails at intervals of 2 ft. This type of floor, while resulting in higher first cost, has the advantage of cheap resurfacing at frequent intervals, and therefore usually gives a smoother roadway than single planking.

A Roadway Joist should be at least 3 in. thick and should not deflect more than 1/400 of the span under the full load. The general sizes of joists used are 3 by 12, 3 by 14, 4 by 14 and 4 by 16 in. When they rest upon the tops of floor beams they may lap or butt, if there is sufficient bearing. When lapped, an air space of 1/2 in. should be left between the lapping ends to permit circulation of air. Neither bridging nor fastening of the joist to the floor beams is necessary, unless planks thinner than 3 in. are used. The floor will be too heavy to be disturbed by wind.

Southern pine and oak joists last from 12 to 15 years, provided they are selected of such depth that they may be turned over once. Joists rot where the planks rest upon them, and when this depth reaches an average of one inch they should be turned and used until the top of the joist, in the new position, rots about the same amount. Southern pine joists are better than oak joists, as they do not warp, and pine rots from the outside and oak often from the inside. The painting of the top of joists with a timber preservative is recommended.

Sidewalk Flooring should be 2 in. thick, dressed one side, 6 or 8 in. wide and supported by joists not over 2 ft. on centers. They should be laid snug, as open joints make rough floors and the public object to seeing through the open cracks of floors of high bridges. Pine floor planks may be spiked with two 20d. nails per joist and oak ones with two 30d. nails. Floors should be given a transverse grade of 3/8 in. per ft. **Sidewalk joists** are usually 3 by 12 or 3 by 14 in., placed 2 ft. on centers. These joists should be fastened to the floor beams, as sidewalks are usually narrow and of light weight per square foot, and if the joists are not fastened the floor may be disturbed by wind, although cases of this kind are extremely rare.

When steel stringers are used the planks in small country bridges are often fastened by clinching the nails under the flanges. The best arrangement is to bolt spiking strips 4 to 5 in. thick to the flanges of the beams, countersinking the bolt heads.

Wheel Guards should be provided on either side of the roadway to protect the adjacent trusses or to act as a curb protection for the sidewalks. They should consist of 4 by 6 or 6 by 6-in. string pieces supported upon 2- or 3-in. shims, 6 to 12 in. long placed at intervals of 4 to 6 ft. on centers. The roadway water should drain through the openings left between the shims. Guard rails should be bolted to the joists or floor beams, the bolts passing through the shims. Joints in the string pieces should be made at the shims and with halved laps. These rails should be protected with steel angle facings when laid upon a steep grade, as they are often used by teamsters as brakes.

Electric Railway Tracks may be supported upon cross-ties or directly upon longitudinal stringers, the latter method being used when the bridge also carries vehicles. Cross-ties should not be less than 6 by 6 in. when the stringers are 6 1/2 ft. on centers. For a greater distance they should be designed to carry the maximum wheel load, assuming a distribution of this load over three ties, the fiber stress not to exceed allowable limits. The openings between ties should not exceed 6 in. Alternate ties should be drift-bolted to the stringers. No notching is necessary. Guard rails 6 by 8 in. should be placed at either side of the track, 3 ft. 7 in. from the track, and lag-screwed to every tie. No notching over the ties is necessary with the use of lag screws, which should be staggered 2 in. in the guard rails.

Solid Timber Floors covered with ballast have been used for trestles and have given satisfactory results. The timber is creosoted and not afterwards cut if it can be avoided. When cut the end surfaces are painted with creosote. This type of floor is expensive to build and maintain and is somewhat difficult to inspect, but is regarded as offering a good protection against fire, decreases noise and gives a better track than the common type of floor. Arguments for and against this type of floor are given with interesting detail in Proc. of Assoc. of Railway Superintendents of Bridges and Buildings, Oct., 1906. Fig. 37 shows a ballast trestle floor on the El Paso and South Western R.R.

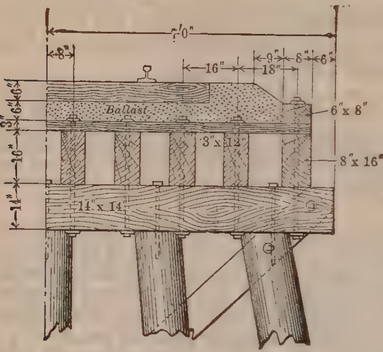

Fig. 37

The 1921 Manual of the American Railway Engineering Association gives the following relative advantages of solid timber ballast deck and reinforced-concrete trestles: **Concrete trestles** have advantage in fire resistance, and permanence; and a slight advantage in bridging waterways subject to flood currents or wide fluctuations of water surface. **Creosoted timber trestles** are more economical than concrete except when the cost of the concrete structure is less than one and one-half times the cost of the wooden structure. Neither type has the advantage in the matter of appearance, nor in general service qualities.

Railway Trestle and Bridge Floors. Figs. 34 and 35 show typical trestle timber floors and Fig. 38 shows floors for Howe bridges.

The following clauses are taken from the 1921 Manual of the American Railway Engineering Association:

It is recommended as good practice to use guard timbers on all open-floor bridges and they should be so constructed as to space the ties properly and hold them securely in their places.

It is recommended as good practice to use inner guard rails on all open-floor and on the outside tracks of all solid-floor bridges, and similar structures longer than 20 ft. in main-line tracks and on similar bridges and structures in branch line tracks in which the speed of trains is 20 miles per hour or more.

The inner guard rails should be of some form of metal section and extend beyond the ends of the bridges for not less than 50 ft. They should be spiked to every tie.

Ties and guard timbers should be sized one dimension. Omit dapping of guard timbers and ties. Use lag screws in every tie. Holes should be bored for lag screws 1 in. deeper than penetration of screw. Holes should be bored 1/16 in. smaller than diameter of lag in guard timber and 1/4 in. smaller than diameter of lag in ties. Lag screws must not be driven but screwed to position. Fasten alternate ties to stringers. Lag screws should be stagged 2 in. in guard timbers.

12. Falsework for Bridges

Truss Bridges are generally erected upon timber trestles or scaffolds consisting of vertical timber posts and outside batter posts, supporting caps upon which rest longitudinal stringers (Fig. 39). The bottom chord of the bridge is laid upon the falsework and blocked several inches above its correct position to allow for settlement of the falsework under the load of the bridge.

Bents are usually placed at panel points of the bridge, but where clearance makes it necessary the panel loads may be carried at any point of the stringers.

Small and light bridges may be erected by gin poles, which are timber masts guyed in a vertical position and carrying a block and tackle at their tops, by means of which the separate truss members are hoisted into their positions. Most bridges were formerly erected by timber travelers, consisting

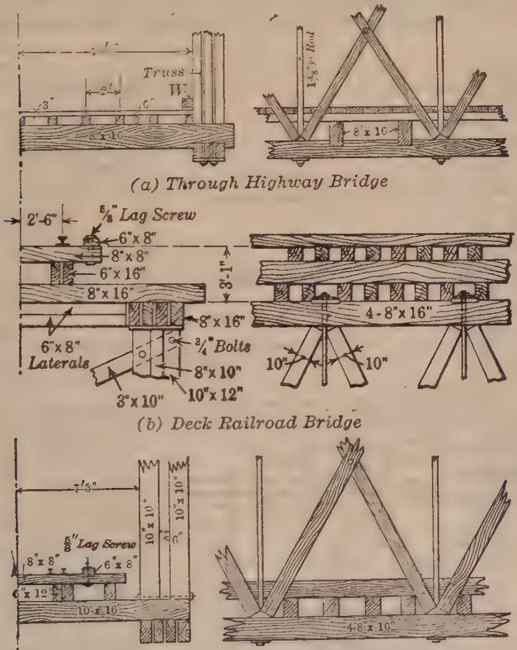

Fig. 38. Floors for Howe Bridges

of two or more overhead bents braced together to form a tower (Fig. 39). Such travelers are no longer used, and modern practice is to erect all but the largest bridges by locomotive cranes or derrick cars. For important large bridges, special steel travelers may be constructed. The falsework must be designed to carry the weight of the bridge and traveler or crane. Where there is danger from injurious freshets or where there must be large clearances maintained as for navigation, trussed falsework, generally of the Howe bridge type, is used. This falsework may be erected upon temporary timber trestles or upon pontoons. Fig. 39 shows the falsework and traveler used on the Baltimore and Ohio R.R. in erection of a small bridge.

Design of Falsework. The loads to be carried by the falsework consist of its weight, which, except for trussed falsework, is negligible; the weight of the bridge, including the girders, but not necessarily the stringers and floor resting upon the girders, and the weight of the traveler or crane. In the design, consideration must be given to wind pressure exerted upon the bridge and the traveler; where a stream is to be bridged the effect of ice and débris carried by freshets must be regarded and preferably the erection completed within a period of time when ice gorges or serious freshets are least probable. Where trussed spans are used, slightly higher unit stresses may generally be used than are allowed for permanent work, as the period of erection is not sufficient for a material deterioration of the timber. The trusses should be

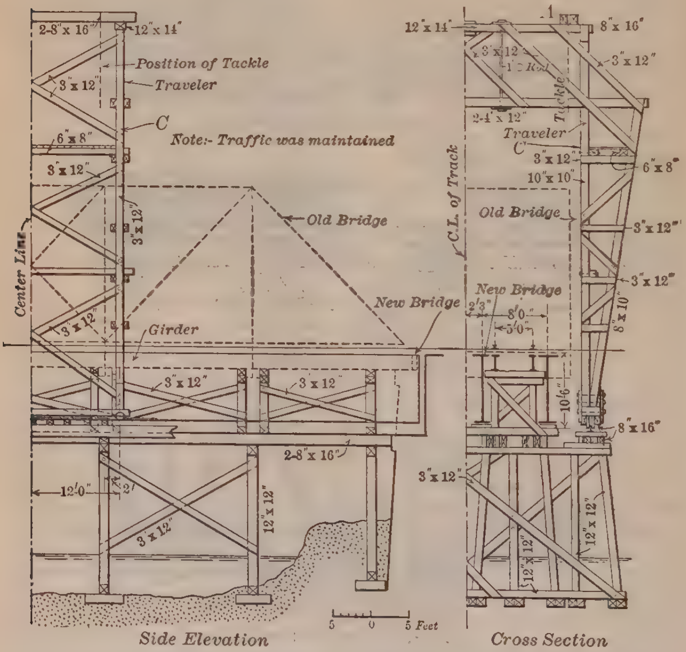

Fig. 39. Bridge Erection, Baltimore & Ohio R. R.

of first-class carpentry work to reduce the truss deflection to a minimum and should be strongly sway-braced.

When viaducts or bridges over land are erected, the falsework may consist of a series of ordinary trestle bents resting upon either mud sills or spread timber footings. The trestles for water work are generally formed, in whole or part, of piles. When the trestles are over 30 ft. high they are generally built in stories of from 15 to 30 ft. high, the timbers of adjacent stories being tied together by fishplates, to transmit tension resulting from wind pressure upon the bridge and traveler.

For light bridges the trestle sills, posts and caps may be of 6 by 6 or 8 by 8-in. timbers, the sway and longitudinal bracing of 3 by 8-in. timbers and the stringers of 6 by 12-in. timbers. For most bridges the sills, posts and caps should be 12 by 12-in., the sway and longitudinal bracing 4 by 10 in., and the stringers 8 by 16 in. The approximate dimensions of the timbers should be determined by computation, but as stiffness and sometimes weight are governing factors the sizes should generally be larger than theoretically required.

All falsework should be designed so as to permit economical erection and demolition and so that the timbers will not be materially injured for future use. Bolts should be used instead of spikes, and beveled, mortised or other expensive joints should be avoided.

The Settlement of the Falsework under its full load should be a minimum consistent with economy. A practically unyielding foundation should be constructed; the number of horizontal joints and particularly the number of joints where end grain bears upon side grain should be reduced to a minimum and the unit compression across the grain should not exceed that allowed in Art. 1. The probable settlement of the falsework, exclusive of foundations, may be approximated as follows: (1) By figuring the columnar shortening, c, in inches, by means of the following formula, $c = 12\ Sl\ /\ E$, in which S is the unit compression per square inch, l = length of column in feet, and E the modulus of elasticity. When pile foundations are used the length of piles should be added to obtain the total columnar length to be used in the formula. (2) By allowing 1/16-in. settlement for each horizontal joint for " taking up" and an additional 1/16 in. at each horizontal joint where end grain bears upon side grain for " biting" of the grain into the side grain, provided the unit stresses of Art. 1 are not exceeded. The total settlement will be the total of that obtained from (1) and (2).

In railway bridge renewals or other bridge erection where the falsework carries heavy locomotive or vehicular loads the locomotives or heavy vehicles may cause settlements of the falsework foundation so much greater than the deformation of the timber that the latter is negligible. Frequently, even in highway bridge construction, falsework foundation settlements of from 6 to 12 in. occur without serious mishap. The panel points are wedged up as the falsework settles, but in design such settlements should be guarded against.

13. Falsework for Arches

Masonry Arches are built upon temporary falsework, called centers or centering, usually of timber consisting of parallel frames, bents or ribs with top members whose upper surface is cut to the curve of the arch soffit. The top members may be joists; or bows, also called back pieces, may be used. Upon the top members plank called lagging are laid which support the stone voussoirs or concrete sheeting of the arch. Wedges or jacks are placed at convenient points of the falsework to lower sections of it after the arch is built. The wedges may be located at any point between the soffit of the arch and the falsework foundation. All arches should be built up symmetrically and the centering should be designed for such loading.

The Centering for Short Span Arches, when the span is under 10 ft. and the arch is flat, may be built of single planks on edge with tops cut to curve of soffit, supporting lagging dressed on one side and supported at the ends by posts resting upon wedges, as at *a* in Fig. 40. If the centering is built for a stone or brick arch, the lagging may be laid with open joints not wider than 1/3 the width of voussoirs or bricks; if for concrete, tongued and grooved lagging should be used. For spans over 6 ft. the top member or bow may be in two pieces tied by small battens (*b* in Fig. 40), the curve of the arch being cut out of the top piece. To save labor of cutting bows when the barrel of the arch is long enough, the bows may be placed 4 or 5 ft. on centers and 2- or 3-in. lagging used. The lagging and bows are computed as beams and the posts as columns under the full load of the arch. In buildings 1 in. lagging is generally used, supported on two or three bows about 12 in. on centers. When the arch is flat and the span is over 10 ft., intermediate props or posts are generally used to shorten the beam length of the bow; 2- to 4-in. lagging may be used, the bows being placed 4 to 6 ft. on centers.

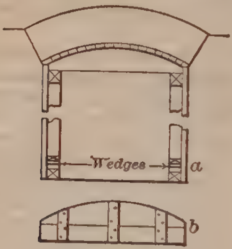

Fig. 40

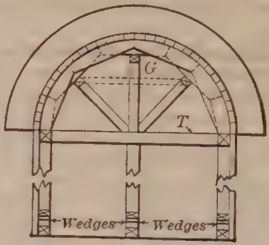

Fig. 41

Centers for Short Span Arches

When the arch has a rise of over 1/6 the span, centering of the form of Fig. 41 may be used. The bow may be made up of two or three planks breaking joints and nailed together. For economy the bows should be as far apart as possible, preferably 4 to 6 ft., using from 2- to 4-in. lagging. For the larger spans, the thicker lagging is the more economical. A center post should be used for spans over 10 ft., and when this cannot be done the bottom piece, *T*, should be stiff and strong enough to carry the load brought by the radial braces. This load is indeterminate, but in design it may be assumed at 1/4 of the total load of the arch, the bow also carrying 1/4 of the load as an arch and the balance being carried by the masonry arch acting as a compression member.

This type of centering may be used up to spans of 30 ft., but for spans over 15 ft. one or two lines of horizontal girts should be used for each frame to take care of the horizontal thrust of the arch load. A girt, marked *G*, is shown in dotted lines in Fig. 41.

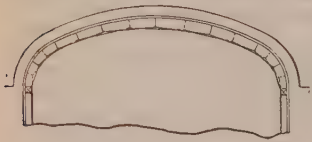

Fig. 42. Bow Centering

Unbraced arch centering of the type shown in Fig. 42 should never be used, except where other forms are impossible, and then only for spans under 20 ft., as it deforms badly, rising at the crown when loaded at the haunches and sinking at the crown under the crown loads, and is at best risky. By placing a temporary load at the crown, the change in the form of the curve can be lessened. If used at all, the carpentry work should be first-class, the abutting sections of the bows in intimate contact, wedges of shingles being used just prior to loading if the shrinkage of the timber has caused the joints to open.

Centering for Arches Over 30 Ft. in span may be of four types: (1) Arches, (2) Howe trusses, (3) Bowstring trusses, (4) Bents. The first is expensive to build, gives small salvage for lumber, deforms badly under loading and therefore requires temporary crown loading and causes cracks at the haunches during the arch construction unless loaded in alternate transverse sections. Where a deep gorge is to be spanned it may be economical. The second type is objectionable for general use for the foregoing reasons, except that the crown will not rise when the haunches are loaded. Maximum stresses should be determined for all web members under various stages of loadings. There is no reason for using this type except to utilize existing available trusses.

The curve of the arch must be built up by additional timbers resting upon the top chord at panel points. For the design of this type see Art. 16.

Bowstring Centering shown in Fig. 43 has been used extensively for spans up to 100 ft., and may be necessary for arches over streams, but should never be used where intermediate supports can be gotten, as in Fig. 44, or where vertical posts may be carried to intermediate foundations. It has all the objections given for type 1, but is cheaper to build and deforms less. This type is preferable to the Howe truss bridge type. Bowstring centering should be built with Pratt bracing, as in Fig. 43. The stresses in the various

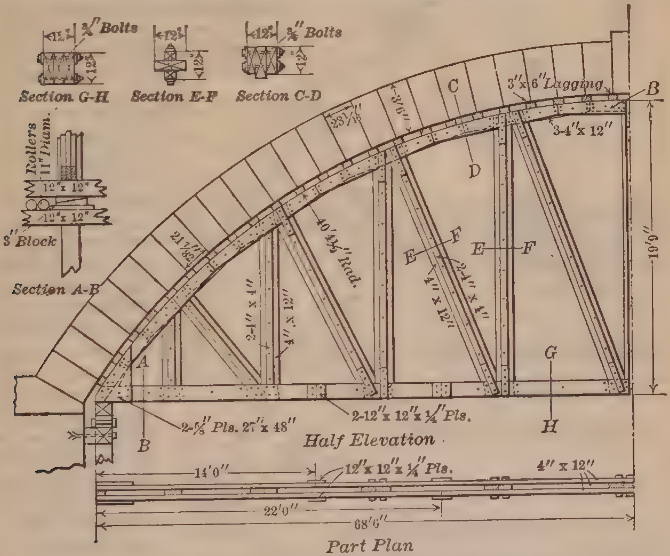

Fig. 43. Bowstring Centering

members should be computed for the centering, one-third, one-half, two-thirds, and fully loaded, and each member designed for the maximum stress. Reversal of stress will take place in the bracing, and all joints of this bracing should be made with straps or gussets to transmit tension as in Fig. 43. The crown of this centering should always be loaded with a temporary load of about 1/6 the total arch load, but even with this precaution hair cracks will generally develop at the haunches, showing that the tensional value of the mortar has been destroyed.

Fig. 44 shows a modification of the bowstring centering which was used in the construction of the Massachusetts Ave. culvert, Washington, D. C. The bowstring truss was designed to be moved ahead in sections upon the bottom bents or A-frames. Eight bows were struck at one time and skidded upon pipe rollers resting upon a stringer track. One additional A-frame was erected in advance in order to permit this movement.

The Bent Type of Centering is recommended for the construction of all arches where clearance does not prohibit its use. Its first cost is generally least, it deforms less than the other types, and gives the greatest salvage of lumber. Its design should not be begun until the method of building the arch has been determined. If the arch is to be built up continuously from the springing line to the crown, it should deform or settle less than if built in either longitudinal rings or alternate transverse sections. But however strongly built, if the arch is built up continuously cracks will develop at the haunches when the crown is built. This of course will not take place if the arch is small enough to be built complete in a day. The stiffer the center, the smaller the cracks. These cracks are not serious except that in the case of a reinforced-concrete arch they may permit the infiltration of water and the rusting of the steel, and they are the cause of the abnormal sinking of the crown of the arch when the centering is lowered. Where the cracks are larger than hair cracks, the masonry above the extrados of the arch should not be built until the centering has been lowered sufficiently to close up the cracks, otherwise the closing up of the cracks in the arch may crack the upper masonry.

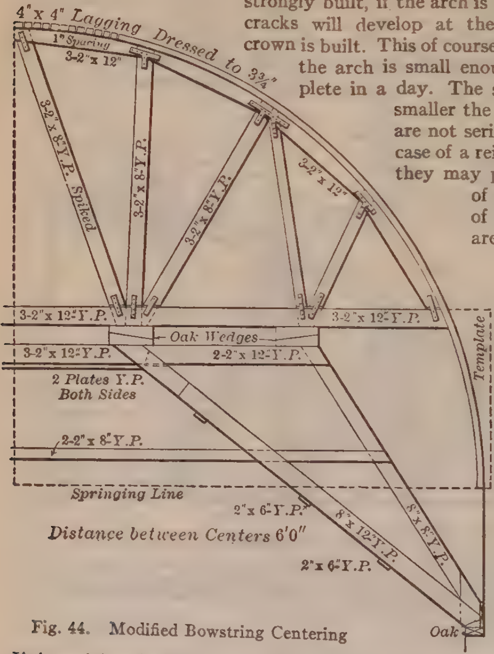

Fig. 44. Modified Bowstring Centering

If the arch is to be built in longitudinal rings three or four feet wide, each ring to be completed in a day, which is common practice in the construction of reinforced-concrete arches, the centering should deform or settle less than if built in transverse blocks, but may deform more than if built continuously for the full width of the bridge. When built in alternate transverse blocks, a settlement equal to 1-1/4 in. per 100 ft., and proportionally for larger or smaller span, is good practice, but a less settlement is desirable. For arches in longitudinal rings, the settlement should be less than half this amount, and for arches built up continuously from the springling line to the crown a smaller settlement should be gotten if possible. Since the settlement of the falsework varies almost directly as the distance from the foundation to the crown, arches of large span and rise and those over deep gorges or valleys should be built in alternate sections, whereas arches of small span and rise over flat ground may be built according to the other methods.

Two Types of Centerings of Bents. The first type (Fig. 47), which is used for concrete arches, generally is designed so that the load upon the lagging is transmitted to joists spaced from 10 to 24 inches on centers, supported by transverse caps resting upon vertical or inclined posts. In the second type, Fig. 45, which is generally used for stone arches, the lagging rests directly upon bows spaced from 3 to 6 ft. on centers, the bows being supported by the posts. In Fig. 45 the voussoirs are shown supported by wedges, but usually lagging is used in lieu of wedges. The first type is preferable for concrete bridges, because, upon the completion of the arches and the striking of the centering, lagging, studs, and wales of proper sizes are available for the balance of the concrete construction. The second type is better for stone arches, because by laying the lagging with open joints the bottom or soffit joints of the voussoirs are accessible and can be " packed with rope or rags " for grouting, the packing removed and the work pointed prior to the removal of the lagging. Further, this second method permits the placing of wedges under each voussoir, allowing small errors in the top curve of the centering or the top curve may be omitted and the curve of the soffit made by shimming pieces and wedges of variable heights, as in Fig. 45.

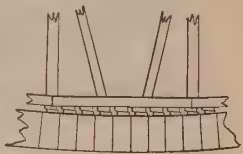

Fig. 45

Loads and Stresses. The centering should be designed to carry the weight of the arch ring alone, except in the case hereafter noted. In the case of concrete the nature of the load varies, the concrete being deposited as a semi-liquid. For unit weights see Sect. 10, Art. 17. The weight of the falsework is negligible, except in very high falsework. It is suggested that, in determining the load upon the centering, friction be neglected, as this is on the safe side and other assumptions reduce to an absurdity. Fig. 46 shows a voussoir or section of stone or concrete, *abcd*, supported by the lagging and by the masonry or strut *SS* below it. The weight *W* is resolved parallel and perpendicular to a tangent to the lagging at its middle point, giving a normal component *N*, which must be carried by the centering. Assuming that there is friction along *ab*, which reduces the intensity of *N*, it is evident that the reduction cannot equal *T* times the coefficient of friction, because, if such were the case, the arch ring from the joint *ab* to the springing line would have to be capable of supporting itself. Concrete when deposited being in a semi-liquid form would cause little friction along the joint *ab*, and the setting of the concrete could not modify the initial stresses.

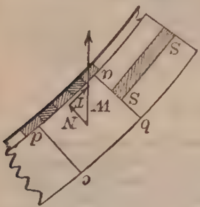

Fig. 46

In addition to the loads of the arch ring, the effect of wind pressure upon the falsework, prior to the keying of the arch, should be considered, and where the arch is over a stream, masonry footings should extend to above the high-water line, or other precautions taken to protect the falsework from injury, due to the pressure of ice or débris.

Information upon the Design of Centerings. The lowest 30° of a semicircular arch and of other arches of less rise exert little vertical pressure upon the falsework and may be built upon a templet or light falsework. In applying this general rule to an arch which is not semicircular, the 30° point is one at which a perpendicular to the tangent to the intrados makes an angle with the horizontal equal to 30°. Fig. 44, which is a design used in the construction of a brick arch, shows that a template was used in the lower portion of the arch.

The settlement of the centering may be computed approximately by using the rules given in Art. 12, but as arch centering should be, and generally is, of a better grade of carpentry work, an allowance is suggested of 1/32 inch for " taking up " and 1/32 inch additional for each joint, where end grain bears upon side grain, provided the unit stresses of Art. 1 are not exceeded. If particular care is not taken with the joints, such as adzing off rough places, the settlement may more nearly equal 1/16 in. for "taking up" and 1/32 in. for "biting."

At the Piney Branch Bridge, Washington, D. C., there were used six joints between the soffit and foundation, two of which were in end bearing (Fig. 47). Assuming first-class carpentry work, which was obtained, the settlement due to "taking up" and "biting" would be 6 × 1/32 + 2 × 1/32 = 1/4 in. To this must be added the columnar shortening which, on the basis of the formula in Art. 12, gives a total of 9/16 in., agreeing closely with the actual measurements. Measurements of other centerings show that the limits lie between 1/16 and 1/32 in., depending upon the grade of carpentry work. However, when the unit compression upon side grain exceeds the allowable unit stresses, the settlement of the centering is greater. In some parts of the Connecticut Ave. and the Edmondson Ave. bridge centerings where the stresses were more than 50% higher than allowed in Art. 1, the "bite" was 1/8 in. per joint, due in part to defective framing.

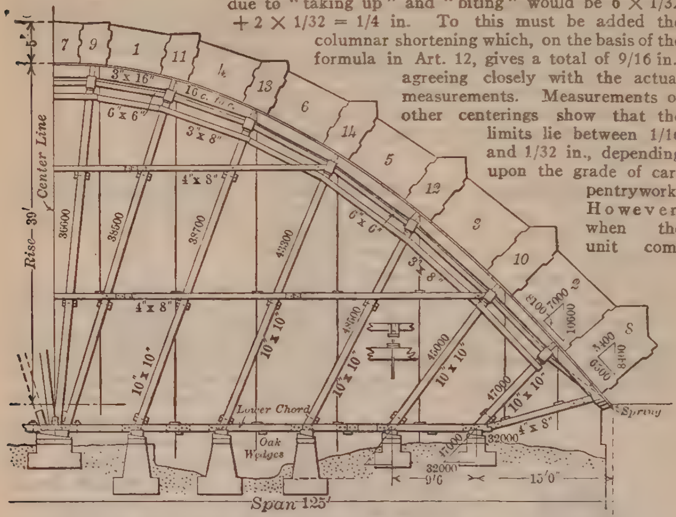

Fig. 47. Centering for Voussoir Arch

When the posts are placed vertically, and not radially or approximately radially, there is a lateral deformation of the centering as well as the vertical. When posts are vertical, struts must bear against the transverse caps, to prevent displacement under the radial pressure, or the joists resting upon the caps must be notched out and shimmed tight against the caps. Centerings are frequently designed with only one-half as much load on the outside posts of the same bent as upon the middle and intermediate ones and the cross-section of all timbers is made the same. As a result the center settles and the face forms, if the arch is of concrete, go out of plumb often as much as 1/2 in. in 5 ft., and if the arch is wide a crack may be formed. When the arch is to be built of concrete, the caps should extend about 3 ft. beyond the face of the arch ring to support the forms for the face of the arch and also to provide a walkway.

Sway-Bracing need not be computed for wind pressure, except for high arches. It should, as a rule, be heavier than such computations indicate to be necessary. A study of successful designs is suggested. Very little longitudinal bracing is required, except such girts as are necessary to take the horizontal component of the load of the arch when vertical posts are used. The use of steel, except for sway rods and in the form of plates or channels to increase end bearing, is not generally recommended. Steel is greatly affected by temperature and should not generally be used. However, in centerings of high arches the posts for 1/3 the height of the centering may be of steel, as their expansion or contraction will have comparatively little effect upon the total height of the falsework.

For a description of the centering of a large arch which collapsed due to insufficient bracing, see Eng. News, Vol. 77, p. 314.

Since centerings are designed for temporary work, the less permanent woods, such as hemlock and short-leaf pine, may be used for posts, lagging, and sway-bracing. Only hard wood should, as a rule, be used for sills, caps, and wedges, although Southern yellow pine is sufficiently hard for caps. Southern yellow pine is best for joists.

Layout. Having determined upon a centering of bents, the types of foundation, span and curve of the arch govern the layout. The distance between the posts at the top of the centering should be, in general, as great as the available depths of joist or, in case of a stone arch centering, the available depths of timber for the bows will permit. Joists cannot generally be obtained of larger dimensions than 6 × 16 or 4 × 16 and sometimes only 4 × 14 in. If rock or other suitable foundation can be obtained at shallow depths, Fig. 47 gives a good layout. If suitable foundation is at considerable depth and foundations are expensive, Fig. 48, which shows the center for the main arch of the Edmondson Avenue bridge at Baltimore, gives a good layout. In this design the railway track near the center of the arch was cleared, which somewhat modified the layout.

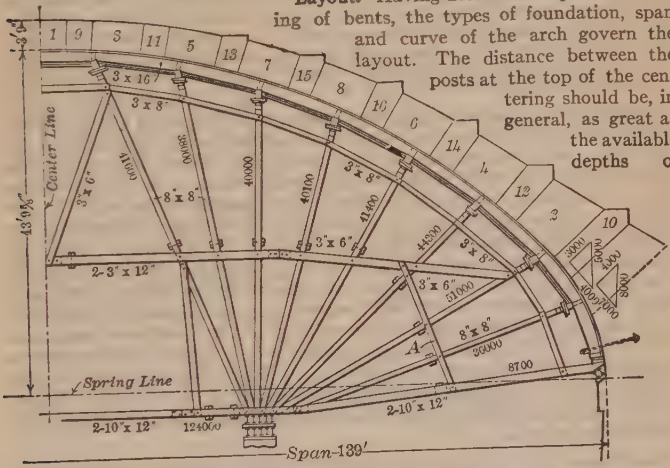

Fig. 48. Centering for Voussoir Concrete Arch

Fig. 44 shows a good way of supporting a centering upon an offset in the foundation masonry. Small arches upon high piers may be supported in a similar manner upon a projecting coping or upon projecting blocks of concrete or masonry.

Details for a Concrete Arch Centering. The **lagging** should be of tongued and grooved flooring, such as second-class Southern pine flooring, dressed one side and having a thickness of from 25/32 to 1 5/8 in., depending upon the distance center to center of joists. The deflection of the lagging under full load should not exceed 1/8 in. per ft. and preferably should be less. **Joists** may have their tops sawed to the curve of the soffit, or a spiking strip 2 in. wide may be used. This spiking strip may be of a low grade of lumber, and its use will result in a saving, particularly where the radius of the curve of the arch is less than 150 ft. **Posts,** when inclined, as in the case of the lower posts of Fig. 48, should be supported at one or more points by timber marked *A* in figure, otherwise they will sag materially and be inefficient as columns. Where end grain bears upon side grain, the end-bearing area may be increased by angles, as in Fig. 47, or by steel plates or channels. The number of joints in side-grain compression should be reduced to a minimum, and therefore for high centering continuous posts are preferred to independent stories.

It is expensive to cut bevels and miters at the ends of timbers and notches at intermediate points, and since the salvage of the timber is less when so cut, they should be omitted when possible. The difference in the cost of framing may be materially increased by failure to consider this point in design. Caps should extend over three or more posts. They should be drawn tight upon the posts by means of bolts or other fastenings and be tied in place by fishplates and bolts, by notches in the joists above them, or by continuous struts, as in Fig. 47.

Wedges may be placed at the tops of posts, as in Fig. 48, or at the bottom, as in Fig. 47. When placed at the top, they permit easier adjustment of the top before concreting, as there is less load to lift. When at the top they should be placed at right angles to the length of the cap, as in this position they are more easily driven than when placed parallel to the cap. Wedges at or near the top should not be loaded with more than 15 short tons per wedge. At the bottom they may be loaded to 20 short tons. With this loading they may be loosed with a 12-lb. sledge hammer. Wedges should be of hard oak with a bevel of 1 : 5 to 1 : 10, preverably the former. They need not be spiked in order to hold them in correct position relative to each other. Lubricants do not appear to facilitate striking, as they are forced out under the pressure of the arch load, and the friction to be overcome is due largely to the mechanical interlocking of the fibers. At Piney Branch Bridge the coefficient of friction of white-oak wedges was found to be about 0.4. Where wooden wedges are liable to become watersoaked, they may be oiled or otherwise weatherproofed.

Sand Boxes have been used extensively in Europe, but only in a few cases in America. They permit the centering to be lowered without jar and quickly if desired. Their first cost is high, but in large arches the cost of striking wooden wedges is so great that it is thought sand boxes result in economy. They cannot be used to raise the centering before it is loaded, in order to adjust the curve, and great care must be taken to keep the sand dry during the entire construction. The sand should be thoroughly washed and dried before being placed in the boxes. Fig. 49 shows details of the sand boxes used in the main arch of the Edmondson Avenue Bridge, Baltimore.

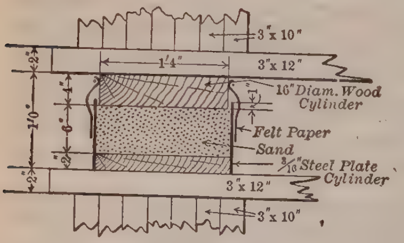

Fig. 49. Sand Box

This sand box consisted of a cylindrical shell built of 3/16-in. sheet steel inclosing, at the bottom of the cylinder, an oak bottom, which fitted snugly against the steel. The box was then filled with dry clean sand, upon which rested a circular oak plunger, which supported the bottom of the posts of the centering. Near the bottom of the box was a 1-in. circular hole, closed by a wooden plug, which was removed when it was necessary to lower the centering, permitting the sand to run out of the hole. The top of the cylinder was covered with several thicknesses of tar paper, in order to exclude rain. The maximum pressure upon the sand was 620 lb. per sq. in. The stress in the steel shell was figured on the basis of this pressure applied to each square inch of the shell, or on the basis of water pressure. (For comments on design and use of sand boxes, see Eng. Rec., Vol. 74, p. 531.)

Erection. A full-size drawing of the centering should be laid out upon a level floor, using transit and steel tape. Templets of thick paper or preferably of white pine should be made of all curved pieces and of the ends of all members having beveled or mitered ends, and the full length of each piece measured, intermediate notches being accurately located. The separate pieces of the centering should be laid out, using these templets and measurements. In making the layout drawing, the true curve should be first laid out and then a second curve drawn, adding sufficient camber to allow for the probable settlement of the falsework.

All carpentry work should be the best class of heavy timber work. Care should be taken to see that all saw cuts are true, and surfaces of abutting timber should be adzed off to make a snug fit. Just before the centering is loaded it should be inspected and all joints which have opened up should be shimmed tight, using shingles or thin wedges. During the construction of the arch similar wedging should be done, as the settlement of the falsework may open joints.

As large centerings are expensive and if destroyed by fire not only the centering but the arch also is lost, they are occasionally insured and given fire protection. At Connecticut Ave. Bridge, the centering for which cost about $50 000, a 4-in. water main was laid along the top of the construction trestle and a hose connection with hose attached provided opposite each large arch. The centering was watered every evening as an additional precaution. The wetting of the centering, however, tends to cause softening of the wood fiber of the side grain, and when used, somewhat lower stresses upon side grain should be used than are allowed in Art. 1.

For concrete arches the tongued and grooved lagging should be laid with a board omitted every 10 ft., to allow for the swelling of the flooring when it rains, otherwise much of the flooring will buckle and have to be relaid. If continuous forms are built to form the face of the arch ring, they should be sawed through with radial saw cuts at intervals of about every 25 ft.; otherwise when the centering settles these forms will twist and warp and an unsightly face results.

It is customary to speak of lowering the centering, but when the wedges at the top of the falsework are loosened, the centering actually rises. It has been held down by the weight of the arch, and when the wedges are driven out, the centering rises due to the elastic resilience of the wood. If the wedges are at the bottom of the falsework, the general movement of the falsework is downward, but the falsework is not really lowered until the timber is no longer under restraint.

It seems to be the common opinion that when wedges are moved and still remain tight the arch is lowering and following the centering. This usually is not true. Arches of concrete, built of alternate blocks, do settle very slightly, due to the fact that the concrete of each block shrinks in setting up, but in arches from 60 to 150 ft., of moderate rise, the settlement is seldom over 1/8 in. Arches built in longitudinal rings settle less.

If the temperature rises after the arch is keyed, the expansion of the concrete may be sufficient to develop arch action while the arch is still on the centering, and if so, probably no settlement will take place. Or if the falsework is weak, the arch will key itself tight, due to its own load. If the falsework is very wet when keyed, the arch may also develop arch action by the shrinkage of the timber due to drying out. If the temperature of the air falls 15° or 20° for any length of time after keying the arch and the centering is stiff, the contraction of the arch masonry may cause cracks to appear in the arch, while still upon the centering, unless the arch is reinforced with steel.

If an arch is built in alternate transverse sections, the falsework may have to carry loads in excess of the weight of the arch, due to the fact that on account of the shrinkage of the concrete in the several sections the arch ring consists of a number of separate blocks which are not quite in contact. A load, A, if placed upon the arch before striking the wedges, may have to be carried by the centering. At both the Connecticut Ave. arch and the Edmondson Ave. arch a settlement of about 1/4 in. took place in the crown when the load *A* was placed. After this there was no appreciable lowering of the crown, except that upon striking the settlement may have been as much as 1/16 in.

Details of a Stone Arch Centering. All the foregoing data are generally applicable to centering for stone arches. The lagging for stone arches may consist of timber from 3 to 6 in. thick and laid with open joints, as in Figs. 43–45. The wedges are placed under the lagging or at lower points. These figures also show typical bows which may be used for the trussed or the bent type of centering. As a considerable portion of the arch stones may be placed temporarily upon the falsework to decrease deformation without inconvenience to the contractor or added cost, the bowstring centering is somewhat better adapted to stone than to concrete arches.

14. Roof Trusses

Definitions and Description. The top chords of roof trusses, sometimes called the main rafters, usually support timbers called purlins, laid at right angles to the planes of the trusses. These purlins support timbers called common rafters, laid at right angles to the purlins or parallel to the main rafters. Upon the common rafters are laid boards called sheathing, and upon the sheathing a roof covering, such as tin, shingles, or terra cotta. The purlins may be laid close together and the common rafters omitted, or heavy planking may be used to span between main rafters and both purlins and common rafters omitted. This latter method is uneconomical and seldom used.

Trusses are usually placed from 12 to 16 ft. on centers, purlins 8 to 10 ft., and common rafters 1 1/2 to 2 1/3 ft. Purlins should be placed at or near panel points so as not to cause flexure in the top chord members. When the common rafters are omitted, the top chord members should always be computed for both compression and flexure. Purlins may be placed with their sides either vertical or at right angles to the main rafters. The latter method is slightly more expensive, except where the purlins are supported by steel hangers.

Roof trusses are designed to support the roof and snow load and withstand wind pressure and occasionally to support a ceiling or lower floors, which are hung from the trusses by means of hanger rods. For loads and computation of stresses see Sect. 12.

Weights of Trusses. The following formula, recommended by H. S. Jacoby (Structural Details, 1910), is based upon 121 designs of English and Belgium roof trusses of spans ranging from 48 to 196 ft., with a rise of one-sixth to one-third of the span, spacing of trusses 8 to 12 ft., a snow load of 25 lb. per sq. ft. and a normal wind load corresponding to a pressure of 40 lb. per vertical sq. ft.

$$W = 1/2\, al\, (1 + 0.15\, l)$$

in which W is the weight of a truss in pounds, a the distance between centers of trusses, and l the span, both a and l being expressed in feet. The above approximate weight of truss is suggested for use in design, but the weight of the truss, when designed, should be estimated and compared with the approximate one used.

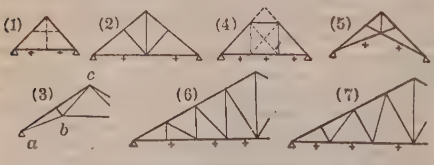

Fig. 50. Types of Roof Trusses

Common Types of Roof Trusses are shown in Fig. 50. In these diagrams the heavy lines indicate timbers, the lighter ones iron or steel ties, the light dotted lines counterbracing and the heavy dotted lines auxiliary timbers. When timbers are used as tension members they are marked with a plus sign. The ends of timber ties should be detailed to transmit tension, using steel straps or gusset plates and bolts for this purpose. Trusses with all tension members of iron or steel are called combination trusses.

Type (1) is used for temporary buildings such as sheds, the spans not exceeding 24 ft. The horizontal tie is generally supported at its middle by a tie rod or plank, shown by the dotted vertical line. An intermediate horizontal plank, shown by the dotted horizontal line, spiked to the main rafters, may be used to stiffen the truss. Type (2) is a king-rod truss, which is a modification of type (1), the rafters being supported by timber struts at their middle points. This type is used for 24- to 36-ft. spans. Type (3) is a combination truss with main rafters supported by struts at middle points, which may be used for spans of 25 to 45 ft. Joint *b* should be pin-connected, and ties *ab* and *bc* should not be in one length. Type (4) is a queen-rod truss suitable for spans between 24 and 36 ft. The middle panel should be counterbraced, as shown by light dotted lines, to take care of the wind pressure upon the roof and eccentric loading. When this type is used with a pitch roof, rafters are placed above the top chord, as shown by heavy dotted lines. For spans between 36 and 45 ft. struts should be placed to support the main rafters at their middle points. Type (5), called a scissor truss, is suitable for spans of 24 to 30 ft., and where a high ceiling is desired. Modifications of this are sometimes used for slightly larger spans. Type (6), called an English roof trusses, is used for spans from 40 to 60 ft., or for larger spans with an increased number of panels. For the shorter lengths it is built in 6 or 8 panels. Type (7), called the Belgian roof truss, may be used for the same spans as Type (6). In this truss the struts are perpendicular to the rafters and there are two less panels in the lower chord than in the upper one.

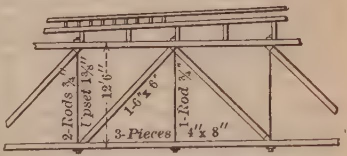

Fig. 51. Howe Roof Truss

Howe trusses are generally used for flat roofs, for spans from 40 to 130 ft. They are built with depths equal to from 1/7 to 1/10 of the span. Fig. 51 shows the middle portion of one or these trusses. The upper chord is horizontal, but the roof is made to have a low pitch by using short vertical struts of different lengths. There are no counterbraces, since there is no rolling load. This figure will apply to roofs of from 85- to 125-ft. span.

15. Design of a Roof Truss

Data of Design. (Fig. 52.) The truss will have a span of 48 ft., pitch 30°, distance center to center of trusses 16 ft. The roof covering will be of 3/16-in. slate laid upon wooden sheathing. The sheathing will be supported by common rafters resting upon purlins at or near panel points of the top chord. Slate roofing is selected in preference to tin, corrugated iron, or wooden shingles because of its permanence and low cost of maintenance, and in preference to clay tile because appearance is not desirable and slate is the cheaper. For slate roofs the pitch should not be less than 1 : 2 or 26° 30′. This rule for pitch may be applied to the other kinds of covering mentioned. The trusses were spaced 16 ft. apart on centers, as this is generally the maximum limit of span for untrussed purlins. This spacing therefore is the economical one. The roof has been designed to carry the dead load, a snow load of 10 lb. per square foot of horizontal area and a wind pressure of 30 lb. per square root of vertical area, which for a 30° pitch gives a pressure normal to the roof of 24 lb. per sq. ft. (see Sect. 12). The weight of the slate covering and sheathing was taken at 11 lb. per square foot of roof.

Unit Stresses. Southern pine, select grade, was used throughout. The allowable unit stresses for dry location are given in Art. 1 as follows: Tension with the grain = 1600; compression with the grain = 1175; compression across the grain = 325, for washers 50% greater or 490; extreme fiber stress in bending = 1600; shearing with the grain for joints = 176; horizontal shear in beams = 117.

Common Rafters. The rafters will be placed 2 ft. on centers, so that 7/8-in. tongued and grooved sheathing dressed one side may be used. Occasionally the sheathing may have to be figured as a beam to carry the load upon it, but usually it may be selected without computation. The vertical load upon the rafter consists of the weight of roof covering and sheathing, snow load and the weight of rafter assumed at 3.5 lb. per lin. ft., or $2 \times 9.25 \times 11 + 2 \times 8 \times 10 + 3.5 \times 9.25 = 396$ lb. The wind load acting perpendicular to the top of the rafter is $2 \times 9.25 \times 24 = 444$ lb.

The total load normal to the top of the rafter equals $444 + 396 \times \cos 30° = 787$ lb. The load parallel to the length of the rafter $= 396 \times \sin 30° = 198$ lb. (Fig. 52*e*). The latter component is transmitted directly to the purlin, although a part may be carried up through the common rafters to the apex of the roof. In this design it will be assumed that the entire component is taken by the purlins. To select the size of rafter, enter the beam table (Art. 3) with a load of $787 \times 1000/1600 = 492$ lb. since the table is based on a fiber stress of 1000 lb. For a span of 9 ft. a 1×6-in. rafter would be not quite strong enough, so that a 2×6-in. should be used. This will be wide enough for nailing the sheathing. If the rafter is investigated for bearing at the ends, horizontal shear and deflection, it will be found large enough.

Purlins. Since the load upon the purlins (Fig. 52*f*) is inclined, it is necessary to find the inclination of the neutral axis in order to find the true stresses. The following formulas from Jacoby's "Structural Details" are recommended:

$$\mathrm{Tan}\,\beta = (d^2/b^2)\tan\alpha \qquad I = 1/12\, bd\,[(d\cos\beta)^2 + (b\sin\beta)^2]$$

$$c = 1/2\,(d\cos\beta + b\sin\beta) \qquad S = Mc/I$$

in which α is the angle made by the load with the longer side of the beam and β is the angle between the neutral axis and the shorter side of the beam; **d** and **b** are the depth and width of the beam in inches; **I** is the moment of inertia; **c** is the distance from the neutral axis to the most remote fiber; **M** equals the bending moment in inch-pounds and **S** equals the maximum fiber stress per square inch.

The load normal to the top of a purlin exclusive of its weight, since there are 8 rafters in each length of purlin, is $787 \times 8 = 6296$ lb.; the load normal to the side of the purlin is $198 \times 8 = 1584$ lb. The weight of the purlin is approximately 22 lb. per ft., or 350 lb. Resolving this weight normal to the top and side of the purlin gives respectively 304 lb. and 175 lb. to be added to the foregoing loads, or the total load normal to the top = 6600 lb. and that normal to the side = 1760 lb. The total load on the purlin equals 6830 lb. and then $M = 6830 \times 16 \times 12/8 = 164\,000$ in.-lb., the load being assumed as uniformly distributed. Tan $\alpha = 1760/6600$. Assuming the dimensions of the purlin to be 8×10 in. and the 10-in. side normal to the main rafter, $\beta = 22° - 35'$, $I = 630$, $c = 6.15$, $M = 164\,000$ in.-lb. and $S = 1600$ lb. per sq. in. which is within the allowable unit stress.

Allowable Compression on Inclined Surfaces. Hankinson's formula for compressive stress on surfaces inclined to the fibers is

$$N = \frac{PQ}{P\sin^2\theta + Q\cos^2\theta} \text{ (see Art. 2),}$$

where θ is angle between the direction of the load and the direction of the grain. For designing joints in the present problem $P = 1175$, $Q = 325$, so that the equation may be written

$$N = 450/(1.382 - \cos^2\theta)$$

This is a convenient form for designing. Either this formula or the table in Art. 2 may be used in designing the timber joints. To facilitate design, the following table is computed from this formula:

$\theta°$	N lb. per sq. in.	$\theta°$	N lb. per sq. in.
0	1175	40	570
10	1090	50	465
15	1000	60	395
20	900	75	340
30	710	90	325

Truss Members. The maximum stresses are given in Fig. 52*c*. For the **top chord** the maximum stress is 36 000 lb. compression. The length of the chord per panel is 9 ft. 3 in. The allowed stress per square inch for columns under 11 diameters is 1175 lb. The approximate net area hence is 36 000/1175 = 31 sq. in. Use an 8 × 8-in. timber in order to allow for the cutting of daps and notches, holes for bolts and tie rods. Although theoretically smaller-sized timbers may be used in the upper panels, it will be cheaper to make the main rafter or top chord of one length, and even where a single splice is necessary, due to the length of rafter, the use of the same size of timber throughout the length is economical. For the **bottom chord** the maximum stress is 31 300 lb. tension and the allowed stress per square inch 1600 lb. To allow for the cutting of daps and bolt holes, particularly at the end joint, *a*, use an 8 × 8-in. timber. Care must be taken to consider actual and not nominal dimensions of timber.

The **strut** *Bc* has a maximum compressive stress of 7200 lb. Its length is 9 ft. 3 in. Since the column length is small, the side-grain compression of the chord by this member will determine its size. For the purpose of selecting the requisite size take the allowable bearing stress from the table above, the angle between the top chord and *Bc* being 60°. The requisite size is 7200/325 = 22 sq. in. Since this member will sag sightly, due to its inclination, use a 6 × 6 in. timber.

The **strut** *Cd* has a maximum compressive stress of 9500 lb. Its length is 12.0 ft. This strut, on account of its length, will be first computed as a column. Assume a 6 × 6-in. section. The l/d would be 12 × 12/6 = 24. The allowable stress as given in the table in Art. 3 is 755 lb. per sq. in. or an allowable load for the strut of 5-1/2 × 5-1/2 × 755 = 22 800 lb. For bearing across the grain of the top chord an area is required of 9500/325 = 29.2 sq. in., which is less than provided.

The **tie rod** *Bb*, if there is no ceiling to be supported as in this design, carries very little stress, its function being to prevent any sag in *ac*; a 5/8-in. rod will be used. The tie rod *Cc* is stressed 3600 lb. To select the proper steel rod, enter table in Art. 6 for recommended stresses in bolts. A 5/8-in. rod is too small, therefore use a 3/4-in. rod which is good for 4830 lb. It should be noted, in this table, that the gross area of a 5/8-in. rod is the same as the net area of a 3/4-in rod; therefore if the ends of a 5/8-in. rod are upset it will be strong enough. A 3/4-in. rod without upset ends will be used, because in small trusses where only a few rods are required they are often made in small local shops and the welds are not first-class. The tie rod *Dd* may be selected in a similar manner, a 1-1/4-in. rod being used; if the ends are upset a 1-1/8-in. rod will answer.

Joint C. The washer for the tie rod should be a beveled one (Art. 4). The end of the strut should be cut as shown in the figure so that the short bevel bisects the angle between the top chord and strut *Cd*. If so cut this bevel will make the same angle with the fiber of both the top chord and *Cd*, and the allowable unit stress will be the same for both the top chord and strut. If cut at any other angle the allowable stress will be less for one member and greater for the other and the lesser will govern. The angle made by the surface of the small bevel with the fiber of both chord and *Cd* equals 50°, the angle between the line of the load and the fiber is 40°, and the safe allowable pressure, from table above, is 570 lb. per sq. in. The pressure on the bevels is found by resolving the stress in the strut, 9500 lb., into two components, one perpendicular to the short bevel and the other perpendicular to the long bevel. This gives a pressure on the short bevel of 4700 lb. and on the long bevel of 6600 lb. Therefore the length of the short bevel must be 4700/570 × 6 = 1-3/8 in. Make the bevel 1-1/2 in. to allow for inaccurate framing. The surface of the long bevel makes an angle with the top chord of 7° 30′ and the safe compression from the table is about 330 lb. per sq. in. The length of the bevel is 5-1/2 in., and the pressure per square inch therefore equals 6600/6 × 5-1/2 = 200 lb., which is safe.

Joint D. The stress in the vertical rod is 14 400 lb., and the washer makes an angle of 30° with the fibers of the chord. The safe bearing from above table, and allowing an increase of 50% for washers, = 600 lb. per sq. in. The net area of washers required = 14 400/600 = 24 sq. in. A standard cast-iron washer can therefore be used, see Art. 4. The horizontal pressure at the joint is 18 700 lb., and the angle of the joint surface with the fibers is 60°. From the table the allowable compression is 710 lb. per sq. in. The net area of contact, deducting the area cut out by the bolt hole, must be at least 18 700/710 = 26.3 sq. in. The actual area is greater than this.

Joint d. The stress in the vertical rod is 14 400 lb. The washer presses against the side grain of the bottom chord, and therefore its net area must be at least 14 400/490 = 29.4 sq. in. Use a 6 × 6 × 3/4 washer (Art. 4). The bevel surface of the angle block makes an angle of 40° with the fiber of the block. The allowable compression from the table is therefore 465 lb. per sq. in., and the stress in *Cd* being 9500 lb., the necessary area is 9500/465 = 20.4 sq. in. The actual area is 36 sq. in. The bearing of the bottom of the block upon the side grain of the bottom chord is evidently sufficient. The dap in which the angle block is seated must be deep enough so that the difference between the horizontal components of the stress in *Cd* and in *C′d* can be transmitted when the wind blows on either side of the truss. The horizontal component equals 2700 lb. Now since both the block and chord bear on end grains, the depth of the dap must be at least 2700/1175 × 8 = 1/4 in. Use 1/2-in dap to allow for the inacccurate framing. In this design it is not necessary to compute the actual horizontal shearing stress in the block, due to the pressure of 2700 lb., as it is evidently very low.

Joint c. The washer was designed similarly to those of joints *D* and *d*. The short bevel at the end of the timber is on the line bisecting the angle between the lower chord and *Bc*, see joint *C*. The angle made by the surface of the short bevel with both the chord and *Bc* is 75° and the allowable compression for both chord and strut is 1000 lb. per sq. in. Therefore since the stress *Bc* is 7200 lb., the length of the short bevel must be 7200/1000 × 6 = 1-1/4 in., but 1-1/2 in. will be used to allow for inaccurate framing.

Joint a. The stress in the tie equals 31 300 lb. The allowable unit tension equals 1600 lb. per sq. in. Therefore the net cross-section of the tie must be at least 31 300/1600 = 20 sq. in. which requires a net depth of timber of at least 2-3/4 in. Using 3 in., the length of the heel bevel of the top chord will be 4.5/cos 30°, or 5-1/4″. The toe bevel in this design will be made 2 in. The total area of end bearing therefore equals (5-1/4 + 2) 7-1/2 = 54.4 sq. in. The angle made by the bevels with the fiber of the bottom chord equals 60°. Therefore, from table in this article, the allowable compression is 710 lb. per sq. in. Therefore the total allowable pressure on the bearing is 710 × 54.4 = 38 600 lb., which is greater than the thrust of the top chord. In order to take care of the horizontal component of the thrust of the top chord, the distance from the heel to the end of the lower timber must be such as to develop the necessary horizontal shear, or the length must be at least 31 300/6 × 176 = 30 in.

In this design the bolt tying the chords together is not figured to transmit stress, but is designed to hold the members together. The bolt at the end of the timber is introduced to increase the resistance against horizontal shear.

The bearing area on the post must be able to take the total reaction of the truss, or 21 600 lb. Since side grain bears on side grain, this area must be at least 21 600/325, or 67 sq. in. The block should therefore be at least 9 in. wide. However, since the truss will deflect under its load, the pressure on the inside of the block will be greater than on the outside. The pressure is not uniform, but the exact difference is unknown. An area of 25% in excess of that theoretically required is recommended, or 67 × 1.25

= 84 sq. in. Since the chord is 8 in. wide, the block should be at least 11-1/2 in. long and a 6 × 12-in. block should be used.

If it is impracticable to get a length of 30 in. to take care of the horizontal shear, a bolt or bolts may be used to take part of the shear as at Fig. 52*b*. Assume that the length is 27 in., then the shear to be taken by the bolt equals 3 × 7-1/2 × 176 = 4000 lb. Resolving this horizontal stress parallel to the bolt and perpendicular to the tie member, as in Fig. 52*b*, gives a stress in the bolt of 8000 lb. Enter the table of recommended stresses for bolts (Art. 6), selecting a 1-in. bolt, which is a little larger than necessary. The top washer, which bears on side grain, should have a net area of 8000/490 = 16.4 sq. in. Use a 4 × 4 × 1 2 in. square plate washer.

A bolster will be used under the end of the truss so that it will not be necessary to cut into the bottom chord timber in order to get a proper bearing for the lower washer. This bolster will stiffen the truss and is particularly valuable when the support cannot be placed directly under the intersection of the neutral axes of the top and bottom chord timbers. The bolster will be made of a 4 × 8-in. timber. It must transmit to the lower chord not only the horizontal component of the pull of the bolts, but must also take the horizontal component of the wind pressure.

The design of the bottom washer is similar to those in joints *C* and *D*. A key of Southern pine will be provided at *A* to transmit the horizontal pressure which amounts to 4000 + 4200 = 8200 lb. The area of bearing of the key in both the bolster and lower chord members, since both the key and adjacent timbers bear on end grain, must be at least 8200/1175 = 7.0 sq. in., and the depth of the key must be 2 × 7/7.5 = 1.87 in. A depth of 2 in. will be used. The length of the key should be 8200/176 × 7.5 = 6.2 in., but 6-1/2 in. will be used. The distance of the end of the key from the end of the bolster will also be 6-1/2 in.

The key tends to rotate, the moment being equal to 8200 in.-lb., the arm of the horizontal forces acting on the top and lower halves of the key being 1 in. This moment compresses the top and bottom of the key and the adjacent chord and bolster timbers. The maximum compression $S = 6\,M/bl^2$ in which M is the rotating moment in in.-lb., b is the width of the key and l its length in inches, or $S = 6 \times 8200/(7.5 \times 6.5 \times 6.5) = 156$ lb. per sq. in., which is safe. The rotating moment also causes tension in the adjacent bolt. This bolt acts with a leverage of at least 1/2 the length of the key, or 3-1/4 in. The stress in the bolt will not exceed 8200/3.25 = 2520 lb. A 3/4-in. bolt, although stronger than theoretically necessary, will be used.

16. Howe Bridge Trusses

General Data. Timber bridges are generally of the Howe type, shown in Fig. 53. All members of this type are of timber except the vertical tension members and the lateral and sway tension members. The depth of the trusses of through bridges is generally governed by the necessary overhead clearance, which is 14 ft. for highways and from 17 to 25 ft. for railways. The weights of Howe trusses and of Howe bridges are about 1/3 larger than those of steel bridges of the same span, character of floor and class of loading. (See Sect. 12, Art. 9.) The stresses in the Howe truss are similar to those in the Pratt type, except that the diagonals carry compression instead of tension. The panels of the Howe truss are seldom over 10 or 12 ft. long and sometimes less. The truss is not suited for long spans, though it has been used for spans up to 250 ft.

Chords. The top and bottom chord sections of the trusses are built of from two to four pieces of timber varying from 3 by 8 in. to 8 by 16 in. in section. The greatest available length of these sections should be used in order to decrease the number of splices. Timbers 65 ft. long have been used for chord timbers. Fig. 53 shows a common method of packing the top and bottom chord timbers. Not more than one timber should be spliced in the same panel. Splices should be made at packing blocks. The simplest lower chord joint is the tabled fishplate type, and other styles are shown in Art. 6.

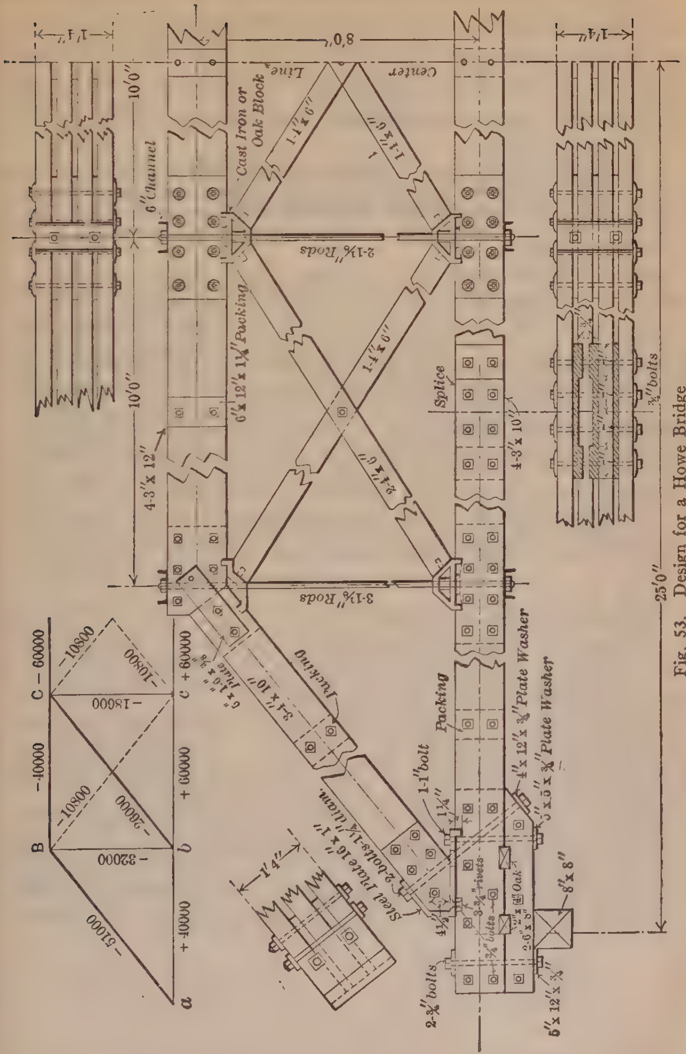

Fig. 53. Design for a Howe Bridge

Typical floors for timber bridges are shown in Fig. 38. For long bridges with heavy loads, more than one floor beam can be used per panel, and for greater strength they are made trussed beams. More than one rod can be used for the vertical tension members of a bridge of this size. The struts are usually made up of two sticks, with counterbracing in the panels made of one stick passing between the two of the strut. The counterbracing is needed to give the truss camber, and to take care of reversal of stress in the diagonal due to the moving loads.

Angle Blocks. Hollow or solid cast-iron or oak angle blocks are used to distribute the compression brought by the web members upon the side grain of the chords, and channel washers extending across the width of the chord as in Fig. 53 are often used in lieu of plate washers to transmit to the chords the pull of the vertical tie rods.

Design of a Howe Truss. The truss in Fig. 53 was designed for a highway bridge having a span of 50 ft. and a width of 16 ft. The bridge was designed for a live load of 100 lb. per sq. ft. and a 15-ton road roller. Southern pine, select grade, was used throughout. The sizes of the members were determined in a similar way to those of the roof truss (Art. 15). The same sizes of timbers are used in all panels of the top chord and all panels of the bottom chord, although theoretically uneconomical. In using the column tables or applying the column formula to the top chord or other built-up compression members, the separate pieces should be regarded as detached columns. When the separate pieces are well packed and bolted, they may act together as a single column, but on account of the shrinkage of the lumber it is not safe to depend upon such action. That chord which supports the floor beams, unless these are placed at panel points, should be computed for both flexure and direct stress. In this design, the floor beams are placed at panel points only.

Joint C. The stress on the vertical tie rod is 18 600 lb. The allowable bearing on the side grain of the top chord from the table of Art. 1 is 490 lb. per sq. in., allowing 50% increase under washers. The necessary net area of washer is 18 600/490 = 38 sq. in. Allowing for the bolt holes, the necessary gross area is 41 sq. in. A 6-in. channel the full width of the top chord, or 16 in. long, is used, as this size washer is needed at joint *B* and the same size will be used throughout.

A cast-iron angle block is shown in the figure, but in this design oak angle blocks might be used. When cast-iron blocks are used, their webs should be designed to transmit the thrust of the main brace and counterbrace. Counterbraces are shown by dotted lines in the diagram of Fig. 53. Each lug should be designed to be able to transmit the entire horizontal component of the main brace to the top chord.

The vertical component of the stress in the brace is 18 600 lb.; therefore the area of the base of the angle block should be at least 18 600/325 = 57 sq. in. In order to provide bearing for the brace and counterbrace the area of the brace will be made much larger. The horizontal component of the stress in the brace being 21 000 lb., the depth of the lugs, assuming that the packing pieces take their part of the horizontal component of the brace must be at least 21 000/16 $\times$ 1175 = 1-1/8 in. Ignoring the packing pieces, the depth should be 1-1/2 in., which depth will be used.

STONE QUARRYING AND CUTTING

1. Building Stone

Selection of Building Stone. In passing upon the suitability of unquarried rock for construction purposes, the engineer must decide the following points: (1) Whether or not the rock can be quarried in blocks of sufficient size for his purposes. This is dependent upon the frequency and character of the seams or joints. (2) Whether or not the stone will weather. This can best be determined by observing exposed faces, to some extent by determining the relative porosity of the stone and by obtaining advice of experienced geologists. The national government in Washington and practically all state governments have experts whose advice is readily obtainable. Similar help can be secured at most colleges and universities. (3) Whether or not the stone can be economically shaped for ashlar. This is dependent upon the hardness of the stone and the extent to which it may contain dry seams. The writer recalls a pier that was constructed from local stone which was so hard and so full of dry seams that the pier would have cost probably less than one-half had the stone been procured at a good quarry a thousand miles away. It was difficult in this case to keep stonecutters at work continuously over a week; their wrists would not stand the work. (4) Whether or not the stone can be effectively carved. Carving requires a fine-grain stone and one that is not very hard or brittle. Some granites can be carved almost as effectively as limestone.

In passing upon a quarry for crushed stone one should determine the following: (1) Its weathering qualities, hardness and durability. (2) The readiness with which it can be quarried. The inexperienced engineer should solicit the opinion of expert quarry foremen or obtain the academic advice of geologists. In any event, he should note the following: (*a*) Whether the rock can be readily drilled. It will be found that some stone contains hard material such as garnets, iron and flint which make drilling very expensive. (*b*) If the rock is fissured it may be difficult to blast. (*c*) If garnets, iron, flint, etc., are found in large quantities the crushing will be difficult and the crusher maintenance very high. (*d*) It should also be noted that some laminated stones break into flat slabby pieces which do not make first-class concrete or road aggregate.

Classification.* Building stones are classified according to origin (igneous, sedimentary, and metamorphic), and subdivided according to mineral and chemical composition, texture and structure, and geologic age. The most common granular crystalline-igneous rocks are granites, diorites, and gabbros or diabases; the more common dense varieties of volcanic origin are rhyolite, andesite, and basalt. Igneous rocks that have conspicuous crystals disseminated through a fine-grained to dense ground mass are called porphyries (e.g., granite-porphyry, rhyolite-porphyry). Sedimentary rocks include conglomerates (consolidated gravel), sandstones and many quartzites, shales (consolidated clays), limestones and dolomites. The more common metamorphic rocks are gneisses, schists, slates, some quartzites, and marbles. Varieties of any one of these rocks are distinguished by certain characteristic minerals (e.g., coarse-grained gneissoid granite, fine-grained thin bedded limestone).

Igneous Rocks.* The most abundant of the granular crystalline rocks is **granite** which consists mainly of feldspars and quartz with minor quantities of mica or hornblende, and minute quantities of certain other minerals.

* Largely from G. F. Loughlin.

Commercially, however, other granular igneous rocks, like **diorite** and **gabbro,** which consist mainly of soda-lime feldspar and hornblende or pyroxene, are referred to as "black granite." These rocks are commonly massive, although closely spaced fractures or joints parallel to the surfaces of some quarries resemble a bedded or stratified structure. **Gneisses** (granular metamorphic rocks similar to granites in mineral composition but distinguished by a foliated arrangement of mineral grains) are also called granite commercially. Granites as a whole are composed mainly of hard minerals that are extremely resistant to chemical weathering and are so firmly welded together by crystallization under great pressure that they make by far the strongest stone in common use. Granites that contain unusually large percentages of mica are comparatively soft, but are resistant to weathering if free from alteration. Gray and light-red granites are generally more durable, as they consist of minerals which are more resistant to weathering. True granite generally has the advantage of breaking with regularity and is readily formed into simple shapes, but is so much harder and tougher than most sedimentary rocks that the elaborate finishing of blocks is comparatively expensive; however, in structures of monumental character and those subjected to severe conditions of physical and chemical weathering it may be ultimate economy to use granite.

Sedimentary Rocks.* **Limestone** is widely distributed and is more widely used for building and crushing than any other kind of stone. It includes many varieties, which differ in color, composition, and adaptability for engineering and building purposes. Many limestones are dull gray or bluish gray and unattractive from an architectural standpoint. Some of these are massive and suitable for crushing, and sufficiently free from impurities to be used in metallurgical and chemical industries; but others contain so many shaly streaks and are so impure that they are of no value unless situated where they can be used with other material in the manufacture of Portland cement. The famous Indiana oölitic limestone, which contributes more than half of the building stone quarried annually in the United States, is a light buff to gray, porous, granular stone, similar to sandstone in mode of origin, although its "sand" grains are practically all minute shells or shell fragments. It is very easily quarried and worked, and is adapted for architectural and engineering uses where chemical weathering is not too severe.

Most limestones and marbles consist mainly of the mineral calcite which is slightly soluble in rainwater and in other waters or vapors containing acids and certain salts, especially ferric sulphate. Dolomite stone, or high magnesium limestone, which consists mainly of the mineral dolomite, is similarly affected but much more slowly. The effect of this corrosion is to roughen the surfaces of unevenly grained stones and gradually to remove small details of finish; but the rate of corrosion on the most exposed parts of buildings in the larger eastern cities of the United States is only about 1 inch in 600 to 800 years. It is much faster where attack by acid waters is more concentrated and continuous. The texture of limestones and dolomites varies from very porous to impervious, and their strength and resistance to weathering vary accordingly; but resistance to freezing depends not so much upon the degree of porosity as upon the size and distribution of the pores and the presence of impurities, especially certain varieties of clay minerals, that readily absorb and give off water with changing climatic conditions.

Sandstones * also vary greatly in color, texture, and usefulness. Their more common colors include light gray, buff, pink, red, and brown. Siliceous sand-

* **Largely from G. F. Loughlin.**

stones consist almost entirely of quartz grains cemented by silica, and the impervious variety of this composition, called quartzite, is extremely hard and difficult to work; but it is used especially in the manufacture of silica brick, and occasionally as crushed stone and building stone. Calcareous sandstones contain calcite (calcium carbonate) as the principal cementing material, and like limestones are noticeably affected by severe or prolonged chemical weathering. Argillaceous sandstone contains clayey material as its chief cementing constituent, and is subject to relatively rapid disintegration, especially if certain of the clay minerals are concentrated along layers. Ferruginous sandstone contains considerable red, brown, or yellow iron oxide in its matrix. Its durability depends mainly upon whether the stone is otherwise siliceous, calcareous, or argillaceous.

Metamorphic Rocks.* Gneiss, marble, quartzite, and slate have already been mentioned in connection with closely related igneous and sedimentary rocks. Mica and hornblende schists if too thinly foliated are of little use for anything but low-class rubble and riprap. The less foliated varieties, however, are locally crushed and used in concrete masonry.

2. Tests for Building Stone

Weight or Density is an important property since upon it depends to a large extent the strength and durability of the stone. Methods of determining the specific gravity are described in Sect. 7, Art. 25; weights of various classes of stone are given in Sect. 7, Art. 37.

Crushing Strength † may be determined as described in Sect. 7, Art. 25. In making tests of crushing strength, the position of the test specimen with reference to bedding planes or other planes of weakness should be carefully noted. As the crushing strength is usually highest when pressure is applied at right angles to the bedding (or to the rift), care should be taken to mark the direction of bedding, or of rift and grain, on the test specimens. (See Art. 4.)

If test specimens are dressed by hand, the concussion of the tool has a shattering effect, especially on small specimens. Tool-dressed 2-in. cubes usually show only about 60% of the strength of sawed and rubbed cubes of the same size, which most nearly represent the conditions of actual practice.

Values of crushing strengths of various classes of stones are given in Sect. 7, Art. 37. These show that granites and slates far exceed any requirements placed upon them in structures; that most marbles do so also; that limestones and sandstones have a great range in strength, even the weakest far exceeding the immediate pressure of the load placed upon them, but subject to some concern as they age. The strongest limestones may not be attractive architecturally, and the strongest sandstones (or quartzites) may be unattractive as well as very expensive to work; but both are quarried to a greater or less extent for crushed stone.

3. Durability of Building Stone †

Methods of Determining Durability. There are three methods of determining the durability of stone under different conditions: examination of old structures, mineralogical examination, and physical and chemical tests. The

* Largely from G. F. Loughlin.
† In part from G. F. Loughlin.

first, when feasible, is the best as it shows exactly how the stone has withstood conditions of natural weathering, pressure of heavy loads, abrasion, corrosion by acid waters, and any other special agencies that affect durability. The stones most resistant to weathering retain sharp edges and corners and delicate tool marks for many years, but there are exceptions to the general rule.

This uncertainty, however, can be cleared away to a considerable degree by mineralogical examination, which shows the minerals present, the manner in which they are held together, and the kind and degree of alteration undergone by the different minerals whereby their strength and durability may be affected. Such an examination will aid in the selection of physical and chemical tests that are necessary to determine those properties of the stone that are of critical importance.

The use of physical and chemical tests is based upon the assumption that the relative durability of stones is proportional to their crushing strength, their absorptive power, their resistance to freezing, and their solubility in acids; but in the making of the tests each element acts by itself, whereas in the structure the stone is exposed to the combined action of all these methods of attack, and their action may be, and frequently is, different from that when acting separately. The principal tests made to determine the durability of a stone are the absorptive power, the solubility in sulfuric and hydrochloric acids separately and combined, the resistance to fire, the loss due to freezing and thawing, and the artificial freezing test, which consists in soaking the sample in a solution of sulfate of soda and then hanging it up to dry, the crystallizing of the salt in the pores of the stone having an effect somewhat similar to that of freezing of water. None of these tests gives wholly satisfactory results. (For description of tests see Sect. 7, Art. 25.)

Increase in Durability may be secured by proper seasoning and by finishing the surface in a suitable manner. All stones, and especially limestones and sandstones, when first quarried contain considerable quarry sap; and when full of sap the stone works somewhat more easily under the tool than when well seasoned. If a stone freezes while full of quarry sap, it is nearly certain to crack; but if it is first allowed to season it is not likely to be appreciably damaged by a single freezing. The hardening by seasoning also adds materially to the weathering qualities of the stone. The increased strength and durability caused by seasoning are due to the fact that the sap holds in solution a small amount of calcareous or siliceous matter, and by the process of seasoning this material is drawn to the surface and is deposited in the pores of the stone by the evaporation of the sap, the matter in solution thus becoming an additional cementing material and binding the grains more firmly together. It is surprising that so small an amount of liquid can produce so marked an effect; but it has been in the stone for such an extremely long time that it has formed around each mineral grain a "colloidal" film of mutually dissolved water and mineral, thus accounting for the softness of the newly quarried stone. When this film has become thoroughly dried, its mineral matter adheres firmly to the grains and matrix, thus increasing the cohesive strength of the stone. When this mineral matter is once deposited it is not readily dissolved again and the stone will not regain its original softness or tendency to injury by frost except when in contact with ground-water for a very long time, unless it contains a large percentage of extremely fine pores. Certain minerals of the clay group are exceptions to this statement, as they both give up and take on water very readily. It is the presence of these minerals that renders argillaceous limestones and sandstones and certain altered igneous rocks subject to rapid disintegration.

The method of dressing a stone may have a marked influence upon the details of weathering. If the surface is finished with a tool similar to the bush hammer, a too severe application of the tool may produce minute cracks that render the tooled surfaces subject to injury by frost; or by crystallization in them of salts leached from mortar or concrete backing. This is especially true of some of the softer granites that contain considerable mica, both as distinct flakes and as microscopic inclusions in feldspar. If the granite is otherwise satisfactory, disintegration due to such causes does not penetrate beyond the limits of these minute cracks, and granites from which the finely hammered surfaces have crumbled in a short time have continued in use as much as 25 years without showing any further effects of weathering. The choice of finished surfaces should be made with a view toward the preservation of details of appearance rather than the durability of the stone as a whole.

Many methods have been devised for preventing or checking the action of the weather upon building stones; but none of them is entirely satisfactory. These preservatives consist of some liquid into which the stone may be dipped or which may be applied with a brush to its outer surface, to fill the pores and prevent the access of moisture. Paint, coal tar, linseed oil, paraffin, and numerous chemical preparations have been used. With porous stone a 10% solution of paraffin in gasoline has been found effective. (See "Exposure Tests on Colorless Waterproofing Materials" by D. W. Kessler, Bureau of Standards Technologic Paper No. 248, 1924.)

Distinctly laminated stone should be placed on its natural bed to obtain its maximum resistance to pressure and to the disintegrating effects of frost action. The advantages gained by placing granite and other strong stone so as to obtain greatest resistance to pressure is too slight to be of importance. Although the Indiana oölitic limestone has a distinct bedding it is not highly laminated and in most structures may be used indiscriminately on bed or on edge. Sandstone should usually be placed on its bed to prevent disintegration.

4. Methods of Quarrying

Hand Tools. When the stone is thin-bedded, it may be quarried by hand tools alone. The principal tools are pick, crowbar, drill, hammer, wedge, and plug and feathers (Fig. 15). The **plug** is a narrow wedge with plane faces, and the **feathers** are wedges flat on one side and rounded on the other. When a plug is placed between two feathers, the three will slip into a cylindrical hole; and if the plug is then driven, it exerts a great force. If these plugs and feathers are placed a few inches apart in a row, and all driven at the same time, the stone will be cracked along the line of the holes, even though it is comparatively thick. The **drill** ordinarily used to cut the holes for the plug and feathers is a bar of steel furnished with a wide edge sharpened to a blunt angle and hardened. It is operated by one man, who holds the drill with one hand and drives it with a hammer in the other, rotating the drill between blows. The holes are usually from 3/8 to 3/4 in. in diameter. Sandstones and limestones occurring in layers thin enough to be quarried as above are usually of inferior quality, suitable only for slope walls, paving, riprap, and concrete.

When the stone is hard a **pneumatic drill** is generally used to make the holes for the plug and feathers. It is handled by one man, and the power may be furnished by a fixed compressed-air plant or a portable compressor with gasoline or electric drive.

Channeling consists in cutting long narrow channels in the rock to free the sides of large blocks of stone. A channeling machine consists of an engine running on a track on the floor of the quarry and operating a drill bit which cuts the channel as the machine is run back and forth along the track. The drill is sometimes a rotary steel or diamond bit, but is usually a percussion bit. The percussion channeler is ordinarily employed for marble, massive limestone, and thick-bedded sandstones; and the diamond drill for the harder stones. With the percussion channeler, the channels are 1 to 3 in. wide according to depth, and may be 10 to 14 ft. deep, different lengths of drill rods being used as the depth of the channel increases. The diamond channeler first bores a series of holes close together, and then bores or channels out the partitions between the holes. Some channeling machines can operate at any angle with the vertical, even horizontal. The channeler is generally operated by steam, and in that case each machine has its own boiler. Compressed air is also used. A special type of operation is by the "electric-air" machine, in which a "pulsator," operated by electric motor, forces air back and forth to the two ends of the drill cylinder.

Quarrying with Explosives. In this method drill-holes are put down to the depth to which the rock is to be split, and the requisite amount of powder or other explosive put in, covered with sand, and fired by a fuse. Sometimes numerous charges in a line of drill-holes are fired simultaneously by means of electricity. Coarse gunpowder is the explosive ordinarily used, since the quick-acting explosives, like nitroglycerine and dynamite, have a tendency to shatter the stone and break it in many directions. For quarrying each class of rock there is a characteristic method employed, which is, however, varied in detail in different quarries. The minor details of quarry methods are as various as the differences existing in the textures, structures, and modes of occurrence of the rocks quarried. Even such an apparently unimportant matter as the form of the bottom of the drill-hole into which the explosive is put has a very marked effect. If bored with a hand-drill, the hole is generally triangular at the bottom, and a blast in such a hole will break the rock in three directions. In some quarries the lines of fracture are made to follow predetermined directions by putting the charge of powder into canisters of special forms.

Drills are of three forms. The **jumper** is a drill similar to that used for drilling holes for plugs and feathers, except that it is larger and longer. It is usually held by one man, who rotates it between the alternating blows from hammers in the hands of two other men. **Churn drills** are long, heavy drills, usually 6 to 8 ft. in length. They are raised by the workmen, let fall, caught on the rebound, raised and rotated a little, and then dropped again, thus cutting a hole without being driven by the hammer. They are more economical than jumpers, especially for deep holes, as they cut faster and make larger holes than hand-drills. **Machine rock drills** bore much more rapidly than hand-drills, and also more economically, provided the work is of sufficient magnitude to justify the preliminary outlay. They drill in any direction, and can often be used in boring holes so located that they could not be bored by hand. They are worked either by steam directly, or usually by compressed air.

Rock-drilling machines use either percussion or **rotary** drills. The method of action of the **percussion drill** is the same as that of the churn drill already described. The usual form is that of a cylinder, in which a piston is moved by steam or compressed air, and the drill is attached to this piston so as to make a stroke with every complete movement of the piston. An automatic device causes it to rotate slightly at each stroke. A well-known type of percussion drill is the "**jackhammer,**" which is obtainable in weights of 27 to 75 lb. This is a one-man drill, and can be used for all types of work. Larger drills (known as "drifters") are generally mounted on tripods. When holes are to be drilled close together, as in channeling, the "quarry-bar" is used. This is a tubular bar, mounted on adjustable legs at each end, the drifters being supported on the bar in such a way that they can be moved back and forth into position, thus keeping all holes in a straight line.

Of the **rotary drills** there are two forms, one in which the cutting is done by teeth on the end of a hardened steel tube and the other by diamonds. In either case the drill-rod is a long tube, revolving about its axis, kept in contact with the rock, and by its rotation cuts in it a cylindrical hole, generally with a solid core in the center. The drill-rod is fed forward, or into the hole, as the drilling proceeds. The débris is removed from the hole by a constant stream of water which is forced to the bottom of the hole through the hollow drill-rod, and which carries the debris up through the narrow space between the outside of the drill-rod and the sides of the hole. The **diamond drill** is the only form of rotary rock-drill extensively used in America. The tube has a head at its lower end, in which are set a number of carbons or black diamonds. The diamonds usually project slightly beyond the circumference of the head, which is perforated to permit the ingress and egress of the water used in removing the débris from the hole and at the same time prevent the head from binding in the hole. When it is desirable to know the precise nature and stratification of the rock penetrated, the cutting points are so arranged as to cut an annular groove in the rock, leaving a solid core, which is broken off and lifted out whenever the head is brought up. Where it is not desired to preserve the core intact, a solid boring-bit is used instead of the core bit. They are made of any size up to 15 inches in diameter.

Dynamite is the name given to any explosive which contains nitroglycerine mixed with a granular absorbent. If the absorbent is inert, the mixture is called true dynamite; if the absorbent itself contains explosive substances, the mixture is called false dynamite. Dynamite is exploded by means of sharp percussion, which is applied by means of a cap and fuse. The cap is a hollow copper cylinder, about 1/4 in. in diameter and an inch or two in length containing a cement composed of fulminate of mercury and some inert substance. The cap is called single-force, double-force, etc., according to the amount of explosive it contains. **True dynamites** must contain at least 50% of nitroglycerine, otherwise the latter will be too completely cushioned by the absorbent, and the powder will be too difficult to explode. **False dynamites,** on the contrary, may contain as small a percentage of nitroglycerine as may be desired, some containing as little as 15%. The added explosive substances in the false dynamites generally contain large quantities of oxygen, which are liberated upon explosion, and aid in effecting the complete combustion of any noxious gases arising from the nitroglycerine. The false are generally inferior to the true dynamites, since the bulk of the former is increased in a higher ratio than its power; and as the cost of the work is largely dependent upon the size of the drill-holes, there is no economic gain. High-power dynamites are required for hard and refractory rock, but for the softer rock a low-power is better. In quarrying, 40% dynamite is ordinarily used.

Gunpowder is sold in kegs of 25 lb. Dynamite is sold in cylindrical, paper-covered cartridges, from 7/8 in. to 2 in. in diameter and 6 to 8 in. long, or longer, which are packed in boxes containing 25 or 50 lb. each. They are furnished, to order, of any required size.

Methods of Quarrying are generally quite different for granites than for the softer limestones and sandstones, being determined largely by the existence or non-existence of joint planes or, in other words, the facility with which the rock can be split. Granites generally have no natural bedding planes, but they usually show a tendency to split more readily in one direction (called the "rift") than in any other. There will also be a plane at right angles to the rift along which splitting is not quite as easy, which is called the "grain" or "run." The direction in which resistance to splitting is greatest is called the "head" or "hardway" (at right angles to rift and grain). In many granite quarries the rift is horizontal or nearly parallel to the surface; in others it may be nearly vertical. Granites that are divided by seams or joints into nearly horizontal layers or sheets which are successively thicker with increasing depth are quarried by cutting each layer into blocks of desired size by wedging or channeling.

In some granite quarries where the ledge is dome-shaped and seams are very scarce, artificial sheets are separated from the mass, just as an onion is peeled, by the successive use of powder and compressed air (Fig. 1). "In the center of the sheet or area to be 'lifted' a drill hole 3 or 4 in. in diameter is sunk to a depth of 5 to 8 ft., depending on the greatest thickness of stone required and the contour of the surface at that particular point. The bottom of the hole is then enlarged into a pocket by exploding half a stick of dynamite, as shown in Fig. 1. A small charge of powder, about a handful, is then exploded in the pocket, thus starting a horizontal crack or cleavage across its greater diameter. Charges increasing in size are then exploded in the cavity, the drill hole being plugged at each blast to confine the powder gases and thus exert a more or less constant force upon the stone.

"After the cleavage has extended to a radius of 75 or 100 ft. in all directions from the lift hole, a pipe is inserted into the hole, tamped tight and connected by means of a globe valve to the pipe line. Compressed air at 70 to 80 lb. pressure is gradually admitted and the cleavage rapidly extended until it comes out upon the sloping face of the quarry in a thin edge, as indicated in Fig. 1. A sheet of granite several acres in extent may be raised in this manner, affording a bed plane approximately level to which the quarrymen can work, thus securing stone of any required thickness." (From pamphlet of North Carolina Granite Corp.)

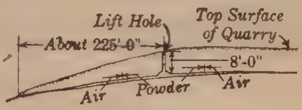

Fig. 1

The sizes of stones that may be quarried by this method are limited only by the handling and transporting equipment. Where horizontal sheeting is absent and the granite is divided into natural blocks by steeply inclined joints, quarrying consists of removing the smaller blocks and cutting the larger blocks into smaller sizes, taking all possible advantage of rift and grain.

In Sedimentary Formations * the beds or strata may lie nearly horizontal or may be inclined at any angle. In some quarries single beds are distinctly separated from one another by open bedding planes or partings, and in others there are few or no such separations and the formation may for practical purposes be regarded as one bed. Marble, limestone, and sandstone are commonly quarried by cutting a bed or layer over a considerable area into rectangular blocks by channeling, and by loosening these blocks, if necessary, from the underlying rock by wedging. Where the dip of the beds is at a considerable angle the channeling may be done on the inclined surface of the beds; but in many quarries it is conducted on a horizontal plane and the dimensions of the quarry blocks are quite independent of bedding. Bedding is usually distinct in the ledge and in large quarry blocks, but may be quite inconspicuous in small specimens.

In channeling the softer stones, care must be taken not to operate the machine so rapidly as to injure the stone. If the blows of the channeler are too violent, the adjacent rock may become overstressed, with the formation of minute seams which may open up when exposed to the weather or may cause trouble when the stone is being carved. This effect is called " stunning."

For references on quarrying, see "Practical Stone Quarrying" by Greenwell and Elsden; "Sandstone Quarrying in the United States," by Oliver Bowles, Bull. No. 124, U. S. Bureau of Mines.

For Reducing the Large Quarry Blocks to proper sizes for the shop, the quarry foreman is furnished a list of pieces required, with the dimensions of each piece, these dimensions including necessary allowance for finishing the surfaces. Each piece on the list is numbered for identification. The quarry blocks are then cut to the sizes given on the list, this subdivision being done by drilling holes along the required lines, and driving wedges or plugs-and-feathers in the holes. The small stones are marked with the same numbers as on the foreman's list, and are then sent to the finishing shop.

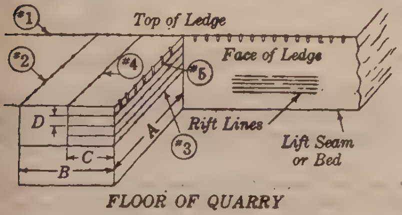

Fig. 1a

Where many small pieces of the same size are required, as for curb stones or paving blocks, the large quarry blocks are cut out originally to sizes which are multiples of

* In part from G. F. Loughlin.

the rough dimensions required for the small pieces. Fig. 1*a* (from J. D. Sargent) illustrates a method used in one of the large granite quarries for getting out curb-stones. Dimension *A* is the rough length of a single curb-stone, *B* is twice the rough height of one curb ($B = 2C$) and *D* is the thickness of the curb before it is finally dressed. The stone is broken successively along the planes numbered 1-5, by drilling and wedging.

When the quarry blocks are not too thick, the sub-dividing may be done as illustrated in Fig. 1*b* (from J. D. Sargent). This shows the method used in preparing granite paving-blocks. A flat slab is first broken out of the quarry, with a thickness of 8 in. (twice the thickness of a rough block) and with a length and width as shown. This slab is then marked on the flat side across its center (transversely) with a sharp chisel, and is broken cleanly along the chisel line by striking a hard blow on the back with a 30-lb. hammer directly opposite the chisel line. This method of breaking the stone is called "knapping." The final subdivision into the small blocks may be done by splitting the stone along the rift or grain with a sharp chisel.

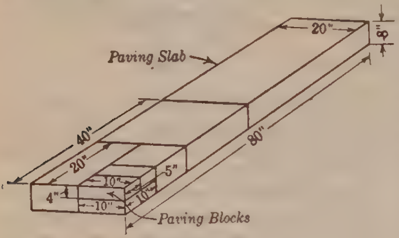

Fig. 1*b*

5. Tools for Stonecutting

A knowledge of the tools used in stonecutting is necessary for an understanding of the methods of preparing stones and is also necessary for a recognition of the names of the various kinds of dressed surfaces. The following names and description of tools were first proposed in 1877 by a committee of the American Society of Civil Engineers and have been widely adopted and used:

The **Double-Face Hammer** (Fig. 2) is a heavy tool weighing from 20 to 30 lb., used for roughly shaping stones as they come from the quarry and for knocking off projections. This is used only for the roughest work.

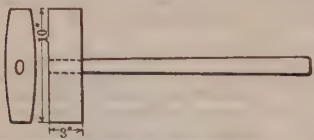

Fig. 2. Double-Face Hammer

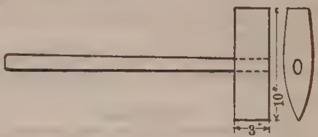

Fig. 3. Face Hammer

The **Face Hammer** (Fig. 3) has one blunt and one cutting end, and is used for the same purpose as the double-face hammer where less weight is required. The cutting end is used for roughly squaring stones, preparatory to the use of finer tools, and also for splitting stones.

The **Cavil** (Fig. 4) has one blunt and one pyramidal, or pointed, end, and weighs from 15 to 20 lb. It is used in quarries for roughly shaping stone for transportation.

The **Pick** (Fig. 5) somewhat resembles the pick used in digging, and is employed for rough dressing, mostly on limestone and sandstone. Its length varies from 15 to 24 in., the thickness at the eye being about 2 in.

The **Ax** or **Peen Hammer** (Fig. 6) has two opposite cutting edges. It is used for splitting and for making drafts around the arris, or edge, of stones, and in reducing faces, and sometimes joints, to a level. Its length is about 10 in. and the cutting edge about 4 in. It is used after the point and before the patent hammer.

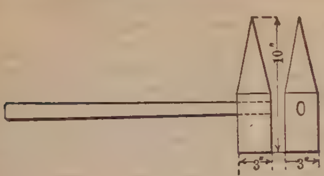

Fig. 4. Cavil

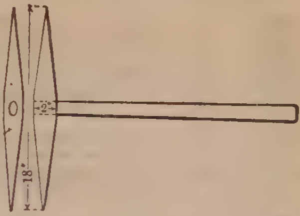

Fig. 5. Pick

The Tooth Ax (Fig. 7) is like the ax, except that its cutting edges are divided into teeth, the number of which varies with the kind of work required. This tool is not used on granite and gneiss.

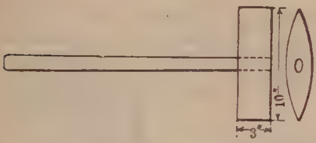

Fig. 6. Ax or Peen Hammer

Fig. 7. Tooth Ax

The **Point Bush Hammer** is a square prism of steel with ends cut into a number of pyramidal points. The length of the hammer is from 4 to 8 in., and the cutting face from 2 to 4 in. square. The points vary in number and in size with the work to be done. One end is sometimes made with a cutting edge like that of the ax.

The **Crandall** (Fig. 8) is a malleable-iron bar about 2 ft. long, slightly flattened at one end. In this end is a slot 3 in. long and 3/8 in. wide. Through this slot are passed ten double-headed points of 1/4-in.-square steel, 9 in. long, which are held in place by a key.

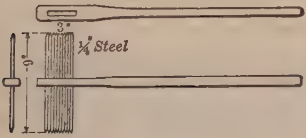

Fig. 8. Crandall.

Fig. 9. Patent Hammer

The **Patent Hammer** or **Bush Hammer** (Fig. 9) is a double-headed tool so formed as to hold at each end a set of wide thin chisels. The tool is in two parts, separated by about 7/8 in., which are held together by the bolts which hold the chisels. Lateral motion is prevented by four guards on one of the pieces. The tool without the teeth is 5-1/2 by 2-3/4 by 1-1/2 in. The teeth are 2-3/4 in. wide. Their thickness varies from 1/12 to 1/6 in. This tool is used for giving a finish to the surface of stones.

The **Bush Chisel** has its end similar to one-half of the patent hammer, and may be used by hand or with the pneumatic surfacer.

The **Pitching Chisel** or **Chipper** (Fig. 10) is usually of 1-1/8-in. octagonal steel, spread on the cutting edge to a rectangle of 1/8 by 2-1/2 in. It is used to make a well-defined edge to the face of a stone, a line being marked on the joint surface to which the chisel is applied and the portion of the stone outside of the line broken off by a blow with the hand hammer on the head of the chisel.

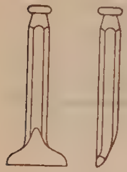

Fig. 10. Pitching Chisel

Fig. 11. Point

Fig. 12. Chisel

The **Point** (Fig. 11) is made of round or octagonal rods of steel, from 1/4 in. to 1 in. in diameter. It is made about 12 in. long, with one end brought to a point. It is used until its length is reduced to about 5 in. It is employed for dressing off the irregular surface of stones, either for a permanent finish or preparatory to the use of the ax. According to the hardness of the stone, either the hand hammer or the mallet is used with it.

The **Chisel** (Fig. 12) of round steel 1/4 to 3/4 in. in diameter and about 10 in. long, with one end brought to a cutting edge from 1/4 in. to 2 in. wide, is used for cutting drafts or margins on the face of stones.

The **Tooth Chisel** (Fig. 13) is the same as the chisel, except that the cutting edge is divided into teeth. It is used only on marbles and sandstones.

Fig. 13. Tooth Chisel

The **Splitting Chisel** (Fig. 14) is used chiefly on the softer stratified stones, and sometimes on fine architectural carvings in granite.

Fig. 14. Splitting Chisel

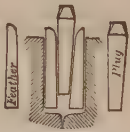

Fig. 15. Plug and Feather

The **Plug**, a truncated wedge of steel, and the **Feathers** of half-round malleable iron (Fig. 15), are used for splitting unstratified stone. A row of holes is made with the **Drill** (Fig. 16) on the line on which the fracture is to be made, in each of these holes two feathers are inserted,

Fig. 16. Drill

and the plugs are lightly driven in between them. The plugs are then gradually driven home by light blows of the hand hammer on each in succession until the stone splits.

Machinery is used to a large extent in all modern stonecutting plants, and consists of pneumatic drills and hand tools, pneumatic surfacing machines, saws, polishing machines, lathes, carborundum machines, and sand-blast equipment. Saws are used in cutting practically all kinds of stone. The reciprocating saw is a thin blade of soft steel, either flat or with vertical corrugations, which cuts by abrasives applied with water between the blade and the stone. Circular saws generally have teeth, either diamonds or carborundum blocks, the diamond saw being used largely for limestone. For thinner stones, a solid carborundum wheel or carborundum steel-center wheel may be used. For round columns, either plain or fluted, and balusters for stone railings, the lathe is used. Carborundum cutting-wheels are used in cutting moldings and for rabbetting, especially in marble and limestone. Hand carving is done largely with pneumatic tools. Machinery has replaced handwork to a very large extent, especially in marble and limestone; but handword is still required for the more intricate details, and especially in finishing architectural granite.

The Sand-blast Process has been used for a number of years in the granite memorial industry, but is equally applicable to the finishing and carving of granite for general structural and architectural purposes. It consists essentially of an intaglio or etching process, whereby a design is engraved or cut into the flat surface of the stone. The face of the stone is first dressed by any of the methods described in Art. 6. The finished surface is then covered with a plastic protective coating, in the form of sheets or melted and poured on, which when hard has a rubber-like consistency. The design to be etched in the stone is drawn or traced on the coating. The coating is then cut out so as to leave the granite accessible to the blast in accord with the design. A blast of white silica sand is blown against the coated surface, and quickly cuts into the area from which the rubber-like coating has been removed, while the portion of the surface which was protected by the coating is left untouched. After the blasting has been carried far enough, the composition coating is peeled off the stone, leaving the ornament as a clean-cut etching. Usually the design is finished with hand tools. If it is desired to have lettering or ornamentation raised above the general surface of the stone, the coating is cut and the background of the design is removed, leaving the design that was protected by the coating. This work is generally done at the quarry shop, though portable equipment is available.

6. Dressing the Surface

Building stones are divided into three classes according to the finish of the surface: unsquared stone, squared stone, and cut stone.

Unsquared Stones include all stones which are used as they come from the quarry without other preparation than the removal of very acute angles and excessive projections from the general figure. The term " backing," which is frequently applied to this class of stone, is inappropriate, as it properly designates material used in a certain relative position in a wall, whereas stones of this kind may be used in any position.

Squared Stones include all stones that are roughly dressed on beds and joints. The dressing is usually done with the face hammer or ax, or in soft stones with the tooth hammer. In gneiss it may sometimes be necessary to use the point. The distinction between this class and the third lies in the degree of closeness of the joints. Where the dressing on the joints is such that the distance between the general planes of the surfaces of adjoining stones is 1/2 in. or more, the stones properly belong to this class. Three subdivisions of this class may be made, depending on the character of the face of the stones: **Quarry-faced Stones** are those whose faces are left untouched as they come from the quarry. **Pitch-faced Stones** are those on which the arris is clearly defined by a line beyond which the rock is cut away by the pitching chisel, so as to give edges that are approximately true. **Drafted Stones** are those on which the face is surrounded by a chisel draft, the space inside the draft being left rough. Ordinarily, however, this is done only on stones in which the cutting of the joints is such as to exclude them from this class. In ordering stones of this class the specifications should state the width of the bed and end joints which are expected, and also how far the surface of the face may project beyond the plane of the edge. In practice, the projection varies between 1 in. and 6 in. It should also be specified whether or not the faces are to be drafted.

Cut Stones include those with smoothly dressed beds and joints. As a rule, all the edges of cut stones are drafted, and between the drafts the stone is smoothly dressed. The face, however, is often left rough where the construction is massive.

The Surface Finishes * usually met in engineering work, arranged in the approximate order of relative cost are: Rock-faced, pointed, peen-hammered, 4-cut, 6-cut, 8-cut, rubbed, honed and polished. **Rock-faced** may vary from ordinary split or quarry-faced stone with split or roughly squared beds and joints, to carefully quarried faces having practically uniform projection, sometimes with rusticated or drafted margins. **Pointed Work** may be rough, medium, fine or machine-pointed. Rough-pointing is used when it is necessary to remove an inch or more from the face of the stone, and is done with the pick or heavy point (Fig. 17). In dressing limestone and granite this operation precedes all others. If a smoother finish is desired, rough pointing

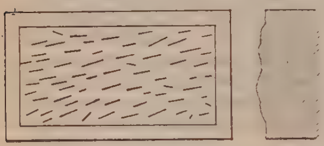

Fig. 17. **Rough-Pointed**

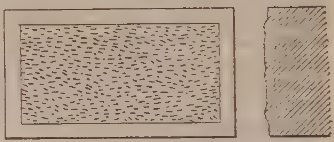

Fig. 18. **Fine-Pointed**

is followed by fine-pointing (Fig. 18), which is used only where this finish is to be final and never as a preparation for a final finish by another tool. Machine pointing is generally more uniform than hand-pointing. The depressions in fine-pointing will be approximately 3/8 in. apart, in medium and machine-pointing 5/8 in. to 3/4 in. apart, and coarse pointing 1 to 1-1/4 in. apart. **Crandalling** is a speedy method of pointing, the effect being the same as fine-pointing, except that the dots on the stone are more regular. The tooth-ax is practically a number of points, and gives the same effect as fine-pointing. It is usually, however, only a preparation for bush-hammering, and the work is then done without regard to appearance so long as the surface of the stone is sufficiently leveled.

Peen-Hammered Finishing (Fig. 19) covers the surface with chisel marks, which are made parallel as far as practicable, and is a final finish. It is adapted to rougher work such as steps, curbings, or to portions of high-class work not exposed to the eye. Peen-hammering is coarser and less regular than 4-cut, and the point marks are not entirely eliminated by the axing.

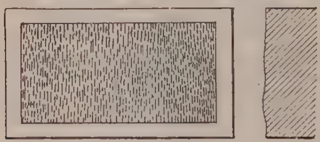

Fig. 19. Peen-Hammered

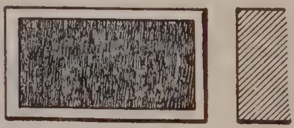

Fig. 20. Bush-Hammered

Four-Cut, Six-Cut and **Eight-Cut** finishes are produced by pounding off the roughness of a stone with the bush hammer and the stone is then said to be "bushed" (Fig. 20). In 4-cut work, the patent hammer contains four blades in each pair of jaws;

* Taken in part from "Architectural Granite," published (1926) by the National Building Granite Quarries Association, Inc.

and, as the jaw opening is about 7/8 in., there are actually about five cuts to the inch, so that the specification of "four-cuts per inch" is incorrect. Similarly 6-cut and 8-cut finishes are sometimes incorrectly specified as 6 or 8 cuts to the inch. In bush-hammered finish the resultant surface has the appearance of being uniformly corrugated to the fineness determined by the number of cuts used, but while the bushing is kept parallel and in the required direction the bush marks are not necessarily continuous or mechanically precise. Six-cut and eight-cut finishes are continuations of the four-cut process, each finer hammer being used consecutively until the required finish is reached. Pneumatic surfacing machines are also used for bushing, especially on all larger surfaces. Sawed surfaces are also bushed, in which case much of the preliminary work is avoided. In sandstone and limestone, bush-hammering should not be used, as experience has shown that soft stone thus treated is likely to scale off (see Art. 3). **Ten-Cut** and **Twelve-Cut** finishes are also produced, but less frequently used on regular building work.

Rubbed and **Honed** finishes are produced by grinding a pointed or sawed surface under the polishing wheel. They vary from coarse-rubbed, with small surface scratches and adapted to work requiring fine smooth finish but not close to the eye, to honed finish with velvet smooth surface practically free from scratches. **Polished** finish is produced by glossing a honed surface under a heavy, felt-coated wheel. Small surfaces and moldings generally have to be rubbed, honed or polished by hand. Polishing usually produces a darker tone, and brings out the color of each crystal, whereas a hammered finish shows up much lighter and softens the colors of the contrasting minerals.

In dressing sandstone, limestone and marble, it is very common to give the stone a plane surface at once by the use of the stone-saw. Any roughnesses left by the saw are removed by rubbing, generally with the carborundum machine. Such stones, therefore, have no margins. They are frequently used in architecture for string courses, lintels, door jambs, etc.; and they are also well adapted for use in facing the walls of lock chambers and in other localities where a stone surface is liable to be rubbed by vessels or other moving bodies. Sometimes the space between the margins is sunk immediately adjoining them and then rises gradually until the four planes form an apex at the middle of the pannel. In general, such panels are called diamond panels, and the one just described is called a sunk diamond panel. When the surface of the stone rises gradually from the inner lines of the margins to the middle of the panel, it is called a raised diamond panel. Both kinds of finish are common on bridge quoins and similar work. The details of this method should be given in the specifications.

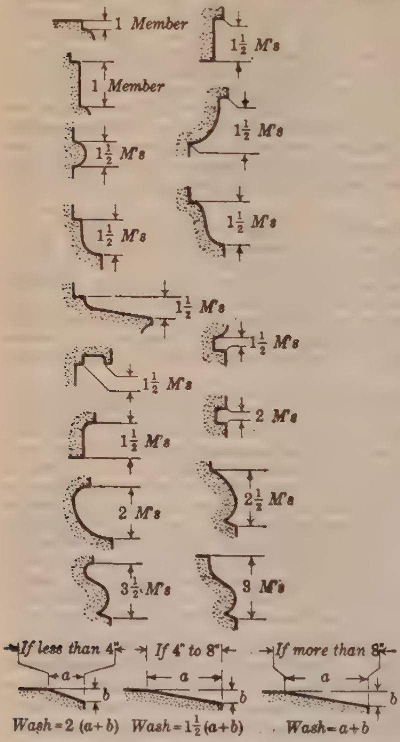
Granite Moldings.* The cutting and finishing of moldings on granite work is almost exclusively a hand process. (Some quarries are equipped with saws and sand-blasts, thus reducing hand cutting.) No practical machine has yet been devised which will do this work and eliminate the more expensive hand-work. In limestone and marble, machine processes are almost universally used on molded work, and here lies one of the most essential differences between the cutting of granite and of the softer stone. The pneumatic tool has materially aided the hand-cutting process, making it possible to produce the most delicate and intricate detail of molding or carving at materially reduced costs. But the cuttings of moldings will continue to be a hand process and its cost one of the principal factors in the total cost of granite work.

In estimating the cost of cutting granite moldings, the so-called "member system" is generally used, by which each molded section is divided into "members." A molded "member" is a more or less arbitrary unit in which the edges, contour and changes in direction of the surface between edges, and the width between edges are taken into consideration. In general, every 4 in. or fraction thereof across the molding is counted as one member. In estimating cost of work, one lineal foot of one molded member equals one

* From "Architectural Granite," published by National Building Granite Quarries Association (1926).

square foot of plain work. The "member chart," Fig. 21, represents the combined judgment of several experienced granite estimators. It is designed for approximate comparisons of relative cost in the study of molded granite details, and is not intended as an exact basis for estimating cost in any particular granite.

For rough estimates, use $2.00 per sq. ft. for plain work or per lin. ft. of a member; thus the molding marked "3 M's" costs 3 × $2 or $6 per lin. ft.



Relative Cost of Wash or Chamfer in Terms of Plane Surface

Fig. 21. Member Chart

Cost of Cut Stone will depend on the character of the rock and conditions at the quarry, as well as on the type of finish required, and can be determined accurately only by obtaining actual bids for any given structure. The cost of transportation is also a large factor. To illustrate the relative cost of various finishes, the following prices for a large **granite-faced** bridge (1926) are given; these prices are in dollars per cubic foot delivered, but do not include placing.

Forming the Surface. The surfaces most frequently required in stone-cutting are plane and cylindrical; but sometimes warped, conical, spherical, and irregular surfaces are required.

To secure a **Plane Surface** the stonecutter chisels draft spots on the three low corners of the face, and cuts down the high corner until it is in the same plane as the other three. Chalk lines are drawn around the

	Rubbed	10-Cut	8-Cut	6-Cut	4-Cut
Facing of piers and abutments below springing line	....	$3.54	$3.34	$3.22	$3.08
Arch voussoirs and spandrel facing	$5.93	4.83	4.70	4.55	4.48
Coping	9.95	6.33	6.01	....	....
Balustrades	19.80	13.08	12.28	....	....

four edges of the stone joining these draft spots, and draft lines are chiseled in the face from corner spot to corner spot to serve as guide lines. To tell when the drafts are in the same plane, he uses two straight-edges having parallel sides and equal widths (Fig. 22). The stone is then sent to the surface cutter, which is a pneumatic machine in which may be used either a point tool or a bush hammer. With this machine the rough surface of the stone between the draft lines is quickly cut down to a true plane surface.

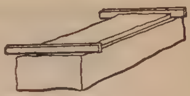


Fig. 22. Plane Surfaces

To form a second plane surface at right angles to the first one, the workman draws a line on the cut face to form the intersection of the two planes; he also draws a line on the ends of the stone approximately in the required plane. With the ax or the chisel he then cuts a draft at each end of the stone until a steel square fits the angle. He next joins these drafts by two others at right angles to them, and brings the whole surface to the same plane. The other faces may be formed in the same way. If the surfaces are not at right angles to each other, a bevel is used instead of a square, the same general method being pursued.

To form a **cylindrical surface,** the stone is first reduced to a parallelopipedon, after which the curved surface is produced in either of two ways: (1) by cutting a circular draft on the two ends and applying a straight-edge along the rectilinear elements (Fig. 23); or (2) by cutting a draft along the line of intersection of the plane and cylindrical surface, and applying a curved templet perpendicular to the axis (Fig. 24).

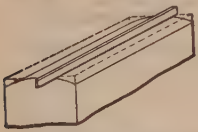

Fig. 23. Cylindrical Surfaces

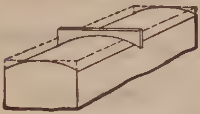

Fig. 24. Cylindrical Surfaces

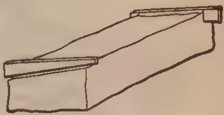

Fig. 25. Warped Surfaces

Warped Surfaces include what the stonecutter calls twisted surfaces, as well as the general warped surface. The former is seldom used in masonry, and the latter almost never. The method of forming a surface equally twisted right and left is shown in Fig. 25. Two twist rules are required, the angle between the upper and lower edges being half of the required twist. Drafts are then cut in the ends of the stone until the tops of the twist rules, when applied as in Fig. 25, are in plane. The remainder of the projecting face is removed, until a straight-edge, when applied parallel to the edge of the stone, will just touch the end drafts and the intermediate surface. If the surface is to be twisted at only one end, a parallel rule and a twist rule are used.

Stereotomy is the art of making the plans and drawings by which the stonecutter is enabled to prepare the patterns, bevels and templets which are required in shaping the blocks of stone for the structure. The engineer should prepare drawings in sufficient detail so that these directing-instruments may be prepared, but fully detailed drawings are not generally necessary.

The general drawings of the stonework should be at a scale of not less than 1/4 in. to one foot, and details should be at least 3/4 in. to one foot. General drawings should show all the dimensions of the structure. Detail drawings may be required for individual stones, and for complicated work the separate stones should be shown in isometric projection. Plane structures (such as retaining walls, wing walls, piers, etc.) may have dimensions of the individual stones directly on the general drawings. Structures with curved or warped surfaces must have the dimensions of the stones properly indicated, these being determined by descriptive geometry. In heavy walls, particularly, the stonecutters should be allowed as much freedom as possible in determining the sizes of individual stones.

Fig. 26 shows an example of the stonework drawing for a small skew-arch culvert, constructed as a "false-skew arch" (Art. 39). This example is rather extreme, as a "false-skew" arch should be used only where the angle of skew is small. The faces

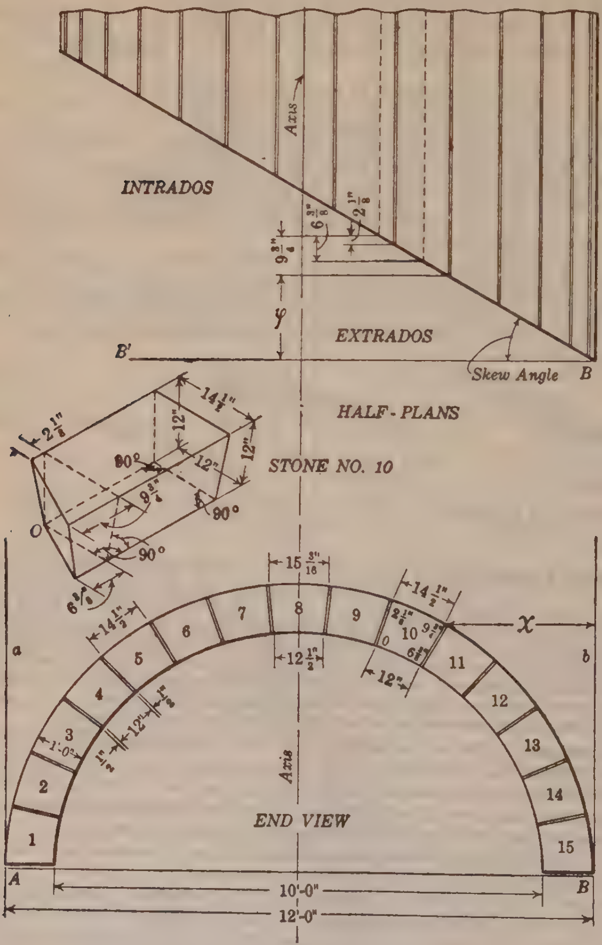

Fig. 26

of the ring-stones are dimensioned in detail. In the end view, figures should be given at the corners of each stone to indicate the distances of these corners from a vertical plane (a different plane for each stone) passing through the corner marked O and at right angles to the axis of the arch. This is indicated on the figure for voussoir 10 only. These dimensions should be computed, and may be checked by scaling from a large-scale plan or preferably from a full-scale drawing laid out upon a floor of a building or upon one especially constructed for this purpose.

The computation is carried out by simple trigonometry, by determining the horizontal distance of each stone corner from a vertical line (Aa or Bb) through A, or B, in the end view. This distance (in this case measured from Bb) is multiplied by the tangent of the skew-angle to obtain the horizontal distance of the given corner measured parallel to the arch axis, from a vertical plane BB', perpendicular to the arch axis. The proper dimensions to be noted on each stone are then readily derived from these computed distances. An isometric view of stone No. 10 is shown, to clarify the meaning of these dimensions.

For examples of more complicated problems, see "Stereotomy" by A. W. French and H. C. Ives, 1902; "Modern Stone Çutting and Masonry" by J. S. Siebert and F. C. Piggin, 1896.

In important or complicated work (right or skew arches), templets should be made for each arch stone and the templets should be checked by laying out the structure at full scale on a large wooden or concrete platform, using steel tape and transit. The proper fitting of the stones can thus be accurately verified, thereby avoiding the necessity of expensive re-cutting.

The joints of the stones back of the face or ring-stones are generally dependent upon the size of the available stones and the judgment of the stonecutter.

STONE AND BRICK MASONRY

7. Kinds of Stone Masonry

Classifications of stone masonry are: (1) according to the finish of the face of the stones, (2) according to whether the horizontal joints are more or less continuous, (3) according to the care which is employed in dressing the beds and joints.

(1) **Quarry-faced Masonry** is that in which the face of the stone is left as it comes from the quarry (Fig. 27). **Pitch-faced Masonry** is that in which the face edges of the beds are pitched to a right line (Fig. 28). The outer edge of a horizontal joint of pitch-faced masonry is straight, while in quarry-faced it is not. **Cut-stone Masonry** is that in which the face of the stone is finished by any one of the methods described in Art. 6, as rough-pointed, fine-pointed, crandalled, axed, bush-hammered, rubbed.

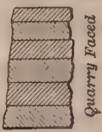

Fig. 27

Fig. 28

(2) **Range Masonry** is that in which a course is the same thickness throughout its length (Fig. 29). **Broken Range** is that in which the course is of uniform thickness for only parts of its length. (Fig. 30). **Random Masonry** is that which is not laid in courses at all (Fig. 31); it is sometimes designated

Fig. 29. Range

Fig. 30. Broken Range

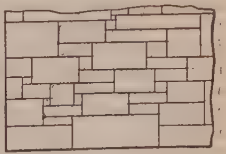

Fig. 31. Random

as one-against-two or two-against-three, the first term indicating that there is one stone on one side of a vertical joint and two on the other, and similarly for the second term.

(3) **Ashlar Masonry** is composed of any of the kinds of cut-stones (Art. 6). It is usually held that when the dressing of the joints is such that the distance between the general planes of the surfaces of adjoining stones is one-half inch or less, the masonry belongs to this class. From its derivation ashlar apparently means large, square blocks; but practice seems to have made it synonymous with cut-stone, and this secondary meaning has been retained for convenience. The coursing of ashlar is described by prefixing range, broken range, or random; and the finish of the face is described by prefixing a name to designate the finish of the face of the stone of which the masonry is composed, as for example fine-pointed ashlar, rubbed ashlar. **Dimension Stone Masonry** is that composed of cut-stones all of whose dimensions have been fixed in advance. Ordinarily the specifications of ashlar are so written as to prescribe the dimensions of the stones to be used, and hence it is seldom or never necessary to make a new class of masonry composed of dimension stones.

Squared-Stone Masonry is that in which the stones are roughly squared and roughly dressed on beds and joints. The distinction between squared-stone masonry and ashlar lies in the degree of closeness of the joints. "When the dressing on the joints is such that the distance between the general planes of the surface of adjoining stones is one-half inch or more, the stones properly belong to this class."

Rubble Masonry is composed of unsquared stones, and it may be coursed or uncoursed. **Coursed Rubble** is masonry composed of unsquared stone which is leveled off at specified heights to an approximately horizontal surface (Fig. 33). **Uncoursed Rubble** is masonry composed of unsquared stones laid without any attempt at regular courses (Fig. 32). The specifications for rubble may require that the stones shall be roughly shaped with the hammer. Rubble is sometimes designated as one-man or two-man rubble, according to the number of men required to handle a stone.

Fig. 32. Uncoursed Rubble

Fig. 33. Coursed Rubble

General Rules. The following general principles apply to all classes of stone masonry: (1) The largest stones should be used in the foundation to give the greatest strength and lessen the danger of unequal settlement. (2) A stone should be laid upon its broadest face, since then there is better opportunity to fill the spaces between the stones. Where stone is used as a veneer covering for steel or concrete, the stones are laid with the broadest face vertical. (3) For the sake of appearance, the thickness of the courses should decrease gradually toward the top of the wall. (4) Stratified stones should be laid upon their natural bed, i.e., with the strata perpendicular to the pressure, since they are then stronger and more durable. (5) The masonry should be built in courses perpendicular to the pressure it is to bear. (6) To bind the wall together laterally, a stone in any course should break joints with or overlap the stone in the course below; that is, the joints parallel to the pressure in two adjoining courses should not be too nearly in the same line. This is briefly comprehended by saying that the wall should have sufficient lateral bond. (7) To bind the wall together transversely, there should be a considerable number of headers extending from the front to the back of thin walls or from the outside to the interior of thick walls; that is, the wall should have sufficient transverse bond. (8) The surface of all porous stones should be moistened before being bedded, to prevent the stone from absorbing the moisture from the mortar and thereby causing it to become a friable mass. (9) The spaces between the back ends of adjoining stones should be as small as possible, and these spaces and the joints between the stones should be filled with mortar. (10) If it is necessary to move a stone after it has been placed upon the mortar bed, it should be lifted clear and be reset, as attempting to slide it is likely to loosen stones already laid and destroy the adhesion, and thereby injure the strength of the wall.

Specifications should be as simple as possible, clear, and not unnecessarily rigid. Care should be taken to keep the terminology consistent. For ashlar work, give depth of bed and end joints. State allowable projection of the face beyond plane of the edge of any stone; whether face is drafted, and width of draft; surface finish between drafts. If rubble is specified, do not call for joints that will require stonecutting. Hollows in the bed face of a stone may not be harmful, especially in hard stone, unless too close to an edge.

For heavy masonry, headers should be not less than 4 ft. long, or else should extend all the way through the wall. Stretchers should be not less than 4 ft. long, with depth of bed 1-1/4 times the thickness. Length of stretchers should be from 2-1/2 to 5 times the thickness.

If full dimensions are not given, specify the limiting dimensions of headers and the proportion of headers (generally not less than 25% of the wall face area), thickness of joints and allowable depressions. Beds of headers need not be dressed to a greater depth than that of the stretchers. Headers may taper horizontally back of the stretchers. Vertical joints need not be dressed to full depth of the stretchers. Insistence on uniform color and texture may add unnecessary expense. The finer finishes are often specified where coarser finishes would be as good. Treads of steps and platforms should never be finer than 4-cut, for safety purposes.

If the stone is paid for at the quarry, the volume of measurement is the smallest rectangular block from which the required stone can be cut. If the masonry is paid for in the structure, the volume should be cubic yards in place, rectangular measure, including joints.

The National Building Granite Quarries Association makes the following suggestions:

Allow at least 2 in. between top of concrete and bottom of steps to obviate bedding off steps. Avoid projections on courses which might otherwise be sawed or machine surfaced. Detail rustication, rabbets and sinkages to take fullest advantage of carborundum saw cutting. Avoid raised seats on balustrade base and substitute round for square plinths on the balusters.

(See also " Graphical Statics and Masonry " by G. F. Swain.)

8. Ashlar Masonry

Ashlar is the best quality of stone masonry, and is employed in all important structures. It is used for piers, abutments, arches, and parapets of bridges; for hydraulic works; for facing quoins, and string courses; for the coping of inferior kinds of masonry and of brickwork; and, in general, for work in which great strength and stability are required. The dimensions of the blocks should vary with the character of the stone employed. With the weaker sandstones and granular limestones the length of any stone should not be greater than three times its depth, as otherwise it is likely to be broken across; but with the stronger stones the length may be four or five times the depth. With the weaker stones the breadth may range from one and a half to two times the depth; and for the stronger stones it may range from three to four times the depth.

Dressing. The dressing consists in cutting the side and bed joints to plane surfaces, usually at right angles to each other. The accurate dressing of the bed joints to a plane surface is exceedingly important. If any part of the surface projects beyond the plane of the chisel draft, that projecting part will have to bear an undue share of the pressure, the joint will open at the edges, and the whole will be wanting in stability. On the other hand, if the surface of the bed is concave, having been dressed down below the plane of the chisel draft, the pressure is concentrated on the edges of the stone, to the risk of splitting them off. Such joints are said to be flushed. They are more difficult of detection, after the masonry has been built, than open joints; and are often executed by design, in order to give a neat appearance to the face of the building. Their occurrence must therefore be guarded against by careful inspection during the progress of the stonecutting.

Great smoothness is not desirable in the joints of ashlar masonry intended for strength and stability, for a moderate degree of roughness adds at once to the resistance to displacement by sliding and to the adhesion of the mortar. When the stone has been dressed so that all the small ridges and projecting points on its surface are reduced nearly to a plane, the pressure is distributed nearly uniformly, for the mortar serves to transmit the pressure to the small depressions. Each stone should first be fitted into its place dry, in order that any inaccuracy of figures may be discovered and corrected by the stonecutter before it is finally laid in mortar and settled in its bed.

The entire bed area of a stone should be dressed to a plane; but, unless the wall is so thin that the stones extend clear through, it is not necessary to dress the entire area of the ends of the stones; and it is not necessary to dress any portion of the back side of the stones. The specifications should state the distance back from the face of the stone that the end is to be dressed to a plane surface. This distance is sometimes stated in inches and sometimes as a fractional part of the thickness of the course. Sometimes specifications permit the vertical joints to be wider than the bed joints. This decreases the cost of cutting, and may not materially reduce the strength of the masonry; but may slightly affect the durability and the architectural appearance.

The thickness of mortar in the joints of the very best ashlar masonry for architectural work is about 1/8 in.; in first-class railroad masonry the joints are from 1/4 to 1/2 in. A chisel draft 1-1/2 or 2 in. wide is usually cut at each exterior corner. In the best work, as fine cut-stone buildings, all projecting courses, as window sills, water tables, cornices, etc., have grooves or " drips," cut in the under surface a little way back from the face, so as to cause rainwater to drop from the outer edge instead of running down over the face of the wall and disfiguring it.

Bond. The bond is the arrangement or overlapping of the stones to tie the wall together longitudinally and transversely, and is of great importance to the strength of the wall. No joint of any course should be directly above a joint in the course below; but the stones should overlap, or break joints from one to one and one-half times the depth of the course, both along the face of the wall and also from the front to the back. The effect is that each stone is supported by at least two stones of the course below, and assists in supporting at least two stones of the course above. The object is twofold: first, to distribute the pressure, so that inequalities of load on the upper part of the structure (or of resistance at the foundation) may be transmitted to and spread over an increasing area of bed in proceeding downward (or upward); and second, to tie the building together, both lengthwise and from face to back.

The strongest bond is that in which each course at the face of the structure contains a header and a stretcher alternately, the outer end of each header resting on the middle of a stretcher of the course below, so that rather more than one-third of the area of the face consists of ends of headers. This proportion may be deviated from when circumstances require it, but in every case it is advisable that the ends of headers should not form less than one-fourth of the whole area of the face of the structure. A header should be over the middle of the stretcher in the course below. **In a thin wall a header should extend entirely through the wall.**

Where very great resistance to displacement of the masonry is required (as in the upper courses of bridge piers, or over openings, or when new masonry is joined to old, or where there is danger of unequal settlement), the bond is strengthened by dowels or by cramp irons of, say 1-1/4-in. round iron set with cement mortar. Stone veneer should be thoroughly anchored to the backing or supporting structure.

Backing. Ashlar is usually backed with rubble masonry which in such cases is specified as coursed rubble. Special care should be taken to secure a good bond between the rubble backing and the ashlar facing. Two stretchers of the ashlar facing having the same width should not be placed one immediately above the others. The proportion and the length of the headers in the rubble backing should be the same as in the ashlar facing. The " tails " of the headers, or the parts which extend into the rubble backing, may be left rough at the back and sides; but their upper and lower beds should be dressed to the general plane of the bed of the course. These tails may taper slightly in breadth, but should not taper in depth. The backing should be carried up at the same time with the facework, and in courses of the same depth; and the bed of each course should be carefully built to the same plane with that of the ashlar facing. The rear face of the backing should be lined to a fair surface. If the backing is concrete, similar care should be given to the bond, and in important structures the stone should be secured to the concrete by metal anchors.

Pointing. In laying masonry of any character, whether with lime or cement mortar, the exposed edges of the joints will naturally be deficient in density and hardness. The mortar in the joints near the surface is especially subject to dislodgment, since the contraction and expansion of the masonry are liable either to separate the stone from the masonry or to crack the mortar in the joint, thus permitting the entrance of rain-water, which upon freezing forces the mortar from the joint. Therefore it is usual, after the masonry is laid, to refill the joints as compactly as possible, to the depth of at least an inch, with mortar prepared especially for this purpose. This operation is called pointing.

The very best cement mortar should be used for pointing, as the best becomes dislodged all too soon. Neat portland-cement mortar is the best, although 1 volume of cement to 1 of sand is frequently used in first-class work. The mortar, when ready for use, should be rather incoherent and quite deficient in plasticity. In the best work, it may be advisable to use a special non-staining cement in the mortar for pointing.

Before applying the pointing, all mortar in the joint should be dug out to a depth of at least 1 in. or better; in setting the stones, the mortar should be kept back an inch or more from the face, and thus save the labor of digging out the joints preparatory to pointing. For the bed joints this may be accomplished by keeping the mortar back from the face of the wall about 3 in., and then when the stone is put into place the mortar will probably be forced out to about 1 or 1-1/2 in. from the face of the joint, and consequently little or no labor will be required to dig out the mortar. Frequently in laying a stone the mortar is spread to the very edge of the joint; and then when the pointing is done, it is so difficult to dig out the mortar that the joint is cleared only about half an inch deep, which depth does not give the pointing sufficient hold, and consequently it soon drops out. The difficulty of digging out the mortar from the vertical joints may be obviated by bending a strip of tin or thin steel to the form of a U having one leg considerably longer than the other, and nailing the long leg to the side of a light strip of wood so that the closed end of the U will project beyond the edge of the wood a distance equal to the depth of the pointing, and then inserting the closed end of the U in the vertical joint before it is filled with mortar.

When the surplus mortar has been removed, the joint should be cleansed by scraping and brushing out all loose material and then it should be well moistened. The mortar is applied with a mason's trowel, and should be well " set in " with a calking iron and hammer. The joint should be rubbed smooth and finished even with the pitch line or with the face of the stone. In the very best work, the joint is also rubbed smooth with a steel polishing tool. Walls should not be allowed to dry too rapidly after pointing; and therefore pointing in hot weather should be avoided.

There are four general forms of finishing the edges of the horizontal joints of cut-stone masonry, whether or not thay are formally pointed as above described. Fig. 34 shows these four forms. When the horizontal joints are finished as in either of the first two examples in Fig. 34 it is customary to finish the vertical joints by the first method; but when either of the last two methods is employed, it is used for both the vertical and the horizontal joints. Occasionally in cut-stone masonry, and frequently in brick masonry, the weather joint is improperly made to slope in the opposite direction, due to the fact that the mason stands at the back of the wall and "strikes" the joint by reaching down and resting the edge of the trowel on the stone below the joint. If the mason stands behind the wall, it is not comfortable to make the weather joint as shown in Fig. 34 at the time the masonry is laid. The grooved joint is frequently called a tuck-pointed joint, and is sometimes made with a V-like face. The beaded joint is not very durable, since the projecting portion soon becomes detached. In making the beaded joint, the beading tool is sometimes guided by a straight-edge, called a "rod," and the joint is then said to be "rodded."

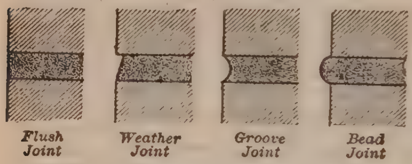

Fig. 34. Finish of Horizontal Joints

The Amount of Mortar required for ashlar masonry varies with the size of the blocks, and also with the closeness of the dressing. With 3/8- to 1/2-inch joints and 12- to 20-in. courses, there will be about 2 cubic feet of mortar per cubic yard; with larger blocks and closer joints, i.e., in the best masonry, there will be about 1 cubic foot of mortar per yard of masonry. For quantities of materials in mortar, see Art. 13.

9. Squared-Stone and Rubble Masonry

Squared-Stone Masonry. Squared-stone masonry is distinguished from ashlar in having less accurately dressed beds and joints; and from rubble in being more carefully constructed. In ordinary practice, the field covered by this class is not very definite. The specifications for "second-class masonry" as used on some railroads usually conform to the above description of quarry-faced range squared-stone masonry; but sometimes this grade of masonry is designated "superior rubble." Squared-stone masonry is employed for the piers and abutments of highway bridges, for small arches, for box culverts, for basement walls, etc. The quoins and the sides of openings are usually reduced to a rough-smooth surface with the face-hammer, the ordinary ax or the tooth-ax. This work is a necessity where door or window frames are inserted; and it greatly improves the general effect of the wall, if used wherever a corner is turned.

The remarks concerning size of stones and backing under ashlar above apply substantially also to squared-stone masonry. As the joints of squared-stone masonry are thicker than those of ashlar, the pointing should be done proportionally more carefully, whereas as a rule it is done much more carelessly. The mortar is often thrown into the joint with a trowel, and then trimmed top and bottom to give the appearance of a thinner joint. Such work is called **ribbon pointing.** Trimming the pointing adds to the appearance but not to the durability. When the pointing is not trimmed, it is called **dash pointing.**

Rubble Masonry. This is the lowest grade laid with mortar; and is built of stones as they come from the quarry without other preparation than the removal of very acute angles and excessive projections from the general figure. The stone used for rubble masonry is prepared by simply knocking off all the weak angles of the block. It should be cleaned from dust, etc., and moistened, before being placed on its bed. This bed is prepared by spreading over the top of the lower course an ample quantity of good mortar of ordinary consistency in which the stone is firmly embedded. The vertical joints should be carefully filled with mortar. The interstices between the larger masses of stone are filled by thrusting small fragments or spalls of stone into the mortar. Careful attention should be given to bonding the wall laterally and transversely. It is frequently specified that one-fourth or one-fifth of the mass shall be headers. The corners and jambs should be laid with hammer-dressed or cut stones.

A very stable wall can be built of rubble masonry without any dressing, except a draft on the quoins by which to plumb the corners and carry them up neatly, and a few strokes of the hammer to spall off any projections or surplus stone. This style of work is not generally advisable, as very few mechanics can be relied upon to take the proper amount of care in leveling up the beds and filling the joints; and as a consequence, one small stone may jar loose and fall out, resulting probably in the downfall of a considerable part of the wall. Some of the naturally bedded stones are so smooth and uniform as to need no dressing; a wall of such stones is very economical, since there is no expense of cutting and no time is lost in hunting for the right stone, and yet strong massive work is assured. However, many of the naturally bedded stones have inequalities on their surfaces, and in order to keep them level in the course it becomes necessary to raise one corner by placing spalls or chips of stone under the bed, and to fill the vacant spaces well and full with mortar. Here the disadvantage of this style of work becomes apparent.

When carefully executed with good mortar, rubble possesses all the strength and durability required in structures of an ordinary character, and is much less expensive than either ashlar or squared-stone masonry. But it is difficult to get rubble well executed. The most common defects are (1) not bringing the stones to an even bearing; (2) leaving large unfilled vertical openings between the several stones; (3) laying up a considerable height of the wall dry, with only a little mortar on the face and back, and then pouring mortar on the top of the wall; (4) using insufficient cement, or that of a poor quality. The only way to prevent the first defect is to have an inspector on the job all the time. The second and third defects can be detected by probing the wall with a small pointed steel rod. To prevent the fourth defect it is customary for the owner to furnish the cement to the contractor. Apparently it is commonly believed that the rougher the stones and the poorer the grade of masonry, the poorer the cement or the leaner the mortar should be. The principal object of the mortar is to equalize the pressure; and the more nearly the stones are reduced to closely fitting surfaces, the less important is the mortar. Consequently, when a substantial rubble is required, it would not be amiss to use a first-class cement mortar, particularly if the stones are comparatively small.

The Amount of Mortar required for rubble masonry varies greatly with the character of the surfaces with which the stone quarries out. If the stone is stratified sandstone or limestone yielding flat-bedded stones with good end surfaces, the rubble may not require much if any more mortar than ashlar built of the more refractory stones; but if the rubble is built of stone that quarries out in irregular chunks and is difficult to dress, a very large per cent of mortar may be required. The amount of mortar required can be considerably reduced by packing spalls into the vertical spaces between the stones, a proceeding that is always economical since spalls are always much cheaper than cement mortar. However, when the cement is furnished by the owner, the mason is apt to fill the joints entirely with mortar since it requires less time.

If rubble masonry is composed of small and irregularly shaped stones, about one-third of the mass will consist of mortar. If the stones are large and regular in form, one-fifth to one-quarter of the mass will be mortar. For quantities of materials in mortar, see Art. 13.

Rubble Concrete is ordinary concrete in which large irregular stones, sometimes called plums, are embedded. This form of masonry is adapted to moderately massive construction. The plums decrease the cost of crushing the stone and also decrease the amount of cement required, and increase the density of the mass. The plums are usually limited to about 40% of the entire volume, to insure that they shall be surrounded by concrete. It is usually difficult and expensive to place more than 25% of plums. If the concrete is wet, there is little or no trouble in getting the large stones thoroughly bedded, and consequently this form of masonry is as good as or better than ordinary concrete.

Cyclopean Masonry. Sometimes in building large structures, as dams, the rubble is made of very large irregular rocks and wet concrete is used instead of mortar. The large stones are placed in the wall by means of a derrick, and concrete is deposited from a bottom-dump pocket. This form of construction was first used about 1900, and is specially applicable in building a dam in which the faces are laid in ashlar, squared-stone, or rubble, and serve as forms in which to place the rock and concrete. The term concrete-rubble is sometimes used for this kind of filling.

10. Dry Stonework

Riprap is rough stone of various sizes placed compactly or irregularly to prevent scour by water. Often riprap is dumped in promiscuously, the size of the stone depending upon the material at hand and the velocity of the current, in extreme cases stone of 15 to 20 cu. ft. being used. Such riprap is sometimes called " cyclopean riprap."

Hand-placed Riprap (sometimes called " slope wall ") is usually made of thin-bedded stones 6 to 12 in. wide set on edge. If the bank on which the riprap is placed consists of material which may be washed out by the water, a layer of sand or gravel should be placed under the riprap, a thickness of 4 to 8 in. usually being sufficient. The stones should break joints horizontally, so that if any stone is displaced those above will bridge the opening and prevent the raveling of the whole bank. The joints should be made reasonably close to prevent the washing out of the bank material, but ordinarily a width of 1 or 1-1/2 in. is sufficient. The length and width of the face of the stone are unimportant, and will depend upon the way the stone quarries out. Ordinarily such riprap can be built more cheaply and better of stones that one man can lift readily, than of two-men stones or larger. The paving should be laid approximately to a plane, and in fairly regular courses. Sometimes the riprap is made of cobblestones or rounded boulders, but such stones are more troublesome to place, and do not make as desirable or stable a protection.

Dry Rubble Masonry is sometimes used for low retaining walls, or at the foot of exposed banks of excavations to prevent the loose material of the bank from flowing into the cut. It is constructed like ordinary rubble masonry but without using any mortar. Walls of dry masonry should be about 60% wider than would be required for rubble work laid up in mortar.

11. Qualities of Brick

Good Bricks have the following qualities to recommend them as a building material: (1) Bricks are practically indestructible, since they are not acted upon by fire, the weather, or the acids in the atmosphere. (2) Bricks may be had in most localities of almost any shape, size, or color. (3) Bricks are comparatively easy to put into place in the wall. (4) In most localities brick masonry is cheaper than stone masonry, even rubble, and under some conditions is a competitor with concrete. The disadvantages of brick as a building material are: (1) Owing to the smallness of the unit, bricks are comparatively expensive to lay, and require considerable skill to secure a strong and good-appearing wall. (2) Ordinarily brick masonry is not as durable as ashlar, since a considerable part of the face of the wall is mortar, which is not as durable as the brick; but by making thin joints or using superior mortar in the exterior edges of the joints, a durable wall may be constructed.

Clay Brick. Until about 1900 the word brick always meant a prism of burned clay; but at about that date bricks composed of sand and lime were put upon the market, and at present many such brick are used annually, although their number is very small in comparison with that of ordinary clay brick. Ordinarily the word brick means a burned-clay brick, and a brick composed of sand and lime is called a sand-lime brick. Clay brick is made by submitting clay which has been prepared properly and molded into shape to a temperature which converts it into a semi-vitrified mass. Building brick are usually made from surface clay, and paving brick from shale (a fine-grained and indurated clay), since the latter gives a tougher, denser, and stronger brick.

The method of molding gives rise to the following terms.

Soft-mud Brick: One molded from clay which has been reduced to a soft mud by adding water. It may be either hand-molded or machine-molded. **Stiff-mud Brick**: One molded from clay in the condition of stiff mud. It is always machine-molded. **Pressed Brick**: One molded from dry or semi-dry clay. **Re-pressed Brick**: Usually a stiff-mud brick which has been subjected to an enormous pressure to render the form more regular and to increase its strength and density. It is doubtful whether the re-pressing increases either the strength or the density. Occasionally in the East, and more formerly than at present, a soft-mud brick, after being partially dried, is re-pressed, which process greatly improves the form and also the strength and the density. A re-pressed brick is sometimes, but inappropriately, called a pressed brick. **Slop Brick**: In molding brick by hand, the molds are sometimes dipped into water just before being filled with clay, to prevent the mud from sticking to them. Brick molded by this process is known as slop brick. It is deficient in color, and has a comparatively smooth surface, with rounded edges and corners. This kind of brick is now seldom made. **Sanded Brick**: Ordinarily, in making soft-mud brick, sand is sprinkled into the molds to prevent the clay from sticking; the brick is then called sanded brick. The sand on the surface is of no serious advantage or disadvantage. In hand-molding when sand is used for this purpose, it is certain to become mixed with the clay and occurs in streaks in the finished brick, which is very undesirable; and owing to details of the process, which it is here unnecessary to explain, every third brick is especially bad. **Machine-made Brick**: Brick is frequently described as "machine-made" but this is very indefinite, since all grades and kinds are made by machinery.

When bricks were usually burned in the old-style up-draft kiln, the classification according to position was important; but with the new styles of kilns and improved methods of burning, the quality is so nearly uniform throughout the kiln that the classification is less important. Three grades of brick are taken from the old-style kiln: arch brick, body brick, and salmon brick. **Arch** or **Clinker Bricks**: Those which form the tops and sides of the arches in which the fire is built. Being overburned and partially vitrified, they are hard, brittle, and weak. **Body, Cherry,** or **Hard Bricks**: Those taken from the interior of the pile. The best bricks in the kiln. **Salmon, Pale,** or **Soft Bricks**: Those which form the exterior of the mass. Being underburned, they are too soft for ordinary work, unless it is for filling. The terms "salmon" and "pale" refer to the color of the brick, and hence are not applicable to a brick made of a clay that does not burn red. Although nearly all brick clays burn red, yet the localities where the contrary is true are sufficiently numerous to make it desirable to use a different term in designating the quality.

The form of the brick gives rise to the following terms. **Compass Brick**: One having one edge shorter than the other. **Feather-edge Brick**: One having one edge thinner than the other. Used in arches; and more properly, but less frequently, called voussoir brick. **Face Brick**: Those which, owing to uniformity of size and color, are suitable for the face of the wall of buildings. Sometimes face bricks are simply the best ordinary brick; but generally the term is applied only to re-pressed or pressed brick made specially for this purpose. **Sewer Brick**: Ordinary hard brick, smooth, and regular in form. **Paving Brick**: Very hard, ordinary brick. A vitrified clay block, very much larger than ordinary brick, is sometimes used for paving, and is called a paving brick, but more often a brick paving-block. **Vitrified Brick**: The introduction of brick for street pavements about 1890 led to a new grade, one burned to the point of vitrifaction and then annealed or toughened by slowly cooling. Vitrified brick and paving blocks, though originally made for paving purposes, are now much used in building and engineering structures.

The Size of common brick varies widely with the locality and also with the maker, and with the same maker the brick are likely to be larger as the working season advances, owing to the wear of the molds or the die. Hard-burned bricks are smaller than soft-burned ones, owing to the greater shrinkage in burning; and this difference varies with the different kinds of clays. The standard sizes accepted by a number of the brick manufacturers' associations in 1923 are: 8 × 3-3/4 × 2-1/4 in. for common and rough-face brick, and 8 × 3-7/8 × 2-1/4 in. for smooth-face brick. For sizes of paving brick, see Sect. 20, Art. 18.

Form. A good brick should have plane faces, parallel sides, and sharp edges and angles. In regularity of form re-pressed brick ranks first, dry-clay brick next, then stiff-mud brick, and soft-mud brick last. Regularity of form depends largely upon the quality of the clay and the method of burning. A good brick should not have depressions or kiln marks on its edges caused by the pressure of the brick above it in the kiln.

Texture. A good brick should have a fine, compact, uniform texture; and should contain no fissures, air bubbles, pebbles, or lumps of lime. It should give a clear ringing sound when struck a sharp blow with a hammer or another brick. A brick which gives a clear ringing sound is strong and durable enough for any ordinary work.

The compactness and uniformity of texture, which greatly influence the durability of brick, depend mainly upon the method of molding. As a general rule, hand-molded bricks are best in this respect, since the clay in them is more uniformly tempered before being molded; but this advantage is partially neutralized by the presence of sand seams. Machine-molded soft-mud bricks rank next in compactness and uniformity of texture. Then come machine-molded stiff-mud bricks, which vary greatly in durability with the kind of machine used in their manufacture. By some of the machines, the brick is molded in layers (parallel to any face, according to the kind of machine), which are not thoroughly cemented, and which separate under the action of frost. In compactness the dry-clay brick comes last. However, the relative value of the products made by the different processes varies with the nature of the clay used.

Formerly it was believed that the capacity of a building brick to absorb water had an important effect upon its ability to resist destruction by frost; but experiments and a more careful study of experience has shown that this has little or nothing to do with its durability. The absorptive capacity varies with the chemical composition of the clay, and there seems to be no close relation between the absorptive power and the strength of a brick or the loss of strength by freezing.

The Crushing Strength is valuable only in comparing different brands, and gives little idea of the strength of walls built of such bricks. The crushing strength of brick is of relatively less importance than that of stone, since owing to the relatively smaller size of the brick and consequently the relatively larger proportion of mortar, the strength of brick masonry is more dependent upon the strength of the mortar than is stone masonry. The strength of the brick is of relatively small importance unless the mortar is nearly as strong as the brick.

Soaking a brick in water decreases its compressive strength, apparently because the water acts as a lubricant on the plane of rupture. In a series of experiments with the United States testing machine at Watertown, of thirty tests upon ordinary building brick from ten localities, all but two showed a loss of strength due to immersion in water for one week; and the wet half of a brick gave an average crushing strength of only 85% of the strength of the dry half.

Experiments indicate that a brick will show maximum strength when tested flatwise, less strength if tested edgewise, and will be weakest when tested endwise. The crushing strength of brick is quite variable, depending on the method of molding, the character of the clay, and the manner of burning. The tentative specifications (1927) for Building Brick of the American Society for Testing Materials contain the following classification of brick according to strength:

Name of grade	Compressive strength flatwise		Modulus of rupture flatwise	
	Mean of 5 tests, lb. per sq. in.	Individual minimum, lb. per sq. in.	Mean of 5 tests, lb. per sq. in.	Individual minimum, lb. per sq. in.
Grade " A "	4500+	3500	600+	400
Grade " B "	2500+	2000	450+	300
Grade " C "	1250+	1000	300+	200

Grades " A " and " B " are usually hard or well-burned. Bricks of grade " C " are usually underburned. The actual strength of well-made brick may be considerably higher than the specified minimum.

Sand-lime Brick consist of a mass of sand cemented together with lime. There are two classes of sand-lime brick: one in which the binding material is carbonate of lime, and the other in which it is silicate of lime.

The first is virtually a brick made of ordinary lime mortar, molded as are soft-mud clay brick, and hardened in the open air or in an atmosphere rich in carbon dioxide (CO_2), either with or without pressure. This form may properly be called a lime-mortar brick. It is the older form of sand-lime brick, and was formerly made in a small way where sand and lime were cheap and clay and fuel were expensive; but the brick is so weak and friable that it has not given satisfaction, and needs no further consideration here.

The second kind is made from a mixture of sand and lime which is molded in a press and hardened by being subjected to steam under pressure. In this case the binding material consists chiefly of hydrosilicate of lime. Probably part of the lime is converted into carbonate by absorbing carbon dioxide; but the most of the lime combines with the silica of the sand and forms hydrosilicate of lime, a stable and comparatively strong cementing material. This form is the only one to which the term sand-lime brick is now applied; but in consulting the past literature on the subject, a careful distinction should be made between the two forms of so-called sand-lime brick. This form of sand-lime brick was first manufactured in Germany about 1880, and was introduced into America about 1900. There are localities where this form of brick is an important factor in building operations.

Sand-lime brick are made which in appearance and quality are the equal of dry-clay (pressed) brick. The average sand-lime brick will be equivalent in strength to medium clay-brick. When sand-lime bricks are manufactured under standard specifications they may be used as a substitute for clay-brick in masonry construction.

12. Lime and Lime Mortar

Lime Mortar, a mixture of lime paste and sand, is generally used for brick masonry because of its cheapness and the comparative ease with which it is used. There are two classes of lime on the market, high-calcium lime and magnesian or dolomitic lime. The former is made of nearly pure limestone, and the latter of a limestone containing a considerable quantity of magnesia; the latter slakes more slowly, evolves less heat, expands less, sets more slowly, and makes the stronger mortar. The former is known as hot or quick lime, and the latter as cool or slow-setting lime.

The lime must be slaked before being mixed with the sand. Lime is usually slaked by placing the lumps in a layer 6 or 8 in. deep in either a water-tight box or a basin formed in the sand to be used in mixing the mortar, and pouring upon the lumps a quantity of water 2-1/2 to 3 times the volume of the lime. If the quantity of water added is just right, the lime will be reduced to a thick paste; but if too much water is used, the lime will be reduced to a semi-liquid condition and a considerable part of its binding quality will be destroyed.

With a High-Calcium or quick-slaking lime the best results are obtained when all the water is added at once; but with a magnesian or slow-slaking lime only a little water should be added at first, and then after the lime and water are hot, more water may be added gradually so as not to chill the mixture and retard the slaking. The slaking proceeds more rapidly and is more complete if the mass is hot. The lime absorbs the water, and the chemical action generates heat enough to change part of the absorbed water into steam which bursts the lumps of lime apart and thus exposes new surfaces to the action of the water; but if cold water is added after the slaking has begun, it chills the mass, prevents the formation of steam and the consequent bursting of the lumps, and hence the slaking is not complete, and the amount of paste formed is less than it should be. Further, when the slaking has been thus retarded, a thin paste forms on the outside of the fragments of the unslaked lime, which excludes the water from the interior or unslaked portion of the lump; and hence it is difficult, if not impossible, to slake lime thoroughly if it has ever been chilled in the slaking. Partial air slaking is harmful in much the same way, since the slaked lime on the outside of a lump prevents the free access of the water to its interior.

Stirring the lime while slaking chills the mass and thereby retards the slaking; but on the other hand, stirring breaks up the friable lumps and thereby aids the slaking. Therefore if the mass is stirred at all, the stirring should be done in such a manner as to cool the mass as little as possible. The swelling of the lime in the lower portion of the mass frequently lifts some of the lumps out of the water, the heat in the lump causes a column of steam to rise from it, and the lump is said to "burn." This burning is detrimental, since a film of slaked lime is formed on the surface of the unslaked portion which tends to prevent complete slaking. Therefore it is important that lumps which are burning should be pushed back into contact with the water. Burning can be prevented by covering the box with boards or a tarpaulin to retain the heat and the moisture.

Lime slakes spontaneously when exposed to the air by absorbing moisture from the atmosphere; and lime that is thoroughly aid-slaked is as good as, or even better than that slaked in the usual way, a popular prejudice to the contrary notwithstanding. However, lime that is only partially air-slaked is undesirable, since it is more difficult to slake by the ordinary process than lime that is not partially air-slaked.

Slaked lime is sold under the name of hydrated lime. It is a dry powder, and is usually packed in paper sacks. In certain classes of work, hydrated lime is of decided advantage, since it is ready for immediate use without waiting to slake it. For quantities of materials in mortar, see Art. 13.

Mortar. Sand is added to the lime paste for four reasons: (1) to divide the paste into thin films and make the mortar more porous, thus allowing the penetration of air and facilitating the absorption of the carbonic acid which causes the setting of the mortar; (2) to prevent excessive cracking of the mortar owing to shrinkage due to the evaporation of the water in the lime paste;

(3) to give greater strength to the mortar against crushing (practically the only stress that comes upon mortar), since sand has a greater resistance to compression than lime paste either before or after it has set; and (4) to reduce the amount of lime necessary to make a given bulk of mortar, thus decreasing the cost. See Sect. 11, Appendix 4, for the requisites of good sand, and Sect. 11, Appendix 2, for cement mortar which is used in brickwork of the highest class.

After the lime is slaked, the sand is spread evenly over the paste, and the ingredients are mixed with a shovel or hoe, a little water being added occasionally if the mortar is too stiff. The mixing should be thorough, i.e., it should be continued until the mortar is of a uniform color.

To determine whether the proportion of sand is right, hold the hoe handle nearly horizontal and lift up a hoeful of mortar. If the mortar will not of itself slide from the hoe, it does not contain enough sand; and if a hoeful of mortar cannot be thus lifted up, it contains too much sand. The brick-mason on the wall by a somewhat similar process checks the proportions of the mortar by the way in which it slips from the trowel. If there is an excess of sand, the mortar will be "brash" or "short," and will drop from the trowel so abruptly as to make it impossible to "string out the mortar," namely, to spread the mortar over several bricks by simply allowing it to flow from the trowel as the latter is drawn along. On the other hand, if there is an excess of paste, the mortar will not flow from the trowel, at least in sufficient quantity to make the joint. This method of proportioning gives a mortar that works well under the trowel, and with reasonably clean sand also a mortar of practically maximum strength.

If the sand is very fine and contains a good deal of finely pulverized clay, the above test may be satisfied when the mortar contains too little lime; but lime paste is so cheap, and lime mortar is so weak, that a sand with any considerable amount of clay should not be used in lime mortar; since the clay is a source of weakness.

Certain forms of diatomaceous silica, originally developed for use in concrete, are claimed to be beneficial in lime-cement mortars. When this material is added to the mortar, it is said to increase the plasticity and also the strength.

13. Laying Brick

Wetting the Brick. Since most bricks have a great avidity for water, it is best to dampen them before laying. If the mortar is stiff and the bricks are dry, the latter absorb the water so rapidly that the mortar does not set properly, and will crumble in the fingers when dry. Neglect in this particular is the cause of most of the failures of brickwork. Since an excess of water in the brick can do no harm, it is best to drench them thoroughly with water before laying. Lime mortar is sometimes made very thin, so that the brick will not absorb all the water. This process interferes with the adhesion of the mortar to the brick. Watery mortar also contracts excessively in drying, which causes undue settlement and, possibly, cracks or distortion. Wetting the brick before laying will also remove the dust from the surface, which otherwise would prevent perfect adhesion. When the very strongest work is desired, as in brick sewers, it is customary to require that the brick shall be immersed in water for 3 to 5 minutes before being laid. Wetting in the pile is not as effective as immersion, since in the pile the water is not likely to reach all the surfaces of all of the bricks. Masons very much dislike to lay wet brick, since the water softens the skin on their fingers and causes it to wear away rapidly. The softer the bricks the more necessary that they should be thoroughly wet when laid. In freezing weather, care should be taken that the water does not form a film of ice on the brick.

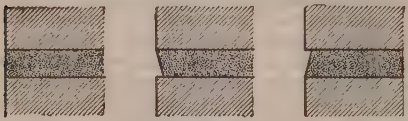
Laying. The bricks should not be merely laid, but every one should be pressed down in such a manner as to force the mortar into the pores of the brick and produce the maximum adhesion. This is more important and also more difficult to accomplish with cement than with lime mortar. The increased value of the cement mortar can be attained only by bringing the brick and the mortar into close contact; and this is more difficult to do, since cement mortar is not as plastic as that made with lime. The mason is apt either (1) to butter the edges of the brick, and thus secure a joint that looks well after the brick is laid; or (2) to place insufficient mortar to make a full bed joint of the required thickness, run the point of his trowel through the middle of the mass, making an open channel with a sharp ridge of mortar on each side, and then lay the brick upon the top of these two ridges, thus leaving the center of the brick unsupported. The first method is the one employed with thin joints, which is a reason why they should not be required; the second method is popular because it requires less exertion and is more rapid than fully bedding the brick.

If strength is a matter of any moment, care should be taken to see that the vertical joints are filled solidly full of mortar; this is called slushing the joints. Unless slushing is insisted upon, masons are apt to butter the end joints, lightly bed the brick, throw a little mortar into the top of the vertical joints, and scrape off the excess above the top of the brick, thus leaving the major portion of the vertical joints open; and sometimes little or no attempt is made to fill the vertical joint between adjacent tiers of stretchers, thus leaving also long and high unfilled vertical spaces. Where resistance to dampness is more important than compressive strength, no particular attempt to fill interior vertical joints is necessary.

For the best work it is specified that the brick shall be laid with a " shove joint"; that is, that the brick shall first be laid so as to project over the one below, both at the end and the side, and be pressed into the mortar, and then be shoved into its final position. Masons are very reluctant to lay brick with a shove joint, partly because it is hard work and partly because many of them have not acquired the art. If brick are not laid with a shove joint, it is highly improbable that the lower part of the vertical joints will be filled with mortar, and consequently the wall will not be as strong or as impervious to water, air and heat as it would otherwise be.

Pointing. In laying inside walls that are to be plastered, the mortar that is forced out when the brick is pressed into position is merely cut off with the trowel; but for outside walls and also for inside walls that are to be left exposed, the joints should be more carefully finished. In laying common brick the mortar in the vertical joints is simply pressed back with the flat face of the trowel; but there are three methods of pointing or finishing the bed joints: (1) flush joints, (2) struck joints, and (3) weather joints.

Flush pointing consists in pressing the mortar flat with the trowel, thus making the edge of the joint flush with the face of the wall (Fig. 35). The struck joint is formed by resting the lower edge of the blade of the trowel upon the edge of the brick below the joint and drawing the trowel along the joint, which smooths the face of the joint and slightly consolidates the mortar, and leaves the joint as shown in the center of Fig. 35. The weather joint is formed as shown in right-hand side of Fig. 35 by pressing the mortar back with the upper edge of the trowel. This form of finish is much more durable than the struck joint, since water will not lodge in the joint and soak into the mortar and on freezing dislodge the mortar; but this form of joint is much more difficult to make, since the mason stands above and back of the brick he is laying. If the weather joint is desired, it must be distinctly specified and the inspector must be watchful to see that it is secured. Brick masonry is usually laid with lime mortar or with lime-cement mortar, the lime giving cohesive strength to the mortar so that enough mortar stays in the joint to permit it to be successfully struck; but when cement mortar or mortar containing but little lime is used, the mortar is so lacking in cohesion that enough does not remain in the joint to permit striking it, and hence with cement mortar it is necessary to formally point the masonry.



Flush Joint *Struck Joint* *Weather Joint*

Fig. 35. Pointing Bed Joints of Common Brickwork

Pressed brick are usually laid with a mortar made of one volume of stiff lime paste (called lime putty) and one volume of fine sand; and when this mortar is used, the brick is buttered, i.e., a little mortar is spread upon only the edges of the brick before it is laid. If the above mortar were spread over the entire surface of the brick, the joint could not be made as thin as is usually specified; but some of the better architects specify thicker joints for pressed work so that the bricks can be laid otherwise than by being buttered. If the mortar is to be spread in the usual way, it should consist of 1 volume of lime paste to about 2 volumes of rather fine sand. Some architects specify 1 volume lime paste, 1 volume portland cement, and 2 volumes of fine sand. Some contractors prefer to substitute at their own expense a rich portland cement mortar and lay thicker joints rather than lay thin buttered joints, since the brick-mason can lay more brick with the former than with the latter.

The joints of pressed-brick work are finished by grooving or beading (Art. 8, Fig. 34), the former being more common. The grooved joint is preferred to the flush joint, because of the variation in light and shade that the former gives to the face of a wall.

Bond is the arrangement of the bricks in successive courses to tie the wall together both longitudinally and transversely. The primary purpose of bond is to give strength to the masonry, but architects employ various longitudinal bonds to improve the appearance of the wall. Although numerous bonds are employed for artistic effect, in the construction of ordinary brick masonry only three bonds are used, the common, the English, and the Flemish. The common bond consists of four to seven (for better work not over six) courses of stretchers to one of headers. The proportionate numbers of the courses of headers and stretchers should depend on the relative importance of transverse and longitudinal strength. The proportion of one course of headers to two of stretchers is that which gives equal tenacity to the wall lengthwise and crosswise. English bond consists of alternate courses of stretchers and headers, and Flemish bond consists of a header and stretcher alternately in each course so placed that the outer end of each header lies on the middle of a stretcher in the course below.

If the wall is more than one brick thick, it should be bonded transversely as well as longitudinally. The exact arrangement of the transverse bond varies with the thickness of the wall, but is easily worked out if a little attention is given to it. The face bond is likely to receive more attention than the transverse bond, and it can be readily inspected after the completion of the wall; but the transverse bond cannot be examined after a course is laid on top of it, and therefore it should be carefully looked after as the work progresses.

The Report of the Building Code Committee of the Dept. of Commerce (June 26, 1924) on " Recommended Minimum Requirements for Masonry Wall Construction " contains many valuable suggestions.

Estimates. The following tables are from "Brick—How to Build and Estimate," published by The Common Brick Manufacturers' Association of America * (1926).

The time required to perform work is based on the average performance of experienced bricklayers and laborers. In some districts where bricklaying is done by men who are not so familiar with the work, the time allowance should be correspondingly increased. Laborer's time includes time for making and handling mortar, handling brick from pile on the ground, waiting on bricklayer, moving scaffold, etc. Laborer's time for cleaning brickwork is not included. Bricklayer's time is given for the average number of brick laid on a small job in a country town. This time may be decreased through good management. On large work and in cities, bricklayers will lay 1500 brick per day (8 hours) on a solid wall, including facing and backing. Under good management, the time for bricklayers given in the table should be considerably reduced. In case the work has many special features, such as pilasters or special patterns, the bricklayer's time should be increased.

* This book also contains other useful information on brick construction.

In figuring the wall area, deduct all openings, using the exact masonry opening. To the cost computed from the table add cost of foreman, rental of hoisting machinery, engineers' time, fuel, special scaffolding, cleaning down, overhead and profit. An allowance should be made in quantity of brick for breakage and waste; in massive work this may be 1 or 2%, for buildings 3 to 5%.

Tables for Estimating Brickwork

	Number of bricks	Cubic feet of mortar	Laborer's time, hours	Bricklayer's time, hours	
				Lime or cement-lime mortar	Cement mortar
I. Piers (1/2-in. joints. All joints filled with mortar).					
8 × 12-*in. solid*—Brick laid flat. Height = 10 ft.	124	2.25	1.	....	1.75
12 × 12-*in. solid*—Brick laid flat. Height = 10 ft.	185	3.25	1.50	....	2.50
12 × 16-*in. solid*—Brick laid flat. Height = 10 ft.	247	4.50	2.	....	3.25
II. Solid Basement Exterior Walls (1/2-in. joints; exterior 4-in. thickness of wall laid with all joints filled. Remaining brick laid on full bed of mortar, but brick touching end to end. Vertical space between each 4-in. thickness filled with mortar. Every fifth course a header course.)					
8-*in. wall*—Surface area = 1000 sq. ft.	12 706	195.	97.	73.	93.
12-*in. wall*—Surface area = 1000 sq. ft.	19 252	314.	149.	110.	140.
16-*in. wall*—Surface area = 1000 sq. ft.	25 797	433.	200.	129.	159.
III. Solid Exterior Walls above Grade (1/2-in. joints, common bond; mortar in joints as per Table II.)					
8-*in. wall*—Surface area = 1000 sq. ft.	12 706	135.	93.	84.	93.
12-*in. wall*—Surface area = 1000 sq. ft.	19 252	195.	140.	128.	140.
16-*in. wall*—Surface area = 1000 sq. ft.	25 797	255.	187.	137.	172.

Tables for Estimating Brickwork—Continued

	Number of bricks	Cubic feet of mortar	Laborer's time, hours	Bricklayer's time, hours: Common bond: Lime or cement-lime mortar	Common bond: Cement mortar	Other bonds: Lime or cement-lime mortar	Other bonds: Cement mortar
IV. Solid Walls. All bonds (1/2-in. joints, all joints filled with mortar. "Other bonds" includes Flemish and English).							
8-*in. wall*—Surface area = 1000 sq. ft.	12 321	195.	95.	90.	99.	104.	110.
12-*in. wall*—Surface area = 1000 sq. ft.	18 482	314.	144.	135.	148.	156.	164.
16-*in. wall*—Surface area = 1000 sq. ft.	24 642	433.	192.	152.	179.	179.	197.

Number of Bricks Laid by One Bricklayer per 8-Hour Day

Class of masonry *	Common bond		Other bonds	
	Lime or cement-lime mortar	Cement mortar	Lime or cement-lime mortar	Cement mortar
I. Piers:				
8 × 12-in.	....	570	....	....
12 × 12-in.	....	590	....	....
12 × 16-in.	....	610	....	....
II. Solid Basement Exterior Walls:				
8 in. thick	1390	1090	....	....
12 in. thick	1400	1100	....	....
16 in. thick	1600	1300	....	....
III. Solid Exterior Walls above Grade:				
8 in. thick	1210	1090	....	....
12 in. thick	1200	1100	....	....
16 in. thick	1507	1200	....	....
IV. Solid Walls:				
8 in. thick	1100	1000	950	900
12 in. thick	1100	1000	950	900
16 in. thick	1300	1100	1100	1000

* See preceding table for joint details.

Quantities of Material for 1000 Cu. Ft. of Mortar

(Based on use of good quality lime. Lime quantities are approximate and will vary with the grade of lime and the size of particles composing the sand. In cement mortars, 1/10 of the cement by weight is replaced by dry hydrated lime or its equivalent in lump-lime paste.)

Mortar	Lump lime, 180-lb. bbl., number of bbl.	Hydrated lime, 50-lb. sacks, number of sacks	Cement, 94-lb. sacks, number of sacks	Sand, cu. yd.
Lime mortar:				
1 : 2-1/2	57	350	....	37
1 : 3	47	292	....	37
Cement-lime mortar:				
1 : 1 : 6	24	146	130	37
Cement mortar:				
1 : 2	16	92	442	34
1 : 3	12	69	331	39
1 : 4	10	55	264	41

In using the above tables, the following points should be considered: (a) Locality has much influence upon the number of brick laid per man. In the small communities, especially in the South, the number of brick laid may be 50 to 60% higher than those laid per man in the large cities of the East. This is influenced also by the available supply of bricklayers. (b) The quality of the brick has a material bearing. Rough, poorly shaped brick are laid at a slower rate than uniform, well shaped brick. (c) The proper and commonly employed method of laying brick is to " butter and shove." In some places only the outside brick are so laid; the others are simply placed and slushed. The latter method results in laying about 50% more brick, but produces a weak wall. (d) The table does not cover special work such as small window arches, small offsets, etc. Engineers generally over-estimate the rate of laying such work. It is thought that in general the rate of doing this special work is about one-third of that given in the above tables. (e) The time of year in which brick are laid seriously affects the rate of laying. When the temperature is below 20° F. all materials should be heated and the work protected against frost. Men wearing gloves and mitts lay only about 50% the usual amount.

14. Efflorescence *

Efflorescence is a white deposit which may occur on the surface of any masonry wall, and which is caused by the crystallization of soluble salts brought to the surface by moisture in the masonry. These salts may have been in any or all of the masonry materials in the wall—in facing, backing, or mortar. The moisture may have entered the wall during construction through exposure to rain or snow; or it may have entered after the wall was completed, from the earth at the base, from improperly flashed parapet walls at the roof, from leaking gutters and downspouts, from lack of drips on cornices and sills, or from poorly filled or cracked mortar joints in the wall.

" Once in the wall, the moisture dissolves some of the salts present, and later passes to the surface when conditions become favorable. When evaporation takes place, the salts are left behind on the wall as efflorescence. No masonry material is always exempt from contributing to the development of noticeable efflorescence, but some materials contain much larger quantities of soluble salts than others, and consequently are much more important sources of trouble."

* This article is based largely on " Wet Walls and Efflorescence," by L. A. Palmer, Research Associate, National Bureau of Standards, and published by American Face Brick Assn., 1928.

"Prevention of efflorescence must begin with the design of the building, follow through the selection of materials and the methods of work during the construction period, and continue with maintenance of the structure after its completion. The neglect of certain simple precautions may bring very unsatisfactory results."

The most important precaution is to prevent moisture from entering the wall, either during construction or later. This precaution will also aid in preventing disintegration of the masonry through the freezing and thawing of the moisture, and the undesirable effects of damp interiors.

"The presence of soluble salts in clay products can be practically eliminated by the manufacturer by certain procedures in the drying and burning of the ware, together with the judicious use of barium compounds in the clay." The resultant increase of cost renders this procedure impracticable in the manufacture of the less expensive building products, though it has been generally used in the face brick industry. "From the standpoint of efflorescence it is therefore very essential that the backing-up materials be protected from excessive water penetration."

One of the important sources of efflorescence is free lime, which occurs in the lime mortar and also in cement. The development of efflorescence from the mortar may be largely prevented by the use of water-repellent materials, especially calcium or ammonium stearate (2% by weight of the cement and lime used in the mortar).

"Mortars so treated are effective in preventing the passage of moisture where only capillary forces obtain. Calcium stearate is a powder which is mixed dry with the cement before adding sand and water, while ammonium stearate is a paste which is usually added to the mixing water. On the ordinary building job the powder has proved the more practical and accurate to use with the equipment commonly available. Although best practice would call for the use of stearate in mortar for backing as well as facing materials, it is especially important that it be employed in laying up the facing where the joints will be subjected to unusual exposure to driving rains or to water running down the surface of the wall."

Joints of copings, window sills and parapet walls are all in need of special care, as well as the repointing of joints that have cracked.

"Specific recommendations that will help in preventing water from entering the wall: Use impervious copings, and point joints carefully with water-repellent mortar. Flash parapet walls, carrying the flashing completely through the wall one or two courses above the roof level, and waterproof the entire inner side of the wall. Always provide adequate drips on all copings, cornices and window sills, making the grooves at least 5/8 in. wide and 3/8 in. deep; and provide projections of 2 in. or more so as to keep the drip away from the wall. Where practical avoid all joints in sills. If brick sills are used, flash under them with metal flashing provided with drips. Protect walls under construction to prevent rain or melting snow from entering. Keep gutters and downspouts in good repair. Point up cracked joints promptly. Coat the backs of retaining walls with an impervious layer, and keep brick building walls away from contact with the earth."

In concrete construction, give particular care to grading of the aggregate, proper consistency, using a minimum amount of water, compacting to get density without too much cement, and careful curing. The use of chemicals may be helpful but cannot be considered a substitute for these precautions.

"Any efflorescence appearing on the wall of a building that is suitably designed, constructed and kept in repair in order to prevent excessive water penetration, will be due to rare and abnormal conditions. It should in time gradually diminish and finally disappear. Prolonged and heavy wind-driven rains will bring out efflorescence on almost any wall, but this is generally of short duration."

Efflorescence may be partially removed by water, and sometimes is easily brushed off. Where special treatment is necessary, the wall should first be washed down with water, then treated with a dilute solution of hydrochloric acid (3 parts to 100 parts of water), and finally washed thoroughly with water.

No great success has been met with the use of washes in waterproofing exposed surfaces; but any wash that will prevent the saturation of the brick and mortar from driving rains should be helpful in decreasing the amount of efflorescence. Such a moisture-proof coating should be applied after the mortar and bricks have dried out.

The writer wishes to emphasize the fact that great care should be taken in the use of calcareous (shell) sand for mortar or concrete. Some calcareous sands give a weaker mortar and one that is more porous and therefore more liable to effloresce. If in doubt use a thicker covering over reinforcing steel for concrete subject to salt water or salt air, or protect the finished concrete by the use of waterproofing materials.

DATA FOR MASONRY DESIGN

15. General Discussion

Stone Masonry. The strength depends upon the strength of the stone, accuracy of dressing and bedding, proportion of headers to stretchers and upon the thickness of the mortar joints and the strength of the mortar. However, the strength of the stones need be given little consideration if they are sound and durable unless the masonry is of the best grade of ashlar and is subjected to high unit stresses. The relative strength of mortar has greater effect especially in rubble masonry, where the joints are usually large and the amount of mortar relative to the total volume of masonry is high.

Unfortunately, the bulk of existing masonry structures throughout the world were built prior to the time when analytical study was possible and when ultra-conservatism was necessary. Therefore the older structures give little indication of safe unit stresses.

Few tests have been made upon stone masonry which give conclusive evidence of the ultimate strength of masonry in actual structures. We are therefore more or less dependent upon actual or computed stresses in actual structures of record. Considerable light, however, is given by experiments made upon brick piers with lime and cement mortar which indicate that the strength of the masonry is much less than the strength of the individual bricks. An increase of 50% in the strength of the brick produces no appreciable effect upon the strength of the masonry; but the substitution of cement mortar for lime mortar increases the strength of the masonry as much as 70%. In stone masonry, and usually in brick, the mortar is the weaker material and therefore the less used the stronger the masonry. Therefore masonry of large dressed blocks with thin joints (ashlar) is stronger than rubble.

The following table shows how difficult it is to predicate design upon existing structures:

Name and location	Short tons per sq. ft.	Pounds per sq. in.
Church of All Saints, Angers, France	43	600
Pont-y-Prydd, stone arch bridge, Wales (1750), hard limestone rubble in lime mortar	72	1000
Saltash Bridge, granite piers	9	125
Brooklyn Bridge, granite masonry	28.5	400
Brooklyn Bridge, limestone masonry	10	140
Washington Monument, dead load	19.8	275
Washington Monument, with wind load	25.4	350

The Washington Monument is faced with marble, the backing being granite. Joints in the marble were about 1/4 in. The joints in the backing were probably thicker and the greater amount of strain in these joints in the lower part of the shaft caused an excessive load to come on the facing. As a result, the facing joints have been almost squeezed tight together, and the pressure tends to chip off the edges of the marble blocks.

Brick Masonry. The allowable pressure upon brick masonry depends upon:

1. The quality of the materials employed.
2. The thickness of the mortar joints and the degree of care with which the work is executed.
3. The accuracy with which the load upon the masonry could be or was estimated.

Referring to the second statement, in some sections of the country bricklayers carefully "butter" each brick and "shove" the joint "hard." In other sections they lay the brick in the wall and "slush" them. The writer cannot state from actual test the relative value of two walls or piers so built, but he is much afraid that the latter method decreases the strength materially. Partly as a result of this, bricklayers at some localities lay only 500 brick per day in a straight wall and in other points they will lay nearly 2000. The amount of brick laid, however, per man day is equally affected by local labor conditions.

Examples of Pressures in Brick Structures

	Short tons per sq. ft.	Pounds per sq. in.
American Surety Building, N. Y., brick piers........	7.25	100
Chimney at Glasgow, 468 ft. high, dead load.........	9	125
Chimney at Glasgow, 468 ft. high, with wind.........	15	210

The U. S. Bureau of Standards made tests on brick piers, 2.5 ft. square by 10 ft. high (Technologic Paper No. 111, 1918), which led to the following conclusions regarding brick masonry:

1. Primary cause of failure is transverse failure of individual bricks.
2. Ultimate strength may be increased by any method of construction which will increase the depth of the component parts of the pier, as by laying the bricks on edge instead of flat, breaking joints every few courses instead of every course, or using bricks of more than ordinary thickness.
3. Strength may be increased by the introduction of wire mesh in all horizontal joints.
4. Varying the number of header courses does not appreciably affect the ultimate strength.
5. Mortar joints should be made as thin as possible and of uniform thickness, and regularity in shape of the bricks is essential.
6. Ultimate strength of brick masonry is proportional to the compressive and transverse strength of the bricks used. (The writer is of the opinion that this is true only for bricks of medium strength, because with the harder and stronger varieties of brick it has been demonstrated that the strength of the masonry is more dependent upon the strength of the mortar and the thickness of the joints.)
7. The kind of mortar used has an important effect on the strength of brick masonry. Pure lime mortar is inefficient under high stress. In 1 : 3 portland cement mortar, 25% by volume of the cement may be replaced by hydrated lime without appreciably affecting the strength of the masonry.

16. Working Unit Stresses

Maximum Safe Unit Stresses for masonry design are given in the following tables. The values are based upon good material and workmanship in accordance with the best practice. It is assumed that the masonry is to be properly bonded and the mortar ingredients suitably tested, also that the foundation is properly designed to carry all the forces which the masonry transmits to it. The masonry is assumed to be laid in mortar of the following proportions:

Cement mortar—1 part portland cement to 3 parts sand.
Lime and cement mortar—1 part portland cement, 1 part lime and 6 parts sand.
Lime mortar—1 part lime paste to 4 parts sand (hydrated lime may be added to cement mortar, up to 15% of the cement by volume).

The unit stresses given are for masonry which is at least two months old if laid in warm weather and six months old if laid when the temperature is below or near freezing.

For large structures, such as dams over 70 ft. high and arches over 150 ft. in span, or in a series of arches where the amount of masonry is great and where each unit of masonry is dependent for its stability upon each and every other unit, it is advisable to use lower working unit stresses than those in the tables. For such cases it is recommended that 75% of the tabulated values be employed.

If, for special reasons, it is desirable to consider masonry laid in warm weather one month old, or that laid when the temperature is below or near freezing, two months old, it is best to use 60% of the values given in the tables.

Ashlar Masonry. The following are safe working compressive stresses recommended to be used in the design of structures of ashlar masonry laid in 1 : 3 portland cement mortar with joints not exceeding 1/2 in. in width. With lime-cement mortar, use 75% of these stresses.

Kind of ashlar	Pounds per sq. in.	Short tons per sq. ft.
Granite, syenite, gneiss	700	50.4
Limestone, hard	600	43.2
Limestone, medium; marble	500	36.0
Limestone, soft; sandstone	400	28.8

For ashlar laid with 1 : 3 portland cement mortar, and having joints greater than 1/2 in. and less than 1 in., it is best to use 450 lb. per sq. in. (32.4 tons per sq. ft.) for all kinds of sound building stone.

For ashlar laid in lime mortar with joints not exceeding 1/2 in., it is best to use 225 lb. per sq. in. (16.2 tons per sq. ft.) for all kinds of sound building stone.

For ashlar laid in lime mortar with joints greater than 1/2 in. and less than 1 in. it is best to use 150 lb. per sq. in. (10.8 tons per sq. ft.) for all kinds of sound building stone.

For Brick Masonry in portland cement mortar, with joints not exceeding 3/8 in., the following working unit stresses are recommended:

	Pounds per sq. in.	Short tons per sq. ft.
For hard, best quality clay brick	300	21.6
For hard to medium clay brick and for sand-lime and concrete brick	250	18.0

For brick masonry in lime-cement mortar, use 75% of these values. For brick masonry in lime mortar use 50% of these values. If the bricks have been tested and show a uniform ultimate compressive strength of at least 7000 lb. per sq. in., and they are laid with great care in portland cement mortar, the safe working compressive strength may be taken at 400 lb. per sq. in. (28.8 tons per sq. ft.). Masonry of soft brick should not be used except for abnormally light loads, its safe working compressive strength being taken at 40 lb. per sq. in. (2.9 tons per sq. ft.).

For Hollow Tile, Concrete Block or Concrete Tile Masonry, the following working compressive stresses are recommended: With portland cement mortar, 80 lb. per sq. in. gross sectional area; with cement-lime mortar (1 : 1 : 4), 70 lb. per sq. in. gross area.

For Rubble Masonry laid in portland cement mortar, the following working compressive unit stresses are recommended:

Kind of rubble	Pounds per sq. in.	Short tons per sq. ft.
Flat or scabbled stones	250	18.0
Irregular stones, not scabbled	200	14.4
Very irregular stones (field stones)	100	7.2

For rubble masonry in lime mortar about 50% of the preceding values should be used as working unit stresses.

For Plain Concrete Masonry made with portland cement the following safe working compressive stresses in pounds per square inch are recommended: 450 for 1 : 2 : 4 concrete, 350 for 1 : 3 : 6, and 250 for 1 : 4 : 8.

The above unit stresses apply to compression from static loads, and do not apply to masonry where only a small portion of the area is under direct compression as under the footings of steel columns. (See Art. 22, Fig. 59*a*.) For shocks lower values should be used. Under bed plates of steel bridges use 50% of above values.

The Working Shearing Unit Stress for all stone masonry should be taken as one-quarter of the working compressive unit stresses above given. For concrete masonry experiments have shown that it may be taken as 30% of the compressive working stress provided diagonal tension does not accompany the shear or is properly provided for by steel reinforcement.

For Stone Slabs or single blocks of stone, the following working unit stresses are recommended, all being in pounds per square inch:

Kinds of stone	Compression	Tension*	Shear	Weight, lbs. per cu. ft.
Granite, syenite, or gneiss		150	200	170
Hard	1500			
Medium	1200			
Soft	1000			
Limestone		125	150	165
Hard	1000			
Medium	800			
Soft	700			
Marble		125	150	165
Hard	900			
Soft	700			
Sandstone	700	75	150	150
Blue stone flagging	1500	200		

* Values in this column apply to both direct and flexural tension.

If the shearing stress occurs without diagonal tension, the working shearing unit stress may be taken at 4/10 of the working compressive unit stress, but with detached blocks and slabs of stone shear is almost always accompanied by diagonal tension.

Tension, whether direct or flexural, should not occur in stone masonry, and working tensile unit stress should be taken as zero in the computations of designing. In the analysis of existing structures, where the mortar is found to be strong and adhesive, a tensile unit stress of 15 lb. per sq. in. may be allowed for masonry laid in portland cement mortar, 10 lb. per sq. in. for that in natural cement mortar and 5 lb. per sq. in. for that in lime mortar.

The resistance of masonry joints against tension is often wholly or partially destroyed by erection stresses, by shrinkage of the mortar in setting, and by expansion and contraction of the mass under changes of temperature. The mortar in the vertical joints, as a rule, wholly loses its adhesion from these causes. The mortar of the bed joints, however, sets under pressure and hence is more or less available to transmit tension. Since the shrinkage of mortar is less below ground, due to ground moisture and a uniform temperature, and since expansion and contraction are also less, masonry below ground is stronger in tension than that in air.

When it is necessary to build masonry to take tension, either direct or flexural, special care should be given to the bond. In the design of concrete footings a tensile unit stress not to exceed 8% of the safe compressive unit stresses may be allowed.

Allowed Working Compressive Stresses in Pounds per Square Inch, for Masonry, According to Building Laws

Kind of masonry	New York 1925	Philadelphia 1927	Baltimore 1924	Washington 1925	Buffalo 1926	Detroit 1926	Kansas City 1927	New Orleans 1927	Denver 1926	San Francisco 1926
Ashlar (portland cement mortar):										
Granite	600	.....	1000	800	.....	.....	600	600	800	389
Limestone	600	.....	600	500	.....	.....	600	600	500	.....
Sandstone	300	.....	400	500	.....	.....	300	300	400	.....
Rubble masonry:										
Portland cement mortar	140	139	125	.....	125	139	170	140	140	.....
Natural cement mortar	110	.....	.....	.....	.....	.....	.....	.....	100	.....
Lime-cement mortar	100	111	100	.....	97	97	120	105	100	.....
Lime mortar	.....	70	60	.....	70	70	70	70	70	.....
Brickwork:										
Portland cement mortar	250	208	150	170	250	208	225	175–450	170	208
Natural cement mortar	210	.....	.....	.....	.....	.....	175	.....	130	.....
Lime-cement mortar	160	167	.....	130	195	153	175	130–340	.....	139
Lime mortar	110	111	110	.....	125	97	120	90–225	90	97
Plain concrete:										
(1 : 2 : 4; portland cement)	500	208	500	400	348	111	500	By test	400	278

In design of structures to be built in cities, the unit stresses permitted by the building codes must be considered.

17. Unit Weights and Other Constants

Unit Weights of Masonry are slightly less than those of the materials of which it is composed. Average values are given in the accompanying table; the third column also gives the approximate moduli of elasticity and the fourth the coefficients of expansion for one degree Fahrenheit (based on using cement or cement-lime mortar).

Physical Properties of Masonry

Kind of masonry	Weight, lb. per cu. ft.	Modulus E, lb. per sq. in.	Coefficient *e* of expansion
Ashlar: granite, syenite, gneiss	165	4 000 000	0.000 0035
Limestone, marble	160	4 000 000	0.000 0035
Sandstone	140	4 000 000	0.000 0035
Mortar rubble: Granite, syenite, gneiss	155	2 000 000	0.000 0035
Limestone	150	2 000 000	0.000 0035
Sandstone	130	2 000 000	0.000 0035
Dry rubble: Granite, syenite, gneiss	130	....	....
Limestone	125	....	....
Sandstone	110	....	....
Brick: Pressed, thin joints	140	2 000 000	0.000 0030
Common, 3/8-in. joints	120	2 000 000	0.000 0030
Soft, 3/8-in. joints	100	....	....
Concrete: Broken stone, 1 : 2 : 4	145	2 500 000	0.000 0060
Broken stone, 1 : 3 : 6	145	2 000 000	0.000 0060
Cinder	110	....	....
Cyclopean: Masonry with maximum volume of stone	155	....	....

Slabs or detached block stone have values of E much higher than those in the table. Approximate values are 7 000 000 for granite, syenite and gneiss, and the harder limestones; 8 000 000 for hard marble; 5 500 000 for soft limestone; 2 800 000 for sandstone. Coefficients of expansion are 0.000 0040 for the granitic rocks, 0.000 0037 for limestone and 0.000 0050 for sandstone.

Values in the last two columns are used in investigating the temperature stresses which may come upon masonry arches (Art. 40) and for computing their deformations.

Weights of Other Materials which may bring pressure upon masonry walls and arches are given in the next table, in pounds per cubic foot.

Weights of Miscellaneous Materials

Sand, dry clean	90	Cinders, bituminous, dry compact	45
Sand, wet	115	Ashes, anthracite, dry compact	30
Gravel, clean	100	Paving in place:	
Broken stone	100	Asphalt top and binder	107
Clay, dry, compact	100	Asphalt block	145
Clay, plastic	100	Granite block	155
Sand, gravel, and clay, mixed:		Wooden block	50
Dry, compact	100	Brick	140
Wet	115	Macadam	105
Mud	110	Water, fresh	62.5
Rock, rotten, soft compact	110	Water, salt	64
Rock, hard, loose	100	Snow, fresh	8

The weight of snow to be used in designing is generally assigned by specification, as is also the lateral wind pressure, the latter being usually 30 lb. per sq. ft. of vertical surface.

The Slope of Repose of a bank of loose earth, in its natural state, is a factor which governs the lateral pressure which the earth may bring to exert against a retaining wall. In the next table the slope is the ratio of horizontal to vertical projection. It will be noted that the weight per cubic foot of filling material generally varies between narrow limits when the slope of repose varies between wide limits.

Slopes of Repose and Weights for Loose Earth

Kind of earth	Slope of repose	Angle of repose	Weight, lb. per cu. ft.
Sand, clean	1.5 to 1	33° 41′	90
Sand and clay	1.33 to 1	36 53	100
Clay, dry	1.75 to 1	29 44	100
Clay, damp, plastic	3 to 1	18 24	100
Gravel, clean	1.33 to 1	36 53	100
Gravel and clay	1.33 to 1	36 53	100
Gravel, sand and clay	1.33 to 1	36 53	100
Soil	1.5 to 1	33 41	100
Soft rotten rock	1.33 to 1	36 53	110
Hard rotten rock	1 to 1	45 00	100
Bituminous cinders	1 to 1	45 00	45
Anthracite ashes	1 to 1	45 00	30

The Angle of Repose given in the third column of this table is the angle ϕ which the sloping face of a bank of loose earth makes with the horizontal (Fig. 36). The cotangent of this angle is the slope ratio given in the second column; thus, 1.5 is the cotangent of 33° 41′. In general, if s is the slope of repose, or the ratio of horizontal to vertical projection, and ϕ the angle of repose, then $s = \cot \phi$. The term "natural slope" is sometimes used as synonymous with "slope of repose." The tangent of this angle is the coefficient of friction for earth upon earth, or $f = \tan \phi$ (Art. 18).

In the theory of retaining walls (Art. 19), the coefficient of friction along planes not on the surface but within the mass of the backing material is of interest. The angle corresponding to this coefficient is termed the angle of internal friction.

It has been found by experiment, that, for non-cohesive materials, the angle of internal friction is generally larger than the angle of repose given for loose earth in the above table, but, in determining the theoretic pressure upon retaining walls, the values of ϕ given in this table are recommended and are on the safe side. Non-cohesive materials, such as dry sand, gravel, broken stone, cinders, etc., consist of granular particles and resist shearing forces through friction only. Attention is called to the fact that the experiments of Jacob Feld show the angle of repose is the greater.

In the case of cohesive backing materials, such as clays which possess a degree of shearing (cohesive) strength, the angle of internal friction is considerably smaller than the angle of repose given in the above table and varies from 0° to 16°. The following table (used in Art. 19) was taken from A. L. Bell's paper (Proc. Inst. C. E., 1915):

Cohesive Strength and Angle of Internal Friction in Clays

Description of material	Cohesive strength lb. per sq. ft. c	Angle of internal friction ϕ_1
Puddle clay, wet	400–900	0°–2-1/2°
Stiff clay puddle	1200	2°
Sandy clay, wet	1200	2-1/2°
Stiff sandy clay	1000	10°
Moderately firm boulder clay	1400	6-1/2°
Very stiff, boulder clay fairly dry	3800	16°

For sand, the cohesive strength is very small, probably not more than 10 lb. per sq. ft., and should be entirely disregarded in practical design.

Material Excavated by a wet or a dry process, and dumped into water, as at the back of a sea wall, has submerged weights and slopes approximated as follows:

Material	Slope of repose	Angle of repose	Weight, lb. per cu. ft.
Sand, clean	2 to 1	26° 34′	60
Sand and clay	3 to 1	18 26	65
Clay	3-1/2 to 1	15 57	80
Gravel, clean	2 to 1	26 34	60
Gravel and clay	3 to 1	18 26	65
Gravel, sand and clay	3 to 1	18 26	65
Soil	3-1/2 to 1	15 57	70
Soft rotten rock	1 to 1	45 00	65
Hard rock, riprap	1 to 1	45 00	65

When the material is excavated by suction dredging and pumped back of a retaining wall which has inefficient drains to carry off the water, the weight per cubic foot may be taken at 110 lb. and the slope of repose as 2 to 1 for sand and clay, clay and gravel, or clay, gravel, and sand combined. River mud in situ may be taken at 100 lb. per cu. ft. with a slope of 3 to 1. If pumped back of wall, use 100 lb., with slope of 10 to 1. For fills placed by hydraulic dredge, see Sect. 8, Art. 26.

18. Data Regarding Friction

The Law of Friction for one stone beginning to move on another along their plane of contact is $F = fN$, in which F is the force parallel to the plane, N is the normal pressure on the surface of contact, and f is the coefficient of friction. Fig. 37 shows a stone about to move along a surface inclined to the horizontal at the angle ϕ, the conditions being exactly the same as those seen in Fig. 36 for a particle of earth on the face of a sloping bank. In both cases $F = fN$ and $f = \tan\phi$, where ϕ is the angle of repose, which in the case of stone surfaces is often called the "angle of friction." When the plane of contact is horizontal, as in Fig. 38, motion is about to begin when the resultant force R against that plane makes with the normal an angle ϕ such that $\tan\phi = f$. The angle of repose ϕ and the coefficient of friction f depend upon the roughness of the surface of contact.

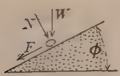


Fig. 36

Fig. 37

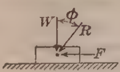

Fig. 38

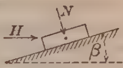

Fig. 39

The following table assumes that the surfaces of the stones are rougher than rubbed work, that is, they are for fine-pointed, bush-hammered, crandalled or sawed surfaces, while the wood surfaces are those of undressed yellow pine. For rubbed surfaces of stone the angles of repose are about 5° less than those given, and for polished stone about 10° less.

Moisture usually increases the angle ϕ, so that wet wood has a larger value than dry wood. For stone surfaces with fresh wet mortar between them, the angle ϕ is about 5° less than that in the table, the value given corresponding to the consistency generally used.

Arch Masonry built upon timber centering has usually a greater angle of friction than given in the table, due to mortar setting between adjacent pieces of lagging; in the case of concrete there is also a mechanical bond with the lagging, since when the lagging is removed the imprint of the grain can always be seen upon the concrete surface.

When a plane makes with the horizontal an angle β less than ϕ, the horizontal force H (Fig. 39) which is required to slide a body up the plane is $H = fN(\cos\beta - f\sin\beta)$, in which N is the pressure normal to the surface. This formula gives also the horizontal force required to slide the body down the plane, if the minus sign be changed to plus.

Coefficients and Angles of Friction

Kind of surface	Coefficient of friction f	Angle of friction ϕ
Granite, Limestone, Marble:		
Soft dressed upon soft dressed	0.70	35° 00′
Hard dressed upon hard dressed	0.55	28 50
Hard dressed upon soft dressed	0.65	33 00
Stone, brick or concrete:		
Masonry upon masonry	0.65	33 00
Masonry upon wood (with the grain)	0.60	31 00
Masonry upon wood (across the grain)	0.50	26 40
Masonry upon dry clay	0.50	26 40
Masonry upon wet or moist clay	0.33	18 20
Masonry upon sand	0.40	21 50
Masonry upon gravel	0.60	31 00
Soft stone upon steel or iron	0.40	21 50
Hard stone upon steel or iron	0.30	16 40

Values of the coefficient of friction given in this table are approximate, and in any actual case may vary within ± 30% of the figures given.

The angle of friction is materially lessened by jar, shock, or vibration caused by blasts, the passage of trains, or motion of attached machinery. For such cases it is recommended that in masonry design the angles of friction be taken as 5° less than those in the table and that the coefficients of friction be likewise modified by the relation $f = \tan\phi$.

For clay foundations it is best to use the values given for wet clay, unless it is reasonably certain that water cannot reach the bed.

19. Lateral Pressure of Earth

Conditions Affecting Earth Pressure. A wall backed with earth is subject to a lateral pressure which tends to overturn it as well as to cause it to slide. The amount of the pressure depends on the density of the earth, and on the internal friction and cohesion that may be developed in the earth and therefore to some extent on the water content.

Many attempts have been made by experiment and theory to determine the direction, magnitude and point of application of the resultant lateral pressure upon the back of a retaining wall so that the design of such walls may be made with precision. The materials used in filling behind walls and the methods and conditions of deposit are variable and it is difficult to determine with any degree of precision the characteristics which would permit the correct use of theory. However, even though only approximate results are obtainable no retaining wall should be designed without the application of theory to determine the distribution of pressures upon the foundation. The failure of retaining walls has generally been due to insufficient foundations, insufficient drainage permitting accumulation of water behind walls or neglect to consider surcharge. (See Art. 26.)

The Pressure on Trench Sheeting follows different laws from those applying to retaining walls. These laws are discussed in Sect. 8, Art. 4.

Earth Pressure Theories. Two principal theories have been proposed for the computation of earth pressure on retaining walls: (1) the "wedge theory," developed chiefly by Coulomb, and (2) the elastic or Rankine theory. All the theories assume that the backing material is of uniform granular consistency without cohesion, that the angle of internal friction is the same at every point in the mass, and that the pressure intensities increase uniformly with the depth (as shown by the arrows in Fig. 40).

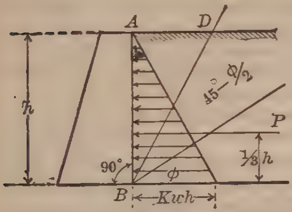

Fig. 40

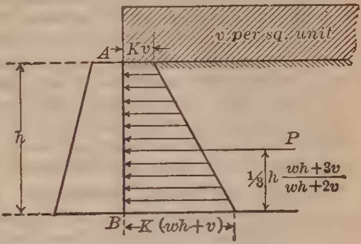

Fig. 41

Rankine's theory of earth pressure upon the back of retaining walls has been most commonly used. It is based on principles of elasticity applied to granular materials, the pressure being determined by means of the ellipse of stress. Coulomb's theory assumes that the maximum thrust on the wall is exerted by a wedge of the backing materials, this wedge being bounded on one side by the back of the wall and on the other side by a plane called the "plane of rupture" (Fig. 42) upon which the wedge tends to slide as the retaining wall is strained under the pressure. Experiments have shown that there is no actual motion on a plane of rupture, the concept of such a plane being useful only for purposes of analysis. However, it has been found that loads on the fill beyond the wedge have practically no effect on the lateral pressure. Actually, if the wall should fall over, the soil would break down with a concave surface rather than on a plane, the upper end of this surface of rupture approaching a vertical direction in many materials.

If cohesion is acting, the true earth pressure will be less than indicated by the theory. The extent to which the actual pressure will correspond to that derived from these theories depends on how homogeneous the filling material is, and upon its compactness and cohesion. As these factors are very uncertain, and quite variable in any given location, no attempt will be made here to include the influence of cohesion in the theoretical analysis. (For theories including cohesion, see "Stresses, Graphical Statics and Masonry," by G. F. Swain, 1927.)

Engineers interested in the pressure of earth on sheet piling should consult "Erddruck, Erdwiderstand," by H. Krey, published by Wilhelm Ernst & Son, Berlin, 1926. So far as the writer knows, this book has not been translated. It is one of the few books giving any information upon the pressures existing below the bottom of a retaining wall or sea wall that will enable one to determine the proper length of sheet piling to be driven below the bottom of the wall, or the weight of riprap to be placed in front of the wall, to prevent any blow-out of the material under the wall.

Direction of Earth Pressure. Different authorities make different assumptions as to the direction of the earth pressure acting on the back of retaining walls. Rankine makes the direction dependent on the slope of the retained bank and on the inclination of the back of the wall. Coulomb's theory gives the direction of the earth pressure upon the back of the wall as between the horizontal and a downward pointing line making an angle with the normal to the back of the wall, this angle not exceeding the angle of friction of earth on masonry.

Experiments made to determine the direction of earth pressure have shown considerable divergence in results. The most recent tests, however, indicate that the resultant pressure may be inclined downward to the wall, deviating from the normal by an angle equal to the angle of friction between the fill and the wall, thus agreeing with Coulomb. The amount of this possible friction is likely to be reduced, however, due to seepage of water behind the wall. For conservative design, therefore, the effect of friction on the back of the wall should be neglected; and the following assumptions are recommended:

(1) In all walls, regardless of whether or not the back of the wall is vertical or inclined, the pressure is assumed to be horizontal.

(2) In walls with backs inclined away from the fill (Fig. 44) the weight of the fill *ABL* resting upon the back should be regarded as part of the wall.

Magnitude and Point of Application. Formulas have been deduced giving the magnitude of the resultant earth pressure for all inclinations of the back of the wall and slope of the bank. Rankine and Coulomb agree as to the formula given below for the magnitude of the lateral pressure of level banks upon walls with vertical backs. Formulas for other conditions are complicated and for these, Rebhann's graphical method, based on Coulomb's theory, is hereafter given and is recommended. It gives results practically in accord with Rankine and is more simple. In the following a slice of wall of unit length will be considered.

Wall with Vertical Back. Level Bank. For conditions shown on Fig. 40, let w be the weight of the earth per cubic unit; ϕ its angle of repose, and h the height of the wall. The magnitude of the resultant earth pressure is

$$\mathbf{P} = 1/2\ wh^2 \frac{1 - \sin\phi}{1 + \sin\phi} = 1/2\ wh^2 \tan^2 (45° - \phi/2)$$

For a similar wall, but with the bank uniformly loaded with a weight v per unit of surface (Fig. 41)

$$\mathbf{P} = (1/2\ wh^2 + vh) \tan^2 (45° - \phi/2)$$

For a backing of clay, denoting the value of the cohesional resistance per unit surface by c and the angle of internal friction by ϕ_1 (Art. 17), Bell proposes the following formula for the resultant lateral pressure.

$$\mathbf{P} = 1/2\ wh^2 \tan^2 (45° - \phi_1/2) - 2ch \tan (45° - \phi_1/2)$$

In these formulas P is expressed in the same unit of weight as w and v.

ϕ	$\text{Tan}^2\left(45° - \frac{\phi}{2}\right)$	ϕ	$\text{Tan}^2\left(45° - \frac{\phi}{2}\right)$	ϕ	$\text{Tan}^2\left(45° - \frac{\phi}{2}\right)$
0°	1.000	20°	0.490	40°	0.218
5	0.840	25	0.406	45	0.172
10	0.703	30	0.333	50	0.132
15	0.589	35	0.271		

Intensity and Point of Pressure Application. In the value of P, $1/2\ wh^2$ and $(1/2\ wh^2 + vh)$ represent the magnitude equivalent to a hydrostatic pressure resulting from a head h of a fluid weighing w per unit volume and loaded with v if any; **tan**^{2} ($45° - \phi/2$) is the ratio of the true lateral pressure of earth to the hydrostatic pressure and is a constant for the same material. It is a fraction which increases when ϕ decreases; in other words, the flatter the angle of repose the greater the thrust. Denoting this ratio by K, the earth pressure P in the case of an unloaded bank is $1/2\ wh^2\ K$ which is equal to the area of a triangle of height h and base Kwh (Fig. 40); in the case of a loaded bank $P = (1/2\ wh^2 + vh)\ K$ which is equal to the area of a trapezoid of height h, the upper side equal Kv and the base equal $K\ (wh + v)$ (Fig. 41). Horizontal lines drawn in these diagrams will represent the intensity of the earth pressure at any point of the back of the wall. The resultant earth pressure will pass through the center of gravity of the intensity diagrams, its distance from the base, therefore, being **h/3** for the unloaded bank and **h/3 (wh + 3v)/(wh + 2v)** for the loaded bank. This latter value is greater than **h/3**, but the most excessive load cannot raise it as high as **h/2**. Jacob Feld has shown (Trans. A. S. C. E. Vol. 86, pg. 1448) that the resultant pressure generally acts at a distance from the base greater than $h/3$, but not more than $.4h$ for an unloaded fill. The ratio of this distance to the height of the wall tends to increase as the wall becomes higher.

Graphic Determination of Earth Pressure. In an embankment made of granulous material possessing friction but no cohesion and supported by a

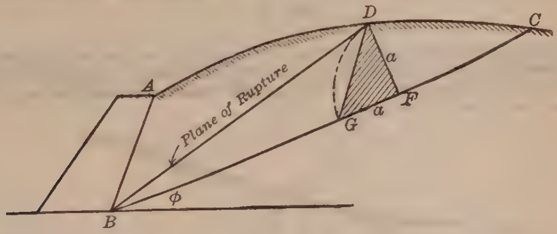

Fig. 42

retaining wall, the plane of maximum shear (plane of rupture) is located as follows: If, in Fig. 42, AB represents the back of the wall, BC the slope of repose and ADC the surface of the bank, then BD is the plane of rupture if area ABD is equal to the area of triangle BDF, DF being perpendicular to BC. Make $FG = DF$. The magnitude of the earth pressure is given by the product of the area, $DFG = 1/2\ DF = 1/2a^2$, and the unit weight of the earth, w. In the case of vertical back and level bank (Fig. 40) the plane of rupture bisects the angle $90° - \phi$ and this graphic method leads to the same formula as given above or $P = 1/2\ wh^2\ \tan^2\ (45° - \phi/2)$.

In the case of a wall with inclined back or supporting a sloping bank, or both, the plane of rupture and the magnitude of the earth pressure can be obtained by a cut and try method, making area $ABD = BDF$ on either side of the plane of rupture BD, or by the following construction. In Fig. 43 a wall with the back slightly inclined toward the fill supports a bank with a positive surcharge. Draw BC to make angle ϕ with the horizontal, C being the intersection of the slope of repose with the surface of the ground, and draw a semicircle with diameter BC. Draw AH perpendicular to BC and make $BF = BH$. Then draw $DF = a$, at right angles to BC and make $FG = DF$. The areas BAD and BDF are then equal and therefore BD is the plane of rupture. The area of triangle DFG, $= 1/2\ a^2$, multiplied by w will give the magnitude of the resultant earth pressure acting upon AB in a horizontal direction. $P = 1/2\ a^2w$. The intensity diagram will be a triangle the base of which is $BM = 2\ P/h$. This solution is perfectly general and applies for all slopes of the bank and inclinations of the back of the walls. In the case of a wall leaning away from the bank, however, the weight W resting upon the back of the wall (ABL in Fig. 44) should be regarded as part of the wall and the earth pressure upon the vertical BL determined. Combine P graphically

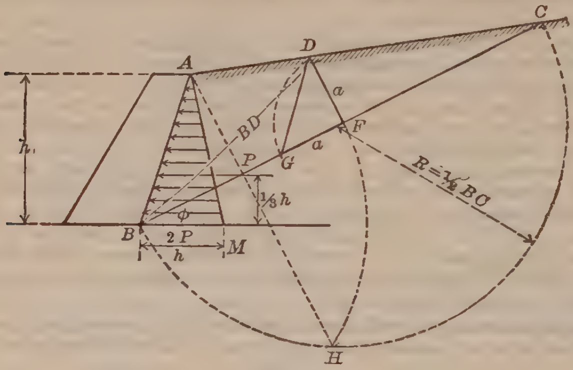

Fig. 43

with W to get the pressure P' upon the back of the wall. P' will be inclined downward.

If the surcharge (Fig. 45) is parallel to the slope of repose of the retained bank, the above (Fig. 43) construction is not necessary, the distance between the lines AD and BC being equal to a in $P = 1/2\ a^2w$.

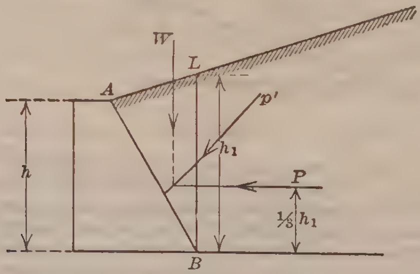

Fig. 44

If the bank is loaded with a load of v per unit surface, draw an imaginary slope, parallel to the true slope and at distance $h_1 = v/w$ above that slope (Fig. 46); find P_1 for the extended wall A_1B by the construction shown in Fig. 43; and construct the intensity triangle for wall A_1B, the base of the triangle being $2\ P_1/(h + h_1)$. Then the area of trapezoid $ANMB$ will represent the pressure P on wall AB, being applied at the center of gravity of the trapezoid.

If the surface of the retained bank is broken, as in Fig. 47, locate the plane of rupture BD by trial and successive approximation so that area $BAMND$ shall equal area BDF. Then $DF = a$ and $P = 1/2\ a^2w$. In this case the point of application of the resultant earth pressure is not at $1/3\ h$ from the base, the intensities not being a linear function of the depth. The actual distribution of the pressure on the back of wall AB and consequently the distance of the resultant pressure from the base cannot be determined graphically in any simple way but for this distance the use of $0.4\ h$ is recommended.

If the bank has a plane top surface, but is only partially loaded, apply the same method as shown above (Fig. 47), the loading being transformed into fill resulting in a broken surface.

In computations h is taken in feet, w in pounds per cubic foot, and v in pounds per square foot, so that values of P are in pounds for one linear foot of wall. For

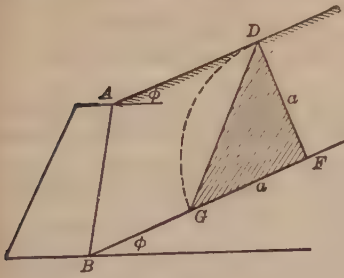

Fig. 45

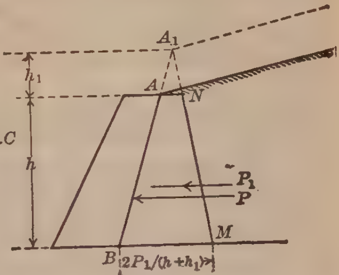

Fig. 46

example, let h = 18 ft., w = 100 lb. per cu. ft., ϕ = 34°. For an unloaded level bank retained by a wall with vertical back (Fig. 40) P is 4580 lb. and its point of application is 6 ft. above the base. If this bank is loaded (Fig. 46) so that v = 120 lb. per sq. ft., then P is 5190 lb. and its point of application is 6.35 ft. above the base.

Experiments on Earth Pressure. Many retaining walls which have stood for years, if investigated by means of the foregoing theories would be found

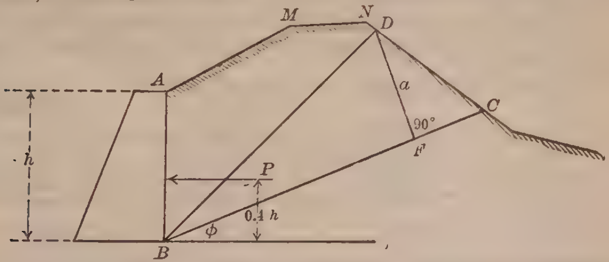

Fig. 47

inadequate. This fact shows that the theories furnish excessive values for the lateral pressure of earth, due possibly to the neglect of cohesion, which to a greater or less amount exists in the backhill, unless the latter is granulous. During the last 40 years many experiments were made to obtain data upon which more accurate theories than those of Rankine and Coulomb might be based. The most important recent experiments were made by Jacob Feld at the University of Cincinnati, 1919-1921 (Trans. Am. Soc. C. E. Vol. 86, p. 1448; this paper also gives a summary of all the important publ shed tests on earth pressure). Many of the earlier experiments were made on small-scale models and the results have not always been confirmed by large-scale experiments. Some of the more important experiments are summarized below:

M. M. L. Leygue (Annales des Ponts et Chaussées, 1885) showed that the amount of cohesion existing in the dry sand is negligible and that the surface of rupture is not plane.

Professor Mueller-Breslau (Erddruck auf Stützmauern, 1906) experimented on a wall 29 in. high. He measured both horizontal and vertical components of the lateral pressure. His results agree closely with the Coulomb theory. He investigated the wedge of rupture photographically, and found that the surface of rupture was slightly curved down at the lower end.

P. M. Crosthwaite (Proceedings Inst. C. E., Vol. 103 and Vol. 109) in experiments made between 1916–1920 found no visible plane of rupture. His results agreed with the Coulomb theory for walls without surcharge, if the angle of internal friction was used. The horizontal component of the earth thrust was independent of the wall friction.

A. R. Fulton (Proceedings Inst. C E., Vol. 109) made tests on a wall 7 ft. high, and obtained results approximating Coulomb's theory, with resultant pressure at one-third the height of wall and making an angle equal to the angle of repose with the normal to the wall.

Dr. Charles Terzaghi has done extensive experimental work on the physical properties of soils and the laws of soil mechanics. His results, however, are more applicable to the bearing power of soils under foundations. (See Sect. 8, Art. 3.)

Measurements of pressure on actual retaining walls 30 ft. high were made by the U. S. Bureau of Public Roads (Public Roads, July, 1925). Pressures were measured by cells placed on the back face of the wall. The results showed pressures varying somewhat from a triangular distribution, with resultant higher than the one-third point. The pressures were found to increase with moisture content in the fill, indicating the importance of suitable provisions for draining the fill.

20. Pressure of Water

Hydrostatic Pressure against a surface immersed in water is wAd, where w = weight of a cubic unit of water, A = area of surface, and d = depth of the center of gravity of the surface below the water level. When dimensions are in feet, the total pressure in pounds is 62.5 Ad for fresh water and 64 Ad for salt water. For an immersed plane the direction of this pressure is always normal to the surface.

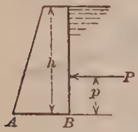

Fig. 48

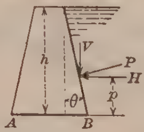

Fig. 49

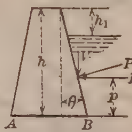

Fig. 50

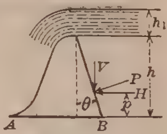

Fig. 51

Pressures on a Dam. In Figs. 48 and 49 the water level is at the top of the dam, in Fig. 50 it is below and in Fig. 51 it is above the top. The horizontal pressure H and the height of its point of application above the base are given by

For Figs. 48 and 49 $\mathbf{H} = 1/2\ \mathbf{wh}^2$ $\quad \mathbf{p} = 1/3\ \mathbf{h}$

For Fig. 50 $\mathbf{H} = 1/2\ \mathbf{w}\ (\mathbf{h} - \mathbf{h}_1)^2$ $\quad \mathbf{p} = 1/3\ (\mathbf{h} - \mathbf{h}_1)$

For Fig. 51 $\mathbf{H} = 1/2\ \mathbf{wh}\ (\mathbf{h} + 2\mathbf{h}_1)$ $\quad \mathbf{p} = 1/3\ \mathbf{h}\dfrac{\mathbf{h} + 3\mathbf{h}_1}{\mathbf{h} + 2\mathbf{h}_1}$

Also the normal pressure and its vertical component are

$$\mathbf{P} = \mathbf{H} \sec \theta \qquad \mathbf{V} = \mathbf{H} \tan \theta$$

The notation is shown on the figures and P is for unit length of dam. The distribution of unit pressures on the back of dams is exactly that for earth illustrated in Figs. 40 and 41. Thus, at the base the unit pressure for Fig. 48 and 49 is $\mathbf{wh}$, for Fig. 50 it is $\mathbf{w}\ (\mathbf{h} - \mathbf{h}_1)$ and for Fig. 51 it is $\mathbf{w}\ (\mathbf{h} + \mathbf{h}_1)$.

An Overflow Dam, or spillway dam, is one where the water flows over the top, as in Fig. 51. The effect of the water above the top is both to increase the pressure P and to raise its point of application. The following are the percentages of increase in P and p over those for the case of Fig. 49, due to different ratios of h_1 to h;

h_1/h........	0.05	0.10	0.15	0.20	0.30	0.40	0.50
For P......	10	20	30	40	60	80	100
For p.......	4.5	8.3	11.5	14.3	18.8	22.2	25.0

The flow of water over a spillway dam may cause a partial vacuum beneath the falling water sheet or nappe if it is not in contact with the masonry. If the atmospheric pressure between the masonry and the falling sheet of water is thus reduced from 14.7 lb. per sq. in. to a value q over the whole front face, the practical effect is to add a unit pressure $14.7 - q$ lb. per sq. in. to the back of the dam and thus to cause an additional normal pressure $144\ (14.7 - q)\ h$ lb., h being expressed in feet, whose point of application may be as high as $1/2\ h$. The possibility of decrease of atmospheric pressure between the dam and the falling water sheet should be kept in mind by a designer, but it is obvious that only a small percentage of the theoretically possible total pressure need be used in design. (Art. 32.)

For a Dam Backed with Earth, the hydrostatic pressure upon the back of the dam may be increased or decreased by the backfilling material depending upon whether or not the material is porous or so non-porous that it will not permit the transmission of water pressure. A puddled bank of sand, clay and gravel in which the clay fills the voids of the harder materials would materially reduce the pressure when compacted. Silt and detritus deposited behind a dam may increase the pressure. Sand, gravel and broken stone (riprap) backing increase the pressure due to water alone. For this case, in addition to the full hydrostatic pressure, the pressure of the backfill must be calculated by the methods given in Art. 19, using the values of w and ϕ as given in Art. 17 for material excavated by a wet process and dumped into water.

Water below the Base exerts an upward pressure upon the base which has the effect of diminishing the weight of the masonry, thereby reducing its resisting value against both overturning and sliding. This is one reason why it is very important to prevent water from entering below the base of a dam as far as it is practicable. To exclude such water entirely and completely prevent uplift is generally difficult, expensive, requires experience and a thorough investigation of the foundation bed and underlying strata. Where the dam rests upon solid unfissured rock the problem is fairly simple but in the average case of a dam resting on ordinary rock, hardpan or more pervious material the problem is difficult. One must allow for uplift of an intensity dependent upon the character of the foundation bed and upon the cost of the special construction necessary to prevent or diminish it. The magnitude of this upward pressure depends upon the head, the character of the foundation, design and construction, and no general rule can be given for its intensity and distribution (Art. 30). Specifications often call for full upward pressure acting at the heel B (Fig. 49) and diminishing to zero at the toe A. This is the extreme case if there is no apron as in Fig. 49. For this case the unit upward pressure at the heel is wh, the **total uplift 1/2 whb,** where b is the base width, and the force is applied at a distance $1/3\ b$ from the heel B. If there is an apron, the unit upward pressure at the toe is greater than zero as in Fig. 87. When uplift is considered as acting upon the base, no diminution of the weight of the masonry is to be made in the computations.

21. Internal Stresses in Walls and Dams

The external forces which act on a masonry structure are its weight and the loads that it carries, the lateral pressures of earth, water and wind, if such exists, and the reactions of the foundation. The deformation caused by these external forces induces internal stresses of compression, shear and sometimes tension within the structure. For the purpose of determining the internal stresses, the wall will be considered as having a uniform cross-section, uniformly acted upon at every unit of its length by the same vertical or vertical and lateral (horizontal or inclined) forces, so that to determine the actual stress in the wall any unit of its length may be considered. It will be assumed in computing stresses that the masonry of the wall is homogeneous and obeys (within the limits of working stresses) Hooke's law for elastic solids, that is, stress is proportional to strain. A horizontal joint of a wall, AB in Figs. 52 to 55 will be investigated. It forms a parallelogram of width $AB = b$, length unity and area b.

Vertical Loads, Normal Stresses on Horizontal Joints. Let W be the resultant of the vertical loads acting on Joint $AB = b$, c the middle point of AB, e the eccentricity of W or the distance of the point of application of W from c, and x the distance of any point of the joint from c, positive if measured in the direction of W and negative for the other half of the joint. Then the normal stress per unit area at any point x, expressed in the same units as W and b, is

$$\mathbf{S} = \frac{\mathbf{W}}{\mathbf{b}}\left(1 + 12\,\frac{\mathbf{ex}}{\mathbf{b}^2}\right)$$

which formula is called the **law of the trapezoid.** At the middle point c, where $x = o$, $\mathbf{S}_c = \mathbf{W/b}$ for all values of e; in other words, at the middle of the joint the unit stress is always equal to the average stress along the joint.

At the edges of the joint where $x = +b/2$ or $-b/2$, the unit normal stress is a maximum (S_1) or minimum (S_2) for any value of e and

$$\mathbf{S}_1 = \frac{\mathbf{W}}{\mathbf{b}}\left(1 + \frac{6\mathbf{e}}{\mathbf{b}}\right); \quad \mathbf{S}_2 = \frac{\mathbf{W}}{\mathbf{b}}\left(1 - \frac{6\mathbf{e}}{\mathbf{b}}\right)$$

S_1 is always positive (compression) for any value of e. S_2 is positive (compression) as long as $e < b/6$ (Fig. 52). It becomes zero if $e = b/6$ (Fig. 53). If the resultant falls outside the middle third, $e > b/6$, the formula furnishes a negative value (tension) for S_2 (Fig. 54) and this formula does not apply unless the masonry is able to develop tension. This case is discussed below. Usually no dependence should be placed upon masonry to take tension.

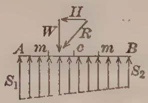

Fig. 52

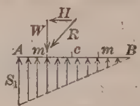

Fig. 53

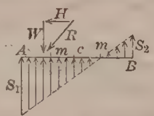

Fig. 54

Since in design the maximum and minimum stresses largely govern, these formulas for the stresses are more generally used and will be further discussed. If $e = o$, the resultant load is applied at the middle point of the joint and $S_1 = S_2 = W/b$ (compression), i.e., the stress is uniform along the joint. If $e = b/6$, the resultant load is applied at the middle third point and $S_1 = 2W/b$ (compression) or twice the average value of the stress, and $S_2 = 0$.

If $e > b/6$ and the joint cannot take tension, part of it will not be stressed at all, while the other part will transmit compressive stresses only. This condition of stress distribution is shown in Fig. 55, where the distance e of the point of application g of the resultant load is greater than $cm = b/6$. Let r be the distance of W from the nearest edge of the joint A in Fig. 55; then the point of zero stress O will lie at a distance $3r$ from this edge and $S_1 = 2W/3r$; for $r = 0$, S_1 becomes infinity. Substituting the safe unit stress s for S_1 we get $r =$

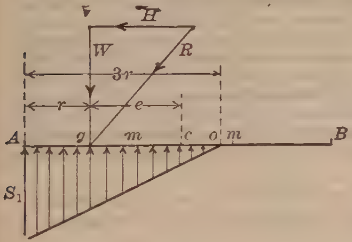

Fig. 55

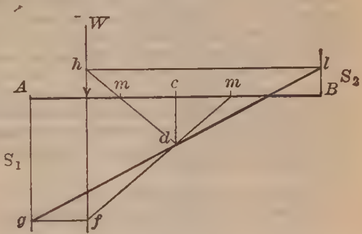

Fig. 56

$2W/3s$. This gives the minimum distance r from the edge of the joint to the resultant permissible with a given safe unit stress.

If tensile stresses are considered in a masonry wall the general formulas given above for S_1 and S_2 should be used even though the resultant falls outside the middle third. For such a case, if $e = 1/2\ b$, the resultant is applied at the edge of the joint, $S_1 = 4W/b$ (compression) or four times the average stress, and $S_2 = 2W/b$ (tension) or twice the average stress.

Graphically the stresses along AB may be found by the following construction. Lay off (Fig. 56) $cd = W/b$ the average stress, connect the middle third points m and m with d and produce lines md to intersect with W in f and h. Draw horizontal fg and hl to intersect verticals A and B in g and l. Then Ag and Bl will be the maximum and minimum normal stresses and the stress at intermediate points will be obtained by scaling the vertical intercept between AB and gl, ordinates above AB indicating tension.

Example. Let $W = 30\,000$ lb. and $b = 6$ ft. Then for W applied at the middle of the joint, $e = 0$, $S_1 = S_2 = 5000$ lb. per sq. ft. For W at the middle third point, $e = 1$ ft., $S_1 = 2\ W/b = 10\,000$ lb. per sq. ft., $S_2 = 0$. For W at $1/3\ b$ from the center, $e = 2$ ft., $S_1 = 3\ W/b = 15\,000$ lb. per sq. ft., $S_2 = -Wb = -5000$ lb. per sq. ft. If the joint cannot take tension, $r = 1$ ft., $S_1 = 2W/3\ r = 20\,000$ lb. per sq. ft. If the masonry is rubble, with a safe compressive stress of 18 tons per sq. ft., how near in safety can the resultant come to the edge of the joint? $r_{min.} = 2W/3\ S = 2 \times 30\,000/3 \times 36\,000 = 5/9$ ft.

Vertical and Lateral Loads. Normal Stresses on Horizontal Joints. If lateral forces act upon a wall, the resultant of these and the vertical loads will be inclined to the joint as R in Figs. 52 to 55. In order to find the normal stresses on the joint, resolve R into a vertical and a horizontal component, W and H at the point of application of R and treat W exactly as shown in the preceding discussion. H, the horizontal component of R, will produce compression on vertical planes and shearing stressses along the joint, if it is capable of taking shear. If not, the stability of the structure is dependent upon the friction developed along the joint. Designers should not add the safe shearing value to the safe frictional resistance, because the latter will not come into action unless the shearing resistance has been overcome.

Shearing Stresses in Walls. Careful consideration should be given to the shearing stresses in the design of dams over 50 ft. in height but they need rarely be considered in the design of other walls. The magnitude and distribution of shear in walls cannot be determined by the customary formulas for beams since they generally are not prismatic and are always subject to axial loads. The only case in which shearing stresses do not exist in horizontal and vertical planes is when the wall has a vertical face and back and carries an axial or an evenly distributed vertical load, but in this case there are shearing stresses along every other plane.

Let a prismatic wall (Fig. 57) be subjected to an axial compressive force P, then the intensity of the compressive stress on joint AB normal to the axis will be $= P/a$, if a is the area of joint AB. On a plane CD whose normal is inclined to the axis at an angle ϕ there is a stress in the direction of the axis and therefore oblique to the plane CD, of intensity P/a_1 where a_1 is the area of joint CD, that is, $a_1 = a/\cos\phi$. The whole stress P on CD may be resolved into two components, one normal to CD and the other a shearing stress tangential to CD. The normal component is $P\cos\phi$, the tangential component is $P\sin\phi$. The unit intensity of normal compression on CD, therefore, is $(P/a)\cos^2\phi$ and the intensity of shearing stress is $(P/a)\sin\phi\cos\phi$. This expression makes the shearing stress a maximum when $\phi = 45°$; surfaces inclined at 45° to the axis are called surfaces of maximum shearing stress, the intensity of shearing stress on them is $P/2a$.

In the case of retaining walls and dams which are subjected to horizontal loads besides vertical ones and generally have a wedge-shaped cross-section, it

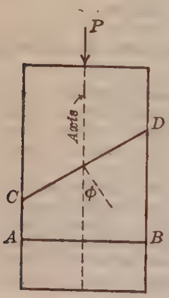

Fig. 57

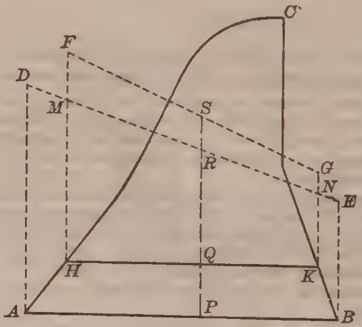

Fig. 58

is obvious that shearing stresses exist on every horizontal joint, the total of such stresses being equal to the resultant horizontal force above the plane of the joint. The intensity of the horizontal shear will vary from point to point along the joint. Its distribution can be determined by applying the principle that at any point of the structure the horizontal and vertical shear intensities must be equal. Let Fig. 58 represent the cross-section of a dam, a slice of unit thickness being considered. According to the **law of trapezium,** the distribution of the normal pressure on joint AB may be represented by $ADEB$; and if forces are expressed in masonry units (the unit of weight being the weight of one cubic unit of masonry) and the same scale used for dimensions and forces, the area $ADEB$ will be equal to the area $AHCKB$. Similarly the distribution of thrust on joint HK will be represented by $HFGK$, which is equal to HCK. The weight of the layer between AB and HK will be represented to the same scale by $AHKB$. Consequently, $ADMH + KNEB = MFGN$. Take any vertical PS. The difference between the vertical forces to the right of PS and acting on AB and HK respectively $= RSGN - KNEB$, and that to the left of $PS = ADMH - MFSR$. These two resultant forces are equal but of opposite sign, and either of these differences represents the resultant of the vertical forces on either side of the layer $AHKB$, to the right or left of PQ, and therefore, the shear on PQ. Hence the intensity of shearing stress at P (horizontal and vertical) is approximately either $(RSGN - KNEB)\ PQ$ or $(ADMH - MFSR)/PQ$. The approximation will be closer the smaller is PQ (Unwin, Engineering, Vol. 79).

Applying the foregoing method to a triangular dam with vertical back, the distribution of the shearing stresses is found to be uniformly varying from zero at the back to a maximum at the face, the shear diagram being a triangle. In the case of a rectangular dam the shear diagram is a parabola with vertical axis; the shear intensity is zero at either face and maximum at the center where its value is $q_{max} = 3\,h^2/4\gamma b$, h being the depth of water to the joint in question, b the width of the dam and γ the density of the masonry relative to water.

For the important practical case of a dam with vertical back and inclined face, E. P. Hill (Proc. Inst. Civ. Eng., 1908, Vol. 172) gives the following formula for the **intensity of shear on horizontal or vertical planes** at any point of a horizontal joint:

$$q = \left[4\,Wm(b - 3d) + \frac{h^2(3b - 2\,mh)}{\gamma}\right]\frac{x}{b^3} + \left[6\,Wm(3d - b) - \frac{3h^2(b - mh)}{\gamma}\right]\frac{x^2}{b^4}$$

In this formula W is the total weight above the joint in masonry units (i.e., if b, h, d and x are expressed in feet, W must be multiplied by the weight in pounds per cubic foot of masonry and q then will be expressed in pounds per square foot), b the width of the joint and h the depth of the water above it, d the distance of the center of gravity of W from the water edge of the joint, x the distance from the water edge of the point where q is to be determined, m the tangent of the angle between the face of the dam and the vertical and γ the specific gravity of the masonry. The formula shows that the shear intensity on horizontal (or vertical) planes is practically proportional to the distance from the back of the dam at which point it is zero. The experiments of Ottley, Brightmore, Wilson and Gore (Proc. Inst. Civ. Eng., 1908, Vol. 172) have verified this with the exception of the joints at and near the base, where, on account of the rigidity of the fixing of the dam, the shear intensities are practically uniformly distributed along the joint. The shearing stresses to be considered in the design are not those at the base but higher up and near the face. For practical purposes, except in the case of a very high dam (for which the closer analysis is necessary), the shearing stress along horizontal joints more than $1/5\ h$ above the base can be taken as uniformly varying from zero at the back to a maximum at the face at which point it equals $2\ H/b$, H being the magnitude of the resultant of the horizontal components of the lateral forces above the joint considered and equal to the total shear along the joint. For the joints near to and at the base, the shearing stress should be taken as uniformly distributed having an average value of H/b. (See example, Art. 31.)

Horizontal Pressures on Vertical Planes. The lateral external forces (water or earth pressure) also generate normal stresses on vertical planes. For a dam with vertical back and inclined face, Hill gives the following formula to determine the intensity p' of these stresses, the notation being the same as in the preceding paragraph:

$$p' = \frac{h}{\gamma} + \left[\frac{2\,Wm^2}{b^3}\left(2 - \frac{9d}{b}\right) - \frac{3h(b - mh)^2}{\gamma b^4} + \frac{m}{b}\right]x^2 + \left[\frac{6\,Wm^2}{b^4}\left(\frac{4d}{b} - 1\right) + \frac{2h(b - mh)\,(b - 2\,mh)}{\gamma b^5} - \frac{m}{b^2}\right]x^3$$

p' is in masonry units, similarly to q in the preceding paragraph. The horizontal stress intensity on vertical planes, therefore, increases from the back. For $x = o$, $p' = h/\gamma$. But since p' is expressed in masonry units, h/γ must be multiplied by $62.5 \times \gamma$ and becomes $62.5\ h$, or in other words, at the back of the dam p' equals the unit water pressure For all walls, except very high structures, where a closer investigation is necessary, the normal stress intensity on vertical planes, for every point of a horizontal joint, can be taken as constant and equal to the intensity of the lateral forces at the elevation of the joint under investigation. (See example, Art. 31.)

Maximum and Minimum Stresses. Both normal and shearing stresses exist at every plane passing through any point of an elastic solid which is in equilibrium under the influence of external forces. These stresses vary in magnitude for the same point according to the direction of the plane and there invariably exists one plane on which the normal stress intensity is a maximum, and another plane perpendicular to the first, on which the normal stress intensity is a minimum. These limiting values of the normal stresses are termed principal stresses and they can be determined both as to magnitude and direction if the normal and shearing stresses at a certain point are known on two planes at right angles to each other. At any point of the horizontal joint investigated, let S and p' be the intensities of the normal stresses on horizontal and vertical planes and let q be the intensity of the shear on these two planes, both kinds of stresses being determined by the methods given above (compressions taken as positive and tensions as negative), then the magnitude of the principal stresses at the same point is given by the formula:

$$f = \frac{S + p' \pm \sqrt{(S + p')^2 - 4(Sp' - q^2)}}{2}$$

the positive sign before the radical furnishing the maximum and the negative sign the minimum principal stress.

Let θ be the inclination of the principal stress to the horizontal, then

$$\cot \theta = (f - p')/q$$

These formulas show that even in the case when the resultant cuts the horizontal joint within the middle third, in other words when S is compression along the whole joint, tensile stresses will occur at some points in a certain direction, if $Sp' < q^2$. According to Levy, in order that tensile stresses should entirely be eliminated, the design should be such that not only shall the resultant lie within the middle third of the joint, but that S_2 (minimum normal stress) shall be not less than the intensity of the horizontal components of the lateral forces at the elevation of the joint investigated (or the hydrostatic pressure in the case of a dam). It can also be shown that Sp' is always greater than q^2 at the toe of retaining walls and dams designed for the requirement that the resultant shall fall within the middle third of the horizontal joints and, therefore, no tension can exist at and near the face of such walls. The maximum shearing stresses in walls with vertical face and back and vertical loading only are inclined 45° to the vertical and equal to $S/2$ for every point of the horizontal joint, S being the intensity of the constant normal stress upon the joint. For other methods of loading, according to Wilson and Gore, the maximum shearing stress can be approximately expressed by the formula $q_{max} = S/2 \cos^2 \phi$, where S is the normal stress on the horizontal plane at the point considered and ϕ the angle between the resultant R and the vertical. According to Bouvier, the maximum stresses in dams of the usual cross-section are about 13/9 times the stresses on horizontal joints. This rule gives good approximate values also for other types of walls for preliminary design.

G. F. Swain shows that the maximum compressive stress at the downstream face is on a plane normal to the face, and equals $S \sec^2 \beta$, where S is normal unit stress on a horizontal plane at the downstream face and β is angle between downstream face and the vertical. (Stresses, Graphical Statics and Masonry (1927), p. 468.)

The above discussion of stresses and the formulas do not take in account the factor of lateral deformation of the masonry which is probably very small. (See example, Art. 31.)

Joints in Arches. The above discussion has been developed for the horizontal joints of walls and dams, but it applies equally well to the radial joints between the voussoirs of stone arches. Against such a joint there acts a resultant force R, and the component of this parallel to the joint gives the total shear H; the component normal to the joint may be called N. Then the preceding formulas apply to such a radial joint if W is replaced by N, and the distributions of the normal stresses are exactly like those shown in Figs. 52-55.

22. Local and Eccentric Loads

A Bridge Pier which sustains only vertical loads whose resultant coincides with the axis of the pier has the compressive unit stresses uniformly distributed on the base. The least area for the base is $A = W/S$, where W is the total vertical load on that base and S is the allowable unit stress from Art. 16. Practical considerations, however, usually necessitate a larger section. Small piers in buildings should have this least area, unless the r length is such that columnar action exists, and then S must be taken smaller (Art. 29).

Under a Concentrated Load on the top of a pier, the compressive unit stress may be taken higher than for a section of the pier lower down. If the area under local compression is 0.3 of the total area of masonry over which the compression is distributed, the values in Art. 16 may be increased 60%; if that area is 0.1 of the masonry area, those values may be increased 200%. For other values of the ratio r the increase may be made in direct proportion: for r between 0.1 and 0.3, per cent increase $= 270 - 700\ r$; for r between 0.3 and 1.0, per cent increase $= 600\ (1 - r)/7$. These percentages apply when the concentrated load is at the middle of the top of the pier as at (a) in Fig. 59; thus, for a steel column having a base 15 by 15 in. and a masonry pier 24 by 24 in. the value of r is 0.4, and the allowable S of Art. 16 may be increased 51% under the base of the column.

An Eccentric Load is one placed so that its line of action does not coincide with the gravity axis of the pier as at (b) in Fig. 59. Here the distributions of unit stresses on the base are like those shown in Art. 21, and when the eccentricity e is large enough the stresses on one side may be tensile. For this case the working unit stress S cannot be increased to the full extent indicated in the last paragraph, and when the load is close to the edge of the pier top no increase should be made. A specially unfavorable condition is that in the first diagram of Fig. 61a, where there is an eccentricity in both horizontal directions, so that the opposite corner of the pier should be anchored down in order to prevent it from rising or from cracking by tension.

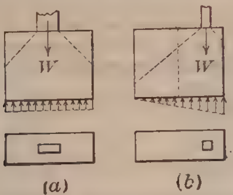

Fig. 59

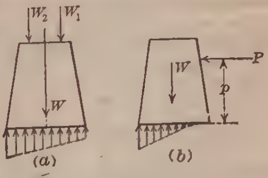

Fig. 60

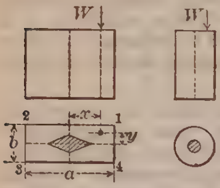
The inclined lines in Fig. 59a show the manner in which the local compression spreads out until it finally becomes uniformly distributed over the horizontal cross-section; the inclination of these lines is about 45°. For the eccentric load in Fig. 59b, one of the inclined lines quickly reaches the edge of the pier, indicating that the unit stress under the column must be taken lower for an eccentric load than for a central one.

A Bridge Pier under Vertical Loads (Fig. 60a) is subject to non-uniform compression on the base when the two adjacent spans of the bridge differ in length or when only one of two equal spans is covered with live load. Thus in Fig. 60*a* let W be the weight of the pier itself above the base, and W_1 and W_2 the weights brought upon the top of the pier from the two spans of the bridge, these being applied at the distance c from the middle of the top. Here the resultant vertical pressure cuts the base at a distance e from the center which is found from $e = c\,(W_1 - W_2)/(W + W_1 + W_2)$, and the distribution of compressive unit stresses on the base is the same as in Art. 21. When $W_1 > W_2$ in Fig. 60*a*, this point is at the right of the center; when $W_1 < W_2$, it is at the left of the center. The proper formula of Art. 21 enables the maximum compressive unit stress to be found.

Wind blowing on a tower or chimney, as shown in Fig. 60*b*, causes a similar eccentricity of the resultant on the base; for this case, the value of $e = Pp/W$. Wind blowing at right angles to the line of a bridge causes a similar longitudinal eccentricity on the base of a pier, whereas the lateral eccentricity due to live loads is the same as given in last paragraph. Two horizontal wind forces may act on a bridge pier, P_1 for wind blowing against the bridge spans and P_2 for wind against the pier itself; here the above equation also holds if Pp is replaced by $P_1p_1 + P_2p_2$.

The Kern is an area on the base of the pier within which the resultant force that acts on the base must lie in order that no part of the base may be subject to tension. To prevent tension on any corner or side of the base of a masonry pier, wall, or dam, the line of action of the resultant must cut the base within the kern. For a rectangular section with sides a and b, the kern is a rhombus which has the diagonals 1/3 a and 1/3 b, the corners of this rhombus pointing toward the middle of the sides of the rectangle as shown in the plan of Fig. 61*a*. For a square with side d, the kern is a smaller square which has the diagonal 1/3 d and the sides of which are parallel to the diagonals of the given square. For a circular section of diameter d the kern is a smaller concentric circle of diameter 1/4 d as in Fig. 61*b*. The resultant is the weight W above the base in case no lateral force acts upon the structure, otherwise it is the R of Art. 21, which is found by combining W and H.



(a) (b)

Fig. 61

A Rectangle with sides a and b (Fig. 61*a*) is the most common case. Let x and y be the eccentricities with respect to axes of the rectangle parallel to the sides a and b. Then the unit stresses at the four corners are

$$S_1 = \frac{W}{ab}\left(1 + 6\frac{x}{a} + 6\frac{y}{b}\right) \qquad S_3 = \frac{W}{ab}\left(1 - 6\frac{x}{a} - 6\frac{y}{b}\right)$$

$$S_2 = \frac{W}{ab}\left(1 - 6\frac{x}{a} + 6\frac{y}{b}\right) \qquad S_4 = \frac{W}{ab}\left(1 + 6\frac{x}{a} - 6\frac{y}{b}\right)$$

When W lies within the kern all of these are compression; the formulas hold, however, even if W is without the kern, provided the masonry can take tension near the corners and edges.

For a Circular Cross-Section of diameter d, the maximum and minimum unit stresses, due to a load having the eccentricity e, are

$$S_1 = \frac{W}{A}\left(1 + 8\frac{e}{d}\right) \qquad S_2 = \frac{W}{A}\left(1 - 8\frac{e}{d}\right)$$

in which A is the area of the circle. The unit stress S_2 is tensile if the load is without the kern, but the formula gives it correctly when the masonry can resist tension. The radius of the kern is 1/8 d (Fig. 61b).

If the material is unable to develop tensile stresses and W acts outside the kern in one of the main axes of the figure comprising the horizontal joint of the pier, the following methods to determine the distribution of normal stresses are recommended.

For a pier rectangular in plan as in Fig. 61a and W being applied on the axis parallel to side a at a distance r from the nearest short side of the joint, $S_1 = 2\,W/3\,rb$.

For a horizontal joint having any symmetrical figure (as, for instance, a chimney section), according to Mohr the following construction will give the compressive stress distribution, Fig. 62. A is the point of application of W lying on the symmetry axis BMB_1 of figure F. Draw an equilibrium polygon for area F with an arbitrary pole distance H. Draw a perpendicular to axis BB_1 at A to intersect the tangent $B'O$ in A'. Draw $B'N$ so that the area of triangle $B'A'N$ shall be equal to area $B'CN$, in other words, that the two shaded areas shall be equal. Then the line NN drawn at right angles to BB_1 is the zero line from which the compressive stresses increase in proportion to the distances. Make $B'D = W/H$ = weight ÷ area (H being measured in the same unit as F); draw DE parallel to $B'N$. Then for the point B, farthest from NN, the unit stress $S_1 = EE_1$ which is drawn parallel to BB_1 from point E. EE_1 is measured in the same unit as W/H.

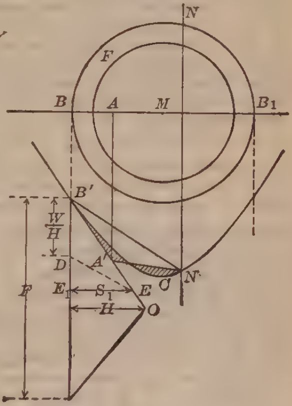


Fig. 62

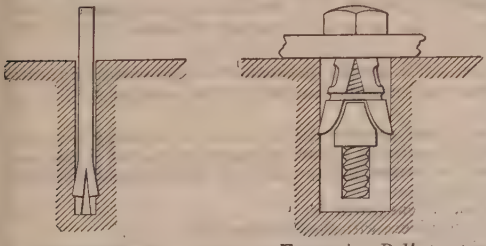
If the point of application of the resultant does not lie on an axis of symmetry of the joint, or if the joint has an unsymmetrical figure, the determination of the purely compressive stresses becomes very complicated. The following method is recommended: Connect the point of application with the center of gravity of the joint and find in this direction the conjugate axis of the ellipse of inertia of the figure. Then the line of zero stress will be parallel to the direction thus found and its location should be determined by trial, remembering that the stresses will be proportional to the distance from the zero line and that the center of gravity of the intensity wedge (the volume of which is equal to the vertical component of the resultant) must fall in the same vertical with the point at which the resultant cuts the joint.



Fox Bolt *Expansion Bolt*
Fig. 63

Anchor Bolts. Masonry structures sometimes are required to be anchored to a rock foundation, especially where tension may occur under eccentricity of loading. A fox bolt (Fig. 63) is a straight iron bar, split for about an inch at the lower end, the split allowing an iron wedge to enter as the bolt is driven down; the end of the bolt then expands and is held in the hole by friction aided by cementing material. The expansion bolt (Fig. 63) is the best form of anchor bolt for fastening timber or steel members to masonry or rock.

Ordinary straight round rods, which should be "hacked" or otherwise roughened, may be cemented in place with lead, babbitt metal or cement grout, the last being most common.

M. Ferret found, for plain round rods in 1 : 2 : 4 concrete, that the holding capacity was 237 lb. per sq. in. of embedded surface. A. N. Talbot found 424, and W. O. Withey 452 lb. per sq. in. Plain square rods give slightly higher values. A working unit stress of 75 lb. per sq. in. is recommended for plain round rods in 1 : 2 : 4 concrete, or 100 lb. per sq. in. if rods are roughened.

For fox and expansion bolts E. S. Wheeler found 264 lb. per sq. in. when embedded in 1 : 2 portland mortar, 843 lb. per sq. in. when in sulphur and 485 lb. per sq. in. when in lead. A working unit stress of about one-fifth of these values should be used. Sulphur should not be used where exposed to rain or other water, as acid will be formed which rusts the steel and often disintegrates the stone near the top of the hole.

Brick Chimneys. The overturning effect of wind on a tall isolated chimney will generally result in some tensile stress in the brick masonry. The amount of this tensile stress may be determined by analyzing the chimney as a vertical cantilever, and computing the bending stresses at various heights. The difference between the compressive unit stress due to dead load and the maximum unit stress from the bending will give the maximum unit tensile stress in the brickwork; the sum of the dead load and bending stresses will give the maximum compressive stress. As the strength of the mortar during construction is greater at the base of the chimney than higher up, due to the greater age of the mortar at the base, the allowable masonry stresses are sometimes given higher values for the lower portions of the chimney. G. Lang (Eng. Rec., July 20, 1901) gives the following formulas for maximum allowable tensile and compressive stresses in brick chimneys:

Tension: $S = 18.5 + 0.056\,L$, for single shell chimneys
$S = 21.3 + 0.056\,L$, for chimneys with complete lining

Compression: $S = 71 + 0.65\,L$, for single shell chimneys
$S = 85 + 0.65\,L$, for chimneys with complete lining,

where S = stress in pounds per square inch, and L is the distance in feet from the top of the chimney to the section considered.

If the computed maximum tensile stress is greater than the tensile strength of the mortar, the joints will tend to open up slightly on the windward side. However, the chimney may be stable even in this case, provided the compressive stress on the other side of the chimney does not exceed the allowable compressive stress for brick masonry. For this condition, Mohr's method (page 909) may be used to compute the maximum compressive stress. An approximate method is also given for concrete chimneys in Sect. 11, Art. 60.

Building codes do not, as a rule, specify methods for design of isolated brick chimneys. The following requirements are given in the code of the City of Toronto:

(1) Based upon a horizontal wind pressure of 25 lb. per sq. ft. as acting over their vertical projection, the circular portions of isolated chimneys constructed of approved radial brick may be designed for stresses, due to weight and wind moment combined, not exceeding the following amounts:

(a) Maximum compression, 17 tons per sq. ft.

(b) Maximum tension in accordance with the following table:

Maximum height of chimney in feet	Tension in tons per sq. ft.	Maximum height of chimney in feet	Tension in tons per sq. ft.
100	2-1/4	225	1
125	2	250	3/4
150	1-3/4	275	1/2
175	1-1/2	300	1/4
200	1-1/4	over 300	0

(2) Radial brick shall be hard burned, also weather and acid proof. The brickwork when laid in place shall weigh at least 120 lb. per cu. ft.

(3) Circular steel reinforcing hoops or rings, not less in cross-sectional area than 3/8 × 2-1/2 in., shall be built into the brickwork at each change of wall thickness and just above and below the flue opening. The spaces between the inside of the hoops and the brickwork shall be well filled with mortar.

It will be noted that the Toronto code specifies a decreasing maximum tensile stress as the height of the chimney increases, which is contrary to Lang's formulas. The writer considers the allowable stresses in the Toronto code to be too conservative. It is suggested for design, based on a wind load of 25 lb. per sq. ft. of vertical projection, that the maximum compressive stress in the brickwork of the chimney be not over 210 lb. per sq. in. (15 tons per sq. ft.) and that the maximum tensile stress at any point in the chimney be not over 28 lb. per sq. in. (2 tons per sq. ft.).

MASONRY WALLS AND DAMS

23. Principles of Stability

Definitions. A **Bearing Wall** is a vertical wall which supports a building and is subject mainly to vertical pressures. A **Retaining Wall** is subject to its own weight and to the lateral pressure of earth which is deposited behind it after it is built. A **Brest Wall,** or face wall, is one built to prevent the fall of an undisturbed bank of earth. A **Buttress** is a projection of masonry built into the front of the wall to strengthen it, and a **Counterfort** is a projection of masonry built into the back of the wall.

A **dam** is a structure to obstruct the flow of a stream or to impound water, thus creating a storage of water, or head, or both. Masonry dams are, as a rule, of the gravity type, resisting the lateral water pressure by virtue of their weight. Arched masonry dams are dams curved in plan and for their resistance against water pressure rely partly or entirely upon arch action.

The front of a wall or dam is the face seen after it is finished, while the back is the face which is acted upon by earth or water. The lowest point of the front, at the top of the foundation, is called the toe, and and the lowest point of the back is called the heel.

The Batter of the face of a pier, wall or dam is its inclination to the vertical, measured by the ratio of horizontal to vertical projection, which is usually expressed in inches per foot of height. The following table gives the angle θ (Fig. 49) between the inclined face and the vertical for various batters and also trigonometric functions of those angles:

Angles and Functions for Batters

Batter, in. per ft.	Angle θ	Sin θ	Cos θ	Sec θ	Tan θ
0	0° 00′	0.0000	1.0000	1.0000	0.0000
1/2	2 23	0.0416	0.9991	1.0009	0.0417
1	4 46	0.0831	0.9965	1.0035	0.0833
1-1/2	7 08	0.1242	0.9923	1.0078	0.1250
2	9 28	0.1645	0.9864	1.0138	0.1667
2-1/2	11 46	0.2039	0.9790	1.0210	0.2083
3	14 02	0.2425	0.9702	1.0308	0.2500
3-1/2	16 15	0.2798	0.9601	1.0416	0.2915
4	18 26	0.3162	0.9487	1.0541	0.3333
4-1/2	20 33	0.3510	0.9364	1.0680	0.3750
5	22 37	0.3846	0.9231	1.0825	0.4166
5-1/2	24 37	0.4166	0.9091	1.1000	0.4582
6	26 34	0.4472	0.8944	1.1181	0.5000

The last column in this table gives the batter expressed as a decimal, that is, the horizontal projection for a vertical projection of unity. The column next to the last gives the length of the inclined face for a vertical projection of unity.

Failure of a masonry wall or dam usually occurs in three ways: (1) by sliding along the joint at the base, (2) by overturning or rotating, (3) by crushing of the masonry. In order that failure may not occur, the design should be so made that the structure may have such size and weight that sliding, rotation or crushing cannot occur.

Failure of retaining walls by tension seldom, if ever, occurs, but tension has been the cause of some of the most disastrous failures of dams. The failure of the Habra dam in Algiers and that of the Bouzey dam in France were due primarily to tension fracture and subsequent shearing action. (Unwin, Min. Proc. Inst. C. E., Vol. 172, p. 160.)

The most common cause of failure of walls and dams is a defective foundation. A washout around the foundation of a wall due to excessive rainfall may cause its destruction. Water entering beneath the base of a masonry dam or around its ends may impair the foundation as well as exert an upward pressure. In this article it is assumed that the foundation is securely built and that precautions have been taken to prevent the action of water beneath it.

Sliding Stability is secured by giving the structure a sufficient weight so that there is no danger of motion along a joint at the base or any other horizontal joint. For the horizontal joint in Fig. 64*a* let H be the horizontal pressure and W the sum of all the vertical weights above the joint. Motion occurs when $H = fW$ where f is the coefficient of friction. In order that there may be no motion, let n be a number greater than unity, called the **safety factor,** then if W is sufficiently large so that $nH = fW$, stability is secured. A common value of n for use in designing is 2, so that the formula $2H = fW$ produces a proper degree of security, and then $W = 2H/f$. For an existing wall or dam the safety factor is $n = fW/H$.

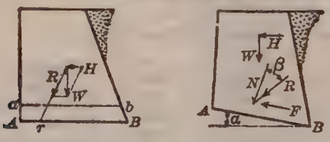
For an inclined joint (Fig. 64*b*) let α be its angle with the horizontal, N the normal pressure on the joint and F the force acting parallel to it; then for motion about to begin $F = fN$, and for stability $nF = fN$. For this case

$$\mathbf{W = H\ (n - f \tan\alpha)/(n \tan\alpha + f)}$$

gives sufficient security if the safety factor n is taken as 2.

Another method of consideration is by means of the angle which the resultant R makes with the normal to the joint. In Fig. 64*b*, motion will occur when the angle β equals the angle of repose ϕ, for masonry upon masonry (Art. 18). For stability the angle β should be less than ϕ, and proper security requires that $n \tan\beta = \tan\phi$, or $\tan\beta = f/n$.

Stability against Rotation is secured by giving the wall or dam such size and weight that R, the resultant of all the external forces above the joint, cuts the base AB well within the joint (Fig. 64*a*). When R passes through A



(*a*) (*b*)

Fig. 64

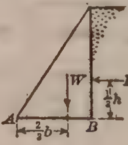


Fig. 65

failure occurs by rotation, and if R passes near A the material may begin to crush so that rotation is imminent. Some writers require that R shall cut AB at the edge of the middle-third or even within it; others require that R shall cut the base at A when the acting horizontal force H is doubled. The first method is used for dams and the second for walls. The **safety factor** against rotation is defined as the number by which the horizontal pressure must be multiplied in order that R shall pass through the toe. Let l_1 and l_2 be lever arms of H and W with respect to A in Fig. 64b; then the safety factor is $n = Wl_2/Hl_1$ for an existing wall or dam. For designing, the value of W must be such that $W = nHl_1/l_2$ and n may be taken as 2 for walls and between 2 and 3 for dams.

For a triangular wall or dam with vertical back (Fig. 65) a safety factor of 2 causes R to cut the base at the edge of the middle third. For a trapezoidal section of top width a and base width b and a vertical back, the safety factor required in order that R may cut the edge of the middle third is $n = 2 + a^2/(b^2 + ab - a^2)$, which shows that n should be 3 for a rectangular dam and between 2 and 3 for a trapezoidal one.

Stability against Crushing is secured by making the greatest compressive unit stress S_1 much less than the crushing strength of the masonry. For S_1 the safe working value given in Art. 16 should be used in design, the wall or dam being given such size that this shall not be exceeded.

The Resistance Line is a line drawn within the cross-section of a wall or dam which shows for every horizontal joint the point where the resultant of the external forces above it cuts the joint. Let ab in Fig. 64a be any horizontal joint in a masonry wall, H the resultant of the horizontal forces above ab, and W the weight of the masonry above ab; then the resultant R of H and W cuts ab at a point r. If ab is conceived to move up and down, the point r describes the line called the resistance line. Figs. 66 to 69 show four forms of walls in each of which two broken lines are drawn dividing each horizontal joint into three equal parts, the middle part being the "middle-third." (See Art. 21.) Fig. 66 is a rectangular pier or wall subject only to its own weight, and the vertical line rr is the resistance line. Fig. 67 is a vertical rectangular wall subject to the horizontal pressure of earth or water, and the curved line rr is the resistance line. Fig. 68 is a triangular wall with vertical back under horizontal pressure, and the straight line rr which cuts the base at the middle is the resistance line. Fig. 69 is a trapezoidal wall with vertical back under horizontal pressure, and the resistance line rr is curved.

Fig. 66

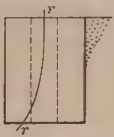

Fig. 67

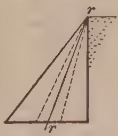

Fig. 68

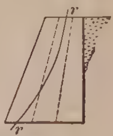

Fig. 69

The conditions of stability discussed in this article apply not only to the base joint but also to every horizontal joint of the cross-section of a wall or dam. In the case of stone and brick structures, the shearing strength of the joints is disregarded, and friction alone is assumed to resist sliding. In the design of concrete walls, including dams, the tendency to slide is assumed to be resisted by the shearing strength of the masonry. Both friction and shear should not be assumed to be simultaneously available to resist sliding because frictional resistance will not come into action until the section has failed in shear.

The conditions of stability (against sliding, rotating and crushing) here discussed apply also to radial joints of masonry arches, where a normal pressure N acts upon the joint and a shearing force H along the joint.

24. Moments for Trapezoidal Sections

The Overturning Moment M for a wall with vertical back is $\mathbf{P \times 1/3\ h}$, where P = horizontal pressure and $1/3\ h$ is lever arm with respect to the toe.

For a level bank of earth Art. 4 gives for this overturning moment per unit length of wall,

$$M = 1/6\, wh^3 \tan^2 (45° - \phi/2)$$

and values of M are given in Table A, below, for earth having w = 100 lb. per cu. ft. and for various values of ϕ. These values of M are in thousands of foot-pounds. This table is useful in making approximate computations and estimates for walls with backs nearly vertical. It does not apply to banks which have upper surfaces inclined.

The table may be used to find M for earth less than 100 lb. per cu. ft. by multiplying the tabular values by the ratio of the unit-weight to 100; for example, for cinders weighing 45 lb. per cu. ft. multiply by 0.45. Interpolation may be made for earths having slopes different from those given. For a height of wall intermediate between the heights given in the table, take the overturning moment for a wall 100 ft. high and multiply it by the ratio of the cube of the height of the desired wall to the cube of 100. For example, for a wall 55 ft. high and a slope of repose 1.33 : 1, the overturning moment = 4 167 000 × $(55/100)^3$ = 692 000 ft.-lb.

For a Loaded Level Bank of Earth (Art. 19, Fig. 41), the overturning moment M may be found by multiplying the tabular values by $1 + 3v/100\,h$, where v is the weight of the load per square foot of level surface and h equals height of wall in feet. When the load consists of merchandise or building materials back of a wall, v may be taken as from 200 to 400, the higher the wall the greater to be the value of v. For walls retaining railroad embankments v should be taken at 750 lb. The tables are not directly applicable to a dock wall or to any wall in which the retained earth is saturated with water.

(A) Overturning Moments for Retaining Walls in Units of 1000 Foot-Pounds

Interpolation is not satisfactorily made except approximately by an arithmetic method in tables (B), (C), (D), (E), for heights intermediate between those given. For a case of this kind, it is recommended that interpolation be made by help of a curve drawn through plotted points whose ordinates represent values taken from the table.

The Resisting Moment of a wall or dam is defined as its weight multiplied by the lever arm of that weight with respect to the toe. Tables (B), (C), (D), (E) give resisting moments in thousands of foot-pounds for masonry walls 1 ft. long of four types, and for various ratios of height to base and for top width between 2 and 3 ft. These types, also called B, C, D, E, are shown in Figs. 70-73. Walls B and C may have a vertical face or one with a batter not exceeding 1 in 3. The weight of the masonry was taken at 150 lb. per cu. ft. in computing these tables. If the unit weight w of the masonry is mater-

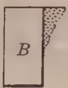

Fig. 70

Fig. 71

Fig. 72

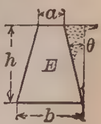

Fig. 73

ially less, multiply the tabulated resisting moments by $w/150$. The resisting moment will be called M_1. The weight of earth upon the back of walls, types C and E, was taken as effective. Assumed weight of earth 100 lb.

The Unit Stress S_1 at the toe of a trapezoidal wall or dam is given approximately in the following table. It applies to each of the four types (Figs. 70-73) when the resisting moment M_1 is twice as great as the overturning moment M. The values are in pounds per square foot when h is taken in feet.

(F) Unit Stress S_1 for Toe of Wall

Type of wall	Height of wall in feet		
	5 to 10	10 to 20	20 to 100
B	400 h	400 h	400 h
C	392 h	392 h to 378 h	378 h to 362 h
D	263 h	263 h to 198 h	195 h to 158 h
E	319 h	319 h to 272 h	270 h to 237 h

Example. To find the compressive unit stress at the toe of a wall of type B, the height being 20 ft. The table gives $S_1 = 400 \times 20 = 8000$ lb. per sq. ft. = 56 lb. per sq. in. When the value of S_1 approaches the working value (Art. 16), the foundation must be widened by an offset on the front side.

Formulas for Use with the Tables. Let a = width of top, b = width of base, h = height, e = distance from middle of base to point where resistance line cuts it; all in feet; f = coefficient of friction. M = overturning moment; M_1 = resisting moment.

Horizontal pressure without surcharge = $P = 3\,M/h$.
Weight of wall, types B and D = $W = 75\,h\,(a + b)$.
Weight of wall and earth on back, type C = $W = 25\,h\,(a + 5\,b)$.
Weight of wall and earth on back, type E = $W = 50\,h\,(a + 2\,b)$ approx.
Eccentricity e of resultant for type B = M/W.
Eccentricity e of resultant for type C = M/W approximately.
Eccentricity e of resultant for type D = $M/W - b/6$ approximately.
Eccentricity e of resultant for type E = M/W approximately.
Unit compression at toe = $S_1 = 2\,W/3\,(1/2\,b - e)$.
Safety factor against rotation = $n = M_1/M$.
Safety factor against sliding = $n = fW/P$.

Centers of Gravity. Let a be the top width, b the base width and h the height of any trapezoid whose back face makes the angle θ with the vertical, this face being inclined forward as in Fig. 73. Then the distance t from the toe to the vertical passing through the center of gravity of the trapezoid is given by

$$\mathbf{t = 2/3\,b - 1/3\,h\tan\theta - \frac{a\,(a + h\tan\theta)}{3\,(a + b)}}$$

When the back is vertical, tan θ is zero. For a rectangular section, $b = a$ and $t = 1/2\,a$. For a triangular section, $a = 0$ and $t = 2/3\,b$. When the back inclines backward, tan θ is to be taken negative. For a wall with vertical back, top width a and base width b, the distance from the toe to the vertical line through the center of gravity is $(2\,b^2 + 2\,ab - a^2)/3\,(a + b)$.

25. Investigation of Retaining Walls

To Investigate a wall is to determine its degree of stability against sliding, rotation, and crushing. Often this may be done by inspection in the case of an existing wall, for if it has stood for many years and no signs of failure are seen, it is to be regarded as safe. The problem, however, generally occurs in the case of a proposed design, where all dimensions and data are given and it is required to ascertain whether these satisfy the conditions of stability. The process of investigation should determine at least these three things: (1) the factor of safety against sliding on the base, (2) the point where the resultant cuts the base, (3) the compressive unit stress S_1 which exists at the toe.

The height of retaining walls seldom exceeds 30 ft. and a height of 60 ft. is about the limit. The condition of stability against rotation, with a proper safety factor, will usually insure against excessive stresses; further, in retaining walls it is not imperative that the whole joint should be under compression. It is therefore not necessary to apply for retaining walls the investigation discussed in the latter part of Art. 21. The vitally important theoretic determination is the maximum unit pressure upon the foundation bed at the toe.

A Graphic Analysis is often convenient and satisfactory. First, the pressure P acting on the back of the wall is to be determined by Art. 19, using for the earth which is to be put behind the wall values of w and ϕ which are most unfavorable to stability. Second, the weight W of the wall and the weight of earth resting upon the back, if any, are computed and the line of action determined, this line passing through the center of gravity of the combined cross-section of the wall and earth upon it. Then a drawing of this cross-section is made to scale and the resultant R of P and W determined, Fig. 64a; this gives the point r where the resultant cuts the base or the lowest point of the resistance line. The ratio W/P may be computed, or may be scaled from the drawing by taking W as unity. Then $n = fW/P$ is the factor of safety against sliding. The base b being divided into three equal parts, it is at once seen if the resultant falls within the middle-third, in which case there is ample security against rotation. Lastly, the distance between the center of the base and the point r is measured, and this gives e (Art. 21), from which S_1 is computed, and if S_1 does not exceed the allowable unit stress there is full security against crushing.

A Better Graphic Method is that shown in Fig. 74, where the force and equilibrium polygons are used. W_1 is the weight of the rectangular part of the wall and W_2 that of the triangular part. The force polygon is seen on the right, R_1 being the resultant of P and W_2, and R the resultant of P and $W_1 + W_2$. The equilibrium polygon is seen within the wall, P being produced to m_2, through which m_2m_1 is drawn parallel to R_1; then through m_1 the line m_1r is drawn parallel to R, thus determining r, the point in the line of resistance where the resultant cuts the base. Finally e is found by measuring the distance from r to the middle of the base. This method, although here illustrated for only two weights, is a general one readily applied to Fig. 75 or to any number of weights (Section 2). It obviates the necessity of computing the line of action of the resultant of the given weights or of finding it by a geometric construction.

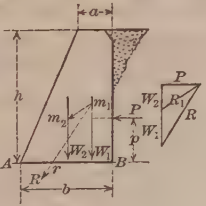

Fig. 74

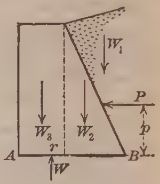

Fig. 75

The Analytic Method computes e by the principles of mechanics, the cross-section being divided into rectangles and triangles whose centers of gravity are known. For example, take the wall with vertical back in Fig. 74 which is held in equilibrium by the forces shown, W_1 being the weight of the rectangle, W_2 that of the triangle, and $W_1 + W_2 = W$ the vertical reaction due to the total weight, its point of application being at a distance e from the center of the base or at $1/2\ b - e$ from the toe A. Here the equation of moments with respect to the toe is

$$Pp - W_1(b - 1/2\ a) - W_2\, 2/3\ (b - a) + W\ (1/2\ b - e) = 0.$$

Inserting for W_1 and W_2 their values vah and $1/2\ v\ (b - a)\ h$, where v is the weight of a cubic unit of the masonry, there results

$$\mathbf{e = 1/2\ b - [vh\ (2\ ab + 2\ b^2 - a^2) - 6\ Pp]/3\ vh\ (a + b)}$$

which is a general formula for computing e for a trapezoidal wall or dam with vertical back. The weight W and the safety factor against rotation are

$$\mathbf{W = 1/2\ vh\ (a + b) \qquad n = vh\ (2\ ab + 2\ b^2 - a^2)/6\ Pp.}$$

The analytic method is more readily subject to detailed check than the graphic method.

Example. A wall of good rubble with a vertical back retains a level bank of earth, the data being w = 100 lb. per cu. ft., $\phi = 34°$, h = 18 ft., a = 2 ft., b = 5 ft., v = 140 lb. per cu. ft., f = 0.65. From Art. 19, P = 4580 lb. per lin. ft. of wall, and p = 6 ft. Then the formula gives e = 2.47 ft., so that the resultant comes outside the middle-third. The safety factor against rotation is n = 1.02, which is too small. For sliding, W = 8820 lb. and $n = 0.65 \times 8820/4580 = 1.25$, which is too low a degree of security, since n should be at least 2 (Art. 23). The thickness of this wall is too small to give proper security against either sliding or rotation.

For the Trapezoidal Wall in Fig. 75, let W_1 be the weight of the triangle of earth above the inclined back, W_2 and W_3 the weights of the masonry, and let p_1, p_2, p_3 be their lever arms with respect to the toe A, while p is the lever arm of the horizontal pressure P. Then the equation of moments is

$$Pp - W_1p_1 - W_2p_2 - W_3p_3 + W\ (1/2\ b - e) = 0$$

the solution of which gives the value of e. Here W is the total vertical force $W_1 + W_2 + W_3$. The factor of safety against sliding is $\mathbf{n = fW/P}$, and that against rotation is $\mathbf{(W_1p_1 + W_2p_2 + W_3p_3)/Pp}$.

After e is found, the compressive unit stress S_1 at the toe is ascertained by the proper formula of Art. 21. For the example given above, where the resultant comes without the middle-third, $S_1 = 2\ W/3\ (b/2 - e)$ = 196 000 lb. per sq. ft. = 1360 lb. per sq. in., which is much greater than the allowable.

Approximate investigations may be quickly made by the help of the tables in Art. 24 if interpolation is not required. Example: Let h = 60 ft., b = 24 ft., a = 3 ft for a wall of type C which retains earth having a slope of 1.3 to 1. Table (A) gives M = 874 800 ft-lb., and table (C) gives M_1 = 2 042 000 ft-lb., so that the safety factor against rotation is $n = M_1/M_2 = 2.3$. Then P = 874 800/20 = 43 740 lb., $W = 25 \times 60\ (3 + 5 \times 24)$ = 184 500 lb. The factor of safety against sliding if f = 0.65 is $n = 184\ 500 \times 0.65/43\ 740 = 2.8$. Lastly, the compressive unit stress at the toe, from table (F), is approximately 370×60 = 22 230 lb. per sq. ft. Table (F) was made for a factor of safety against rotation of 2, and should not be applied, except for design or roughly approximate pressures, when factor of safety exceeds or is less than 2.

To find the resistance against sliding upon the foundation bed, by the help of the tables of Art. 24, use $F = f\ (W_1 + M_1/Kb)$, in which F = resistance in pounds, M_1 = resisting moment taken from the proper table, b = width in feet of base of wall as previously determined, W_1 = weight of foundation in pounds, f = coefficient of friction of masonry upon the material of which the foundation bed is composed; also K = 0.50 for wall B, K = 0.47 for wall C, K = 0.66 for wall D, K = 0.57 for wall E.

26. Design of Retaining Walls

General Data. The top width of a retaining wall should not be less than 2 ft. where frost penetrates into the ground more than 3 ft., and not less than 1.5 ft. for smaller penetrations. For railway walls these widths should be increased to 3 ft. and 2.5 ft. The front face of the wall should have a batter of at least 1 in 24, preferably 1 in 12. The foundation masonry should be offset at least 6 in. both at heel and toe. Offsets to reduce the unit compression on the foundation bed should always be at the toe (Fig. 76), never at both heel and toe, since the compression at the heel will be small under the horizontal pressure of the earth. A factor of safety of 2 against rotation is recommended, although this always brings some tension in the back joints over the heel.

Fig. 76

Convenient Approximate Data on retaining walls of type C for preparation of estimates and use in the field will now be given. Let h = the height of a wall in feet; P = the horizontal pressure in pounds applied at $h/3$ above the heel, for a wall one foot long; W = the weight of the wall including earth upon its back in pounds for a wall one foot long; W_1 = weight of foundation masonry in pounds for a wall one foot long; b = width in feet of the wall at top of foundation; b_1 = width in feet of bottom of foundation masonry; S_1 = the pressure upon the toe of the wall in tons per square foot; S_0 = the safe load upon the foundation base in tons per square foot; f_1 = the coefficient of friction of masonry upon rock = 0.66: f_2 = the coefficient of friction of masonry upon sand and gravel = 0.50; and f_3 = the coefficient of friction of masonry upon clay = 0.33.

For approximate design, the width of the base may be taken as $b = 0.45\ h$ for ordinary walls retaining level banks; $b = 0.66\ h$ for railway walls; $b = 0.70\ h$ for surcharged walls, that is, walls retaining an inclined bank. The batter of the foundation masonry with a vertical line may be taken as 1 : 0.9. Also $b_1 = 1/2\ b\ (1 + 0.18\ h/S_0)$, and $P = 13\ h^2$ for ordinary unsurcharged walls, $P = 20\ h^2$ for railway walls, $P = 22\ h^2$ for surcharged walls, $W = 50\ h^2$ for ordinary unsurcharged walls, $W = 80\ h^2$ for surcharged walls, $W = 85\ h^2$ for railway walls, and $S_1 = 0.2\ h$. The resistance to sliding $= f(W + W_1)$, which must be greater than P.

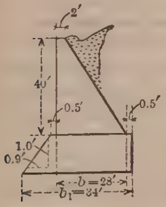

Fig. 77

To determine, in the field, the necessary width of base and of foundation, proceed as in the following example of a design made for estimating purposes (Fig. 77). Let h = 40 ft. for a surcharged wall which is to be built upon a foundation having a safe bearing capacity of 5 tons per sq. ft. The above approximate formulas then give $b = 0.70\ h$ = 28.0 ft., and b_1 = 14.0 (1 + 1.44) = 34.2 ft.

A retaining wall is probably slightly stronger if the back is built in steps. This is the most convenient form of construction for ashlar and rubble walls, but when the wall is to be built of concrete, either the stepped or unstepped back may properly be used. In calculating the stability of a wall with a step back, it may be regarded as having a uniform batter. The placing of earth back of a retaining wall in layers, and ramming it, may or may not reduce the horizontal pressure against the wall, but the calculated width of wall should not be reduced if the earth is to be so compacted. The ramming of soft rotten rock or earth which is a combination of clay, sand and gravel, may reduce the earth pressure.

Designing by Tables. As an example take a retaining wall 30 ft. high for a highway bridge approach which for architectural reasons must have a vertical face. The masonry will be taken at 150 lb. per cu. ft. and the earth at 100 lb. per cu. ft. The slope of repose of the earth will be taken at 1.33 : 1. A factor of safety 2 will be used for rotation and hence the overturning moment in Table (A) must be doubled. Entering table (A) for a slope of repose of 1.33 : 1 and a height of 30 ft., M is found to be 112 500 ft-lb.; hence the overturning moment for the proper factor of safety is 225 000 ft-lb. As a vertical faced wall is desired, either type B or C must be used. Type B is a very uneconomical type and should be used only for dry walls. Therefore type C will be adopted in the design.

Entering table (C) with the multiplied overturning moment, the nearest resisting moment is 259 000 ft-lb. for a wall 30 ft. high, and the required ratio of the base of the wall to its height is found to be 4/10 and therefore a base 12 ft. wide is needed. Entering table (F), the compression at the toe of the wall is found to be intermediate between that for a 20-ft. and a 100-ft. wall. By proportion the expression for the compression upon the toe of a 30-ft. wall is found to be 376 h or 11 280 lb. per sq. ft. or 5.6 + tons per sq. ft. If the foundation bed is rock or hard rotten rock and the bed is rough so that the wall will not slide, the design is completed. Offsets of 6 in. should be made at the top of foundation for reasons heretofore given. The stability of the design may now be investigated in detail by the methods of Art. 23.

The capacity of a granite ashlar wall to resist overturning, as compared with a concrete wall, is generally overestimated. Since both kinds of walls resist the overturning thrust of the earth by gravity alone, the granite ashlar wall is little stronger than the concrete one. Calling the resistance of a concrete wall 1, the resistance of a granite ashlar wall for types B, C and D would be 1.07, 1.05 and 1.07 respectively. A brick wall is only 0.85 as strong as a concrete one. A sandstone ashlar wall has about the same strength as a concrete. On the basis of the recommended factor of safety 2 against overturning, the maximum unit compression stresses are so low that, except for masonry laid in lime mortar, they need not be considered. The maximum compression in a retaining wall 100 ft. high is given in table (F) as 400 h = 20 tons per sq. ft.

Walls with Vertical Backs. The top width a is assumed and the horizontal earth pressure P computed by Art. 19. Then for the case where the resultant cuts the base at the edge of the middle-third, so that the compression at the heel is zero, the width of base is

$$\mathbf{b = -1/2\,a + 1/2\,\sqrt{5\,a^2 + 8\,P/v}}$$

where v = unit weight of the masonry. When the condition is inferred that the resultant cuts the toe when P is doubled, the formula is

$$\mathbf{b = -1/2\,a + 1/2\,\sqrt{3\,a^2 + 8\,P/v}.}$$

The first formula gives the greater value of b, and it should be used when it is important that no tension should exist at the heel. See Art. 27 for a comparison of designs made by these two methods. For rectangular sections, where $b = a$, these formulas become $b = \sqrt{2\,P/v}$ and $b = 2\,\sqrt{P/3\,v}$.

In Construction a trench is excavated in which to lay the foundation of the wall. Fig. 78 shows a wall whose foundation $aebd$ is at a considerable depth below the ground surface sg, while m_1m_2 and n_1n_2 are the sides of the trench which will be excavated in order to lay the foundation masonry $aebd$. It is important that upon the completion of the retaining wall the remaining trench spaces m_1aem_2 and $bn_1n_2\,d$ be filled with well selected earth thoroughly rammed into place. This gives an additional factor of safety against overturning. If the wall leans forward it will meet resistance at the front, which is shown by P_1 applied at $1/3\ ae$ measured down from a and also at P_2 applied at $1/3\ bd$ measured up from d. The values of P_1 and P_2 cannot usually be approximated, but the most extreme case is that where $P_1 = 0$, and then the height of the wall would be that of the top above the foundation bed. In construction, however, it is important that backfilling the space between the masonry and the sides of the trench should be well done. In very deep foundations the trench sheeting should be left in place so as not to disturb the earth back and front of the foundation masonry.

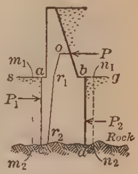

Fig. 78

Deep foundations for retaining walls, however, are very seldom used, because it is more economical, as a rule, to use piles to transmit the loads to soil of sufficient bearing capacity. In pile foundations it is important in the design to take care of the horizontal thrust by land ties or battered piles.

In the case of clay foundations also the proper backfilling of the trench is important, as it tends to keep water away from the foundation.

Sliding on the Base is to be prevented by making the base as rough as possible. For a wall on a timber grillage, some of the top timbers well bolted to the grillage may project above the level of the top of the grillage, or bolts well fastened to the timbers may project into the vertical masonry joints. When this is not possible the base should be placed on an inclined grillage. Fig. 64*b* of Art. 23 applies to this case and there will be no force F parallel to the incline AB if $\tan \alpha = H/W$, and it is usually easy to secure such an inclination in construction. Bonding the stones together will usually give ample security against sliding of a portion of a wall, on a lower portion. The designer should provide such methods of preventing sliding rather than to widen the base and thereby increase the weight in order to meet the theoretic condition of stability against failure by this cause.

The Principal Cause for the Failure of retaining walls is inadequate foundations. The application of theory is recommended in the design of all retaining wall foundations to guard against excessive toe pressures and sliding upon the foundation bed. The foundation bed, if of compressible material, should be investigated by borings to determine the character of the underlying strata. A wall built on a side-hill may require a special study against sliding and against movement of the side of the bank on account of the foundation pressure. Springs in side-hills not only endanger the foundations but may bring excessive pressure upon the wall itself if there is not adequate drainage provided.

The manner of placing the backfill may have serious effect upon the stability of a retaining wall. Less pressure is brought upon the wall if the fill is placed in layers, especially if these layers are compacted as they are placed. On the other hand, with low walls, the additional surcharge of a roller may have serious effect. If the layers are placed so as to dip away from the back of the wall somewhat less pressure is brought upon the wall and the drainage of water away from the wall is accelerated. The placing of a crushed rock or gravel drain over the whole area of the back of the wall is beneficial, provided that adequate drains are provided at the base of the wall to allow a free discharge of accumulated water.

The following references to failures should be read: Engineering News-Record, 1920, Vol. 85, p. 1058, p. 1076; Engineering News-Record, 1927, Vol. 98, p. 146; Vol. 99, p. 681.

Waterproofing and Drainage. Fig. 79 shows a design of a retaining wall to be built of concrete or of concrete faced with ashlar. If it is important that the face of the wall shall be dry, the treads of the steps of the back must have a batter with the horizontal, as shown in Fig. 79, of at least one inch.

Fig. 79

The back of the wall should be given two coats of coal tar pitch or one of the standard brands of waterproofing material; and immediately adjacent to the back a stone drain, marked *d-d* in the figure, should be built. Near the bottom of the wall, but at such height above the surface of the ground as will permit free discharge of the water back of the wall, drain pipes not less than 3 in. in diameter should be laid in the masonry. These drains should be at every 25 ft. of the length of the wall, and at their inside ends piles of broken stone, from 1/4 cu. yd. to 1 cu. yd. in volume, should be placed, depending upon the height of the wall. This broken stone prevents the pipes from becoming stopped up with earth. The ground in front of the wall should also be properly drained.

In order to guard against seepage of water through cracks which may result from temperature changes, a concrete wall may be built with vertical expansion joints at intervals of 50 ft., which extend from the foundation bed through the coping. This method of construction causes the temperature cracks to occur at known vertical lines. If expansion joints are provided, the sections should be properly keyed together to maintain the wall in alignment, as at *c*, Fig. 80. The wall may also be built without such expansion joints, provided it is reinforced with sufficient steel to take care of the tension in the concrete resulting from the shortening of the wall under fall of temperature. Water may be prevented from seeping through these joints by forming a rectangular vertical recess, as the wall is built up, which is filled with plastic clay well rammed in place or with asphalt. Fig. 80 is a plan of a portion of the length of a wall showing a horizontal section of the vertical expansion joint and the recess *a a a a* into which the clay is packed. Even though there should be a slightly uneven settlement of the adjacent sections, the clay will be effective in stopping the seepage of water.

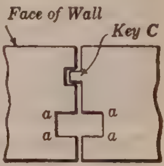

Fig. 80

A Frost Batter is a forward inclination of the back face near the top of the wall, as shown in Fig. 74. The object of this is to allow the earth to lift upward under the action of frost, and thus prevent an additional horizontal pressure at the top of the wall. A drainage ditch, parallel to the wall, a few feet away from the top, is often provided to carry off rain water before it percolates into the earth.

Pre-cast Concrete Crib Walls. These walls are built of pre-cast reinforced concrete, each member approximating in cross-section and length a railroad tie. The crib is then built up like a timber crib or one constructed of cross ties. This type may be advantageously used for temporary work and, if the concrete "ties" are held in stock, for emergency work. Where installed for temporary use they have much salvage value (see Engineering News-Record, Vol. 91, p. 783; Vol. 96, p. 654).

27. Comparison of Retaining Walls

The Profile of a wall or dam means the shape of its cross-section as shown by the bounding lines. An economical profile is one which has the least material consistent with proper stability and with the local conditions where it is built. Retaining walls are usually of trapezoidal form, but the batter of the faces has much influence upon economy of material. A sea wall may have its front face more or less curved, the curve being introduced to deflect upward the waves that strike it and thus to lessen the lateral pressure which may be caused by their impact.

The Relative Economy of retaining walls of different types may be approximately ascertained by comparing their resisting moments given in the tables of Art. 24. In type C the weight of the earth upon the back of the wall adds to the resistance. The efficiency of earth above the back in resisting overturning of the wall has been demonstrated by the successful construction of reinforced-concrete walls with counterforts where stability against overturning depends almost entirely upon the weight of the earth resting upon the wall. It should be noted in table (F) that the pressures upon the toe of walls of type D are much less than for C or in fact any other type, and therefore type D is a desirable one when the carrying capacity of the foundation bed is low. This type, however, cannot often be used in cities, since its front batter encroaches upon valuable land. Type B should rarely be used except for dry rubble walls, since it is a very uneconomical type. It has one advantage, however, that, due to the greater weight, it offers the most resistance to sliding, of all the types. Even in this respect, however, type B has little advantage over type C. Type D offers the least resistance to sliding. Type E is really a modification of C, and when the front batter of E is small compared with its back batter, type E becomes type C. Type E need be given little consideration in practice.

Counterforts on the Back are advisable only when built of reinforced concrete, because of the practical impossibility of taking care of the tension at the junctions of the back face and base with the counterforts, especially in walls of rubble or ashlar. Buttresses should rarely be used except when needed to prevent failure of a wall which is seen to be weak. A buttressed wall has no place in engineering except for architectural effect.

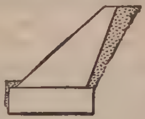

Fig. 81

Fig. 82

A Wall with Back Inclined Backward (Fig. 81) is not usually an economical one, owing to the added cost of construction, although theoretically such a form tends toward economy of material. Fig. 82 shows an excellent form of wall with a short and steep batter *aa* at the front a little above the surface of the ground, while the greater part of the front is vertical. In walls of types B and C the batter of the front face should be at least 1 : 24.

Theoretic Comparison of Walls. The following is a comparison of the width of base computed for several retaining walls with vertical backs all being 18 ft. high, masonry 150 lb. per cu. ft., and retaining a level bank of earth weighing 100 lb. per cu. ft. and having a slope of repose of 34°. The top width a in feet in the first line being assumed, the base width b in feet in the second line is computed under the condition that the distance e (Art. 21) shall be 1/6 b, thus giving a high degree of stability against rotation.

$a =$	0	1	2	3	4	5	6	7	7.8 ft.
$b =$	7.8	7.4	7.1	7.0	7.0	7.1	7.3	7.5	7.8 ft.
% =	50	53	58	65	71	78	85	93	100

The last line shows the relative amounts of materials in these walls as percentages of the rectangular wall in the last column. The triangular wall ($a = 0$) has 50% of the material in the rectangular one.

The following shows a comparison for the condition that there shall be a factor of safety of 2 against rotation, that is, that the resultant cuts the toe of the wall when the pressure P is doubled:

$a =$	0	1	2	3	4	5	6	6.4 ft.
$b =$	7.8	7.4	7.0	6.7	6.6	6.5	6.4	6.4 ft.
% =	60	66	70	76	83	90	97	100

The width of base is here less than for the more rigid requirement, that for the rectangular wall being 1.4 ft. less. The triangular wall has here only 60% of the material of the rectangular wall. In practice 1.5 ft. is the least allowable width of the top of a retaining wall (Art. 26).

28. Brest Walls and Dock Walls

A Brest Wall, often called a **face wall,** is one built against a bank of earth or rock to prevent it from falling. Since theory has so far proved useless in determining pressures from earth in situ, experience and practice are the only guides. The following rules may serve as a basis for thickness needed for different materials.

Hard rock and hard firm rotten rock will usually stand with a vertical face or with a slight batter 1 : 10 to 1 : 4 for an indefinite length of time. If the dip of the rock is away from the face, a wall is seldom necessary. If the dip of the rock is toward the face, a base of wall greater than 4/10 its height is seldom necessary, provided, however, that drains are built into the wall so as to prevent the wall being forced out by the formation of ice between the face of the rock and the back of the wall. Brest walls for all classes of material should have drains not only at the bottom but also at frequent intervals between the bottom and the top. Soft and seamy rotten rock, the dip of which is away from the face, seldom requires a wall with base greater than 1/5 its height. Soft and seamy rotten rock, the dip of which is towards the face, seldom requires a wall whose base is greater than 1/4 its height.

Firm sand and combinations of clay, sand and gravel seldom require a wall with base greater than 1/4 its height. If the dip of the stratum, however, is steep and toward the face, a base at least 4/10 the height of the wall should be used. If the walls are surcharged, these ratios should be increased to 4/10 and 5/10 respectively.

Clay and other materials resting upon a moist stratum of clay back of the wall, that dips toward the face, may exert enormous pressures, particularly when the wall is surcharged. If, for this case, the earth back of the wall is level with its top, a base larger than 6/10 its height is seldom required, and for a level top, if the dip is away from the face, a base larger than 5/10 its height is seldom required. If the wall is surcharged and the dip of the moist clay stratum is away from the face, a base 6/10 its height is usually sufficient. If the wall is surcharged and the dip of the moist clay stratum is towards the face and making an angle with the horizontal not exceeding 15°, a base 6/10 its height is usually sufficient. If the wall is surcharged and the dip of the moist clay is toward the face and over 15°, but under 30°, a base equal its height is usually sufficient. If the dip exceeds 30°, the ratio should be increased to 3/2. If any such walls rest on a clay foundation exceptional precautions may be necessary to prevent sliding, especially if the foundation is wet.

A Dock Wall differs from an ordinary retaining wall in that water pressure is exerted against its front face in the lower portion of the wall, while water, and earth submerged in water, exerts pressure upon its back in the lower portion of the wall; also the weight of the masonry below the water line is reduced by the weight of the volume of water which the wall displaces.

Assumption for Design. The water pressure upon the face of the wall should be regarded as balancing the water pressure upon its back. When the wall is built in tidal water, particularly when the range of tide is large, there is probably a lag in the tide back of the wall, and therefore it is advisable above low water to increase the width of the wall arbitrarily above the average back batter line, as shown in Fig. 83 by the dotted lines marked *rs*,

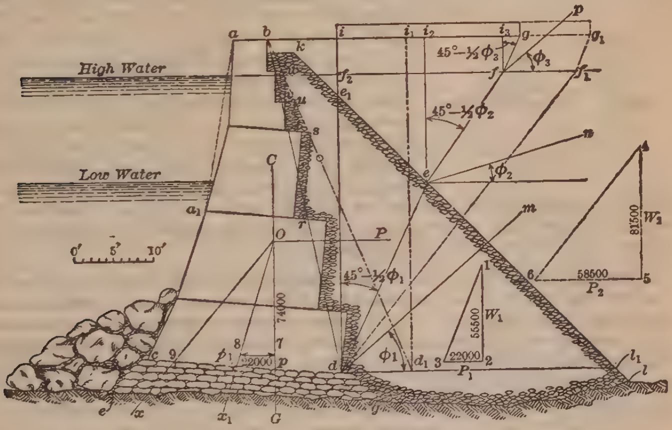

Fig. 83. Concrete Dock Wall on Rock

tu and *vw*. The weight of the earth on the inside of the wall and below high water is decreased by the weight of the volume of water displaced. The angles of repose of submerged earth will generally be much less than for earth above high water. The angle of repose of riprap or large cobble stone is not decreased by submergence and this fact makes both materials desirable as filling, back of a sea wall. Art. 17 gives the weights and angles of repose of submerged earth. It should be noted that the weight of river mud is given as 100 lb. per cu. ft. and its slope of repose as 10: 1. River mud should therefore be regarded as a liquid whose weight is 100 lb. per cu. ft. exerting a horizontal pressure against the back of the wall equal to 50 h_1^2, in which h_1 equals the vertical distance from the heel of the wall to high water. This horizontal pressure is applied at 1/3 h_1 above the heel. To get the net or effective pressure against the back of the wall, due to river mud, subtract from the liquid mud pressure the pressure of the water against the front, which gives 18.8 h_1^2 for fresh water and 18 h_1^2 for salt water. The pressure of liquid mud against the back of a wall need seldom be considered, but in the case of high walls, and where the earth filling is dumped from the shore toward the wall (Fig. 84), the river mud becomes banked against the back of the wall and exerts great pressure. The wedge b_1 b_2 a will be a mixture of river mud and earth with angle of repose of practically 0°. Due to the filling from the shore, a wave of mud, caused by the sudden settlement of the fill ab_3b_4, may add impact to the river mud and exert enormous pressure. Therefore when the depth of river mud is great, the filling should be made from the top of the wall, but even if this is done, it is advisable to regard the slope of repose of the submerged earth filling as having its base increased 30%; because the mud mixes with earth filling and the result is a flattening of the angle of repose. For example, riprap should be regarded as having a slope of repose of 1.3 : 1, and clay, sand and gravel as having a slope of 2 : 1.

The pressure at the back of a dock wall is considered, in what follows, to be applied at 4/10 the height of the wall above the heel. The point of application of the horizontal pressure is raised above that recommended in the design of ordinary retaining walls because the submerged portion of the earth back of the wall is generally semi-liquid in character, that is, it has a flat angle of repose. If the back fill were a liquid, under an abnormally large live load, the point of application of the horizontal pressure would never be higher than 1/2 the height of the wall above the heel. The effective weight of a masonry dock wall, below high water, equals its weight in air less the weight of the volume of water displaced by the wall, or the weight per cubic foot of masonry below high water should be taken as its weight in air less 62-1/2 lb. for fresh water and 64 lb. for salt water.

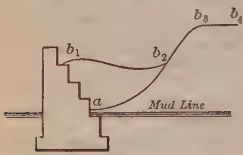

Fig. 84

Masonry Docks have walls of three general types: (1) A gravity masonry wall resting upon rock or other hard foundation or upon piles in firm material extending to the pile tops. Fig. 83 shows this type of wall founded upon rock. (2) A masonry wall resting upon a timber or concrete platform, called a relieving platform, the top of which is generally from 12 to 18 in. above low tide, resting upon a pile foundation, Fig. 85. (3) A rubble wall resting upon riprap; this is seldom used for dock walls, but may be so used by the construction of a timber wharf in front. It is more generally used in the reclamation of land from the sea.

Dock Wall of Type 1. Fig. 83 shows a type of dock wall founded upon rock. The rock should be cleaned off by dredge and divers, and the foundation of concrete in bags be laid by derrick boat and divers. Assume the safe unit compressive stress of well-bonded portland cement bag concrete as 10 tons per sq. ft. If the wall is built in salt water where the temperature of the air falls below 32° F. the face of the dock wall between the top and 2 ft. below low tide should be faced with ashlar masonry, which will withstand the action of salt water and frost. Type 1 is generally built of large blocks of portland cement concrete from the top of the foundation concrete to several feet above low tide. These blocks weigh from 15 to 80 tons, depending upon the size of the wall, and are generally cast on the shore, hauled by boat to the site of the wall and lowered by a derrick boat. The blocks are made with their beds beveled approximately 10 : 1, so that the bed joints are approximately normal to the resultant pressure. Grooves or recesses are molded in the vertical joints of each block and these grooves or recesses are connected by a hole passing through the block. By means of chains passing through these grooves and holes, the blocks are lowered into place, and when in place the chains are removed. The vertical grooves are made to match, and the square recesses thus formed by adjacent blocks are packed with concrete. Above low water the concrete is molded in place. The top of the wall should be at least 3 ft. wide to withstand shock from vessels. The front of the wall may be built with an increasing batter forming a curve as in Fig. 83. The back of the wall should be built in steps to agree with the heights of the concrete blocks, or the back of each block may be divided into several steps. If the wall rests upon a foundation bed of material that may be scoured out if unprotected, a bank of riprap should be placed in front of the wall to protect its foundation.

The resultant pressure P for a section one foot long in Fig. 83 is found as follows: The wall is to be built of concrete weighing 150 lb. per cu. ft., and in sea water weighing 64 lb. per cu. ft. It will be backed with riprap, and will have a live load back of it equal to 750 lb. per sq. ft. The filling back and above the riprap will be a combination of gravel, sand and clay. All material above high water will be regarded as dry and below high water will be regarded as submerged. The following data are here applicable:

Kind of material	Slope	Angle	Lb. per cu. ft.
Hard rock or riprap, submerged	1 : 1	45° 00′	65
Hard rock or riprap, dry	1 : 1	45 00	100
Gravel, sand and clay, submerged	3 : 1	18 30	65
Gravel, sand and clay, dry	1.33 : 1	36 50	100

Draw an inclined line bd, which is an average line for the stepped back. This line should pass through the heel d always; through d draw a vertical line di and a horizontal line dl_1 to intersect with kl, the line which represents the limiting surface of the riprap which is placed back of the wall to reduce the intensity of the earth pressure; through d draw de making an angle $45° - \phi_1/2$ with the vertical, in which ϕ_1 is for riprap and e is a point in kl; at e draw ef making an angle $45° - \phi_2/2$ with the vertical, ϕ_2 being for submerged gravel, sand and clay, while f is a point in the line of high water; at f draw fg making an angle $45° - \phi_3/2$ with the vertical, ϕ_3 being for dry gravel, sand and clay. Then d-i-g-f-e is the wedge which tends to slide down the lower plane de and cause a horizontal pressure P against the back of the wall, this being applied at a distance 4/10 di measured from d. To the weight of the wedge must be added the live load of 750 lb. per sq. ft., or, since a wall one foot long is being considered, a load of 750 lb. per lin. ft. The weight of the sliding wedge in pounds equals area $de_1e \times 65$ + area $e_1f_2fe \times 65$ + area $f_2igf \times 100 + 750\,ig = 55\,500$ lb.

To find the horizontal pressure P lay off to any scale of intensity 55 500 on the line 1–2; at 1 draw line 1–3 parallel to de and at 2 draw horizontal line 2–3 to intersect 3. Then length of line 3–2 gives 22 000 lb. = horizontal pressure P. The weight of the material between the back of the wall and di will be regarded as helping the wall to resist the overturning moment of the horizontal pressure. The center of gravity of this material can be found analytically or graphically. It should be remembered in getting the weight of this material and its center of gravity that submerged and unsubmerged materials have different weights. In finding the center of gravity of the masonry and its weight also, it should be remembered that the masonry above high water weighs 150 lb. per cu. ft. and below high water $150 - 64 = 86$ lb. per cu. ft. CG is a vertical passing through the combined center of gravity of the wall and the earth bid resting upon it. The total weight acting through CG is 74 000 lb.

To find the resultant pressure P, lay off on any scale the line 0–7 equal to 74 000 lb., and from 7 lay off line 7–8 = P = 22 000 lb. Then line 0–8 gives the resultant in direction and magnitude, and this intersects the base at p_1. Dock wall designs need not be investigated for pressures at the toe, because their weight is materially reduced by the buoyancy of the water. Their foundation pressures and their tendency to slide upon their foundations should be investigated as in retaining walls and all designs of dock walls should be investigated for overturning. The factor of safety against overturning for this example equals the ratio of the distances pc to pp_1 or 3.4. For dock walls the factor of safety against overturning should be at least 2.5.

If no riprap is placed back of the wall, df_1 is the plane of rupture down which the wedge dig_1f_1 tends to slide and the live load is applied to ig_1. The line 4–5, to the same scale as line 1–2, represents the weight of wedge dig_1f_1 and its live load, while line 5–6 equals the horizontal pressure of this wedge. The line Ox gives the position and direction of the resultant pressure for the wall without rip-rap. The factor of safety against rotation of the wall without riprap equals the ratio of the distances pc to p_9, or 1.3 : 1. The wall is therefore not safe, and either riprap should be placed back of it or its base should be increased to cd_1 for a factor of safety of 2.5 against overturning. The foregoing analysis shows the value of riprap in decreasing the pressure upon the back.

Dock Wall of Type 2. (Fig. 85.) This wall is built where rock or other hard foundation bed lies at considerable depth, and for permanent work, but not where the piles are subject to the action of the teredo. It is also used where a hard foundation cannot be reached by piles, that is, where the wall is floated in mud; in this case, no analysis is of much value in making or checking a design, but the wall should be designed so as to permit settlement and forward displacement without demolition, and land ties should be used to keep the wall from excessive forward movement. Fig. 85 shows the method

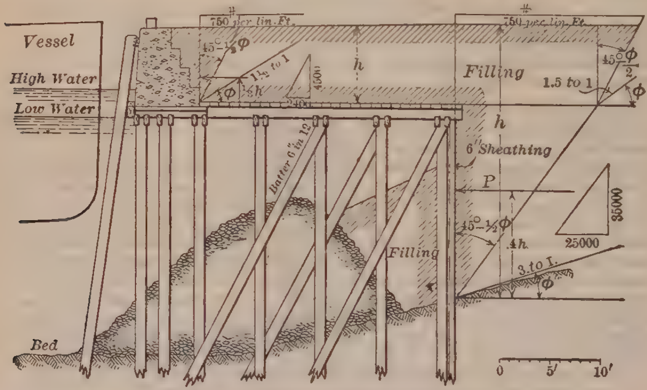

Fig. 85. Relieving Platform Dock Wall

of finding the horizontal pressure against the back of the masonry wall and also that against the timber sheeting; these methods are similar to those for type 1. For discussion of the timber substructure see Sect. 9, Art. 9. This type may also be constructed with a concrete platform on piles. If the water is infested with the teredo, concrete piles can be used instead of wood piles.

Engineers interested in the pressure of earth on sheet piling should consult "Erddruck, Erdwiderstand," by H. Krey, published by Wilhelm Ernst & Son, Berlin, 1926. So far as the writer knows, this book has not been translated. It is one of the few books giving any information upon the pressures existing below the bottom of a retaining wall or sea wall that will enable one to determine the proper length of sheet piling to be driven below the bottom of the wall, or the weight of riprap to be placed in front of the wall, to prevent any blow-out of the material under the wall.

Dock Wall of Type 3. This wall may be used for any class of foundation bed, and is well adapted to mud flotation. The riprap walls settle and go out of line, but cannot be overturned, and, if possible, the construction of the masonry wall should be delayed for a year or two after the riprap is placed. The riprap extends up to the low water line, its slope on the land side being 1 to 1 and on the water side 1-1/2 to 1. The rubble wall on top of the riprap is about 6 ft. in width. This wall is generally the cheapest type of permanent sea wall, but is unsightly, and vessels cannot approach so close to it as to the other types. When floated on mud, dock walls cannot be subjected to computation, but they require extraordinary precautions in design and construction. See paper by S. W. Hoag in Proc. Munic. Engrs. of City of New York, 1905. For examples of quay and dock walls, see Sect. 19.

29. Walls and Piers in Buildings

A Building Bearing Wall may fail (1) by the crushing of the masonry, (2) by tension of the masonry over openings, (3) by overturning about any horizontal joint due to the thrust of arches adjacent to corners, (4) by overturning of an exterior wall about any horizontal joint, due to wind, or (5) by failure of foundation. For (1) the same methods of preventing failure are to be used as for retaining walls (Art. 23). For (2) arches of masonry or lintels of stone, reinforced concrete, or metal must be provided to support the load of the masonry over openings. For (3) tie rods or buttresses must be provided to take care of the horizontal pressure when the width of wall outside of the arch is insufficient to act as an abutment. For (4) the walls must have a thickness not less than hereinafter recommended.

Failures are liable to occur during construction, due to the application of concentrated loads, as a rule eccentrically applied and when the mortar is not well set. Many cracked stone lintels are to be found over openings, but these seldom cause failure except of a local nature. Eccentric loads resulting from placing the bearing plates of beams and lintels very close to the inside edges of the masonry walls may cause failure by shearing the masonry or by overturning the walls. The flexure of beams and lintels causes an inclined reaction which tends to overturn the walls. Failures may also be caused by the lack of sufficient anchorage of the floor-beams or joists to the wall.

Thickness in Inches of Exterior Walls of Buildings

(Recommended for design)

	Residence buildings	Public and business buildings
Walls over 75 ft.:	In.	In.
Uppermost 25 ft. of wall.........	12	16
Next lower 35 ft. of wall.........	16	20
Next lower 40 ft. of wall.........	20	24
Next lower 40 ft. of wall.........	24	28
Etc.		
Walls under 75 ft. high:		
Uppermost 25 ft. of wall.........	12	16
Next lower 30 ft. of wall.........	12	16
Remainder of wall...............	16	20

Walls not over 60 ft. high may have uppermost 20 ft. with thickness of 12 in.

Walls not over 40 ft. high may be 12 in. thick throughout.

Basement walls should be at least 4 in. thicker than the walls immediately above.

The values given apply to masonry walls of brick, stone, plain concrete or hollow building blocks. If built of rubble stone, increase the specified thickness by at least 4 in., with a minimum thickness of 18 in.

Bearing walls with face brick bonded with clip courses or ties, and walls faced with ashlar should have a thickness increased by at least 4 in. over that given above. However, if the ashlar is at least 8 in. thick in alternate courses and is bonded to the wall, the thickness specified need not be increased.

When clear span between bearing walls is over 26 ft., increase the thickness by 4 in. for every 13 ft. that span is over 26 ft.

All walls over 100 ft. long between cross-walls, or suitable piers or buttresses, should be increased in thickness by at least 4 in. for every 100 ft. that their length exceeds 100 ft.

Reinforced-concrete walls may have a minimum thickness two-thirds of that specified above.

The height of stories for all given thicknesses of walls must not exceed 11 ft. in the clear for basements, 18 ft. in the clear for the first story, 15 ft. in the clear for the second story, and 14 ft. in the clear average height for any upper stories, unless the walls of such story and all the walls below that story shall be increased 4 in. in thickness in addition to the thickness already mentioned.

In case any wall is increased in thickness in accordance with one of the above requirements, it need not be further increased to meet other requirements.

The writer considers the above requirements reasonable. All engineers and architects, in designing structures to be built in cities, must conform to the requirements of the local building code.

The following specifications are quoted from "Minimum Requirements for Masonry Wall Construction," report of Building Code Committee of U. S. Department of Commerce (1925):

"The minimum thickness for solid brick bearing or party walls shall be 12 in. for the uppermost 35 ft. of their height, and shall be increased 4 in. for each successive 35 ft. or fraction thereof, measured downward from the top of the wall; except that the top story exterior bearing wall of a building not exceeding three stories or 40 ft. in height, or the wall of a one-story commercial or industrial building, may be 8 in. thick, provided that such 8-in. wall does not exceed a 12-ft. unsupported height and that the roof beams are horizontal.

"Where solid brick exterior bearing or party walls are stiffened at distances not greater than 12 ft. apart by cross-walls, or by internal or external offsets or returns at least 2 ft. deep, they may be 12 in. thick for the uppermost 70 ft. measured downward from the top of the wall, and shall be increased in thickness 4 in. for each successive 70 ft. or fraction thereof.

"The minimum thickness of solid brick exterior non-bearing walls shall be 12 in. for the uppermost 70 ft. of their height, and shall be increased 4 in. for each successive 35 ft. or fraction thereof measured downward from the top of the wall; in other respects, minimum thickness of non-bearing walls is the same as for bearing walls.

"Solid brick walls shall be supported at right angles to the wall face at intervals not exceeding 18 times the wall thickness in the top story or 20 times the wall thickness elsewhere.* Such lateral support may be obtained by cross-walls, piers or buttresses when the limiting distance is measured horizontally, or by floors when the limiting distance is measured vertically. Sufficient bonding or anchorage shall be provided between the wall and the supports to resist the assumed wind force acting in an outward direction."

When girders are supported at the ends by masonry walls the center of the bearing plates shall be practically concentric with the center of the wall. Small joists of steel or wood need not have more bearing in the wall than is necessary to reduce the unit stresses of the bearing within safe limits.

Stone Beams may be designed by $\mathbf{w} = \mathbf{Sbd^2/9}l^2$, where w = safe total uniform load in pounds per linear foot, b = width and d = depth of beam in inches, l = clear span in feet, S = working tensile strength (Art. 16) in pounds per square inch; for a concentrated load at middle use $1/2\ w$. For depth of a stone lintel in inches use $d = 4 + a\sqrt{l^3}$, where l = span in feet, and $a = 0.65$ for granite, 0.75 for limestone and marble and 0.85 for sandstone.

In Designing Piers with the unit stresses given in Art. 16, the piers should not have a greater ratio of unbraced height to least width than 12 for monoliths of stone and portland cement concrete and ashlar piers or blocks having the full horizontal dimensions of the piers, 10 for brick and well-bonded ashlar piers laid in portland cement mortar, 8 for brick and well-bonded ashlar piers laid in lime mortar, 8 for rubble piers of flat or scabbled stones laid in

* The writer thinks these requirements are too conservative.

portland cement mortar, 6 for rubble piers of unscabbled stones laid in portland cement mortar, and 4 for rubble piers of unscabbled stones laid in lime mortar. The use of bond stones at intervals in brick piers is not advocated, as they are apt to split under fire exposure.

The Unit Stresses of Art. 16 should be reduced for piers when the ratio of the unbraced height to least width exceeds 10 for monoliths of stone and portland cement concrete and ashlar blocks having the full horizontal dimensions of the piers, 8 for ashlar masonry, 6 for brick masonry, 4 for rubble masonry. This may be done by multiplying the S of Art. 16 by $(1 + 0.1c/d - 0.1h/d^2)$, in which h is height of pier in feet, d is the least width of pier in feet, h/d is the ratio of unbraced height to least width, and $c = 10$ when S is from 700 to 500, $c = 8$ when S is from 500 to 300, $c = 6$ when S is from 300 to 200, $c = 5$ when S is from 200 to 100, $c = 4$ when S is below 100 lb. per sq. in. When brick piers are faced with pressed brick, thin ashlar or terra-cotta, the facing should be neglected in figuring the area of the piers.

Example. Find the safe compressive unit stress for a brick pier of hard brick laid in portland cement mortar, the unbraced height being 16 ft. and least width 16 in. From Art. 16, $S_1 = 300$ lb. per sq. in., $c = 8$, $h/d = 12$, $h = 16$, and $d = 1.33$. Therefore the pier may be built of the stated dimensions, but the unit stress must be reduced by the above method to 210 lb. per sq. in.

30. General Data for Masonry Dams

Engineers interested in the flow of water over dams, or in the design of earth dams, siphon or shaft spillways, should consult "Hydraulic Laboratory Practice," edited by John R. Freeman and published in 1929 by the Am. Soc. Mech. Engineers, New York.

Introduction to Dams. The design of a gravity dam is a comparatively simple matter until one reaches the foundation. There the engineer is confronted with greater difficulties and responsibilities than in the design of the foundations of most engineering structures. In all cases, the design of a dam should be predicated upon extensive and thorough borings and test pits. The engineer may find it difficult to induce the owner of the dam to provide adequate funds for this purpose, but it is incumbent upon the engineer to insist that the necessary information be obtained in advance of the design and construction. Even though the results of extensive subsoil explorations are available, difficulties will arise during construction which will require changes in design to be determined by sound judgment.

The foundations must be designed not only to take the horizontal or lateral thrust of the water, but also to be as nearly as possible watertight. Twenty-five years ago the highest masonry dam in this country was the New Croton Dam, 297 ft. high above bottom of excavation. The highest existing masonry dam (1928) is tbe Pacoima Dam in California, about 400 ft. high, and engineers are now discussing dams up to 800 ft. in height. The amount of horizontal thrust varies with the square of the height. The tendency to leakage increases in a generally unknown proportion with the height of the dam, and in dams of over 200 ft. the problem of watertightness is an extraordinary one to solve. One may be reasonably content, for dams 50 or 60 ft. high, with borings and general personal study of the geology of the dam and reservoir site; but in the higher dams (100 ft. or more) it is suggested that a report of a practical geologist should also be obtained unless the terrain is thoroughly well known to the designer and the constructor. The engineer must study the watertightness not only at the dam site itself but throughout the reservoir to make sure that it will hold water. In this investigation the aid of a practical geologist should be of great value.

If the engineer is not a geologist it may be well to have his judgment confirmed as to the probability of any soft foundation rock becoming softer or slippery when the reservoir is filled and when the dam and its foundation are subjected to the pressure of water. Such changes in consistency are found in the case of certain hardpans, soft rocks and fissured rocks in which there has been an infiltration of clay into the joints or fissures. As infiltration of clay is usually of shallow depth, the fissured rock should be removed to a point where the clay has disappeared or is negligible.

Further, there remains the problem of properly tying the dam into the banks on either side of the valley, because lack of care in this respect is probably the most frequent cause of worry and occasional failure. The rock on the banks may be weaker than in the bottom of the valley. The end of the dam may abut against a ridge projecting from the side of the valley, so that there is less rock in front of the toe at that part of the dam; or the rock in the bank may dip downstream from the structure. Under such conditions, the ends of the dam should be very thoroughly anchored into the banks.

The writer does not wish to criticise unduly the tremendous amount of mathematical talent that for a generation has been expended in the determination of economical dam profiles with the view of saving a few per cent of masonry. He does, however, wish to emphasize that almost any engineer can with intelligent study of the standard rules determine a safe and reasonably economical cross-section of a dam; but, when this is done, little of the real problem of safe design has been accomplished. The foundations are the real problem. This fact is too little understood.

Due to the high cost of construction and the alleged commercial necessities, the profession has been contented to work with lower factors of safety than are customary in the design of most other engineering structures. This is properly justified in the construction of the dam above its foundations because it is a simple structure with definite loads. When the foundation is reached, however, the hazards are greater and the factors of safety there should be at least as great as in any other statically determinate structure.

Gravity dams are usually designed with the line of pressure at the outer edge of the middle-third, which gives a factor of safety against rotation of slightly over 2. The writer recommends that the line of pressure lie within rather than at the edge of, the middle-third. The factor of safety against sliding within the body of the dam is much less if friction alone is considered. The writer recommends that in every plane of the dam the resultant horizontal pressure be resisted by shearing in the masonry with a factor of safety greater than 2, ignoring friction—this being accomplished by proper bonding of the masonry. In the design of foundations resting upon hardpan or rock, it is recommended that the dam be stepped or sunk into the foundation to such a depth that the factor of safety against sliding or shearing of the foundation shall be at least 4. The base of the dam should be sunk into the foundation a sufficient distance to carry the entire horizontal pressure by the bearing of the vertical face of the toe or steps against the foundation, omitting the consideration of frictional resistance on the foundation.

Attention is called to Fig. 85*a*, showing a dam 185 ft. high from base of dam to water surface, and with the base sunk into the rock foundation to a depth of 10 ft. at the toe. The horizontal pressure on the back of this dam amounts to approximately 580 tons per lin. ft. Ignoring friction and assuming a unit bearing pressure of 40 tons per sq. ft. at the vertical face of the toe, such a dam would have to be sunk into the rock a depth of 14 ft. For most ordinary rock with the usual seams, the safe load on the rock in front of the dam would probably not be in excess of 20 tons per sq. ft., in which event a dam of this height should be sunk into the rock at the toe approximately 28 ft., and in soft rock approximately 30 or 35 ft. If the rock surface is roughened or stepped as shown by the dashed line of Fig. 85*a*, the sum of the heights of the vertical shoulders may be considered as the height of the rock face at the toe for resisting horizontal thrusts.

At the banks, the dam should be sunk into the foundation to a greater percentage of the height than at the middle of the valley. If the dam is a spillway and the rock is soft or fissured it should be protected at and below the toe against erosion of the falling water, otherwise one cannot safely count upon the rock immediately in front of the toe being permanently available to take the horizontal thrust of the water.

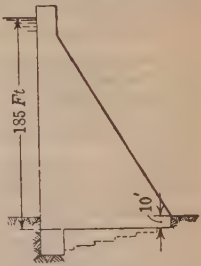

Fig. 85*a*

Extreme care must be taken to prevent a dam from sliding should the rock slope downward from the heel of the dam toward the toe. This is especially true in high dams on laminated rock. In that case there is a possibility of the rock bulging in front of the dam or shearing along lamination planes.

Thorough borings and test pits at the dam site are recommended not only for design but also to assure against excessive cost, because otherwise upon excavation the foundation rock may be found at a greater depth than assumed. The cost of many dams has been far in excess of the money provided due to the fact that the borings made were not sufficient to locate accurately the rock and overlying material in advance of construction.

If the foundation rock is at all fissured and requires grouting, this should be thoroughly done under expert supervision. The amount of grouting that may be found necessary in such rock cannot well be determined in advance unless the explorations have been extensive, by core borings and test pits. The engineer in his estimates, therefore, must allow a considerable amount of money for grouting if the explorations indicate that it may be needed.

Dams are often constructed at a great distance from the operating engineer's headquarters, and daily or weekly inspection of the finished structure is left to laborers or farmers living in the vicinity. Just how frequent expert inspection will be made cannot usually be foreseen by the designers and constructors. The writer recommends four engineering inspections a year and that at least a weekly record be kept of all leaks through the dam or adjacent banks. Practically all dams leak and this is true of the adjacent banks, and the amount of leakage varies from week to week and year to year. If there is no undue or irregular settlement and no cracks in the masonry and if these leaks do not increase materially and the issuing water is not discolored, it may usually be assumed with reasonable safety that the dam foundation is all right. The writer wishes, however, to accentuate the fact that the matter of discoloration or the carrying of materials from the dam foundation is not a matter that should be left to inspection by laymen. Water which is apparently clear if put in a clean glass and held up to the sunlight may indicate the carrying of minute particles even though there is no discoloration which can be determined by observing the issuance of the water.

Needless to say, if the amount of water is increasing from time to time it should be most carefully watched under expert supervision. In order that one may not be unduly apprehensive in the matter of leaks below the dam or through the banks, a careful observation should be made of all springs in the adjacent banks and below the dam prior to the filling of the pond. Otherwise it may be difficult to determine after the pond is filled whether or not these are old springs or new leaks.

Theory of Design. **Dams** built up to the middle of the 19th century apparently were designed without theoretical analysis. The principles upon which safe and economical dams should be designed were laid down first by Sazilly in 1853 and after him by such authorities as Graeff, Delocre, and Rankine. According to these principles the requirements of a safe dam are:

(a) At all horizontal sections, the resultant of the acting forces shall strike at or within the middle-third for all conditions of the water elevation behind the dam. This principle implies the condition that no tensional stresses are permissible in a masonry structure of this character, the assumption being made that the pressure intensities along the section or joint vary uniformly, according to the law of trapezium. (Art. 21.)

(b) At no point along any horizontal joint or the base shall the unit normal stress upon the plane be more than a specified safe limit. (Art. 16.)

Investigations of the old Spanish dams, standing for over three hundred years, show a maximum compression stress on horizontal joints of from 11 to 14 tons per sq. ft.

(c) The friction developed by the weight of the structure at any horizontal joint or at the base shall be greater than the resultant horizontal force acting upon the joint tending to slide the part of the dam above it. (Art. 18.) Frictional resistance on the base or at horizontal sections above the base may be reduced by the entrance of water beneath or within the dam.

No exact mathematical expression has been found as yet which would determine the outline of the dam section in accordance with the three requirements enumerated and with given data as for permissible stress and specified factor of safety against sliding and overturning. If only condition *a* is considered, the economical section will be a right triangle with back vertical and base width $= h/\sqrt{\gamma}$, where h is the height of water above the base and γ the specific weight of the masonry. The authorities mentioned and a number of others have endeavored to find the best modification of this triangle form to comply with requirements *b* and *c*, the result being a series of proposed forms of more or less complex outline, but none having an unimpeached general value and most being entirely impracticable. A very complete record of these forms and of the dams built according to the different theories can be found in E. Wegmann's "The Design and Construction of Dams." The "practical profiles" recommended by him (Art. 32) represent a valuable addition to the profiles mentioned.

In 1895 M. Levy and following him in 1904 Karl Pearson and Atcherley made thorough analytical studies of stresses in gravity dams of masonry and came to the conclusion that in such dams the planes subject to maximum compressive and tensional stresses are not horizontal as a rule; that the direction of the maximum pressure intensity is parallel to the face of the dam and the pressure is greatest near the outer profile; and that, in every case, in a dam designed according to the heretofore accepted principles tensional stresses occur on inclined planes near the heel. These analytical deductions have been verified by the famous experiments of Ottley and Brightmore on plasticine models and by the experiments of Wilson and Gore on India rubber models. To eliminate tension at or near the heel, Levy proposes to design dams so that "the normal pressure on every joint at the upstream face should be greater than the hydrostatic pressure at that point." Recently built French dams are all designed on this principle. German engineers use a clay or loam fill at the back of high dams, to assist in the plastering of the masonry on the waterside and to fill every crack possibly developed by tensional stresses. Wilson and Gore pointed out the advantage of a rounded or projecting inner heel to decrease tensions. In American practice this method is extensively used.

It is recommended that for the lower one-fifth of the height of dams, the safe working stresses of Art. 16 shall be reduced 30% if the dam is designed without considering the maximum stresses resulting from the combination of normal and shearing stresses. (Art. 21.)

Horizontal Pressure on Dams. Whereas the physical properties of water are well known (Art. 20) it takes a good deal of judgment to determine the horizontal forces exerted by water upon a dam. As a rule the stratum upon which the dam is built is covered by more or less pervious or impervious layers of sand, gravel, loam or clay. The dam generally extends through this overlying material and the question arises, how far down and to what extent shall the horizontal water pressure be considered. In the case of spillway dams the back pressure from the water downstream (tailwater) may decrease the net pressure upon the back and this pressure may also be exerted through the material overlying the foundation.

How much numerical value should be given to this underground pressure is entirely dependent on the kind of overlying material. Clean gravel will practically not reduce the hydrostatic pressure at all, fine sand will reduce it to a great extent, while puddled alluvial soil may not transmit any water pressure at all, but such soil quickly disintegrates with a running leak. The intensity of this horizontal underground water pressure cannot be accurately determined but its possibility should not be overlooked. The overlying material also exerts a horizontal thrust upon the back of the dam which should always be considered in the design (Art. 20), although usually this pressure is practically negligible. The active thrust and passive resistance of the overlying material at the downstream side of the dam on the other hand should generally be disregarded.

Uplifting Pressure on Dams. Masonry dams of the gravity type are preferably built upon rock, but low dams of a gravity type have been successfully constructed upon gravel and sand. These materials may afford a safe foundation if compact (of the nature of hardpan), or if the free percolation of water under the dam is prevented by carrying down a cutoff at the heel to a depth of 1/2 to 3/4 of the height of the dam, by concrete, steel or wood piling. (See also Dams on Sand Foundation.)

In the design of all dams, except those whose foundations will rest on solid, impervious and unfissured rock, careful consideration must be given to the possibility of uplift or upward water pressure upon the base due to the water being forced under the base of the dam through veins, fissures or interstices. Neglect to consider this great force may result in disaster. The designer must allow for uplift or upward pressure on the base of the dam on all but the best rock foundations or he must provide an absolutely impervious cutoff that will prevent uplift entirely or make it negligible. In "Professional Memoirs," Jan.-Feb. 1915, Capt. W. A. Mitchell describes many experiments and observations made on the uplift on dams, especially those made on the Ohio River dams built by the federal government.

The amount of uplift which should be assumed either on rock or on sand and gravel foundations is a matter of judgment and can only be subject to broad general rules. The observations that have been stated relative to the uplift in existing structures and laboratory experiments are indicative only. The wide variation in the character of rock, sand and gravel leaves the matter to judgment, and experience in the construction of dams makes one feel that ultra-conservatism is necessary. The writer therefore recommends that, except where the dam rests on impervious rock or where an impervious concrete cutoff is carried to such rock, full uplift on the whole area shall be considered at the heel and zero uplift at the toe; or if there is any probability of water in the lower pond, the uplift at the toe should be assumed equal to the full head of the lower pond water. In designing the dam the center of pressure should fall within the middle-third considering uplift and a reasonable amount of ice pressure (p. 941).

Experiments by D. M. Francis, F. R. Shunk and J. P. Jervey show that water percolates through joints between concrete and rock and travels in small veins in these joints. If allowed free exit, the pressure varies irregularly between upper and lower pools; if the exit is closed the pressure quickly becomes that of the upper pool as soon as enough water has passed through the veins to fill the test holes. The amount of space of these small veins, that is, the area of upward water pressure, varies from nearly zero in excellent granite foundations to 50% or more in rotten shale. The final height of the rise of water in the test holes when free exit is provided below the dam varies roughly as the distance from the lower pool relative to the distance between pools. If efficient drains are introduced downstream of the cutoff, the upward pressure beyond such drains is practically negligible in good rock. The drains must be effective, must not be too small and must not be stopped. With rock foundations the Ohio River Board in a general case used the following rules:

(a) Upward water pressure varying at a constant ratio from upper pool at upstream edge to lower pool at drains.

(b) Drains to be located in the rock on the downstream side of the key or cutoff.

(c) Pressure under 50% of base for firm, solid rock and under 100% of base for weak rock.

(d) Neglecting upward pressure, the center of pressure to fall within the middle-third of the base; including uplift, the center of pressure to fall far enough inside the toe so that the maximum compression shall not exceed 400 lb. per sq. in. for good rock and 70 lb. per sq. in. for poor or doubtful rock.*

Tests were made by the Bureau of Reclamation at the Willwood Dam of the Shoshone Irrigation project in northern Wyoming (Eng. News-Rec., Vol. 99, p. 660; Trans. Am. Soc. C. E., Vol. 93, p. 1538). This is a concrete gravity overflow dam, about 55 ft. high, built upon horizontally stratified and seamy shale and sandstone. The foundation was grouted and observation pipes were conducted from the dam foundation to the inspection gallery built within the dam. The uplift at the heel was about one-half the reservoir head and at the toe full tailwater head. These measurements were not sufficiently extensive to give indication as to what proportion of base was acted upon by water pressure. It will be helpful to the designer and the profession at large, and no great expense to the owner, if uplift observation pipes are provided as in the case of the Willwood Dam. These will also be useful in the inspection of the structure from time to time.

Uplift may also occur between concrete or masonry joints of the dam above the foundation bed, and in constructing the dam special precaution should be made to decrease this uplift to a minimum. The writer recommends the following rules, regardless of any attempts that may be made to eliminate such uplift; at all sections of a gravity dam uplift equal to 25% of the reservoir head above any joint shall be considered at the back of the dam and zero at the front; without uplift the resultant should lie well within the middle-third, and considering such uplift the line of pressure should not go outside the middle-third. (See also Art. 20.)

Waterproofing the back of the dam will decrease uplift and also disintegration of the concrete where subjected to water and the atmosphere alternately. Waterproofing may be applied as an exterior asphaltic or wash coating or by "gunite" as at the Elephant Butte Dam, or by enriching the cement content for a space of one or two feet from the back of the dam as was done at Arrowrock and Hetch Hetchy dams.

Cutoff Walls and Drains. It is customary and proper to build a cutoff of concrete as shown in Fig. 86, the concrete being made of the best quality,

* The writer believes that the center of pressure should fall within the middle-third for reasonable assumptions of uplift.

most carefully placed so as to prevent the water getting under the dam or at least to increase the travel of the water by the length *abcd*. The higher the dam and the more pervious or fissured the strata the deeper this cutoff should be. Sometimes the cutoff wall is made quite deep, the rock being channeled out by machine. It is good practice to provide at *d* (Fig. 86) a continuous drain with proper openings *p* extending to the face of the dam, so that any water that passes the cutoff may not exert uplift except of little intensity, but will flow out at *e*. On account of the possibility of these small drains and discharge pipes getting stopped up it is recommended in large dams to build instead of a small drain, as in Fig. 86, a gallery (Fig. 94) of such height that a man may walk in it from one end to the other to inspect and clean the drains so that the real uplifting pressure will be known. This gallery should be reached through manholes located at or near the top of the dam.

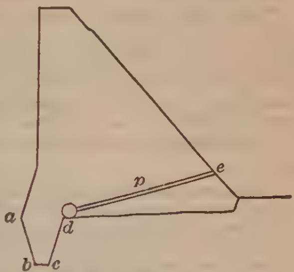

Fig. 86

Experiments made on the Gatun dam and the Ohio River at Dam No. 18 show that water pressure is transmitted through concrete and is transmitted through joints between old and new concrete more freely than through solid concrete. If allowed free exit, the pressure is practically negligible. Mitchell suggests that in order to utilize the full value of the weight of the masonry, drainage should be provided from near the back of the dam at other levels than the base only; or if such drainage is not provided for in the design, allowance should be made for the upward pressure at every horizontal joint investigated, but a smaller relative intensity can be assumed than that considered at the base. Uplift on joints above the base or drains above it have rarely been considered. Certainly if entirely disregarded, the line of pressure above the base should lie well within the middle third.

Dams Built on Sand. In the first paragraphs of this article, the writer has sounded a word of caution to designers and constructors because of foundation difficulties. Should the engineer be confronted with the problem of building a dam upon sand he will in all probability find the foundation problem exceedingly difficult.

Fig. 103 (p.960) shows the cross-section of the Sherman Island Dam which is one of the best cross-sections developed for a reasonably high dam upon a soft bottom. While this dam was designed for sand, it was built upon a mat of interlocked glacial boulders 5 or 6 ft. deep overlying saturated fine sand. This interlocked mat of boulders gave a great deal of resistance against sliding. There are two lines of sheet piling at the heel of the dam, one line 55 ft. deep and the other 45 ft. deep; and at the middle of the base of the dam a large mass of concrete was provided to add resistance to sliding. There is also a concrete apron below the dam, from *F* to *G*, to increase the percolation factor; and the dam base and apron were weighted with sand and gravel to give greater weight against sliding. Upstream a sand and gravel backfill was placed to further increase the percolation factor. Before there can be leakage under the dam the water must travel from *B′* to *B*, *B* to *C*, *C* to *D*, *D* to *E*, *E* to *F*, *F* to *G*. This gives a percolation factor of about 5.

It is thought that this dam could not have been built without steel sheet piling, but the mere use of steel sheet piling was not in itself a guarantee against serious percolation. It was only intended to drive one line of sheet piling 55 ft. in length. After this was driven it was discovered that at three points the sheet piling did not interlock at the top, and it was therefore highly probable that it did not interlock at the bottom. It was then decided to drive an additional lapping piling at these three points so as to provide a certain barrier. It was also decided to protect the dam further by driving a second line of steel sheet piling (as shown on Fig. 103) back of the original 55 ft. of piling. There is a record of steel sheet piling having been driven into sand containing boulders, as a cutoff, where one or two sheets when driven "curved up" and came to the surface of the stream bed. Steel sheet piling makes high dams on sand possible, but only if driven with great care.

There is no satisfactory way of grouting sand, and test borings give only approximate information as to the condition of the sand into which the piling is to be driven. The hazard of water cutoff for a dam on sand is so great that it is doubtful if any masonry dam should be built upon sand to a greater height than 75 or 80 ft. In such high dams upon sand the writer recommends increasing the percolation factor by placing a backfill, as shown by Fig. 103, and also recommends increasing the length of the apron as shown in this sketch.

The Sherman Island Dam presented a particularly difficult problem because the ends of the dam rest on rock while 90% of the length of the dam is on a mat of boulders overlying fine sand. It was necessary to make expansion joints in the foundation mat at a point where the rock ended and sand began, and under one buttress the rock was excavated and the base built upon a layer of sand 2 ft. thick resting directly upon the rock. This permitted adjustment without cracking. The writer is of the opinion that had there been no boulder overlay at this site the resistance against sliding should have been further increased either by flattening the back slope of the dam or otherwise spreading the dam base, and possibly also by extending the apron and placing additional earth fill on it.

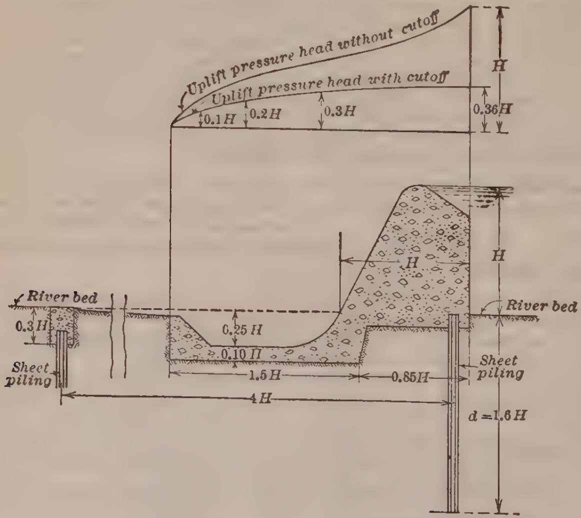

Fig. 87. Spillway Dam on Sand Foundation

The uplifting pressure of water below the base is most serious in the case of dams built on sand or gravel foundation. Water pressure is transmitted more or less freely through washed sand, gravel aggregate and washed river gravel. Sand offers the greatest, clean gravel the least resistance to uplifting action. Besides being dependent on the physical properties of the foundation strata, the magnitude and the method of distribution of the upward pressure are functions of the depth of the cutoff or sheet piling, of the location of sheet piling and of the width of the base and apron. A watertight sheet piling or cutoff wall is most effective if located at or near the heel of the dam. Another line of sheet piling placed near the toe will be effective in confining the material below the base but will increase the uplifting pressure if made watertight. The results of a thorough analytical investigation of the matter are published in Trans. Am. Soc. C. E., 1911, vol. 73, by G. E. Smith, in discussing A. C. Koenig's paper on dams on sand foundation. Figs. 87 and 88 are taken from this article, illustrating the influence of the depth of the cutoff wall and the width of the base of the dam and the length of the apron upon the distribution of upward water pressure. The diagram above the dam section, Fig. 87, shows that for the relative dimensions of this particular instance the total of uplift is reduced by the sheet piling to about one-half of that which would prevail without cutoff. For other dimensions the uplift can be estimated with the help of the diagram, Fig. 88. Koenig, in the paper above referred to, proposes the following formula for the depth d of the necessary penetration of the sheet piles:

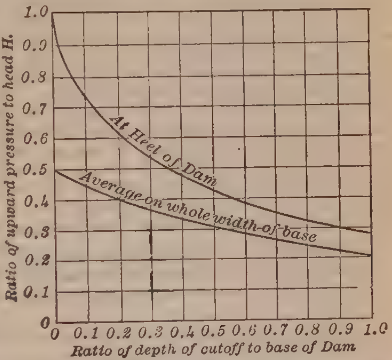

Fig. 88. Variation of Upward Pressure with Change in Depth of Cutoff

$d = h/sx$ where h = the maximum head of water on the upstream side above the bed of the stream, s = the specific gravity of the material penetrated and x = the proportion of solids in the strata. In sand with $s = 2.65$ and $x = 0.6$, $d = 0.629\ h$, which is the absolute minimum depth needed. For low heads, Koenig suggests $d = 2\ h$ and for medium heads up to 30 ft. $d = h$.

J. D. Justin proposes a somewhat different method for determining the depth of sheet piling, based on assumed factors defining the velocity of flow of water through the soil. (Trans. Am. Soc. C. E., Vol. 87, p. 54.)

A number of failures of dams occurred due to the uplifting action of water upon the aprons of dams. The floor of the Lost River dam, California, and that of the Narrora weir on the Ganges were destroyed by being lifted up by upward water pressure.

Percolation. The flow of water under dams on porous foundations can not be entirely stopped and this is the origin of a frequent cause of failure of such dams, the " blow out " at the toe, which is due directly to a higher rate of percolation than permissible for the material in question. If the percolating water has a greater velocity than a certain limit, it will carry with it parts of the material lining the vein of its passage, thus increasing the size of the vein. This action being progressive, the size of the vein continues to increase until it becomes a large hole and the dam collapses from lack of support. The blowout always starts with the appearance of a boil at the toe of the dam, that is, a strong spring carrying sediment. The time between the first appearance of the boil and the blowout varies from a few hours to several days.

The only way to prevent a blowout in pervious foundations is to cut down the velocity of the percolating water below that necessary to disturb the particles of the foundation bed, by artificially making the underground travel of the water from headwater to tailwater as long as is necessary for this purpose. The ratio of this length of underground travel to the head of water is called the **percolation factor**. The most efficient way to create a large percolation factor is by a cutoff or sheet piling.

W. G. Bligh (Eng. News, 1910) proposes the following percolation factors: Fine sand and silt 18, fine micaceous sand, 15; ordinary coarse sand, 12; gravel and sand, 9; boulders, gravel and sand, 4–6. The percolation factor may also be increased by a substantial impervious apron downstream or an impervious mat upstream of the dam, which latter may be an upstream concrete apron or a protected clay fill or the dam may be given a large inclination on the upstream face. These types have been mostly developed for dams across streams in India, where many failures occurred before the importance of the use of a proper percolation factor was recognized. The knowledge there acquired was used to good advantage on some dams in the United States. The Laguna weir across the Colorado River, with a head of 15 ft., has a total base width of 244 ft., whereas the Madaya weir in Burmah, India, for a head of 11 ft. is 288 ft. wide. In the example shown on Fig. 87 the sheet piling, the base of the dam and the apron take care of a percolation factor of about 6, corresponding to a foundation stratum of gravel and sand. If steel sheet piling is used, it must be driven with care to insure proper tightness, or else " piping " may result in spite of the cutoff piling.

Grouting of sand foundations, especially if saturated with water, is of questionable value. Primarily successful grouting can be accomplished only where there is a vent, as in the case of seamy rock, to permit the displacement of water or air with grout. It is thought that the forcing of material under pressure into sand disturbs the sand and that the grout may not restore it to the same degree of compactness that prevailed before grouting. The writer has tried it without success. Some success may be expected in loose gravel.

Grouting of soft or hard rock foundation should decrease the percolation of water under the dam if such grouting is so done as to permit free discharge of the water or air in the crevices or fissures. It is recommended in all except solid rock without fissures or open joints. If the fissures in the rock are very fine, neat cement grout must be used. Where the fissures or openings in the rock are sufficiently large, grout consisting of one part cement and one part fine sand may be used.

An excellent description of the methods used in grouting the dams of the Catskill reservoirs is given in Trans. Am. Soc. C. E., Vol. 83, p. 1042.

Usually the best method is to drill holes into the rock to a depth of from 1/10 to 4/10 the height of the dam, depending on the character of the rock, these holes to be placed from 5 to 20 ft. apart, also depending on the character of the rock. Grouting should then be started at one side of the valley and the grout forced in at only one hole at a time, noting whether or not it rises in the other holes. The same method should be carried on across the dam slowly so as to permit the grout to set up in each set of holes before grouting goes on in the near vicinity. There are records of grout having traveled several thousand feet in very seamy rock.

At the Mazoe River Dam in South Africa the shale foundation was solidified by starting the grouting at the top because the shale was too weak to sustain high grout pressures. To achieve this the grout holes were filled with clay to within 3 ft. of the top and then grouted. The hole was then cleaned of grout and clay to a further depth of 3 ft., and grout again injected. This process was repeated until the entire shale formation, about 25 ft. deep, was thoroughly grouted.

In the Hales Bar Dam on the Tennessee River, the Dix River Dam in Kentucky, and the Wilson Dam in Alabama, asphalt grouting proved successful. These were cases where there were large fissures in the rock through which water flowed with appreciable velocity. This grouting work was accomplished by installing a pipe in a grout hole, the lower end of the pipe being perforated. An electrical resistance wire was placed inside of the pipe, fastened at its bottom and insulated from the pipe. The hot asphalt was pumped into the pipe, flowing through the perforations and being kept in fluid condition by the electrically heated wire. When the asphalt reached the open fissures it cooled and hardened and was not washed away by the water, which would have been the case had cement grout been used. (See Eng. News-Rec., Vol. 96, p. 798; Vol. 100, p. 627.)

Ice Pressure at the top of the dam must sometimes be taken into account in the design and use of the dam. The under surface of a sheet of ice, being in contact with water, remains practically at the freezing point, while the temperature of the top surface may be as low as that of the atmosphere with resulting shrinkage cracks. These cracks subsequently fill with water and freeze. When the temperature rises the sheet tends to expand, and if the ice is confined it will develop thrusts. If the area of the reservoir is very large the thrust action will be lessened due to buckling of the ice sheet, and if the reservoir banks have flat slopes it is thought the pressure will be negligible.

Some designers disregard ice pressure where reservoirs are designed to be filled during the flood season and drawn down in whole or part during the winter to a level where the ice pressure would have a negligible effect. The writer feels that it is unwise to design and build a dam on the assumption that the reservoir is to be operated in any definite manner that will protect the dam structure. Conditions of operation change and operators have little regard for theory.

After a dam has been built (this should not be considered in its design) ice thrust is often made negligible where there is frequent change in the reservoir level as in the case of a forebay dam. The rise in the water level will cause the ice to break 10 or 15 ft. back of the dam. The writer has observed four thicknesses of ice adjacent to the back of a forebay dam, each about a foot thick, separated by about a foot of water and so broken as to be harmless. The damage to an existing dam by ice may be prevented by maintaining a narrow channel of water back of the dam by cutting, steam or compressed air. The following statements indicate the great difference among designers as to assumed ice pressures. Investigations in Norway indicated that the maximum thrust per lineal foot would not exceed 12 000 lb. for a 30-in. sheet and 18 000 lb. for a 40-in. sheet of ice.

The table below gives the ice pressure assumed in the design of several large dams:

	Lb. per lin.ft.
Wachusett, Mass.	47 000
Olive Bridge, N. Y.	47 000
Kensico, N. Y.	47 000
Croton Falls, N. Y.	30 000
Cross River, N. Y.	24 000
New Croton, N. Y.	0
Scioto, Ohio	34 000
Wanaque Reservoir, N. J.	20 000

The writer thinks that except where the back of the dam is approximately vertical and where also the reservoir shore is steep and the distance from the dam to the shore does not exceed 200 times the assumed thickness of the ice, these tabulated pressures are far in excess of actual ones, otherwise low dams which have been built would have failed on account of ice pressure, whereas the only records which have come to the writer's attention of the failure of low dams have occurred where the back of the dam and the banks were practically vertical and the distance between the dam and the banks small.

The writer computed some years ago that, based on such assumed ice pressures, a dam 10 ft. high should have a base 40 ft. wide, which is absurd. (See Trans. Am. Soc. C. E., Vol. 75, p. 219; Eng. News-Rec., Vol. 99, p. 742.)

Effect of Wave Action. The height of the top of the dam and the thickness of the top should be sufficient to prevent overtopping and to withstand the force of the waves.

Temperature Changes often seriously affect dams, and expansion joints should be provided in gravity dams perpendicular to the axis of the dams at intervals of about 30 to 60 ft. If expansion joints are not provided at about these intervals, cracks may form which will be unsightly and will leak. (See Sect. 11, Art. 1.)

Comparative Cross-sections of several high masonry dams are shown in Fig. 89, and data regarding them and a large number of other dams are given in Sect. 15.

Cost of Masonry for Retaining Walls and Dams. The cost of masonry for retaining walls and dams varies with the locality, size of wall, availability of local materials, the difficulties of foundation construction and, in the case of dams, with the difficulties of handling the water during construction. The average cost per cubic yard is about as follows: Ashlar facing, first class masonry \$40.00 to \$50.00 per cu. yd.; second class and backing \$30.00 to \$35.00 per cu. yd., rubble \$15.00 to \$20.00, concrete \$8.00 to \$12.00 depending on location and quantity involved.

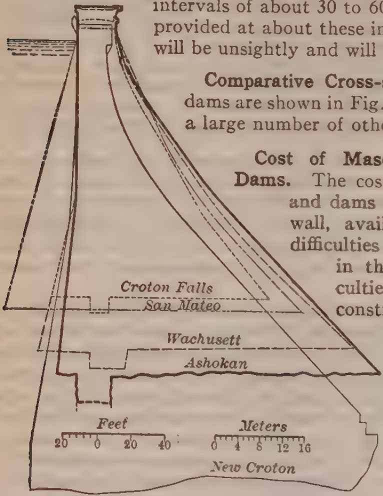

Fig. 89. Five American Dams

31. Investigation of Masonry Dams

An Investigation of a Proposed Section must be made for two cases: (1) when the reservoir is full and the water level is at its maximum height; (2) when the reservoir is empty. In the first case, the resultant should always be within the middle-third, and then the compressive unit stress is greatest at the toe and least at the heel. (Art. 21.) In the second case, the resultant may be allowed to come at the edge of the middle-third nearest the heel, and then the compressive unit stress is greatest at the heel and least at the toe. Maximum economy of material will result when the resistance line for reservoir full lies just inside the limit of the middle-third and when the resistance line for reservoir empty coincides with the limit of the middle-third nearest the back. For other heights of water the resistance line will lie well within the middle-third.

The following formula gives the safety factor against rotation

$$n = \frac{Wt}{Hp}$$

where W = weight above any horizontal plane considered;
t = distance from toe to point where resistance line cuts that plane;
H = horizontal water pressure above the plane;
p = height of H above the plane.

A Trapezoidal Section, such as is generally used for low dams, can be investigated by the methods given for retaining walls in Art. 25. The resultant must cut the base within the middle-third for all cases. This will always occur when the reservoir is empty, so that the entire base is then under compression. For reservoir full to the top of the dam, the resultant cuts the base on the other side of the middle, and it should also lie within the middle-third in order that the entire base may be under compression.

Example. Fig. 74 may represent a section of a trapezoidal ashlar masonry dam of 30-ft. height, 5-ft. top, and 18-ft. base, the back face plumb and the foundation sound, impervious rock. The weight of the masonry will be taken at 160 lb. per cu. ft. Let a be the top width, b the base width, and h the height, all in feet; then the weight of a section one foot long is $80\,h\,(a + b)$ = 55 200 lb. The line of action of this weight passes through the center of gravity of the trapezoid whose horizontal distance from the toe A is

$$t = (2\,b^2 + 2\,ab - a^2)/3\,(a + b) = 11.64 \text{ ft.}$$

Therefore the resisting moment about the toe is M_1 = 55 200 × 11.64 = 642 530 ft-lb. For reservoir full the water surface is taken as level with the top of the dam, and its horizontal pressure P is 31.25×30^2 = 28 125 lb. The overturning moment about the toe is $M = P \times 1/3\,h$ = 281 250 ft-lb. Hence the factor of safety against rotation is $M_1/M = 2.3$, which is ample provided the resultant cuts the base within the middle-third. That this is the case is found by using the formula

$$e = 1/2\,b - t + 1/3\,Ph/W = 2.45 \text{ ft.},$$

where t is the distance 11.64; the value of e is less than $1/6\,b$, so that the resultant lies within the middle-third. The ratio $6\,e/b$ is $6 \times 2.45/18 = 0.817$, and $W/b = 3070$; hence (Art. 21), the maximum and minimum pressures on the base are $S_1 = 3070\,(1 + 0.817) = 5580$ lb. per sq. ft., and $S_2 = 3070\,(1 - 0.817) = 560$ lb. per sq. ft. The coefficient of friction required to prevent sliding on the base with a safety factor of 2 is $f = 2\,P/W = 1.02$, so that the rock should be made very rough. For reservoir empty, $e = 9.0 - 11.64 = 2.64$ ft. on the other side of the middle, so that here $6\,e/b = 0.88$, and hence the pressure at the heel is slightly greater than at the toe for reservoir full, and the pressure at the toe is slightly less than at the heel for revervoir full, but the line of resistance here also falls within the middle-third. For ice pressure see Art. 30. The formulas for walls with a vertical back (Art. 25) could have been used in this example.

Fig. 74 shows a simple graphic analysis for this case by the use of the force and equilibrium polygons, the trapezoid being divided into a rectangle and a triangle whose centers of gravity are known without computation and the lines of action of the weights W_1 and W_2 being drawn through these centers.

A Dam with Curved Front (Fig. 90) is 60 ft. high, 40 ft. wide on the base, top width 10 ft., built of granite ashlar weighing 160 lb. per cu. ft., and is to be founded on impervious rock. The first step in its investigation is to divide the cross-section into subdivisions A, B, . . . G by horizontal lines, these being sufficiently near together so that the dubdivisions may be regarded as trapezoids. The areas and centers of gravity of the subdivisions are next found, the latter marked on the drawing by small circles. The horizontal lines at a, b, . . . g are, for brevity, called joints, although no joints may really exist. P_a, P_b . . . P_g denote the horizontal water pressure acting above the joints a, b, . . . g, each of these being applied at a distance above the joint equal to one-third of the depth of the joint below the water level at O.

Resistance Line for Reservoir Full. To determine the point where the resistance line cuts any joint as b in Fig. 90a, the weight of $A + B$ is to be laid off vertically through its center of gravity and P_b produced until it intersects this vertical at the point marked by the small square, then the resultant of the weight $A + B$ and the pressure P_b is determined, and this, being produced until it intersects the joint, locates a point in the line of resistance. The steps of the graphic analysis are as follows:

(1) In Fig. 90*b* the resultant forces acting against the joints are found. The load line O_1g_1 is first laid off to scale to give the different weights, O_1a_1 being that of A, a_1 b_1 that of B, and so on. On the horizontal line at the top the distances O_1P_a, O_1P_b, etc., are laid off to represent the horizontal forces

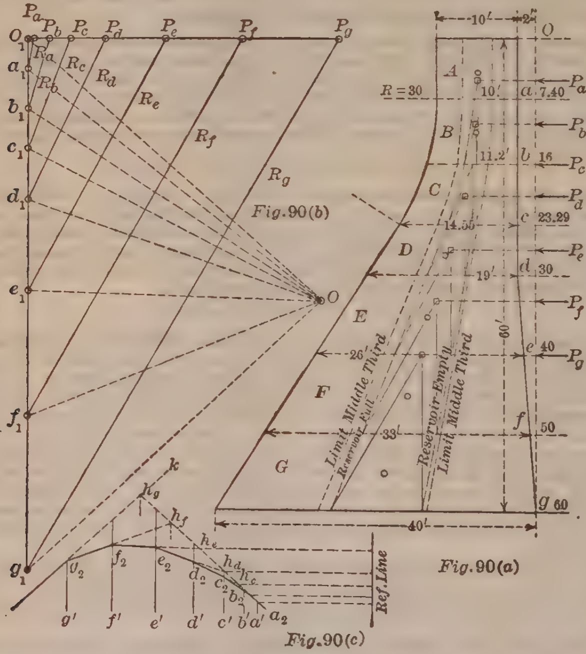

Fig. 90. Graphic Analysis of a Masonry Dam

P_a, P_b, etc. Joining corresponding points R_a, R_b, etc., are the resultants in direction and magnitude which act on the joints a, b, etc.

(2) In Fig. 90*b* a force polygon is constructed with pole at any point O, as shown by the broken lines, this to be used for locating lines through the centers of gravity of the areas $A + B$, $A + B + C$, etc., the points where these lines intersect the horizontal forces P_b, P_c, etc., being indicated by small squares.

(3) To find these vertical lines, Fig. 90*c* is used where verticals through a', b', etc., are first drawn at the same horizontal distances apart as the small circles on Fig. 90*a*. Usually a larger scale is used for Fig. 90*c* and the horizontal distances are laid off to this scale from a reference line, these corresponding to the horizontal distances from a vertical through the heel g to the small circles. Then an equilibrium polygon a_2, b_2, . . . g_2 is constructed

and its sides produced to cut the first side in the points h_a, h_b, h_c, . . . h_g. The distances from these points to the reference line are the distances to be laid off on Fig. 90*a* from the vertical through the heel, proper consideration being given to the different scales, in order to find the verticals through the centers of gravity of $A + B$, $A + B + C$, etc.

(4) Producing the horizontal directions of P_a, P_b, . . . P_g to these last vertical lines, the points of intersection are marked by small squares. Through these points draw lines parallel to the resultants R_a, R_b, . . . R_g in the force polygon, and the intersection of these with the joints a, b, . . . g will give points on the resistance line for reservoir full. A curve is then drawn through these points, and it is seen that the resistance line for reservoir full lies well within the middle-third, so that there is full security against rotation and against any ocurrence of vertical tension at the heel of the dam.

Resistance Line for Reservoir Empty. Through the small squares draw verticals to cut the corresponding joints and pass a curve through the points thus determined. The resistance line thus determined is also within the middle-third but nearer to its limit than for the preceding case.

Stresses at the Base Joint. The weight of the dam, equal to the full load line O_1g_1 in Fig. 90*b* is 201 050 lb. and hence the average normal pressure on the base is 5026 lb. per sq. ft. The resistance lines for reservoir full and empty cut the base at distances of 5.5 and 6.0 ft. from the middle, so that the ratios for $6e/b$ are 0.825 and 0.9. Then for reservoir full, using formula $\mathbf{S = W/b \times (1 \pm 6e/b)}$, (Art. 21), the maximum vertical pressure intensity is at the toe and is equal to 5026 (1 + 0.825) = 9170 lb. per sq. ft., whereas for reservoir empty the maximum vertical pressure intensity is at the heel and is equal to 5026 (1 + 0.9) = 9550 lb. per sq. ft. Both these are very low for both the masonry and the rock foundation. The value of the principal stresses will now be found for the case of reservoir full. The following data are necessary:

Vertical pressure intensity at the toe	S_1 = 9170 lb. per sq. ft.
Vertical pressure intensity at the heel	S_2 = 880 lb. per sq. ft.
Intensity of water pressure	$p' = 60 \times 62.5$ = 3750 lb. per sq. ft.
Average intensity of shear	$q = 1/2 \times 60^2 \times 62.5/40$ = 2810 lb. per sq. ft.

Then the principal stresses at the toe will be (Art. 21)

$$S_{max} = 1/2\ \left(9170 + 3750 + \sqrt{(9170 + 3750)^2 - 4\ (9170 \times 3750 - 2810^2)}\right) = +\ 10\,365 \text{ lb. per sq. ft.}$$

$$S_{min} = 1/2\ \left(9170 + 3750 - \sqrt{(9170 + 3750)^2 - 4\ (9170 \times 3750 - 2810^2)}\right) = +\ 2555 \text{ lb. per sq. ft.}$$

Both principal stresses being positive at the toe, no tension exists there on any plane.

The principal stresses at the heel will be

$$S_{max} = 1/2\ \left(880 + 3750 + \sqrt{(880 + 3750)^2 - 4\ (880 \times 3750 - 2810^2)}\right) = +\ 5470 \text{ lb. per sq. ft.}$$

$$S_{min} = 1/2\ \left(880 + 3750 - \sqrt{(880 + 3750)^2 - 4\ (880 \times 3750 - 2810^2)}\right) = -\ 840 \text{ lb. per sq. ft.}$$

The latter value being negative a tensile stress of about 5.8 lb. per sq. in., which is so small as to be negligible, exists on a plane at the heel of the dam, which plane is inclined to the horizontal at an angle θ determined by the relation

$$\cot\theta = -\frac{840 - 3750}{2810} = -\ 1.63 \text{ from which } \theta = 121°\ 30'$$

Security against Sliding. The base of masonry dams on rock foundation is usally placed several feet below the surface of the rock (Fig. 94). If the base line of the dam here investigated (Fig. 90*a*) represents the joint at the level of the original rock surface, sliding of the dam is prevented by the shearing resistance of the masonry. If the dam were placed with its base upon the surface of the rock it would slide on the base if the tangent of the angle between the resultant pressure on the base and a vertical line is greater than the coefficient of friction between the materials of the dam and the foundation, or if the coefficient of friction were less than $P/W = 0.56$. For full security the base should be roughened so that the frictional resistance will be greatly augmented. In high dams " stepped shoulders " should be cut in the rock in sufficient depth and number so that independent of the frictional resistance at the base the entire horizontal thrust might be taken by these shoulders without too high stresses on the rock shoulders or the abutting concrete, thus assuring at least a factor of safety of 2 against sliding. If the rockbed slopes downward from the heel of the dam, these steps are especially necessary. In high dams or poor laminated rock the possibility of the rock bulging up in front of the dam should be considered. Make doubly sure that the dam will not slide. Serious dam failures have been quite usually due in whole or part to failure to provide adequately for the transfer of the horizontal thrust to the foundation bed.

32. Details of Design of Masonry Dams

The Back of the Dam is often vertical or has a uniform batter, this being always the case for a low dam. For a high section, however, the profile of the back as well as the front of the section is often formed by straight lines of different inclinations (Fig. 93), but more often the front is curved. The water pressure is normal against a battered back, but its horizontal and vertical components may be used instead. (Art. 20.) It is customary to neglect the vertical component V (Art. 20), since such neglect is on the side of safety, and since the percolation of water beneath the heel would entirely annul it. For a uniform inclination above an assumed joint the normal water pressure $\mathbf{P} = 1/2\ \mathbf{wh_1^2 \cos\theta}$, where h_1 = depth of joint below water level and w = weight of water per cubic unit. For further security it is best to consider θ as 0, and then $\mathbf{H} = 1/2\ \mathbf{wh_1^2}$, which is strictly true for a vertical back.

Above the assumed joint there are hence only two forces acting, the horizontal water pressure and the weight of the masonry. The resultant of these should cut the base within the middle-third. The point where the resultant cuts the planes of several joints gives points through which the resistance line can be drawn. This may be done either graphically (Art. 31) or analytically, the latter leading to complicated formulas.

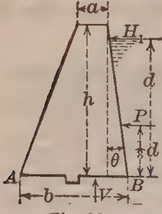

Fig. 91

Trapezoidal Dams with vertical backs are designed by the same methods as those given in Art. 25 for retaining walls, the water pressure being taken horizontal and equal to $\mathbf{1/2\ wd^2}$ when no overflow occurs, or in pounds $\mathbf{P = 31.25\ d^2}$, if d is in feet; d is height from water line to base, this being usually less than the height h of the dam. The resultant should cut the base at or inside the edge of the middle-third for reservoir full, and for the resultant at the edge required width of base is $\mathbf{b = -0.5\,a + \sqrt{1.25\,a^2 + d^2/s}}$, where s is the specific gravity of the masonry. This formula applies for water pressure only and takes no account of the action of ice or waves.

For any Trapezoid (Fig. 91) let a = top width, h = height, d = height of water line above base, θ = inclination of back to vertical, w = unit weight of water, v = unit weight of masonry, H_1 = ice or wave pressure acting at water line on one unit of length of dam. Then proper base width so that resistance line cuts base at edge of the middle-third is $\mathbf{b} = (\mathbf{A}^2 + \mathbf{B})^{1/2} - \mathbf{A}$, in which

$$A = 1/2\ (a - h \tan\theta) \qquad B = a^2 + 2\,ah \tan\theta + (6\,H_1 + wd^2)\,d/vh$$

Example. For Fig. 74, let $a = 5$, $h = d = 30$ ft., $\theta = 0°$, $w = 62.5$, $v = 160$, $H_1 = 0$; then $A = 2.5$, $B = 376.5$, and the formula gives $b = 17.1$ ft. If, however, $H_1 = 43\,000$ lb. for ice pressure, then $B = 537.8$ and the formula gives $b = 20.8$ ft. The amount of material in this dam is increased over 30% by taking ice pressure into account.

A trapezoidal dam with vertical back requires less material than one with inclined back if vertical water pressure on the inclined back is ignored. For example: $h = 60$ ft., $d = 57$ ft., $a = 9$ ft., $v = 150$ lb. per cu. ft., $H_1 = 0$. Then

for $\tan\theta = 0$	$b = 32.7$ ft.	area = 1251 sq. ft.	per cent = 100
for $\tan\theta = 1/12$	$b = 36.2$ ft.	area = 1356 sq. ft.	per cent = 108
for $\tan\theta = 1/6$	$b = 39.8$ ft.	area = 1664 sq. ft.	per cent = 117

When a trapezoid is used for a high dam, the compression at the toe may become greater than the allowable value even though the resultant cuts the base at the edge of the middle-third. When this is found to be the case by computation or graphic analysis, the section is too small and the base must be widened. Let S be the safe working compressive stress, and the other quantities as above; then the required width of the base is $\mathbf{b} = (\mathbf{C} + \sqrt{\mathbf{C}^2 + \mathbf{D}})$, in which $C = 1/2\ vh^2 \tan\theta/S$; and $D = (wd^3 + vha^2 + 2\,vah^2 \tan\theta)/S$.

A Pentagonal Section (Fig. 92) is a modification of a triangular one by giving to the top a width of 5 ft. or more and then making the front face fg vertical until it reaches the inclined line dc. The top width may be 10 to 17% of the average height, though this width may be governed by ice pressure, or the desirability of a roadway on top of the dam. For a triangular section the necessary width of the base is $b = 7.91\ h\sqrt{1/v}$. For the pentagonal section the width of base should be $b_1 = b/\sqrt{1 + 2\,r^2 - 2\,r^3}$, where r is the ratio of the width of the top to the computed b. A short back batter of height 1/4 h above the heel, and base width of 1/12 b_1 may here, as in other cases, be advantageously used to diminish any tendency to tension at the heel. This formula does not include the effect of ice or wave pressure at the water line.

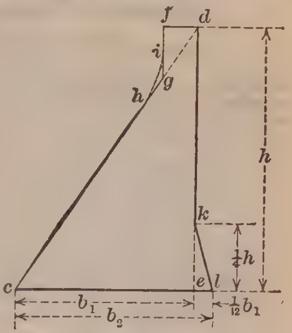

Fig. 92

Water under the Base reduces the unit weight of masonry by 62.5 lb. per cu. ft. if this produces a full uniform pressure. It is best to keep the unit weight of masonry at its full value, however, and to introduce beneath the base such upward pressures as may be specified. For discussion of the uplift see Art. 30.

Dams over 60 Feet High may be designed by means of Fig. 93, known as Wegmann's "Practical Type No. 2," and with the help of the following table, these being taken from Wegmann's "Design and Construction of Dams" (1927) and modified in columns 4 and 5 in order to diminish the tendency to tension at the heel (Art. 21). The figure gives this profile for a 200-ft. dam, the masonry of which was assumed to weigh 145.8 lb. per cu. ft. This profile is drawn for a top width of 20 ft. or one-tenth the height of the dam, and the table is made for the same ratio of top width to base. For a dam of the same top width cut off the section at any desired height. For a dam of less top width, for example 12 ft. and 100 ft. high, draw a dam 12 ft. × 10 or 120 ft. in height, by reducing the given profile in the proportion of 120/200 and cut off a height of 100 ft. If the width of the top of the dam is less or greater than 20 ft., the pressures in columns 6 and 7 must be reduced or increased proportionately.

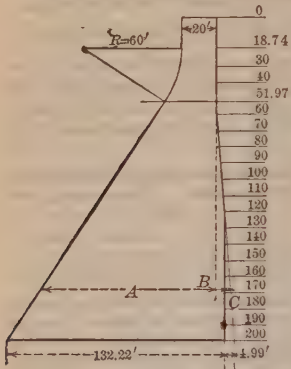

Fig. 93

For a dam having a top width of 12 ft. and a height of 120 ft., the maximum pressure on the base for reservoir full is 14.32 × 0.6 = 8.59 tons per sq. ft., and for reservoir empty 14.65 × 0.6 = 8.79 tons per sq. ft. The minimum width of the top of a dam over 60 ft. should be at least 8 ft., and this width must often be arbitrarily increased by the designer on account of the pressure of ice. The height of the dam above high-water level varies from 2 ft. in low dams to 10 ft. in high dams. The tables and profile recommended are for dams upon impervious

Elements of Wegmann's Practical Profile No. 2

Slightly modified in fourth and fifth columns

Depth of water below top of dam, ft.	Length of joint in feet				Maximum pressure, tons per sq. ft.		Tangent of resultant with vertical

rock, no upward water pressure being considered. For dams upon pervious rock proceed as in trapezoidal and pentagonal dams. The profile recommended is made without regard to the effect of ice pressure in tending to overturn the dam, except that the upper section has been arbitrarily increased so as to provide for this pressure. For heavy ice pressures the specified pressures per linear foot at the water line can be taken into account in a graphic analysis.

The Ashokan Dam, completed in 1912, in the lower Catskill region, for impounding the additional water supply of the city of Greater New York, has some novel features in design which are shown on Fig. 94. The length of the central and masonry section of the dam is 1000 ft., height 220 ft., width of base 190.2 ft., width of top 23 ft., which is corbeled to 26.3 ft. The dam is built of cyclopean concrete faced with solid concrete blocks laid up as ashlar. The interior of the masonry is drained into galleries approximately level, one at the water level and the other about 40 ft. above the base. The galleries are connected at intervals by vertical porous concrete drains. This drainage system is designed to intercept water so as to prevent seepage through the dam.

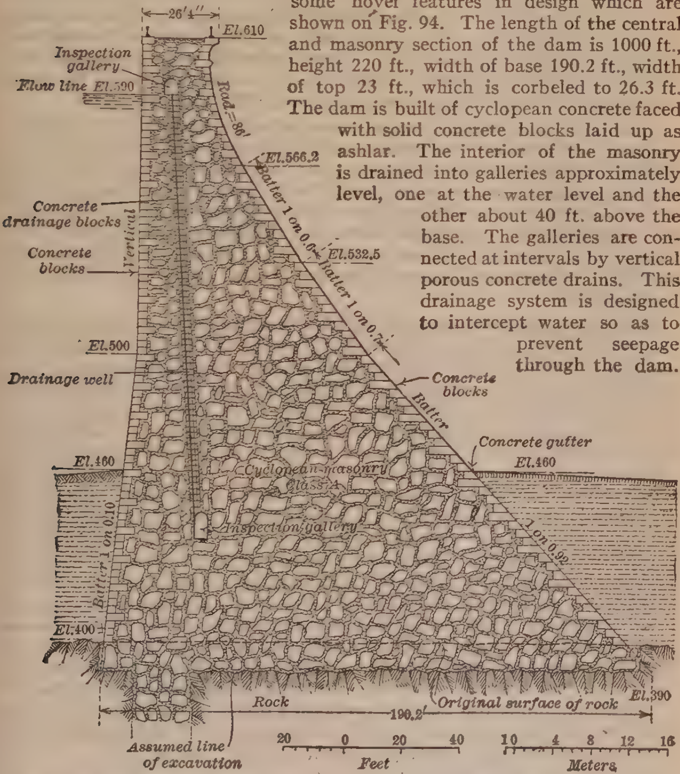

Fig. 94. Maximum Section of Ashokan Dam

A Spillway Dam is one built to discharge water over its crest. The design of the spillway dam embodies all the essential features of the design of masonry dams in general and besides must provide for the thrust and discharge of the overtopping water. The spillway dam is subjected to all the forces of a reservoir dam and in addition to the pressure of the overtopping water and, if not properly designed, to a pressure resulting from the formation of a partial vacuum between the face of the dam and the overflowing water (Art. 20). To prevent the formation of such a vacuum the face of the dam must have a sufficiently flat slope so that the falling sheet of water will not separate from it in transit from the top to the bottom. Special care must be taken to so design the bottom of the dam that the water in leaving the dam will cause a minimum amount of erosion. This is accomplished by so designing the base of the dam that the delivery of the water is tangential to the stream bed below the dam. If it is not of the hardest rock, the lower stream bed adjacent to the dam should be paved with concrete or masonry and in some cases a pool is created at the toe of the dam to absorb the shock of the falling water. If the designer is not experienced in the erosive action of falling water he should, before designing the spillway section, make a thorough study of such effect by observing the erosion at other existing dams. Often the paving is made too light or is not carried far enough below the dam, or the downstream end of the paved apron is not provided with a proper cutoff trench filled with masonry.

Unless it is made with the greatest care and of the best grade of materials, concrete has not usually been found satisfactory for the discharge surface of spillways, especially of high dams and those built in northern latitudes. The writer recommends concrete for the discharge surface of spillways only in southern latitudes, or in northern latitudes for spillway dams having a height not exceeding 50 ft. For higher dams and those in northern latitudes it is recommended that the discharge surface be paved with either hard brick thoroughly bonded to the concrete backing or with ashlar built of hard and durable stone.

The Form of the Crest, as shown by the Cornell experiments on weirs (Sect. 13, Art. 14), has an important bearing on the discharging capacity and on the economy of spillway dams. It is often difficult, in narrow valleys of large drainage area, to get sufficient length of spillway to discharge freshets without a great depth of water passing over the dam. Every effort should be made to keep this depth a minimum because it increases the pressure on the dam and the scour at the bottom and increases back water and thereby floods more land.

Flat-topped rectangular dams up to 1 ft. top-width discharge practically the same volume of water as the standard sharp-crested weir. With wider crests, the discharge diminishes rapidly, a 6-ft. horizontal crest passing only 80% of the standard discharge. So-called compound crests (Fig. 96), with a sloping top (dotted line in figure), discharge more than standard weirs, the volume of discharge being about 20% more for an inclination of 45 deg. of the sloping top, which is connected by a circularly or parabolically rounded portion to the down-stream face. This face should be inclined about 30 deg. to the vertical (Fig. 96) so that the nappe of the overflowing water will adhere. For any dam the precise profile to insure an " adherent nappe " may be computed by the ordinary principles of hydraulics, assuming the depth of the overflow.

The sloping top is also useful in preventing injury of the upper part of the dam, due to ice and logs, and also reduces ice pressure of the reservoir if full, since the ice will slide up the slope without exerting pressure.

If to the compound crest and sloping face a smooth transition to the river bed or to an apron protecting same is added (*ik* in Fig. 96) the familiar ogee section results. This section, which, in masonry spillway dams, is of general use, not only approximates the theoretical economical section, but possesses several practical advantages. The lower curved part helps to keep the eddies and back waves at a distance from the toe of the dam and thereby protects the dam against the impact of logs and ice revolving with great velocity in these eddies and waves. The inclined face and the rounding of the downstream top make the falling sheet of water adhere to the dam, eliminating the possibility of a vacuum below the nappe, and help somewhat to destroy by friction a part of the energy of the falling water. This energy may be very large and is the cause of the greatest danger to spillway dams by the scouring action upon the bed of the stream at and near the toe. The destruction of this energy is sometimes attempted by building the downstream face in steps, as for instance at the Pedlar River dam in Virginia (Fig. 97). The Gilboa Dam of the New York City water supply was built with a stepped spillway, the action of the steps in dissipating the energy of the overflowing water being increased by the addition of baffle vanes on the top step. (See Trans. Am. Soc. C. E., Vol. 86, p. 280.) The use of a stepped spillway may not be advisable with a concrete dam in that it means the pounding out of the energy of the overflow upon the dam itself. This may result in rapid wear of the concrete steps, requiring numerous expensive repairs; and the rounding off of the steps may destroy their effectiveness in breaking up the sheet of overflowing water. The face of the Bassano dam (height of spillway 38 ft., 13 ft. of water over the crest) is equipped with two staggered rows of baffle piers built like snow plows and pointed upstream. The baffle piers are not designed to take the shock of the falling water, but to split and divert the stream into interfering jets and so create eddies and disturbances within the body of the downstream pool, which is 50 ft. long. The Gatun dam (height of spillway 59 ft., 18 ft. of water over the crest) has two staggered rows of baffle piers on the apron close to the toe. These piers have vertical upstream faces, the upper row consisting of piers 14 ft. wide and 9 ft. high and 12 ft. long. They are designed to take the shock and are faced with heavy cast-iron protection. The destruction of the kinetic energy of the falling water is almost complete. The cast-iron protection was later extended around the sides of the piers to prevent erosion of the concrete; and the spillway floor for a distance of 3 ft. in front of and around the sides of the piers was protected with 3/4-in. steel plates, for the same reason. The wear on the concrete was due only to the impact of the water, as there is no silt carried over the spillway. The metal protection has been quite effective.

Baffle piers were also used on the spillway aprons of Pitt River Dams Nos. 3 and 4, in California, the baffles being staggered in two rows and placed just beyond the toe and in a pool about 15 ft. deep. (Trans. Am. Soc. C. E., Vol. 93, p. 451.)

The necessity of adequate protection of a dam with free overfall is shown at natural waterfalls where at the foot a deep pool is formed in the stream bed. The erosion of the bed stops as soon as the pool becomes deep enough for the contained water cushion to take up and dissipate the shock of the falling water. A similar artificial pool, the bottom and sides well protected by heavy concrete lining, should therefore be built at the toe of free overfall dams, except in case of low dams on hard rock, the dimensions of the pool and its lining being a function of the material of the river bed, the height of the fall and the volume of the discharged water.

In the case of a spillway dam with an ogee face or any other form with adherent nappe, it is customary to protect the bed of the stream with a concrete or masonry apron for a considerable distance below the toe of the dam. The design of this apron on any but the hardest rock foundation is a matter of the greatest importance. Besides its function of protecting the bed from scouring, it also increases the percolation factor of dams built on sand, gravel or other pervious foundations. (Art. 30.) The apron should extend far enough downstream so that the river bed would be protected at least to the point where the velocity of the flow becomes normal, in other words where the velocity of the flow becomes the same as it was before the dam was built. The dissipation of the energy of the water flowing over a dam apron may be conveniently and economically accomplished by the creation of the " hydraulic jump " close to the toe of the dam. (Sect. 13, Art. 17.) If this energy is not dissipated and the stream bed is readily erodible it may be highly important to create an hydraulic jump near the toe of the dam to save the expense of extensive paving down the stream.

Professor Sherman M. Woodward (Eng. News-Rec., Vol. 99, p. 974) states in part: " There is some lack of agreement among authorities as to just what phenomena should be considered to be the typical hydraulic jump, but probably all will agree that the jump occurs in its most definite, striking and conspicuous form when it is produced on a practically level floor by a stream of water moving with a high velocity striking against a higher wall of relatively quiet water. In this typical jump the kinetic energy of the moving stream is transformed . . . into heat so that the out-flowing water moves away in a quiet, placid stream with a uniform low velocity . . . . In order that the jump may form, however, there must be a definite mathematical relation between depth and velocity of the high velocity stream and the depth of the tail water . . . . The easiest way to insure the formation of the jump is to provide a sloping floor so that by moving up or down the slope the jump may automatically adjust itself to such position as will provide the needed depth of tail water. Although a sloping floor provides a convenient automatic regulation of the jump, it has the disadvantage that if the floor is given much slope the nature of the slope is modified. If the slope is made greater than 1 on 3, experiments indicate that the certainty and effectiveness of the jump in destroying energy are perceptibly reduced. If the slope is made as steep as 45 deg. the usefulness of the jump is mostly lost."

See also "Hydro-Electric Handbook," by W. P. Creager and J. D. Justin, p. 142;

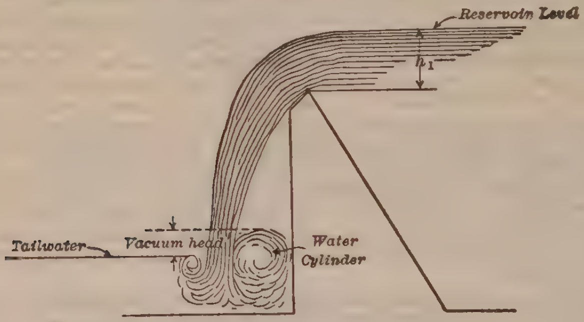

Fig. 95

"The Hydraulic Jump and Critical Depth in the Design of Hydraulic Structures," by J. Hinds, Eng. News-Rec., Vol. 85, p. 1034.

The thickness of the apron must be so proportioned that it will more than equalize, by its weight, the uplifting force from below, or it will "blow up." Weep-holes can be used if the foundation is seamy rock, but they should be avoided in material which easily erodes. It is best to give the apron a form similar to Fig. 87, where an artificial pool of moderate depth is formed. Such an apron is very efficient in dissipating the kinetic energy of the falling water and brings the location of the jump to the point desired, i.e., to the lower end of the pool. Baffle walls on the ogee or on the apron will be found necessary only in the case of very high dams or if a very large volume of water is discharged.

Rarefied air space forms between the nappe and the face of the dam if the nappe is not adherent and the space between the falling sheet of water and the dam is not connected with the outside atmosphere. Air ducts are occasionally provided for to equalize the pressure of the air, as shown in Fig. 97 illustrating the Pedlar River dam. There is, however, a tendency among engineers to attribute too much importance to the vacuum which may possibly occur behind the nappe (Art. 20), some authors stating that the hydrostatic pressure may thereby increase by as much as the full atmospherical pressure, equivalent to 34 ft. of additional head. Observations do not admit the possibility of such a condition. When the air is gradually exhausted from behind the nappe by action of the falling water, a water cylinder is pushed up into the space between the nappe and the dam from the foot of the overfall. The height to which this cylinder (Fig. 95) rises is a measure of the rarefaction of the air and of the additional pressure upon the dam. The cylinder, however, reaches only a certain limiting height which has been found to depend upon the quantity of the discharge over the spillway. When this height is reached, the nappe is pierced very soon and air admitted through it so that the pressure beneath the nappe again becomes atmospheric. In one case, where the water stood about 2-1/2 ft. over the crest, the nappe was pierced every 10 seconds with a thunderlike report, at which time the pressure of the air in the enclosed space under the nappe was diminished by about 1/20 atmosphere. The experiments were repeated with different amounts of the overflow and showed that the limit of the rarefaction is proportional to the thickness of the nappe. It is recommended, for a dam with non-adherent nappe and the space between nappe and the face not ventilated, that an increase of pressure on the back equivalent to 60% of the height of the water above the crest be considered.

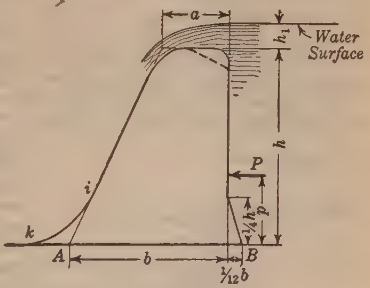

Fig. 96

The spillway dam is usually treated as a masonry dam with trapezoidal cross-section, the curved portion *Aik* (Fig. 96) being disregarded in design and investigation. For the magnitude of the acting forces and their point of application, see Art. 20 and Art. 21.

The spillway dam at Austin, Tex., which failed in 1900, was 60 ft. high and had an effective width at the base of 44 ft., the height of the water above the crest being 11 ft. at the time of the failure. Sliding occurred on the defective rock foundation and also shearing on four vertical cross-sections so that two pieces of the dam, each about 250 ft. long, were pushed out of the main portion and moved downstream without overturning. For full details, see Eng. News, April 14, 1910.

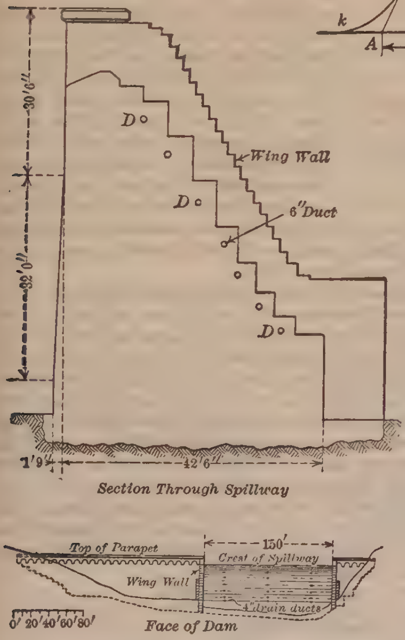

Fig. 97. Pedlar River Dam

The Siphon Spillway, a simple form of which is shown in Fig. 98, is adapted to cases where close regulation of reservoir level is desirable. The common overflow spillway requires considerable rise of water surface above crest level before the discharge reaches any large amount unless the length of spillway is very great. The only way in which the discharge can be increased, without lengthening the spillway, is by increasing the head on the spillway. This may be accomplished without raising the pond level by using flashboards or crest gates, or by constructing a conduit within the dam with its discharge end at an elevation lower than maximum pond level.

Flashboards may be used to limit backwater rise during floods, but do not give a close regulation of pond levels because the water must rise considerably above top of flashboards before the boards will go out and the boards cannot be replaced until the flood has subsided. Ordinary crest gates may be used to give close regulation of pond levels, even during floods, but they are not automatic like flashboards, and involve considerable expense for operation. Automatic crest gates may be used, but they are expensive, and their operation may be uncertain due to complicated machinery, especially if they are designed to maintain close regulation of pond level.

The siphon spillway is automatic and involves no operating cost and it permits close regulation of the pond level. While more expensive than an overflow spillway with flashboards, it should compare in cost with crest gates, for the same discharge capacity. It may be used in conjunction with an overflow spillway, the siphon serving to regulate the pond level for ordinary rates of flow, while floods are discharged in part over the main spillway. As the water entrance is below freshet water level, this type of spillway is useful where it would be undesirable to discharge débris or ice below the dam. On the other hand, if close regulation of pond level is not essential, the siphon spillway may not be desirable, for it prevents storage of water above ordinary pond level, as is possible with flashboards, and it may involve considerable loss of water in case of a slight rise of pond level.

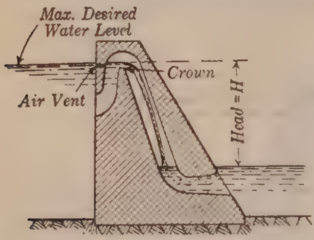

Fig. 98

The essential feature of a siphon spillway is that it takes advantage of a considerable portion of the head between pond water and tailwater level. The siphon consists of a conduit constructed within the dam, as shown in Fig. 98, the upper entrance being below the desired maximum water level in the reservoir. The lower end of the conduit may discharge into the air or under a pool of water at the downstream side of the dam. The discharge end is placed lower than maximum water surface of the reservoir, but this difference should not be more than the atmospheric head unless the cross-sectional area of the conduit is reduced toward the lower end. For efficient operation the siphon at all points should lie below the hydraulic gradient (Sect. 9, Art. 8). The crown of the siphon is placed somewhat below maximum desired water level. An air vent must be provided from the top of the siphon to the upstream face of the dam, its upstream entrance lying between maximum desired water level and the level of the siphon crown.

The discharge of the siphon in cubic feet per second is:

$$Q = C A \sqrt{2 gH}$$

where C is a coefficient depending on the detail of the conduit and the curves of entrance and exit and varying between 0.6 and 0.8, A is minimum cross-sectional area in square feet, H is head in feet and g = acceleration of gravity. As the velocity of flow varies with the square root of the head, the discharge does not change much for considerable variations in the head. If the total head from the highest point of the siphon to the outlet minus frictional losses is greater than atmospheric head, the lower end of the conduit must be reduced in area in order to avoid breaking the water column. The capacity of the siphon, however, will not be increased by making the gross head greater than atmospheric head.

In operation, as the water in the reservoir rises above the crown of the siphon, the air vent is cut off and water begins to flow through the conduit. The air trapped in the siphon is exhausted by the flowing water and siphonic action is quickly started. When the pond level starts to fall again, the air vent is exposed and admission of air to the conduit breaks the siphonic action. The water will then merely flow over the crown of the siphon until the pond drops below this level. If an air valve is placed at the top of the siphon, the siphonic action can be stopped or prevented by opening the valve.

Where several siphons are used, their crowns may be placed at different elevations, so as to cause the siphons to come into action successively as the pond level rises, thereby preventing all the siphons from acting under a slight rise of pond level. At the Conklingville Dam of the Hudson River Regulating District, siphon spillways are provided in order to prevent breaking up the ice-sheet on the reservoir and canal due to a sudden rise of water level above the overflow spillway. In some cases, the siphons have been constructed at a convenient location near the dam, but separately from the dam itself. Siphons have also been used in place of sluice gates in canal locks. (See paper on "Siphon Spillways" by G. F. Stickney, Trans. Am. Soc. C. E., Vol. 85, p. 1098; also Eng. Rec., Vol. 67, p. 488.)

A Shaft Spillway consists of a vertical shaft usually built in rock connected with a tunnel for the purpose of discharging water from the upper to lower ponds in lieu of the normal spillway. It may be economically used in connection with an earth-fill or rock-fill dam and where the cost of a separate spillway built adjacent to the earth-fill or rock-fill dam would be prohibitively expensive, or in a narrow and deep gorge where the handling of freshet water during and after construction cannot be satisfactorily worked out without it.

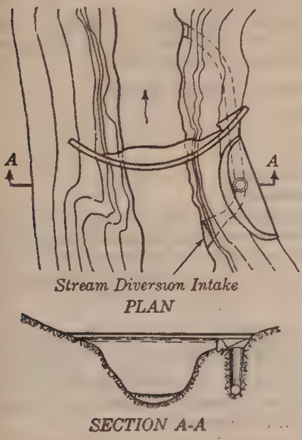

Fig. 99

The writer has had occasion to design two such spillways where the shaft type was necessary because of the narrowness and depth of the gorge, the available width being hardly more than was required for the power house, and this type affording the further advantage of using the tunnel portion of the spillway during construction. Fig. 99 indicates a shaft spillway and tunnel planned for an arch dam in a narrow gorge. A somewhat similar spillway was built at an earth-fill dam on the North Platte River, Wyoming. (Eng. News-Rec., Vol. 100, p. 264.)

A shaft spillway was used at Davis Bridge Dam (see article by Ford Kurtz, Trans. Am. Soc. C. E., Vol. 88, p. 1). This type of spillway was built in connection with an earth-fill dam, the tunnel being used during the construction period and the shaft in connection with the tunnel after completion. The article referred to goes carefully into the hydraulics of the design, and is followed by most interesting criticism.

Special care is required in the design to insure that the actual discharge capacity of the shaft for a given head will be equal to that assumed, or the reservoir level may rise to dangerous height in case of flood. The mouth of the shaft must be protected against inflow of logs and ice in order to avoid damage to the lining of the shaft and tunnel, and if high velocities are used in the shaft and tunnel the lining must be given careful consideration. Where large trees may be carried by the stream as a result of freshet in storm, care must be taken to protect the tunnel against stoppage in whole or part.

33. Arched Dams

Single Arch Dams. When a masonry dam is to be built in a gorge with firm rock sides it may be economical to curve it in plan so that it will act as an arch, although the masonry near the rock foundation will act partly as a cantilever beam. Even in a high, straight gravity dam in a narrow gorge, it is obvious that arch action must take place to some degree, although this may reduce to a wedging effect in extreme cases. Consideration of arch action will permit the use of less masonry than in the gravity type. This saving will be increased where the costs of materials and labor are high as in the case of dams built at inaccessible places.

Although there are obvious economies in the volume of masonry required in an arch dam, there are certain objections:

1. The internal stresses are more indeterminate than for a gravity dam, and therefore low unit stresses must be used in the design.
2. In the upper portions where the masonry is thin, greater care must be taken to build a watertight structure, seeping through the masonry being detrimental on account of leeching out of soluble material and injury by freezing.
3. The rock foundation, being subject to high pressures, must be of good quality.

An arched dam may be considered as consisting of two systems of structural elements:

1. Horizontal arches cut by parallel horizontal planes.
2. Vertical elements contained between radial planes which transfer part of the water load directly to the foundation through beam action. If these elements are fixed to the foundation they will act as cantilevers.

To determine the approximate thickness, use the "cylinder formula,"

$$T = PR/s,$$

where T = thickness of the arch ring in feet;
R = radius of upstream face in feet;
P = water pressure in pounds per square foot;
s = allowable stress in pounds per square foot.

It will be noted from this formula that the thickness increases with the height, that is, with the water pressure, and decreases with the assumed allowable stress. It may be proven theoretically that the volume of concrete will be a minimum when R is such that the subtended angle between the abutments is about 133 deg. This principle forms the basis of design of the "constant angle" form of dam. (Trans. Am. Soc. C. E., Vol. 78, p. 685).

A few years ago all arched dams were designed by the cylinder formula, this being possible because of the low unit stresses assumed. In designing high dams, however, and for economy of material, a more accurate method of computation is desirable. In such designs the influence of cantilever action is considered. The problem then is divided into two parts:

1. Division of the water load between the arches and the cantilevers.
2. Computation of stresses in the arches and in the cantilevers.

The problem is complicated by the fact that, although the arches may be symmetrical, the cantilevers are not all the same length. As the subdivision of the load between arches and cantilevers depends upon relative stiffness, in any given horizontal arch the portion of the water load carried by the arch will be much greater in the middle than near the abutments. This factor, however, is disregarded in most methods of analysis.

The methods that have been recently developed for analyzing arch dams are summarized below, the details being omitted as it is evident that more correct methods of analysis are in the process of early development with the help of models.

1. Method of F. A. Noetzli (Trans. Am. Soc. C. E., Vol. 84, p. 1). The distribution of water load is computed at the center of the dam (crown of the arches) and is assumed to be the same throughout the length of the dam. The relative amount of load carried by the arches is fixed by the condition that the deflection of any arch at the crown must be equal to the deflection of the cantilever at the same elevation. A trial division of the load is assumed and the deflections computed, the load division being adjusted until the deflections of the arches and cantilever are approximately the same. Arch deflections are computed approximately for temperature and load, the arch being assumed to have hinged ends. Noetzli's method neglects the following:

(a) Influence of shear.

(b) Influence of Poisson's ratio (the fact that an elastic material that is under stress in one direction will develop strains in a plane at right angles to that direction).

(c) Unsymmetric profile of dam.

(d) Temperature and shrinkage cracks.

2. Method of B. H. Smith (Trans. Am. Soc. C. E., Vol. 83, p. 2027). This method is a mathematical analysis of

(a) A cylindrical dam of uniform thickness.

(b) A cylindrical dam with a trapezoidal cross-section, the thickness therefore varying uniformly from crest to base. This method involves most of the approximations of Noetzli's method, but is possibly more precise mathematically, though its application is complicated.

3. Trial Load Method. Described by C. H. Howell and A. C. Jaquith (Trans. Am. Soc. C. E., Vol. 93, p. 1191). This method is similar to Noetzli's but takes into consideration the variable heights of the cantilevers and the unsymmetric dam profile. The arch deflections are computed by the elastic theory, taking into consideration temperature and rib shortening. This method seems more laborious than Noetzli's but appears to be somewhat more accurate.

In all the foregoing methods the computation of the arch stress is dependent on the assumptions as to distribution of water load over the arches, that is, the division of the water load into that carried by the masonry as an arch and as a cantilever. If the loading on any given arch is assumed to be uniform throughout its length (as in Noetzli's and Smith's methods) the computation of arch stresses may be simplified by the use of formulas that have been developed by Professor Wm. Cain (Trans. Am. Soc. C. E., Vol. 85, p. 233; Vol. 90, p. 522). These formulas have been plotted diagrammatically by F. H. Fowler (Trans. Am. Soc. C. E., Vol. 92, p. 1512). The Cain formulas assume horizontal circular arches of constant thickness, fixed or hinged, and subjected to uniform water pressure. These formulas include the influence of shear on arch stresses, and take into account that the neutral axis of a thick arch is closer to the intrados than the extrados. If the arch load is not assumed as uniform, the elastic method of arch analysis must be used. (See also Trans. Am. Soc. C. E., Vol. 93, p. 1191.)*

The theory of arch dams involves so many indeterminate factors and is so difficult of mathematical analysis that attempts have recently been made to check the available theoretical analysis or enable the development of better methods by means of experiments on models. Engineering Foundation made observations of an experimental arch dam at Stevenson Creek, California. This dam was 60 ft. high, 2 ft. thick at the crest, 7-1/2 ft. thick at base, and had a constant upstream radius of 100 ft. It was built in a narrow canyon. Facilities were provided for measuring deflections, strains and temperature changes.

* An excellent paper on "Load Distribution in High Arch Dams," by R. A. Sutherland (Trans. Am. Soc. C. E., Vol. 93, p. 1623), gives a summary of various methods of determining load distribution on arch dams, and develops formulas and diagrams to assist in computing loads and stresses.

The Stevenson Creek experiments have also been checked by tests upon a celluloid model made by Prof. G. E. Beggs. A model was constructed to a scale of 1 to 40 and loaded with mercury in order to magnify the liquid load. The results of the model experiments compared with those at Stevenson Creek are indicated in Figs. 100, 101 and 102.

The laboratory experiment furnishes an excellent check upon the field tests. It is thought that the reason for certain disagreements was the cracking of the concrete in the Stevenson dam, and that results from the celluloid model would check the Stevenson Creek Dam even more closely if the model were grooved deeply to simulate cracks in areas of high tensile strain. Both experiments indicate combined arch and cantilever action; and they show that an appreciable portion of the water load at the intermediate levels is transferred to the upper arches through the cantilevers, as indicated by the fact that the curvature of the cantilevers is reversed near their upper end. Fig. 100 shows the peculiar effect of an appreciable upstream deflection near the quarter points of the upper arches. The field and laboratory experiments indicate that the theoretical methods should give approximately correct values for stresses in the dam, provided proper assumptions are made as to the degree of fixity of the dam at the base and at the abutments. The report of the Committee on Arch Dam Investigation of Engineering Foundation is published in Proc. Am. Soc. C. E., May, 1928. Every engineer engaged on design of arched dams should study this report carefully.

It is believed that the use of laboratory models is worth while in the design of large arch dams and as a check on stresses computed by theoretical methods.

The writer, though convinced of the economy resulting from the use of arch dams in narrow rock gorges, thinks that the design should be conservative in the unit stresses used because of indeterminate stresses. Based on a 1 : 2 : 4 portland cement concrete made according to the best practice and with first-class aggregates, the maximum unit stress computed by the more accurate methods should not exceed 400 lb. per sq. in. The following stresses computed by the cylinder formula were used in design:

Multiple-Arch Dams. The multiple-arch dam will be found economical in many locations. This type requires less masonry than the gravity dam but involves more labor. If of concrete, the formwork is increased and the narrowness of the forms results in a higher cost of placing. Usually reinforcing steel is also required. Further, on account of the thinness of the masonry the dam must be built more carefully to insure strength and watertightness and is therefore more expensive per unit.

In approximate terms, the multiple-arch dam on a rock foundation will require from one-fourth to one-half as much concrete as a solid gravity dam and will cost from one-half to two-thirds as much as the gravity type. It is more advantageous where the cost of materials is high and the cost of skilled labor is relatively low. In a spillway dam the saving in material and cost is smaller, due to the necessity of providing a slab upon the downstream side of the buttresses for the overflow water.

This type of dam, if an inclined back is used, has the further advantage of making use of the weight of the water upon the inclined back to increase the

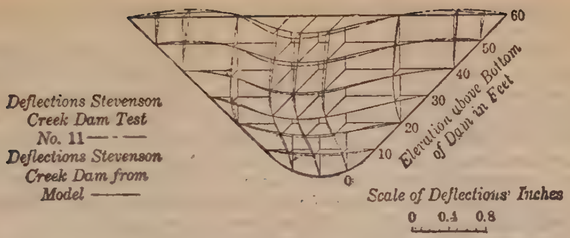

Fig. 100. Comparison of Deflections of Stevenson Creck Dam with Those Computed from Celluloid Model

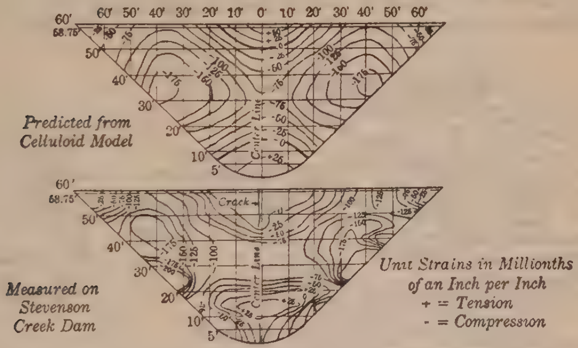

Fig. 101. Measured and Predicted Values for Equal Horizontal Strain, Down-stream Face, 60 ft. Head

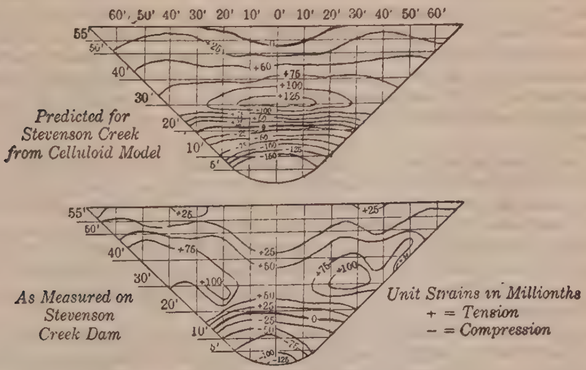

Fig. 102. Measured and Predicted Values for Equal Vertical Strain, Down-Stream Face, 60 ft. Head

stability against sliding and overturning and to obtain a lower pressure per square foot upon the foundations.

On a rock foundation the only advantage a multiple-arch dam usually offers is a saving in cost. On a soft foundation it may be the only feasible masonry type, the designer having to choose between a multiple-arch dam or an earth-filled dam due to the fact that a gravity section brings excessive pressures upon the soft foundation. Further, the wide base of the multiple-arch type increases the distance the water must travel under the dam and therefore the safety of the structure. With a multiple-arch dam, by flattening the slope of the back and by steepening the face of the buttress as in Fig. 103, the pressure upon the foundation may be distributed over a very large area.

When constructed upon a soft or porous foundation special provision must be made to prevent percolation of the water under the dam and the washing out of the sub-soil (for discussion of cutoff walls see Art. 30). A recent multiple-arch dam upon a soft foundation was constructed at Sherman Island in 1922, which is shown in Fig. 103. (Trans. Am. Soc. C. E. Vol. 88, p. 1257.)

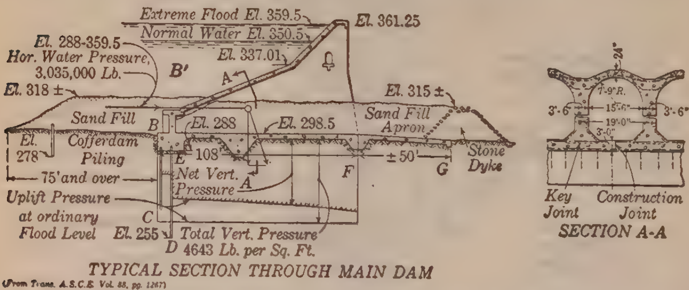

Fig. 103. Sherman Island Dam

The early designs of multiple-arch dams were constructed with buttresses which were braced together with tie struts to prevent buckling and to take the unbalanced arch thrust during construction. With this type of buttress the economical limit of height is about 125 ft. More recent designs use hollow buttresses or solid buttresses with counterforts which serve the same purpose as tie struts. With buttresses of this type it has been possible to construct economically multiple-arch dams, more than 200 ft. in height, on rock foundations.

On soft foundations, sand or gravel, the possible safe height of the dam is limited by the practicability of getting a water cutoff and also by the low supporting capacity of the foundation bed. Assuming the maximum safe depth of the steel sheet pile cutoff in sand or gravel at 75 ft., the maximum safe height of a multiple-arch dam is thought to be less than 100 ft. Even if a concrete caisson cutoff is extended to rock, the practical safe height is probably not greater than this due to the resulting high pressures upon the foundation bed.

In order that the resultant thrust of adjacent arches may lie parallel to and substantially coincident with the middle line of the buttresses, all arches should have the same span in any multiple-arch dam. If this is not possible the buttresses must be designed to take the unbalanced thrusts.

The economical arch span will depend somewhat upon the height, being about 25 ft. for a dam 30 ft. high, and increasing to 50 ft. for a dam 100 ft. high. This theoretically economical span, however, must be reduced for soft foundations in order to avoid excessive bending in the foundation slab between buttresses.

If the dam is built with an inclined back the arches should preferably be circular in any horizontal plane, resulting in an ellipse on a plane normal to the axis of the arch barrel. The horizontal radius of the upstream face should be constant throughout, and for a minimum of material the angle subtended between the abutments should be between 120 and 145 deg. The amount of material saved by this limitation of angle is, however, small unless the angle is smaller than 100 deg. or greater than 160 deg. The economical slope of water face will usually vary between 50 and 60 deg. with the horizontal, but with a soft foundation the slope should be flatter in order to spread the load over a greater foundation area. For convenience and economy in construction of inclined arches, it may be advisable to design the extrados and intrados on a section normal to the axis in the form of a three-centered curve approximating an ellipse. In this way the horizontal sections can be maintained approximately circular. The form work will be greatly simplified if the same intradosal curve is used throughout the height of the dam and if the increase in the thickness of the arch is attained by offsetting the interior or exterior forms at intervals.

After a preliminary design is made a check should be made of the arch stresses, considering the water pressure and the weight of the concrete. The arch should be analyzed in slices perpendicular to the axis, the arch being divided into voussoirs with lengths such that I/s is constant (see Art. 39). The weight of each voussoir should be resolved into two components, one parallel to the sloping face of the arch and one normal to the slope, that is, in a direction parallel to the plane of the abutment. The water load upon each voussoir should be added to the second component of the weight and the arch analyzed by the usual methods. For preliminary design the static method may be used (Art. 36). The final design should be checked by the elastic method (Art. 38) and the effect of temperature and rib shortening considered (Art. 40). It may be necessary in large arches to consider combined temperature and dead load with the reservoir empty. The arches should not be made unnecessarily heavy as this will cause high stresses from temperature changes when the reservoir is empty. If the computations indicate that tension will exist in the concrete, reinforcing steel must be introduced in the design and construction.

The upper portions of the arches should not be made very thin, because the difficulty of placing the concrete, especially if reinforcing steel is used, would be increased and the watertightness jeopardized. If the arches are vertical the thickness should be further increased where ice pressure is expected.

The buttresses should be analyzed as gravity walls, considering the computed reactions of the arches and the weight of the buttress and bracing. If, however, the arches are vertical the weight of the arch concrete cannot be assumed to be of value against overturning unless there is sufficient shear value to transmit the concrete arch weight to the buttress. The method of analyzing the buttresses will be similar to that given in Art. 31 for masonry dams. If the dam is high it may be necessary to brace the buttresses by struts or counterforts or by using the hollow reinforced type. (Trans. Am. Soc. C. E. Vol. 87, p. 342.)

If the buttresses rest directly upon the foundations (rock or hardpan) it will be unnecessary to consider hydraulic uplift; if the buttresses rest on spread footings (soft ground) or a continuous foundation slab, uplift must be considered.

A multiple-arch dam with a steep face is likely to have a small factor of safety against sliding upon the foundations, requiring special provision against sliding by roughening the foundation or providing keyways (see Fig. 103, showing Sherman Island Dam).

In the higher dams of reasonably thick cross-section, considerable saving in cost may be obtained by the use of large-sized aggregate; but watertightness is jeopardized unless the arch cross-section is relatively large.

It is of special importance that the foundation of a multiple-arch dam upon soft ground shall be uniform, to guard against cracks and leakage of water. In the case of Sherman Island dam 90% of the buttresses rest on a concrete slab built upon sand; the buttresses at either end, however, rest upon rock. In order to prevent non-uniform settlement, it was necessary on one side of the river to excavate the rock and cover it with 2 ft. of sand upon which the buttress slab was constructed.

In constructing this type of dam it is probable that the arch action may be developed by the impounded water back of the dam before it is complete. This assumes that the dam will first be built for one-half or two-thirds the river width, the freshet water discharging in the remaining portion of the river. If the remaining width of the river is not adequate, water will be impounded against the back of the arches of the incompleted dam and therefore provision must be made to take this unbalanced thrust, either by having an anchor buttress at the end of the incomplete series of arches or by provision of tie struts. Such enlarged buttresses or tie struts are recommended in any large series of multiple arches to facilitate construction.

Among recent multiple-arch dams constructed on soft foundations may be mentioned:

Sherman Island Dam (Fig. 103), constructed on Hudson River in 1921–23. 80 ft. high, 590 ft. long; buttresses 19 ft. on centers, standing on concrete base 108 ft. by 3 ft. Upper portion of arch barrel 18 in., lower portion 24 in. thick. Built on sand, with steel sheet-pile cutoff. Interior of bays filled with sand to increase resistance to sliding. Apron slab extended 50 ft. downstream to increase length of water travel under dam; sand fill on upstream side for same purpose. (See also Art. 30, p. 937, Dams Built on Sand.)

Cave Creek Dam, near Phoenix, Arizona (1922). 60 ft. high above river bed, 120 ft. to foundation of cemented gravel. Buttresses 44 ft. on centers. Total length 1692 ft. Upstream face vertical at top and curved to 56 deg. slope 80 ft. below crest; below this point, arches are vertical. (Trans. Am. Soc. C. E., Vol. 87, p. 402).

The following are some of the high multiple-arch dams constructed in recent years:

Palmdale Dam, Little Rock Creek, California (1923–24). Maximum height 175 ft.; 690 ft. long. Buttresses 24 ft. on centers, braced with tie struts and counterforts. Arch slope 45 deg., top 10 ft. vertical.

Lake Pleasant Dam, Arizona (1927). Maximum height 256 ft., 170 ft. above river bed; 1850 ft. long. Double-wall buttresses, 16 ft. out to out, with cross walls. Buttresses 60 ft. on centers; no tie struts. Arch slope 47 deg. (Eng. News-Rec., Vol. 100, p. 180; Vol. 102, p. 275.)

Sutherland Dam, Santa Ysabel Creek, near San Diego (started Feb., 1927). Maximum height 180 ft.; length 780 ft. Buttresses 60 ft. on centers, 3 ft. thick at crest, and 10 ft. thick at 180-ft. level.

Tirso Dam, Sardinia (1919–23). Maximum height 239 ft.; length 930 ft. Buttresses of cut-stone masonry, 49.2 ft. on centers, 8.2 ft. thick at top, 23.8 ft. thick at 200-ft. level; with tie struts. Arches of concrete. Arch slope 57 deg. (Trans. Am. Soc. C. E., Vol. 87, p. 397.)

Pavana Dam, Italy (1924–25). Combination of multiple-arch and hollow gravity types. Maximum height of multiple-arch section 177 ft.; spans 54.1 ft. Arch slope 60 deg.

Tidone Dam, Italy (1924–25). Maximum height 171 ft.; length 900 ft. Buttresses 32.8 ft. on centers, 2.3 ft. thick at top, 7.2 ft. at base. Arch slope 45 deg.

Gleno Dam, Italy. As built, about 160 ft. high. This dam failed, but the failure was due to improper construction and not to its design as a multiple-arch structure. This is the only recorded instance of the failure of an arch dam.

The Flat-Slab Reinforced-Concrete Dam is closely related to the multiple-arch dam. This type is known as the "Ambursen Dam." It is a hollow structure, with buttresses similar to those of the multiple-arch dam, but the upstream face is built of flat reinforced-concrete slabs instead of masonry arches. The action of the structure as a whole is similar to that of the multiple-arch dam. Therefore all the statements under the heading Multiple-Arch Dams, except those referring to the arches, will apply to the Reinforced-Concrete, or Ambursen Dam. This is true as to economical location, stability and safety, precautions to be taken with soft or porous foundations, slope of water face, design of buttresses, safe height, uplift, safety against sliding, and importance of uniform foundation.

The Flat-Slab Dam has certain **advantages** over the Multiple-Arch Dam: (1) It is less subject to injury due to slight inequalities in settlement of the buttresses, on soft foundations. (2) The formwork is less expensive. (3) There are no unbalanced arch thrusts on the buttresses during construction. The Flat-Slab Dam has the **disadvantage** that the economic span (distance between buttresses) is less than for a multiple-arch dam. This spacing is generally between 15 and 20 ft. Expansion and contraction under temperature variations are arranged in the flat-slab dam by providing a sliding joint on both sides of each deck slab. Expansion and contraction of the multiple-arch dam are taken up by the flexibility of the arches, which must be adequately reinforced for the resulting stresses.

The details of design will be similar to those of other reinforced concrete structures (Sect. 11).

MASONRY ARCHES AND PIERS

34. General Data for Arches

Definitions. Fig. 104 shows most of the technical terms relating to the construction of stone arches. The **span** is the horizontal distance between abutments. The **soffit** is the under or concave surface of an arch. The **back** is the upper or convex surface of an arch, marked *BBB* in figure. The **rise** is the vertical distance between the lowest and highest points of the soffit. The **crown** is the highest part of the arch ring. The **skewback** is the inclined surface or joint upon which the end of an arch rests. The **springing line** is the inner edge of the skewback. The **axis** is an imaginary horizontal line, parallel to the abutments, passing through the middle point of a line joining the springing lines; in an arch built to withstand horizontal pressure only, as for a shaft, the axis is vertical. The **intrados** is the line of intersection of the soffit with a vertical plane perpendicular to the axis. The **extrados** is the line of intersection of the back with a vertical plane perpendicular to the axis. The **arch ring** is the entire arch included between the skewbacks, the soffit and the back. The **haunch** is the portion of the arch ring between the springing line and the crown; **haunching** or **backing** is masonry, with bed joints nearly horizontal, which is placed above the haunch. The **spandrel**

is the space between the extrados and the roadway, marked *SSS* in figure. **Spandrel filling** is earth deposited between the back and roadway. A **voussoir** is one of the wedge-shaped blocks of stone or concrete of which the arch is composed; in design the voussoir is regarded as having a depth equal to the depth of the arch ring, but in construction the voussoir may be of less depth; the **keystone** is the highest voussoir. **Ring stones** are voussoirs which show at the ends or faces of the arch ring. **Arch sheeting** comprises all voussoirs ex-

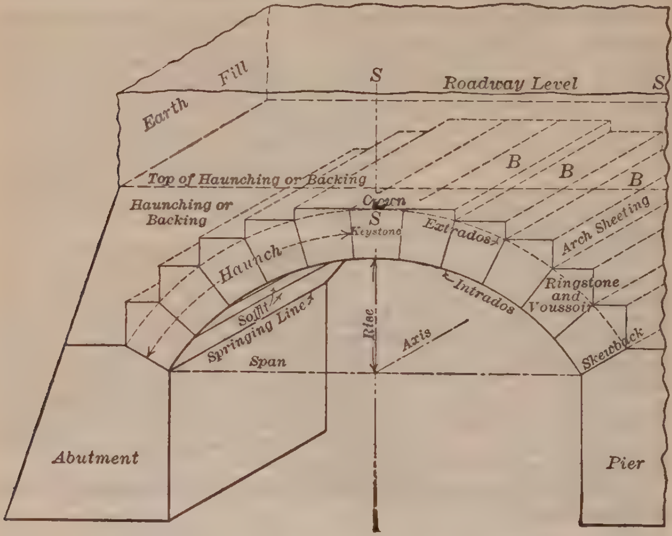

Fig. 104. Technical Terms for Masonry Arches

cept the ring stones; in concrete arches, which are not faced with stone voussoirs, the term arch sheeting includes the entire arch ring.

Kind of Arches. **Hinged arches** are those with stone, steel or lead hinges at crown and springing line; hinged masonry arches are always built with three hinges. **Fixed arches** are those constructed without hinges. A **full-centered arch** is one whose intrados is a semicircle. A **segmental arch** is one whose intrados is less than a semicircle. A **pointed arch** is one in which the intrados

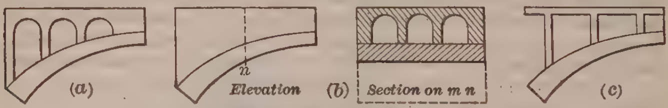

Fig. 105. Spandrel Arches and Columns

consists of two arcs of radii greater than the half-span, these arcs intersecting at the crown. A **right arch** is one terminated by vertical planes perpendicular to its axis. A **skew arch** is one terminated by vertical planes oblique to its axis. **Spandrel arches** are those which rest upon the back of the larger or main arch; they are called transverse when their axes are parallel to that of the main arch (Fig. 105*a*) and longitudinal when their axes are at right angles to that of the main arch (Fig. 105*b*). **Spandrel columns** are shown in Fig. 105*c*.

Loads. Dead load includes the weight of the masonry itself, the weight of the spandrel filling and that of the roadway. The live load to be used in investigating a masonry arch is the greatest that comes or is liable to come upon its roadway, while for design that given in the specifications is to be employed. Since the spandrel filling distributes the load to a large extent, uniform live loads are often used, about 150 lb. per sq. ft. for heavy highway traffic and about 700 lb. per. sq. ft. for railroad traffic for spans over 80 ft., and 1000 lb. per sq. ft. for shorter spans. Culverts and small arches are designed for a uniform live load over the entire span. Larger arches are to be analyzed not only for full uniform load but also for a live load extending over certain portions.

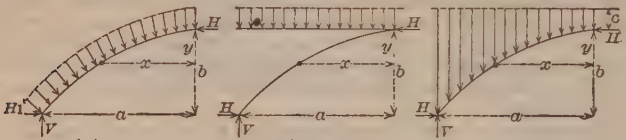
Earth-filled arches should be designed for uniform live load over the span and half-span. Arches with the roadway supported on spandrel arches or spandrel columns should be designed for uniform live load over the span, half-span, middle-third of the span, and the outer thirds of the span. Narrow highway arches with spans under 100 ft., and all railway arches should be designed for concentrated loads. Impact of live loads need not be generally considered except for short span arches with arched or column spandrels. In northern latitudes a snow load of 25 lb. per sq. ft. over the entire span should be considered for a highway bridge if a uniform live load of less than 100 lb. per sq. ft. is provided for. Arches for aqueducts must be figured for the live load of the water. Wind loads are rarely taken into account for the arch, but may be needed for a pier.

In computations an arch one unit in width parallel to the axis is considered. The total live load over the portion considered being divided by the width of arch gives the weight per unit of width, and this may be reduced, for convenience of representation on the drawings, to a rectangle whose height is that of an equivalent weight of masonry.

For an Arch with Horizontal Axis under water pressure, the loading at any point of the extrados depends on the depth of that point below the water surface, and its direction is normal to a tangent to the extrados at that point. If the arch is circular, bending moments as well as thrusts are developed in the arch. For symmetrical arches, the loading (both dead and live) will be symmetrical. The arch may be analyzed by the usual methods, taking into consideration both the vertical and the horizontal components of the water pressure.

A Horizontal Thrust H (Fig. 109, Art. 35) is produced at the crown when the arch is loaded symmetrically. For non-symmetrical loading an inclined pressure P acts at the crown, and its horizontal component H is also called the horizontal thrust for that loading. The semi-arch is held in equilibrium by the system of forces consisting of the horizontal crown thrust, the vertical loads and the reaction of the skewback. For any joint 2-2 the part of the arch on the right is held in equilibrium by the horizontal thrust H, the vertical loads W_1 and W_2 and the reaction of the arch below the joint. This reaction is equal and opposite to the resultant of H and the loads W_1 and W_2, and the point r_2 where this resultant cuts the joint is a point in the resistance line, the definition of this term being the same as in Art. 23, except that in the arch the joints are not horizontal. The resistance line itself is a curve joining the points $o\ r_1r_2r_3r_4r_5$.

A Linear Arch is a curve which is in equilibrium under the action of a given system of loads; it is an equilibrium polygon with an infinite number of sides. In an actual arch the resistance line is a linear arch for the actual loading. Each kind of loading has a linear arch which corresponds to it and which holds that load in equilibrium. The three simplest cases are: (1) The linear arch for water pressure is a circle if the axis of the arch is vertical or if the depth of water over the crown is very large compared to the rise of arch (Fig. 106*a*). (2) The linear arch for uniform horizontal load is the common parabola (Fig. 106*b*). (3) The linear arch for a load of uniform density between a horizontal roadway and the curve itself is the transformed catenary (Fig. 106*c*). Let a be the half-span and b the rise of a linear arch. Let x and y be abscissa and ordinate of any point in the curve with respect to the crown as an origin. Let



(*a*) *Circle* (*b*) *Parabola* (*c*) *Trans. Catenary*

Fig. 106. Loadings for Linear Arches

c be the depth of the load at the crown, and $n = (b + c)/c$. Then the equations of these linear arches are:

for circle, $y = r - \sqrt{r^2 - x^2}$, where $r = 1/2\, b + a^2/2\, b$.
for parabola, $y = bx^2/a^2$.
for transformed catenary, $y = c\,(\cosh\,(\beta x/a) - 1)$

in which β is the Napierian logarithm of $n + \sqrt{n^2 - 1}$. Let w = load per linear unit at the crown. Then the horizontal thrust at the crown and the vertical reaction at the skewback are:

for circle, $H_1 = wr - wb$ $H = wr$ and $V = wa$
for parabola, $H = wa^2/2\,b$ and $V = wa$
for transformed catenary, $H = wa^2/c\beta^2$ and $V = (wa/\beta)\sinh\beta$

The resultant thrust at the skewback is the square root of the sum of the squares of H and V. (For tables of Napierian logarithms and hyperbolic functions see Sect. 1.)

Curves for Arches. The central curve of an arch, that is, the curve lying half-way between intrados and extrados, may be the circle, the parabola, the transformed catenary, the ellipse, or various combinations of these. In Fig. 107 are shown the first three curves for four different ratios of rise to span, these having been plotted from the above equations. The transformed catenary curves are for a height of roadway above the crown equal to 1/20 of the span, or $c = 1/10\,a$. When the ratio of rise to span is 1/10 or less, the three curves are practically the same. **Economic curves,** or those giving a minimum amount of masonry for various loadings, have been determined to be as follows: (1) A circle should be used for water or other fluid material under a head which is large compared with the span. (2) A parabola should be used for a uniform load on the horizontal projection, which is closely the case for an arch having spandrel columns or spandrel arches. (3) A transformed catenary should be used for vertical loads like those of Fig. 106*c* or for an earth-filled arch having a ratio of rise to span less than 1/4. (4) An ellipse should be used for an earth-filled arch having a ratio of rise to span greater than 1/4.

The transformed catenary is difficult to lay out and is unsightly, but an approximate catenarian curve consisting of a compound curve made up of circles of different radii may be used. The parabola may be modified for the sake of appearance by short circular curves at its ends, made tangent to the parabola and to the vertical side of the pier.

When arches are built of cut-stone voussoirs, the cost of cutting each stone to a different curve more than offsets the saving in material resulting from using the theoretically correct curves. Many designers for this reason prefer the segmental arch, and for flat arches use the same depth of voussoirs from the crown to the springing line. The economic curves may be used advantageously for concrete arches, because falsework may be laid out as easily for a parabolic, elliptical or multi-centered arch as for a segmental arch.

When the maximum waterway for the given span and height of crown is desired the ellipse must be used. The flatter the ellipse the greater the area of waterway. The flatter the arch, however, the greater the thrust and the larger and more expensive the requisite abutments. For economic abutment design the ratio of the rise of the arch to its span should be as large as possible.

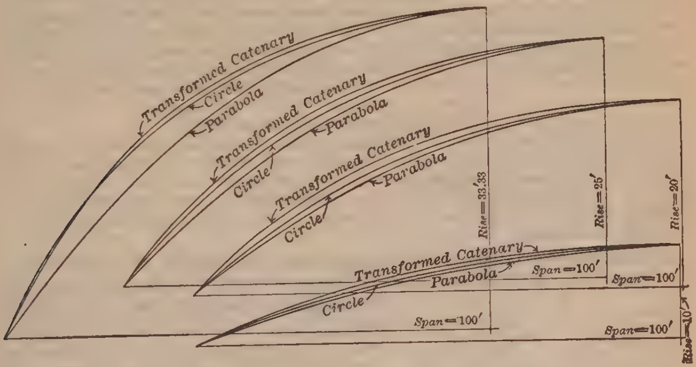


Fig. 107. Comparison of Curves for Arches

The Span and Rise are, as a rule, determined by physical conditions. A creek or river must be spanned and ample waterway provided. Roadways must pass under the bridge in fixed positions. Railway rights-of-way must be left unobstructed. Piers and abutments must be located, if possible, where the cost of foundation is a minimum. Where the cost of foundation is uniform from end to end of bridge, a series of arches should for economy be of equal spans. When unequal spans are mandatory, the spans should be made as nearly equal as possible. The rise of the soffit of the arch is always governed by the necessary clearance under the arches or the necessary level of the roadway or by both.

The length of span and the curve of an arch are often determined by the necessities of river travel. The position of the piers should be made parallel to the thread of the current, and this condition may necessitate a skew arch. Passage of vessels may require maximum clearance over certain portions of the river, or a maximum waterway may be necessary on account of freshets or ice gorges.

Appearance is sometimes the governing factor in selecting the curve of an arch. The semicircular arch best satisfies this demand, and next in sequence are the segmental, modified parabolic and basket-handle arches. A series of arches should, for appearance, always be of approximately equal spans, unless the profile of the ground demands unequal spans; if of unequal spans, a symmetrical arrangement of spans is desirable. The number of spans should, for appearance, always be odd unless the number exceeds seven, in which case it may be odd or even. For the most satisfactory appearance, the spans should increase slightly in length from the banks toward the center of the bridge, and the profile of the roadway should be cambered. If the spans are all of the same length, the middle span will appear shorter, due to an optical illusion; and if the profile is straight, the roadway will appear to sag at the middle of the bridge. If the spans are unequal, the piers must be large enough to withstand the unbalanced arch thrusts.

Economic Types. If the arches are of low rise or of high rise and under 100-ft. span, the earth-fill bridge is generally the cheapest type. However, if the foundations are poor, regardless of span, the three-hinged ribbed arch (Fig. 110) is the safer one and therefore the better type to use. If the foundations are neither poor nor first-class, the arches should be heavily reinforced with steel, to provide better for possible deformation of the arches due to settlement, however small.

If the arches are of high rise and spans over 100 ft., the arch with arched or column spandrels is generally cheaper. This is due to the great cost of the retaining walls of earth-filled bridges. However, for very wide bridges where the cost of the retaining walls per foot width of bridge is small, comparative designs should be made before selecting the type of design. The three-hinged ribbed type of bridge is generally expensive, due to the cost of the hinges and the added cost of two-faced masonry, or, if concrete, due to the added cost of formwork. The column spandrel is used only for reinforced concrete, but it is cheaper than the arched spandrel.

Masonry arches may be built of cut stone, or plain or reinforced concrete. Concrete is generally more economical if suitable materials are available, as it does not require skilled labor and permits a lighter structure, especially if reinforced. A stone arch, however, is more permanent, as it is less subject to attack by weathering, and the workmanship is liable to be better. A stone arch is generally a more beautiful structure, but more costly.

Dimensions for Designs. The approximate thickness at the crown of an arch built of masonry, with portland cement mortar, is given in the table below in feet, l being the span of the arch in feet. The thickness at the springing line may be approximated by the following empirical rules in which the percentages are to be added to the crown thickness found from the table: (1) Add 50% for circular, parabolic and catenarian arches having a ratio of rise to span less than 1/4. (2) Add 100% for circular, parabolic, catenarian and three-centered arches having a ratio of rise to span greater than 1/4. (3) Add 150% for elliptical, five-centered, and seven-centered arches. These thicknesses should be measured along radial joint as in Fig. 108, namely at *aa* for cases (1) and (2) and at *bb* for case (3).

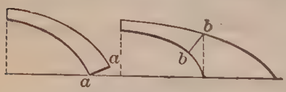

Fig. 108

Thickness in Feet at Crown for Highway Arches (Original)

Kind of masonry	Span in feet			
	Under 20 *	20 to 50 *	50 to 150 †	Over 150 ‡
First-class ashlar....	$0.04\,(6+l)$	$0.020\,(30+l)$	$0.00012\,(11\,000+l^2)$	$0.018\,(75+l)$
Second-class ashlar or brick...........	$0.06\,(6+l)$	$0.025\,(30+l)$	$0.00016\,(11\,000+l^2)$	$0.025\,(75+l)$
Plain concrete......	$0.04\,(6+l)$	$0.020\,(30+l)$	$0.00014\,(11\,000+l^2)$	$0.020\,(75+l)$
Reinforced concrete..	$0.03\,(6+l)$	$0.015\,(30+l)$	$0.00010\,(11\,000+l^2)$	$0.016\,(75+l)$

* For culverts under a high fill, add 60%; for railroad arches, add 25%. † For railroad arches add 20%. ‡ For railroad arches, add 15%.

The Top Thickness of a Pier capable of supporting adjacent arches of equal span may be taken as 3-1/2 times the crown thickness. In a series of arches of more than five spans, abutment piers capable of resisting the entire thrust of one adjacent arch should be introduced at every third or fifth span, so that in case of failure of the foundations of one arch the entire series would not fail. The top width of abutment piers may be assumed at five times the crown thickness.

Cost of an Arch Bridge in 1928 was approximately given in dollars as follows:

For a bridge of concrete, plain or reinforced, Cost $= 2.0\, bl \sqrt{d}$.

For a bridge of ashlar, Cost $= 3.5\, bl \sqrt{d}$,

in which b = the width in feet of the bridge, l = its length in feet, and d = the average depth in feet of the bed of the stream below the roadway level. These formulas cannot be used when foundation work is expensive.

Before laying out the spans and the curves of the arches, a contour map and profile of the site of the bridge should be made. On the profile the depth and character of the foundation and its overlying material should be indicated. The position of the piers should be located with reference to economic foundation, clearance of waterway, roadway and right of way; the spans to be made equal unless impossible or, on account of the cost of foundation, manifestly uneconomical to do so. The most economical type of bridge should then be selected and also the curves of the arches requiring a minimum amount of material, due consideration being given, however, to cost of labor of cutting stones, clearances and appearance.

Long Span Stone Masonry Arches

35. Equilibrium and Stability

Methods of Failure. A masonry arch may fail in the following ways. (1) By crushing of the masonry. (2) By sliding of one voussoir upon another. (3) By one voussoir or section of masonry overturning about an adjacent voussoir or section. (4) By shearing in a horizontal or vertical plane, this applying to solid concrete arches and not to voussoirs. (5) As a column when the ratio of the unsupported length of an arch to its least width is greater than 12. (6) From striking the centering before the mortar is hard or when the arch, though stable under the full load, is not stable under its weight alone. (7) By striking the centering or loading the arch during construction unsymmetrically. (8) By settlement of the foundations. (9) By sliding upon the foundations. (10) By overturning about any point in the pier or abutment. Methods (8) and (9) are the most common ways of failure. All methods of failure, however, must be guarded against in design.

Just before an arch fails the forces acting upon it are in equilibrium, but there is no stability. For any degree of stability, however, the forces acting on the arch are in equilibrium. The conditions of stability are, in general, the same as those explained in Art. 23 for walls and dams.

Conditions of Stability corresponding to the above methods of failure are as follows: (1) The unit compression must not be greater than the safe unit compressive stress given in Art. 16. (2) The angle between the resistance line at any joint and a normal to the joint should be less than the angle of friction of masonry upon masonry. (3) The resistance line should lie within the middle-third of the arch ring; in reinforced-concrete arches it may depart a small distance outside the middle-third, but there should be sufficient steel to take care of the tension which will develop upon the portion of such joints farthest from the resistance line. (4) The greatest tendency to shear is in a horizontal plane for a high arch, and in a vertical plane for a low arch; it is sufficient to calculate the shear for points near the springing line, and the frictional resistance in the vertical or horizontal plane should be regarded as an additional factor of safety against failure by shear. (5) When the span is more than twelve times the width of the arch at the crown, either the crown width must be widened or the faces of the arch ring must be battered so as to reduce the ratio; for an arch formed of independent ribs, the ribs must be well bonded together by transverse walls. (6) The exposed mortar in the joints should always be inspected before striking the center, and in case of large concrete arches it is best to drill holes through the last concrete placed, to make sure the concrete is set up within the interior of the arch ring; an analysis should be made to find whether the arch ring is stable under its own weight, and if not, the centering should not be struck until the total dead load rests upon the arch. (7) If the masonry above the arch is to be built after the center is struck, it should be built symmetrically; if for any reason this appears impracticable, the arch must be analyzed for the desired unsymmetrical load. (8) Foundations for fixed arches must be practically unyielding, and the allowed unit load should not, as a rule, exceed 50% of that for ordinary foundations. (9) The horizontal thrust on the foundation should be less than the vertical load upon the foundation multiplied by the coefficient of friction of masonry upon the material of which the foundation bed is composed, or in case of hard or rotten rock, the foundation bed should be roughened; when piers and abutments rest upon piles, the piles should be driven parallel to the line of the resultant thrust or they should be braced by means of horizontal struts to unyielding foundation. (10) The line of thrust must lie within the middle-third of the piers and abutments, including the foundation masonry.

The External Forces (Fig. 109) holding a semi-arch in equilibrium are the vertical loads W_1, W_2, etc., the horizontal thrust H, a vertical reaction V_1 at the skewback, and a vertical shear V_0 at the crown which is due to the action of the other semi-arch. When both semi-arches are loaded equally and symmetrically, then $V_0 = 0$. For the case where the position of the resistance line within the arch ring is known, so that the half-span a and the rise b of the linear arch (Art. 34) are also known, the forces V_1, V_0, H are found as follows: first, the vertical reaction V_1 is computed in exactly the same way as for vertical loads on a simple beam, by taking the center of moments at the right end of the arch; second, the shear V_0 is equal to the sum of all the loads on the semi-arch under consideration minus V_1; third, the horizontal thrust H is found by taking moments about r_5 at the left end, or $\mathbf{Hb + V_0a = \Sigma W\mathit{l}}$, in which the last term is the sum of the moments of the loads.

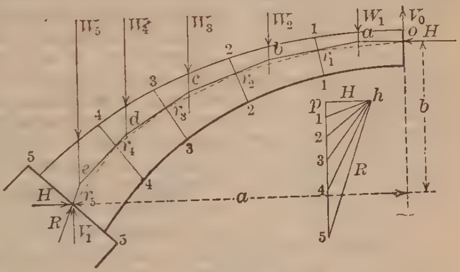

Fig. 109

Example. For arch loaded symmetrically, let $a = 30$ and $b = 21$ ft.; $W_1 = 3$, $W_2 = 4$, $W_3 = 7$, $W_4 = 10$, $W_5 = 12$ tons, their lever arms being $l_1 = 28$, $l_2 = 16$, $l_3 = 10$, $l_4 = 4$, $l_5 = 1.5$ ft.; here $V_1 = 36$ tons and $V_0 = 0$; $H \times 21 = 3 \times 28 + 4 \times 16 + \text{etc}, = 276$ ton-ft., whence $H = 13.1$ tons. For arch with no load on right-hand span and above loads on left-hand span: $V_1 \times 60 = 3 \times 32 + 4 \times 44 + \text{etc.} = 1882$ ton-ft., whence $V_1 = 31.4$ tons; $V_0 = 36.0 - 31.4 = 4.6$ tons, which acts downward upon the right half-span or upward upon the left half-span; $H \times 21 + 4.6 \times 30 = 276$ ton-ft., whence $H = 6.6$ tons.

For a Three-Hinged Arch (Fig. 110) the above method gives the correct values for V_1, V_0 and H, since a is the half-span between end and middle

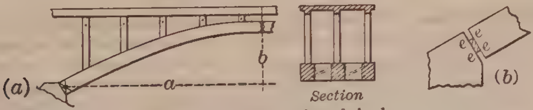

Fig. 110. Three-Hinged Arch

hinge and b the rise of the middle hinge. For a common unhinged arch it is usual to take a as the horizontal and b as the vertical distance between the middle of skewback and middle of crown, but the values found are approximate only, since the assumption that the resistance line passes through the middle points of crown and skewback joints is rarely correct, and since the method of computing V_1 is not exact.

The three-hinged arch in Fig. 110*a* consists of three ribs, which support the roadway on spandrel columns. Each rib has hinges at both ends and one at the crown, the hinge being a steel pin set in a pedestal and upon which abuts the steel shoe which holds the end of the concrete arch. Another form is that in Fig. 110*b*, where a lead plate or a steel plate covered with lead is placed between two abutting concrete surfaces; this form limits the resistance line to a smaller area, but can scarcely be called a real hinge. (See Art. 37.)

Stability against Sliding along any joint will be secured when the resultant of all the forces on each side makes an angle β with the normal to the joint such that 2 tan β is less than tan ϕ where ϕ is the angle of friction of masonry upon masonry (Arts. 18 and 23). Or, let F and N be the components of the resultant parallel and normal to a joint (Fig. 111) and f the coefficient of friction; then fN/F should not be less than 2. After V_0 and H have been found, F and N for any joint are computed by $F = H \sin \theta - (W - V_0) \cos \theta$, $N = H \cos \theta + (W - V_0) \sin \theta$, in which W is the sum of all the loads between the crown and the joint, and θ is the angle which the joint makes with the vertical. When F is positive it acts upward; when negative it acts downward.

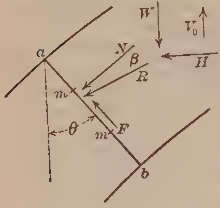

Fig. 111

Stability against Rotation at any joint is secured when the resultant cuts the joint ab within the middle-third mm (Fig. 111), for, the entire joint being then under compression, no tension or opening of the edges of the voussoirs will occur (Arts. 21 and 23).

Stability against Crushing of the material is secured if the compressive unit stress S_a at the edge nearest the resultant is less than the allowable value given in Art. 16. The average unit stress on the joint is N/A, where A is the area of the joint, and the unit stress at a is found by multiplying N/A by $1 + 6\,e/b$, where b is the length of the joint and e is the distance from its middle to the point where the resultant R cuts it (Fig. 111). When R cuts the joint without the middle-third, this rule must be modified unless the joint can take tension (Art. 21).

At each and every joint throughout the arch the above conditions must be satisfied in order that security may prevail throughout. The points cut by the resultants at all joints being connected by a curved line, the resistance line is constructed. The most important of the above conditions is that the resistance line must lie within the middle-third. Although the word joint has been used in this discussion, all the conclusions apply to the imaginary radial joints of a plain concrete arch.

36. Static Analysis of an Arch

The Static Method of investigating an arch is that outlined in a general way in Art. 35, and is so called because only the principles of statics are used. To determine the horizontal pressure H by that method it is necessary to assume its point of application at the crown joint and also the point of application of the resultant at the skewback joint. Then H can be computed and the resistance line be drawn within the arch ring, but there is no assurance that this is the true resistance line. It is, however, generally accepted that an arch has proper stability against rotation if a resistance line can be constructed which will lie within the middle-third of the arch ring at all radial joints. Hence, different assumptions as to points of application are to be made and different resistance lines to be constructed, and the design should be pronounced deficient in stability if a resistance line cannot be found which lies within the middle-third. (See " Stresses, Graphical Statics and Masonry," by G. F. Swain, 1927, p. 411.)

The static method was used in America almost exclusively prior to 1900. Although the elastic method (Art. 38) has the advantage that it determines both H and its point of application, yet the static method is still of great value in preliminary investigations.

The Resistance Line can be constructed, after H has been computed, by help of the force polygon. In Fig. 109 the thrust H is laid off horizontally and the loads vertically in succession; then from h as a pole the rays are drawn to the points of division between the loads, the last ray thus giving the magnitude and direction of the resultant R on the joint 5-5. An equilibrium polygon is then constructed, the first side being in the line of H produced, the second parallel to the first ray, and so on until the last side through e gives the position of R. The points r_1, r_2, r_3, r_4, r_5, where these sides cut the joints, are points in the resistance line, and the resistance line itself is the curve joining them.

This force polygon is for the the case of symmetrical loading on the arch so that the crown shear V_0 is zero. The method, however, is perfectly general and may be used to give closely approximate results for unsymmetrical loading by drawing V_0 as the first vertical force in the force polygon, laying off its value upward if the same is positive and downward if it is negative.

A Graphic Method of finding the horizontal thrust H is shown in Fig. 112 for a simple case where only three loads are used for the sake of clearness. The arch has the live load on the half-span shown, while the other half-span has only dead load. The horizontal thrust is assumed to act at the crown at the upper middle-third limit, and the resultant at the skewback is assumed to act at the lower middle-third limit. The correct horizontal thrust H on the foregoing assumptions is that which will, with the three loads W_1, W_2, W_3, give an equilibrium polygon passing through the assumed point a at the crown and the assumed point r at the skewback. The procedure is as follows:

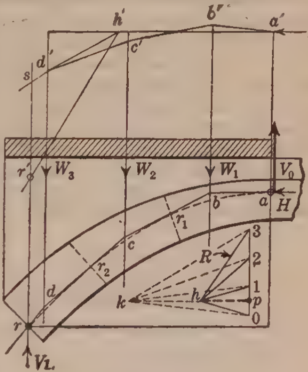

Fig. 112

(1) The reaction V_1 is computed in exactly the same way as for a simple beam. The crown shear V_0 is found by subtracting V_1 from the sum of the three loads. The load line for the force polygon is laid off from p, the distances 3–2, 2–1, 1–0, op being made equal on a proper scale to the values of W_3, W_2, W_1, V_0, respectively.

(2) Assume pk in the force polygon to be the value of H; with k as a pole draw the rays $k0$, $k1$, $k2$, $k3$, the last of which should be the resultant at the skewback if the assumed H is correct. Above the arch, in order not to confuse the drawing, extend upward the lines of action of the loads and place the points a' and r' above a and r, and at the same vertical distance apart. Then construct the equilibrium polygon $a'b'c'd's$, each side being parallel to the corresponding ray in the force polygon. The last side $d's$ of this trial equilibrium polygon does not pass through r'. Extending its line of direction upward until it meets that of H', there is found at h' the point through which the resultant of the vertical forces acts. Then a line joining r' and h' gives the direction of the true resultant.

(3) In the force polygon, draw R parallel to $r'h'$ then ph is the value of the horizontal thrust H on the scale employed. From h draw a new set of rays, and in the arch ring itself construct the equilibrium polygon $abcdr$, which must now pass through the point r on the skewback joint.

(4) This equilibrium polygon cuts the two radial joints at the points r_1 and r_2, these being points in the resistance line, which is a curve joining a, r_1, r_2, and r. This curve lies everywhere within the middle-third of the arch ring, and hence there is full stability against rotation. The direction and magnitude of the resultants acting on these joints are given by the rays $k1$ and $k2$ in the force polygon.

An Actual Investigation of a proposed design by the static method involves no principles not explained above. The practical procedure is as follows: (1) Vertical lines are drawn dividing the arch structure into an even number of parts, about 16 parts being used for a span of 80 ft. (2) The weight of the masonry and earth filling for each of these parts is found for an arch one unit in width, as also the line of action of that weight; earth is usually reduced to an equivalent height of masonry, and then the center of gravity of an area is the point through which its weight acts. (3) For loads W_1, W_2, etc., which act through these centers of gravity the horizontal thrust may be found and the resistance line be located as above explained. (4) The points assumed at crown and skewback may be the middle points for the first investigation, but the upper limit of the middle-third at one joint and the lower limit at the other joint may be used for other resistance lines. (5) One set of lines should be found for full dead and live load over the whole span, another for the case when the live load is on the left half-span only. Lines for other loadings may be sometimes necessary (Art. 34).

To Design an Arch by this static method, a drawing is made which seems to give good proportions and dimensions for the given local conditions and loads, the thickness of the arch ring being assumed from the data in Art. 34. Then several resistance lines are constructed, and, if none can be found which lies within the middle-third, the proportions or thicknesses are unsafe ones and must be changed. Another drawing with different dimensions is then made and resistance lines constructed for it. When several drawings or designs all furnish proper stability for the given loads, then that one should be chosen which can be built for the minimum cost.

Cain's Method of finding the crown thrust H and crown shear V_0 for a case of unsymmetric loading is as follows (Fig. 113). P_1 = weight of left half of arch and the load upon it, P_2 = weight of right half of arch and the load upon it, P_3 = weight of the portion of the arch and load between a joint rr_1 and the crown, other notations in the figure. It is necessary to assume the points of application of the resultants on the lowest joints mm_1 and nn_1 and the point of application of the resultant upon some other intermediate joint as at L, while I, L, and K are points through which it is desired to pass the resistance line. All of the points should be taken within the middle-third of their respective joints. If I and L are on the more heavily loaded half of the span and K therefore on the more lightly loaded half, I should be assumed a little below the middle of its joint and L and K a little above the middle of their joints. If I and L are on the lighter half and K on the heavier half, I should be taken a little above the middle of its joint and L and K a little below the middle of their joints. The following formulas (Cain's Voussoir Arches, 1904) give the horizontal and vertical components of the inclined crown thrust and its point of application:

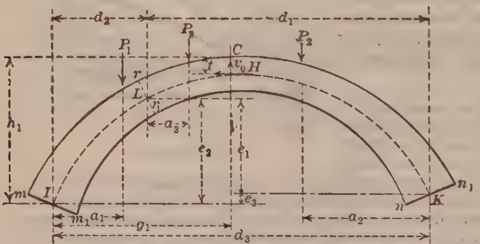

Fig. 113. Unsymmetric Loading

$$V_0 = \frac{a_1e_1P_1 - a_2e_2P_2 + a_3e_3P_3}{e_2d_3 - e_3d_2} \qquad H_0 = \frac{a_1d_1P_1 + a_2d_2P_2 - a_3d_3P_3}{e_2d_3 - e_3d_2}$$

$$t = h_1 - (a_1P_1 - g_1V_0)/H$$

Limitations of Static Method. The static method of design gives curves of resistance which agree closely with those determined by the elastic method. The maximum unit stresses determined by the static method agree with those found by the elastic method within less than 10%, and usually the difference is less than 5%. It is therefore a safe method of design, and may, in general, be used for the design of an arch. The elastic method, however, should be used in the final design of all important arches. The static method ignores temperature stresses (Art. 40). Inclined loads, resulting from pressure of earth, may usually be treated more simply by the elastic method.

Longitudinal Walls and masonry haunching resting upon the back of the arch do not exert their full weight upon the back of the arch, but, for safety, the full weight of walls and haunching should be used in determining the line of resistance.

A Retaining Wall resting upon the back of the arch exerts greater pressure upon the arch at the toe of the wall than at the heel, and the pressure varies between the heel and toe, but it is exact enough to regard the pressure upon the base of the wall as uniformly distributed upon the back of the arch. The ring stones should be tied by iron cramps to the sheeting back of the ring stones, otherwise the horizontal thrust upon the back of the retaining wall may separate them from the arch sheeting.

Change in Spandrel Loading. The line of resistance may be shifted in position so as to lie closer to the neutral axis, by changing the spandrel loading. For instance, in Fig. 114, which is an arch of an earth-filled bridge, the resistance line will be changed if transverse hollow arches are formed through the haunches on each side of the arch; such hollow tunnels are used in the longest masonry arch in the world, that at Plauen in Saxony. Changes in the spacing of spandrel columns will also modify the resistance line; such changes, however, should be mainly confined to cases where errors in design are detected after the arch is erected and before the spandrel columns are built. In an earth-filled arch it is manifestly impracticable to change the line of resistance by changing the unit weight of the earth fill at selected points.

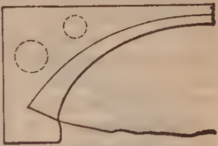

Fig. 114

Transverse Spandrel Arches (Fig. 115). The spandrel columns or walls of transverse arches should not generally be spaced parallel to the span at

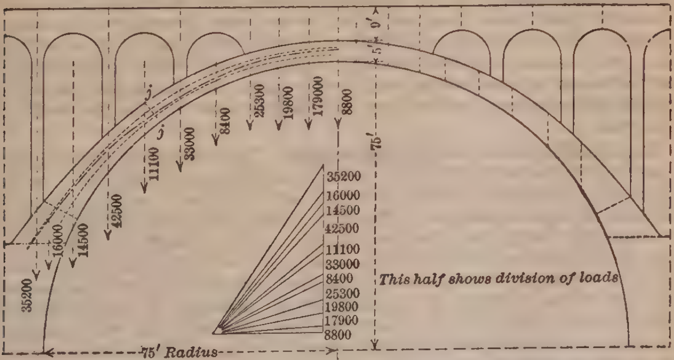

Fig. 115. Connecticut Ave. Arch, Washington, D. C.

intervals exceeding about 1/7 of the span. The spandrel columns should not generally be spaced parallel to the axis of the arch, transverse to the span, at intervals exceeding about two and one-half times the thickness of the arch ring upon which the columns rest. When the columns are so placed, the load brought upon the back of the arch may be regarded as distributed uniformly across the transverse section of the arch. In the case of a reinforced-concrete arch this transverse spacing of the columns may exceed two and one-half times the thickness of the arch.

Fig. 115 shows the method of determining the resistance line for transverse spandrel arches, this being shown by a heavy dot and dash line, while the limits of the middle-third are shown by light dotted lines. This arch is one of the main spans of the Connecticut Avenue bridge in Washington, D. C. The 5-ft. arch ring is of concrete blocks and the arch sheeting of plain monolithic concrete. The arch is a full-centered one of 150-ft. span, and the span of transverse arches is 14 ft. The analysis shown is for a full uniform load over the entire span. The resistance line comes nearest the edge of the middle-third at the joint *jj*, and the maximum compression there is 350 lb. per sq. in.

37. Three-Hinged Arches

Advantages. (1) If the foundations are compressible, such as pile or clay foundations, the three-hinged arch offers the best type, as it permits considerable settlement without injury to the arch. (2) If the arch has a rise of less than 1/4 the span, on account of the high temperature stresses in a solid arch, the three-hinged arch is the better. (3) Since the temperature stresses are practically nothing, and as the arch is statically determinate, higher unit stresses may be used than in the solid arch.

Disadvantages. (1) High cost of the hinges, which may be offset somewhat by the saving in concrete for long-span arches. (2) Difficult maintenance and possible short life of the hinges, if of iron or steel, as compared with the life of the masonry. (3) The three-hinged arch usually lacks the graceful appearance of most fixed arches, due to the increased thickness that is necessary at the haunches.

Approximate Design. The crown thickness t_0 may be taken a little less than those given by empirical rules for the solid arch. The thickness at the springing line may be approximately 1.25 t_0, and that at the middle of the haunch approximately 1.5 t_0. Having selected these dimensions, the arch should be drawn to a large scale and be analyzed according to the static method. The cheapest type of the three-hinged arch is one of detached ribs supporting spandrel columns, although there appears to be no reason why an arch with continuous sheeting should not be used. In what follows the lower hinges will be assumed at the same level and the crown hinge at the middle of the arch.

Dead and Live Load over the Entire Span. The weights and lines of application of the loads may be found as in the static method (Art. 36). As the loads are symmetrical, only the left-hand half of the arch need be considered. The crown shear is here zero. The crown thrust H, which is horizontal for symmetrical loading, may be computed from $\mathbf{H = \Sigma Wz/b}$, in which W = any load applied upon the left half of the arch, z = horizontal distance from it to the left hinge, b = rise of arch measured from the horizontal line passing through the lower hinges to the crown hinge. Knowing H, lay off the load line, construct the force and equilibrium polygons as in the static method, applying H at the center of the crown hinge. If the graphical work is correct, the last line of thrust will pass through the center of the lower hinge.

For dead load on entire span and live load on the left half, let W = any dead load of the left half-span, W' any live load, and z and z' be the horizontal distances from them to the left end hinge. Then

Thrust $\mathbf{H = (\Sigma Wz + 1/2\ \Sigma W'z')/b}$ Crown shear $\mathbf{V_0 = +\ \Sigma W'z'/2a}$

in which a = half-span. For dead load over entire span and live load on the right half the same formulas apply, except that V_0 is negative. The force polygon for either case is then constructed as in Fig. 112, and the equilibrium polygon drawn, taking H and V_0 as applied at the middle hinge; the last line giving the direction of the resultant thrust at the skewback should pass through the end hinge.

Special Method for Thickness of Arch Ring. The hinges may be drawn at the given points and the approximate loads of the spandrels and arch be applied as shown in Fig. 116. These loads and their point of application may be determined by a practically complete design of the spandrels made prior to the arch design. The weight of the arch ring may be approximated, using the dimensions recommended, but the arch ring itself need not be drawn. After computing H and V_0 for each case construct the equilibrium polygons or thrust lines for (1) dead and uniform live load over the entire span, (2) for dead and uniform live load over the right half-span, (3) for dead and uniform live load over the left half-span. The first line is shown in Fig. 116 as a full

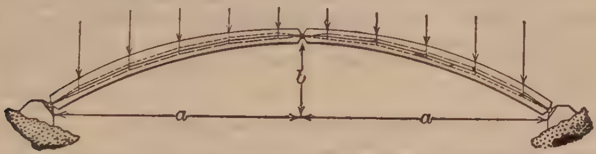

Fig. 116. Three-Hinged Arches

line, the second by a line of dashes and the third by a line of dots. After the lines are drawn, knowing, from the force polygon, the intensity of the resultant thrust at any point, the correct thickness of the arch ring at any point may be determined by keeping all thrust lines within the middle-third and the unit stresses within safe limits. If the assumed thicknesses are found to be wrong, a second analysis may be necessary.

This method, considering only dead load, or dead and uniform load over the entire span, may be used to determine the curve of the neutral axis of a solid arch, which will closely approximate the linear arch. This approximate linear arch would be the one requiring a minimum amount of material for any given loading.

Hinges have been used for stone masonry arches in many European bridges, but they are almost unknown in America. Recent European practice has been to construct concrete arches also with hinges. The lack of experience with such construction has been the chief cause for not using hinges with concrete arches in America. Hinges may be of cut stone, structural or cast steel pins (Fig. 110*a*), lead plates (Fig. 110*b*), or reinforced concrete. The steel hinge requires painting, but locates the line of thrust more precisely than the others. The lead hinge requires no maintenance; it should not carry a greater pressure than 1250 lb. per sq. in. for a plate 1/2 in. thick, 1000 lb. per sq. in. for 3/4 in. and 750 lb. per sq. in. for 1 in. in thickness. Adjacent to the hinges, blocks of hard stone should be placed to withstand the high unit pressure; or if concrete is used, it should be rich and heavily hooped. Stone hinges have not been used to an extent to warrant their general adoption.

A recent development in French practice is the use of reinforced-concrete hinges. These are not true hinges, but consist of a decided reduction in thickness of the arch at the crown and springing lines, with the addition of reinforcing steel, so that the flexibility of the structure at the reduced section is greatly increased. This type of hinge has given satisfactory service, and requires no maintenance. (See Hool's "Reinforced Concrete Construction," Vol. III; also article by J. F. Brett, Journal Western Soc. of Engineers, Sept., Oct., 1926.) Examples of long-span reinforced-concrete arches with flexible concrete hinges are given in Art. 34.

In some cases, arches have been made "semi-hinged." These are constructed as 3-hinged arches in order to keep the resistance line for dead-load closer to the center of the masonry. After the centering is removed, and the arch has attained its dead-load deflection, the hinges are filled in with concrete or mortar, and the arch is then fixed under live load and temperature stresses. The stone masonry arch at Morbegno, Italy (see Table in Art. 34), was constructed by this method. The Knox Bridge over the Aqueduct Canal, near Montreal, was constructed with flexible concrete temporary hinges (Canadian Engineer, Vol. 52, p. 521, May 17, 1927). In reinforced-concrete arches, the main arch reinforcement may be carried past the hinges, or overlapped at those points, and both hinges and main reinforcement are then concreted in solid to complete the structure. The Candelier Bridge near Charleroi, Belgium, was constructed with two permanent concrete rolling hinges at the abutments. This arch was actually 3-hinged for dead load, as jacks were provided at the crown to introduce a horizontal thrust into the arch (see Method of Rib-Compensation, Art. 43), but is a 2-hinge arch under live-load and temperature.

38. Elastic Method of Analysis

The True Resistance Line for an arch ring is found in the static method by a series of approximations which start with assumed points on the crown and skewback joints. In the elastic method this true line is found without such approximations in its exact location. This can be done entirely by computation, but graphic work may also be used to draw the equilibrium polygon within the arch ring after H and its point of application have been found. An arch one unit in length is considered, as in the static method, and the **neutral axis** of the flexural forces is represented by a central line drawn half-way between intrados and extrados. The thickness of the arch at any joint being called t, the moment of inertia of the surface of that joint for an arch of a unit length about the neutral axis is $I = 1/12\ t^3$. The **bending moment** for any point on the neutral axis is the algebraic sum of the moments of all the forces on one side of that point. A moment is positive when it tends to increase the compression on the back of the arch, this being the same convention as for beams (Sect. 7). The **resisting moment** at any joint is the product of the normal pressure N acting upon the joint and its distance e from the middle of that joint. The word "moment" when used without qualification applies to the bending moment.

Notation (Fig. 117). At the crown: V_0 = vertical shear, H = horizontal thrust. M_0 = bending moment, e_0 = distance of H from crown of the neutral axis, He_0 = resisting moment. For any point: x = horizontal distance from it to crown, y = vertical distance of it below crown, V = vertical shear, M = bending moment, R = resultant thrust on joint, N = component of R normal to joint, e = distance of N from middle point of joint or from the neutral axis, Ne = resisting moment.

Preliminary Steps. (1) The arch ring is to be drawn to scale and be divided into an even number of parts by the broken radial lines shown in Fig. 117, while half-way between these are drawn solid radial lines to represent joints. When the arch ring is of constant thickness, the arch divisions are equal in length; when it increases in thickness from crown to skewback, the lengths of the divisions are to be determined so that the ratio I/s shall be the same for all, s being the length of any division and I the average of the moments of inertia of the two limiting joints. Let the middle points of the joints be marked 1, 2, 3, etc., and the coordinates x and y be found for each point by computation or measurement. (2) Let Σx = sum of the values of x for these points, Σx^2 = sum of the squares of the abscissas, Σy = sum of their ordinates, Σy^2 = sum of the squares of these ordinates. (3) For a load W, placed at one of these points, let z denote the distance from it, toward the nearest skewback, to another middle point; also let Σz = sum of all these distances, that is, the sum of the distance of W from each of the points nearer the nearest skewback, Σzx = sum of the products of all values of z by the corresponding x, and Σzy = sum of all products of z by the corresponding y; that is, each z

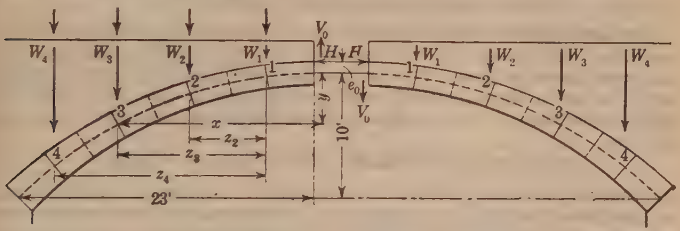

Fig. 117. Data for the Elastic Method

in the last two summations is multiplied by the x or y of the point back of W which corresponds to Z.

For a Single Load W on the left semi-arch of Fig. 117, the elastic theory of the arch furnishes the following formulas, n being the number of parts into which the semi-arch is divided.

For horizontal thrust, $$\mathbf{H = 1/2\,W\frac{n\Sigma zy - \Sigma y.\Sigma z}{n\Sigma y^2 - (\Sigma y)^2}} \qquad \text{(A)}$$

For moment at crown, $$\mathbf{M_0 = (1/2\,W\Sigma z - H\Sigma y)/n} \qquad \text{(B)}$$

For shear at crown, $$\mathbf{V_0 = 1/2\,W\Sigma zx/\Sigma x^2} \qquad \text{(C)}$$

Summations are for the half arch only. The value of H is always positive; that of M_0 may be either positive or negative, depending upon the position of W. The formula for V_0 gives positive values only, this force acting upward with respect to the left semi-arch, the load being on the left of the crown, but downward with respect to the right one.

When W is on the right semi-arch the same formulas apply if z is measured from W toward the right-hand skewback. For this case, however, the value of V_0 is to be taken as negative with respect to the left semi-arch, and positive with respect to the right one.

For Two Symmetric and Equal Loads, such as W_2 on the left and W_2 on the right in Fig. 117, let W be the weight of each; then the horizontal thrust and crown moment due to both loads are double those found by the above formulas, while the crown shear V_0 is zero.

For Several Loads, the formulas are to be applied to each in succession and the results added. Thus if one load produces a crown moment of 640 ft-lb. and another − 870 ft-lb., then for both loads M = − 230 ft-lb.

The denominator in formula (A) depends only on the coordinates of the curve and is independent of the span. Hence, when H is to be computed for several loads, the different numerators should be added and then their sum be divided by the constant denominator. Art. 39 gives an example.

For any Joint whose middle point is at horizontal distance x from the crown, values of the moment and shear may be computed, after H, M_0, V_0 are known, from the formulas

$$\mathbf{M} = \mathbf{M}_0 + \mathbf{H}\mathbf{y} + \mathbf{V}_0\mathbf{x} - \Sigma\mathbf{W}\mathbf{z} \qquad \mathbf{V} = \mathbf{V}_0 - \Sigma\mathbf{W} \tag{D}$$

where ΣW is sum of all loads between that joint and the crown, and ΣWz is the sum of the moments of those loads with respect to the middle of the joint. The components of the resultant thrust normal and parallel to the joints are

$$\mathbf{N} = \mathbf{H} \cos \theta - \mathbf{V} \sin \theta \qquad \mathbf{F} = \mathbf{H} \sin \theta + \mathbf{V} \cos \theta \tag{E}$$

where θ is the angle which the plane of the joint makes with the vertical (Fig. 111). The resultant thrust itself is $\mathbf{R} = \sqrt{\mathbf{H}^2 + \mathbf{V}^2}$.

Resistance Lines should be determined, in the design of an important arch, for at least three cases: (1) For dead load only. (2) For dead load plus live load over the entire span. (3) For dead load plus live load on left of crown only. In each of the cases let M_0 and H be found for the crown, and M and N for any other joint. Then the distances from the neutral axis to the resistance line are

$$\text{At the crown, } \mathbf{e}_0 = \mathbf{M}_0/\mathbf{H} \qquad \text{At any joint, } \mathbf{e} = \mathbf{M}/\mathbf{N} \tag{F}$$

and thus that line may be located at every joint. Or, after having found e_0, an equilibrium polygon can be drawn as in the static method, but here no approximation is needed, since H and e_0 being correctly found for the crown, the force and equilibrium polygons are immediately drawn in correct magnitude and position.

The coefficient of friction which is necessary in order that there may be full security against sliding along the joint is $f = nF/N$, in which F and N are to be computed from (E) and n should be 2 or greater.

A common masonry arch is a statically interderminate structure like a continuous beam or like a beam fixed at its ends. The elastic theory, by which the above formulas are deduced, makes the following assumptions: (1) that the material is elastic and obeys Hooke's law; (2) that the material is homogeneous so that modulus E is the same in all parts of the arch; (3) that the arch is fixed at its ends so that a tangent there remains unchanged under the loading; (4) that the loads cause no change in the length of the span; (5) that the ends remain in the same horizontal plane under all loadings. Although it is often difficult in practice to secure the complete observance of these assumptions, the theory gives correct results if they are fulfilled. When an arch is built upon piles or compressible soil the conditions (3), (4), (5) may be fulfilled only partially, and for such cases the three-hinged arch (Art. 37) may be preferable. For rock foundations the elastic theory is entirely satisfactory, and in an important case the old static method of trial and approximation ought not to be used, except as a check.

In concrete arches with reinforced-concrete floor and spandrels, the use of models will be helpful to indicate errors resulting from the application of the elastic theory and the difficulty of properly considering the effect of the stiff superstructure upon the actual stresses. (See Art. 42.)

39. Example of the Elastic Method

Data. It is required to design a plain concrete arch for a double-track railroad which shall have a width of 24 ft., a span of 46 ft. between centers of skewback joints, and a rise of 10 ft. from the springing line to the center of the crown joint. The railroad track is to be 3.6 ft. above the center of the crown joint, and the filling above the back of the arch will be earth. The live load per linear foot of track is specified as 4000 lb. Assume the thickness of the arch as 1.42 ft. at the crown and 2.14 ft. at the skewback. Through the given end and middle points draw a curve approximating a parabola, and lay off these two radial joints. Then draw the extrados and intrados curves so that the radial distance between them shall increase uniformly from middle to end, that is, so that the thickness of the arch at horizontal distance x from crown is $1.42 + 0.0313\ x$. Following is an investigation of this proposed design (Fig. 117).

(1) Divide the central curve of one semi-arch into four parts, of unequal length, those nearest the crown being the shortest. Let the lengths of these divisions, measured on the curve, be represented by s_1, s_2, s_3, s_4. Let radial lines be drawn through the middle points of these divisions and their lengths t_1, t_2, t_3, t_4 be found. Compute the ratios t_1^3/s_1, t_2^3/s_2, t_3^3/s_3, t_4^3/s_4; if these are equal, the division is correctly made; if not, the process must be repeated until four points 1, 2, 3, 4 are found for which these ratios t^3/s have approximately the same value.

A convenient graphical method for making this sub-division is shown in Fig. 118. A curve is plotted showing the variation of I $(= t^3/12)$ with respect to the distance, S, along the arch axis, starting from the crown. A series of isosceles triangles is drawn under this curve (as shown in the figure) with parallel sides but variable heights, the slope of the sides being determined by trial, so that the base of the last triangle will just reach the skewback. The bases of these triangles will then represent the proper lengths of the arch subdivisions, measured along the arch axis.

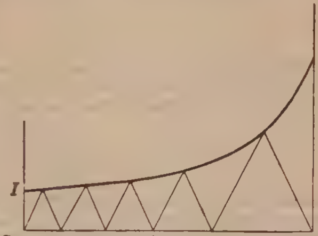

Fig. 118

(2) Let the final results of this work be that the thicknesses of the four joints are $t_1 = 1.52$, $t_2 = 1.72$, $t_3 = 1.90$, $t_4 = 2.06$ ft.; that the abscissas of their middle points are 3.22, 9.47, 15.20, 20.50 ft.; and that the corresponding ordinates are 0.21, 1.84, 4.62, 8.31 ft. These coordinates are entered in the second and third columns of the table below.

(3) Drawing vertical lines at the limits of the four divisions, the loads for the points 1, 2, 3 are, for an arch one foot in length,

For dead load, $W_1 = 4500$ $\quad W_2 = 5400$ $\quad W_3 = 7000$ lb.
For live load, $W_1 = 2100$ $\quad W_2 = 2000$ $\quad W_3 = 1800$ lb.

The last load, W_4 in this case, is not used, because by this method of division and computation it does not produce stresses in the arch; in reality, it does, of course, cause stresses, but they are small on account of its nearness to the skewback. In Fig. 117 the dead loads are shown for both halves of the span, but the live loads are shown only for the left-hand half.

(4) The summations and quantities involving only x and y, which are required for use in the formulas of Art. 38, are computed and entered in the following table; the denominator in the formula for H has the constant value 150.9 for all loads in all positions.

Point	x	y	y^2	x^2
1	3.22	0.21	0.04	10.4
2	9.47	1.84	3.39	89.7
3	15.20	4.62	21.34	231.0
4	20.50	8.31	69.06	420.2
$(\Sigma y)^2 = 224.4$ $\quad n = 4$ $n\Sigma y^2 - (\Sigma y)^2 = 150.9$		$\Sigma y = 14.98$	$\Sigma y^2 = 94.87$	$\Sigma x^2 = 751.3$

(5) The products and summations involving z, which depend upon both position of load and the other points of division, are computed and entered in a second table.

Since the load W_1 is taken as applied at point 1, the values of z for it are found by subtracting the first value of x from each of the following ones; also for W_2 the second value of x is subtracted from the following ones. The distances z_2, z_3, z_4, shown in Fig. 117, are the values of z for the load W_1.

Point	Values of z			Values of zy			Values of zx		
	W_1	W_2	W_3	W_1	W_2	W_3	W_1	W_2	W_3
1	0	......	......	0	......	......	0	......	......
2	6.25	0	......	11.5	0	......	59.2	0	......
3	11.98	5.73	0	55.3	26.5	0	182.1	87.1	0
4	17.28	11.03	5.30	143.6	91.7	44.0	354.2	226.1	108.6
Σz =	35.5	16.8	5.3	......	......	......	......	......	......
$\Sigma y.\ \Sigma z$ =	531.8	251.7	79.4	......	......	......	......	......	......
Σzy =	......	......	......	210.4	118.2	44.0	......	......	......
Σzx =	......	......	......	......	......	......	595.5	313.2	108.6

(6) Formula (A) of Art. 38 is now used to obtain the horizontal thrust caused by each load, and then Formulas (B) and (C) to find the crown moment and crown shear. For example, the work for the first load is

$$H = 1/2\ W_1\ (4 \times 210.4 - 531.8)/150.9 = 1.026\ W_1$$
$$M_0 = (1/2\ W_1 \times 35.5 - 1.026\ W_1 \times 14.98)/4 = 0.595\ W_1$$
$$V_0 = 1/2\ W_1 \times 595.5/751.3 = 0.396\ W_1$$

This value of V_0 is positive if W_1 is on the left and negative if it is on the right of the crown, because it is understood that the left semi-arch is the one for which the analysis is to be made. For each load in Fig. 117 the computed results for the crown now are

for W_1, $H = 1.026\ W_1$ $\quad M_0 = 0.595\ W_1$ $\quad V_0 = 0.396\ W_1$
for W_2, $H = 0.733\ W_2$ $\quad M_0 = -\ 0.645\ W_2$ $\quad V_0 = 0.208\ W_2$
for W_3, $H = 0.320\ W_3$ $\quad M_0 = -\ 0.535\ W_3$ $\quad V_0 = 0.072\ W_3$

(7) Only one case of loading will be here investigated, namely, that when the live load covers the left semi-arch only, as in Fig. 117. For dead load over the whole span, the values $W_1 = 4500, W_2 = 5400$, $W_3 = 7000$ lb. are to be inserted above, the products added and the sums doubled for H and M, while those for V cancel each other on account of the double sign. For live load over left semi-arch only, the values $W_1 = 2100$, $W_2 = 2000$, $W_3 = 1800$ lb. are to be inserted and the products added. Thus, for

dead load, $\quad H = 21\ 600 \quad M_0 = -\ 9100 \quad V_0 = 0$
for half live load, $\quad H = 4\ 200 \quad M_0 = -\ 1000 \quad V_0 = +\ 1400$

Lastly, the addition of these gives the final values for the case of loading shown in Fig. 117, namely, $H = 25\ 800$ lb., $M_0 = -\ 10\ 100$ ft-lb., $V_0 = 1400$ lb. The negative sign of M_0 shows that it tends to produce tension on the back of the arch.

(8) These final crown moments and shears reduce formula (D) of Art. 38 to

$$M = -\ 10\ 100 + 25\ 800\ y + 1400\ x - \Sigma Wz, \qquad V = 1400 - \Sigma W$$

and the values of the moment and shear for each joint are placed in the table below. Also the first formula (E) takes the form $N = 25\ 800 \cos\theta - V \sin\theta$, and the computed normal pressures for each joint are given in the last column.

Joint	x, ft.	y, ft.	cos θ	sin θ	M, ft-lb.	V, lb.	N, lb.
Crown	0.0	0.0	1.00	0.00	− 10 100	+ 1 400	25 800
1	3.2	0.2	0.99	0.12	− 460	+ 1 400	25 370
2	9.5	1.8	0.94	0.34	+ 8 390	− 5 200	26 020
3	15.2	4.6	0.86	0.50	+ 8 390	− 12 600	28 490
4	20.5	8.3	0.79	0.61	− 9 570	− 21 400	33 440
Skewback	23.0	10.0	0.77	0.64	− 19 210	− 21 400	33 560

(9) Finally, the eccentricity e, or the departure of the resistance line from the neutral axis, is obtained for each joint by formula (F) of Art. 38, namely $e = M/N$. The following table shows that the resistance line is within the middle-third of the arch ring except at the crown and at joint 2 and skewback; the values of $1/6\ t$ are distances from neutral axis to limits of middle-third. The maximum compression S_1 and the maximum tension S_2, using the formulas of Art. 21, and using only the normal component N of the thrust, are computed for the joints under the assumption that no rupture of the material occurs under the tensile stress; if such occurs, then the compression on the other side is increased to the value shown in the last column.

Joint	Thickness, t, ft.	Middle-third, 1/6 t, ft.	Eccentricity, e, ft	Maximum unit stress, lb. per sq. in.		
				Compression, S_1	Tension, S_2	S_1
Crown	1.42	0.237	−0.391	330	80	370
1	1.52	0.253	−0.018	120	....	....
2	1.72	0.287	+0.322	220	13	230
3	1.90	0.317	+0.294	200	....	....
4	2.06	0.343	−0.286	210	....	....
Skewback	2.14	0.357	−0.572	280	65	310

Other cases of loading cannot here be investigated, but a live load over the entire span, or perhaps live loads W_1 and W_2 acting on both sides of the crown, may produce a greater moment at the crown and raise the resistance line higher above the neutral surface. The result of the investigations thus far made shows that the resistance line passes outside the middle-third at three points, and hence the design must be modified in order to be satisfactory. This may be done by increasing the rise, by increasing the thickness of the arch ring at the crown, or by introducing steel reinforcement.

The above method, in its essential features, was first given in America by Howe (Arches, 1890), the formulas being materially simplified by Turneaure and Maurer (Reinforced Concrete, 1907); both formulas and tabulations are here given in somewhat different form. The way of obtaining the loads and applying them above the centers of the joints is regarded as not perfectly satisfactory. There is, however, nothing in the theory which requires the loads to be applied at the points 1, 2, 3 in Fig. 117; they may be applied at any other positions, but the x's for any W must be measured from the position of W to all the points between it and the skewback.

Multiple-Arch Bridges on high, elastic piers are difficult to analyze since the elastic deformation of the piers affects the stresses in the arches. Elaborate analytical methods have been proposed for this purpose. (Trans. Am. Soc. C. E., Vol. 90, p. 1094; Vol. 88, p. 1142; Vol. 91, p. 459.) A simpler method of deriving stresses for such structures is by the use of models (see Art. 42).

Skew Arches should be avoided if possible because they are more expensive and involve many complications in design and construction. An approximate method of analysis is outlined in G. F. Swain's "Stresses, Graphical Statics and Masonry" (1927), p. 426. (Also see Eng. News-Rec., Vol. 88, p. 638.) An elaborate analytical method is given by J. C. Rathbun, Trans. Am. Soc. C. E., Vol. 87, p. 611. See also article by S. C. Hollister in Proceedings, Am. Concrete Inst., Vol. 24 (1928).

A skew stone arch may be one of three types: (1) If courses are laid parallel to arch axis, it is called a "false skew arch." (See Stereotomy, Art. 6.) This method is suitable only where the angle of skew is small (not over 20 deg.) unless the span is very short. (2) A ribbed skew arch (Fig. 134) in which the soffit is offset at regular intervals, each rib being constructed as a right arch. The ribs should be tied together by cramps at the extrados. (3) The real skew arch is constructed with the courses laid out in spiral curves, so as to maintain the joints perpendicular to the pressure line. (Books on Stereotomy referred to in Art. 6 contain descriptive matter.)

40. Temperature and Deformation

General Effect of Temperature. If a ring of any elastic material, as in Fig. 119, is rigidly fastened to fixed abutments, the expansion of the ring under a rise of temperature exerts a horizontal thrust against the abutments. The abutments being immovable, the ring distorts, and the points *dd* retreat from the horizontal diameter *ab*. If the temperature falls, the ring is also distorted, but the points *dd* approach *ab*. Since the ring is still in equilibrium, the stresses at all sections will have undergone a change. The removal of the lower half of the ring would evidently not affect the distortion of the upper half under the change of temperature, provided the upper half is rigidly fastened to the immovable abutments. The condition of the upper portion of the ring is approximately that of a solid masonry arch built upon a rock foundation. If the upper portion of the ring is of loose voussoirs (Fig. 119*b*),

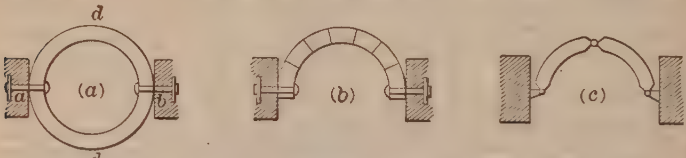

Fig. 119. Influence of Temperature

that is, without mortar in the joints, it is evident that the arch would adjust itself with but little strain. In practice, however, the arch ring is held down by the loads upon it so that the stresses due to the loads are increased or diminished by a change in temperature. Fig. 119*c* shows a three-hinged arch which, disregarding friction of the hinge, is free to move under change of temperature without developing temperature stresses.

Changes in Crown Thrust and Moment occur when the temperature varies from that prevailing at the time of closing the arch. When the temperature rises above the standard, the horizontal thrust is increased; when it falls below the standard, the horizontal thrust is decreased. Let H' = the change in H due to a change of T degrees; let e = the coefficient of expansion and E = modulus of elasticity of the material (Art. 17); let n = the number of divisions into which the half arch ring is divided and m = the constant ratio I/s for each division (Art. 38); let Σy and Σy^2 be the sum of the ordinates and the sum of their squares for the middle points of the several joints; let a = half-span of the arch. Then, for a rise of T degrees,

$$\text{Horizontal thrust} = \mathbf{H'} = \frac{\mathbf{ETenma}}{\mathbf{n\Sigma y^2 - (\Sigma y)^2}}$$

$$\text{Crown Moment} = \mathbf{M'_0} = -\mathbf{H'\Sigma y/n} \qquad \text{Crown shear } \mathbf{V_0} = \mathbf{0}$$

The bending moment at any point due to this rise in temperature is $\mathbf{M'} = \mathbf{M'_0} + \mathbf{H'y}$. The computed values of H', M_0' and M' are to be combined with those found for H, M_0 and M in Art. 39 for the case of loading under consideration. For a fall of temperature T is to be taken negative.

The standard temperature is usually assumed in the design at 50° Fahr. and a range of from 20° to 45° above and below it is allowed, or $T = \pm 20°$ for a spandrel filled arch and $T = \pm 45°$ for an isolated arch ring. Instead of using a standard temperature, it is best to compute the design with reference to the temperature conditions that will probably be met. These will be not only a function of latitude and altitude, but also of the time of year in which the arch will be built and, to some extent, of the method of building. For instance, if the arch is built as a continuous monolith the heat resulting from chemical action will add to the normal temperature. If, however, keyways are provided and these keyways are not concreted until a week or so after the balance of the arch has been built, there will be little added temperature as a result of chemical action.

There are few actual temperature observations of arch concrete. Some tests, however, indicate that the variation of the temperature in the arch will be about 75% of the mean seasonal atmospheric variation for a spandrel filled arch; and for an exposed arch ring the temperature of the arch will vary nearly as much as in the atmosphere. (See Bulletin 30, Eng. Exp. Sta., Iowa State College, 1913.)

The values of M due to temperature are most conveniently taken from a diagram, being the ordinates between the neutral axis and a straight horizontal line drawn at a distance $(\Sigma y)/n$ below the crown if the ordinate below the crown represents on a certain scale the value of M_0', or these ordinates in feet multiplied by H'.

Example. For the arch discussed in Art. 39, the value of m is 0.45. Then for T = 45° and E = 2 500 000 × 144 lb. per sq. ft., the horizontal thrust due to temperature is $H' = \pm$ 27 000 lb. Hence under dead load the horizontal thrust ranges from 21 600 + 27 000 = 48 600 lb. at 95° Fahr. to 21 600 − 27 000 = − 5400 lb. at 5° Fahr.

Temperature changes will often, on the basis of the formulas, cause the line of thrust to pass outside of the middle-third of the arch ring. It does not, however, seem necessary, when temperature is considered, that the line of thrust at all joints, based upon the maximum moments, shall lie inside the middle-third. The following tabulation shows the stresses, in pounds per square inch, as given by the formulas, for an arch of 150-ft. span with a uniform thickness of 4 ft., the range of temperature being 40° Fahr. from the normal.

Ratio of rise to span	Crown			Skewback		
	Concrete *	Ashlar †	Ashlar ‡	Concrete *	Ashlar †	Ashlar ‡
1/2	40	35	65	70	65	110
1/4	110	105	180	210	190	340
1/5	150	140	240	270	250	445
1/10	340	320	550	625	580	1010
1/20	770	720	1260	1375	1280	2245

* E = 2 500 000 lb. per sq. in. and e = 0.0000060. † For average joints, E = 4 000 000 and e = 0.0000035. ‡ For very thin joints, E = 7 000 000 and e = 0.0000035.

Shortening of the Arch Ring under the compressive stresses would produce the same effect as a decrease in temperature if the compression were uniform throughout. If S = average compressive unit stress in the arch ring, this being found by taking the average of several values, or known in advance by specification, then the shortening per unit of length is S/E instead of eT, and accordingly

$$\text{Horizontal thrust } \mathbf{H'} = -\frac{\mathbf{Snma}}{\mathbf{n\Sigma y^2 - (\Sigma y)^2}}$$

but the expression for crown moment is same as before and crown shear is zero. For the numerical example of Art. 39, this value of H' is − 5300 lb., or about 25% of the thrust due to dead load.

If keyways are not provided the shrinkage of the concrete after setting will have the same effect as shortening of the arch ring under compression. There is no accurate way of computing the horizontal thrust resulting from shrinkage, but the following formula indicates the elements that enter into it.

$$\mathbf{H''} = -\frac{\mathbf{EC_snma}}{\mathbf{n\Sigma y^2 - (\Sigma y)^2}},$$

where C_s = shrinkage coefficient (Sect. 11, Art. 2).

The writer has given this formula to indicate that stresses result from concrete shrinkage, but suggests that in design it is best to use conservative allowable unit stresses rather than to attempt to apply any formula.

The Deflection of the Crown under load may be closely found by the following formula. For dead load, or for full live load, it is

$$f = -(M_0\Sigma x + H\Sigma xy - \Sigma Wzx)/mE$$

in which the summations are for the half span only, as in Art. 39. For any loading on the left of the crown the deflection of the crown is

$$f = -(M_0\Sigma x + H\Sigma xy + V_0\Sigma x^2 - \Sigma Wzx)/mE$$

and this expression applies also to any loading on the right of the crown if the negative sign be used before V_0. With these formulas, a positive result indicates downward deflection, and a negative result shows upward deflection.

The stiffness of the arch will be considerably increased if the roadway is part of a concrete superstructure which is integral with the arch. This will be the case with an open spandrel bridge, if the spandrel columns are fastened rigidly to the arch by reinforcing steel; or with a closed spandrel bridge with hollow superstructure, where the interior walls or columns are similarly attached to the arch. The resulting increase in stiffness will generally reduce the stresses in the arch due to dead and live loads, but may cause a decided increase in temperature stresses. The actual effect of the superstructure on the arch stresses is difficult to determine analytically, but may be investigated by the use of models. (See Art. 42.)

For Temperature Changes the deflection of the crown is much greater than that due to the loads. If the rise of the arch is b, and the half-span a, the deflection may be computed from

$$f_1 = -eTb - \frac{eTa(n\Sigma xy - \Sigma x\Sigma y)}{n\Sigma y^2 - (\Sigma y)^2}$$

the deflection being negative (or upward) for an increase in temperature.

In this formula, the first term gives the change in the rise of the arch which would occur if the ends were entirely free to move under temperature variations, and the second term gives the change in rise due to the restraint of the abutments. This is also shown in Fig. 120, in which SCS is the arch curve under normal temperature, $S''C'S''$ is the shape which the arch would assume after a temperature increase if the abutments were entirely free, and $SC''S$ is the shape which the arch must take due to the restraint at the ends. Most engineers have been accustomed to compute temperature deflection according to the second term of the above formula, neglecting the influence of the first term, but this results in a computed deflection less than the writer believes to be correct.

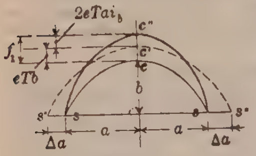

Fig. 120

The above equation can also be written

$$f_1 = -eT(b + 2ai_b)$$

where i_b is the thrust at the crown due to a unit vertical load on the arch at the crown. (See article by Prof. Hardy Cross, Eng. News-Rec., Vol. 96, p. 190.)

For important arches the deflection from load and temperature should be computed and allowance for this deflection should be made in the cambering of the centering.

In computations for deflection, either from direct loads or from temperature, it is essential that the sub-divisions of the arch be made relatively small in order to avoid errors due to the summation process involved in the formulas. This is particularly true in the case of an arch which has a considerable variation in thickness from crown to skewback. Where the skewback is exceptionally heavy, it may be better to consider the lower portion of the arch as part of the abutment, basing the computations on an arch of reduced span and rise.

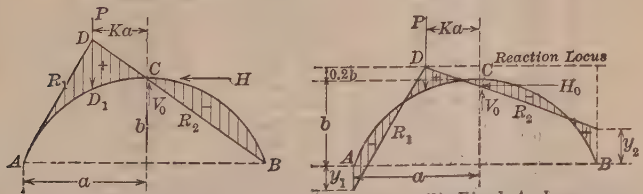
Tests made by the Austrian Society of Engineers on masonry arches ranging in span from 6 to 75 ft. have confirmed the correctness of the above formulas for deflection under load, and hence also the validity of the elastic theory (see Eng. News, Nov. 21, 1895, and April 9, 1896). Measurements of temperature deflections were made on a 145-ft. arch of the 6-span concrete bridge at Danville, Ill., in 1927, by the Engineering Experiment Station of the University of Illinois, the results confirming the above formula for temperature deflection. (Bulletin 174, Eng. Exp. Sta., Univ. of Illinois.)

Flow of Concrete. The elastic method of arch design assumes that the deformation of the masonry under a sustained load is the same as under a load applied for only a short time. Experiments and tests, however, have shown that when concrete is subjected to continuously acting stress, the deformation does not stop after the application of the load, but gradually increases during a considerable period of time, and the concrete is subject to additional deformation without increase of stress. (See paper by R. E. Davis, Proceedings Am. Concrete Inst., Vol. 24, 1928.) This yielding or "flow" of the concrete is variable, depending on the proportions of the concrete aggregate, conditions of mixing and curing of the concrete, and the intensity of the stress. In arches, temperature changes are generally gradual and extended over a considerable length of time, and the stresses due to temperature change will cause a gradual flow of the concrete, which tends to neutralize the temperature effect to a considerable extent. It is suggested that in reinforced concrete arches with reinforced spandrels and floor, if temperature stresses are computed as described hereinbefore, the unit allowed stresses given in Art. 16 may be increased 25%.

41. Diagrams and Influence Lines

Formulas for a Three-hinged Arch (Fig. 121*a*). For a single load on left of the crown,

$$\mathbf{H = Pa\,(1 - k)/2\,b} \qquad \mathbf{V_0 = P\,(1 - k)/2} \qquad \mathbf{M_0 = 0}$$



(*a*) *Three-Hinged Arch* (*b*) *Fixed Arch*

Fig. 121. Moments due to Load *P*

The moments are shown by the vertical lines above and below the arch curve. The moments at all hinges are 0. If the ordinate DD_1, to some scale equals the moments at D_1, then the moment at any other point equals the length of the vertical line at that point included between the neutral axis ACB and the resultant R_1 or R_2, measured to the same scale. Or the moment at any point equals H multiplied by the vertical line or ordinate included between ACB and R_1 or R_2, measured to the same scale as the arch. For uniform load over the entire arch, $H = wa^2/2\,b$, while $V_0 = 0$ and $M_0 = 0$. The resistance line is a curve passing through the hinges; it may coincide with the neutral axis or may lie above or below this axis.

Formulas for a Fixed Parabolic Arch (Fig. 121*b*). For a single load P at a distance ka from the crown,

$$y_1 = 2\,b\,(1 - 5\,k)/15\,(1 - k) \qquad y_2 = 2\,b\,(1 + 5\,k)/15\,(1 + k)$$

$$H = \frac{15\,Pa\,(1 - k^2)^2}{32\,b} \qquad V_0 = \frac{P\,(2 - 3\,k + k^3)}{4}$$

$$M_0 = \frac{-\,Pa\,(3 - 16\,k + 18\,k^2 - 5\,k^4)}{32}$$

y_1 and y_2 are laid off above AB when positive and below AB when negative. The reaction locus, or the locus of the intersection of all loads with their resultants, is a horizontal line 0.2 b above the crown of the neutral axis. The moments are shown graphically at all points of the arch. This may be drawn for any load by laying off the reaction locus and y_1 and y_2 computed by formulas. This moment diagram should be interpreted in the same manner as explained for the three-hinged arch. For uniform load over the entire arch, $H = wa^2/2\,b$, while $V_0 = 0$ and $M_0 = 0$.

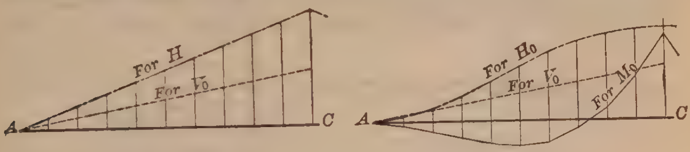
The following Table for Fixed Parabolic Arches is useful in obtaining H, V_0, and M_0 for a single load P at a distance ka to the left of the crown. The numbers of each column should be multiplied by the factors shown in the first line. This table may be used for the design of earth-filled bridges or for arches with spandrel arches or columns, if the loads are applied at tenth points. By use of formulas this table may be extended to cover all classes of parabolic arch design. The table may be used as a close approximate check for all positions of loading and for non-parabolic arches in which b/a is less than 0.5.

Thrust, Crown Shear, and Moment for Fixed Parabolic Arches

k	H	V_0	M_0
0	0.4687 Pa/b	+0.5000 P	+0.0938 Pa
0.1	0.4593	+0.4252	+0.0494
0.2	0.4320	+0.3520	+0.0161
0.3	0.3881	+0.2818	−0.0069
0.4	0.3308	+0.2160	−0.0203
0.5	0.2636	+0.1562	−0.0254
0.6	0.1920	+0.1040	−0.0240
0.7	0.1219	+0.0608	−0.0181
0.8	0.0607	+0.0280	−0.0103
0.9	0.0169	+0.0072	−0.0031
1.0	0.0000	+0.0000	−0.0000

An Influence Line is a line whose ordinates represent the values of a function as a single unit load travels over the span, the ordinates being drawn at the positions of the load. Thus in Fig. 122*a* let a load P travel from the left end A of the span to the middle C. Then the influence line for the horizontal thrust H is constructed by laying off from AC an ordinate at each position of the load to represent the value of H for that position. Since H varies as the first power of k in a three-hinged arch, the influence line is straight and it is only necessary to determine the ordinates for $k = 0$ and $k = 1$. For the three-hinged arch both H and V_0 are 0 when the load is at the springing line, and reach their maximum values at the crown, while M_0 is always 0. For the arch with fixed ends. Fig. 122*b* shows influence lines for H_0, V_0 and M_0 which have been constructed by the help of the preceding table. For both cases the ordinates for the other half span have the same values as for CA, except that those for V_0 are negative, as the load travels from C to B. The influence lines clearly show that loads near the crown produce the greatest thrusts, shears, and moments.

Where a moving live-load must be considered, the influence lines are most useful in determining the distribution of the loading which will cause maximum moments, shears and thrusts. Thus, from Fig. 122*b*, the maximum positive



(*a*) *Three-Hinged Arch* (*b*) *Fixed Arch*

Fig. 122. **Influence Lines**

value of M_0 will be found by multiplying the several positive ordinates of the influence diagram by the loads which may be applied at those points and taking their sum; and similarly, to obtain the maximum negative value of M_0.

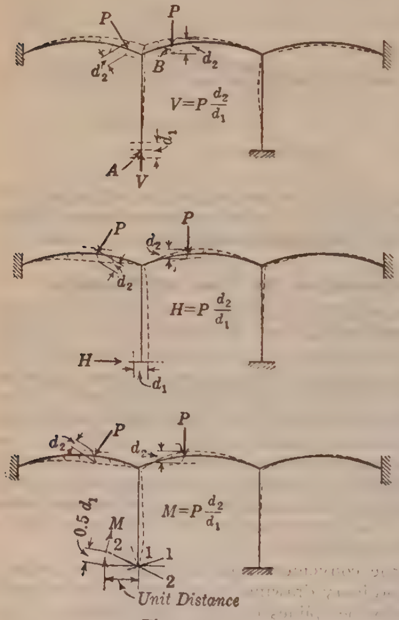
42. Analysis of Structures by Use of Models

Many masonry structures, especially bridge arches and arched dams, are statically indeterminate, i.e., their stresses can be computed only by taking into consideration the elastic deformation of the structure. As pointed out in Art. 38, the use of the elastic theory for this purpose involves certain assumptions and approximations which render the results approximate. Moreover, the correct use of this theory for the analysis of any complicated structure is accompanied with serious mathematical difficulties. To eliminate these troubles, various methods have been developed by which it is possible to find the stresses in a statically indeterminate structure by producing known deflections at selected sections of a model of the structure, and observing deflections at points of assumed loading. The writer recommends the use of models for checking stresses in indeterminate structures.

In order to make possible the convenient application of these methods within the limited space of an ordinary drawing board, use is made of small-scale elastic models. These may be splines of steel, hard rubber or other elastic material for the case of continuous beams or simple frames of uniform section. For more complicated structures, the models may be cut from celluloid sheets or fine quality cardboard. The widths of the model members are varied so that the moment of inertia of any section of the model will be proportional to that of the corresponding section of the actual structure.

An elementary application of the model method, for analyzing a continuous beam, is described by R. Fleming, Eng. News-Rec. Vol. 83, p. 428 (Aug. 28, 1919). This method is credited to Prof. George E. Beggs of Princeton University, and was first used by him to check the reaction influence lines for the Bessemer and Lake Erie Bridge near Pittsburgh. The extended development of this method for the practical solution of continuous structures of various kinds was described by Professor Beggs in Proceedings Am. Concrete Inst., Vol. 18, p. 58, (1922) and Vol. 19, p. 53 (1923).

Others employ steel splines or metal rods of suitable thickness, clamped or soldered together to form models of proportionate stiffness. Reference is made to the "Continostat" developed by Otto Gottschalk, Buenos Aires (described in Journal of Franklin Institute, July 1926, p. 61; and in Journal of Boston Society Civil Engineers, Vol. 14, p. 495); and to the "Nupubest" of Christian Rieckhof, Darmstadt, Germany (see Bauingenieur, Heft 7, 1925). A home-made apparatus applicable to continuous beams and simple frames employs hardened brass wires soldered together at joints by special details (see description by Anders Bull, Eng. News-Rec., Vol. 99, p. 920; also Vol. 100, p. 370). In the methods used by Gottschalk, Rieckhof and Bull, appreciably large deflections are applied to the model so that the desired deflections at the load points may be read without magnification. Although such devices are in special cases more convenient, they cannot easily be applied to structures with rapidly varying sections. They are not so generally applicable as Professor Beggs's apparatus. A detailed comparison of existing devices for use with structural models is given by Rudolph Bernhard in Bauingenieur, Heft 8, 1928, pp. 127-132.



Figs. 123–125

The above methods of analysis by models are based in general on Maxwell's theorem of reciprocal deflections. As a corollary to this theorem, it follows that for any elastic structure (Fig. 123) the reaction V at a point A due to a load P at B is given by $\mathbf{V = Pd_2/d_1}$, provided the deflections d_1 and d_2 are so minute that the structure is not appreciably deformed from its geometrical shape. The value of the ratio d_2/d_1 may be obtained by an experiment with an elastic model. It is only necessary to introduce a relatively small known deformation d_1 at the point A in the direction of the desired reaction component (see Figs. 123–125), and measure accurately the corresponding deflection component d_2 at B in the direction of the assumed applied load. Then for any assigned value of the load, the reaction component is computed by the formula $P\,d_2/d_1$. It is evident that this deflection ratio is independent of the value of the coefficient of elasticity E, provided E is constant in the range of stress.

Professor Beggs has developed the Deformeter Gage, shown in Fig. 126, for the accurate production of the deformations noted as d_1, in Figs. 123, 124 and 125. The essential feature of this instrument is the pair of clamps at Y. The upper bar is screwed to the drawing board; the lower bar is clamped tightly to the model, and is held to the upper bar by spring bolts. By changing the size or shape of the pins in the V-notches (marked g) a definite deflection d_1 of known amount may be applied to the model, either as a vertical or horizontal translation, or as an angular rotation. Thus, by changing from plugs h to i, a vertical upward deflection is produced in the model; plugs j will cause a counter-clockwise rotation; plugs k will produce a horizontal deflection to the left and plugs l a horizontal deflection to the right. By means of a microscope, the reciprocal deflection d_2 of the model at the assumed load point P is measured. The reaction at V is then given by the relation: $V = Pd_2/d_1$. The Beggs apparatus can be used to study practically any type of structure for which a model of suitable material has been made. (See description in

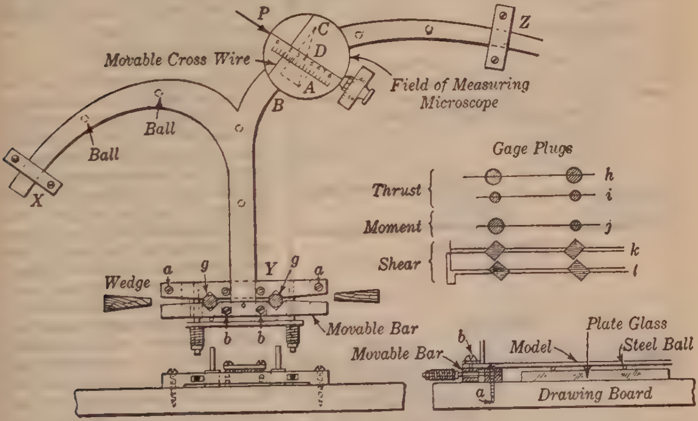


Fig. 126

Trans. Am. Soc. C. E., Vol. 88, p. 1208; also Journal Franklin Institute, March, 1927.)

The advantages of using models in analyzing indeterminate structures are:

1. This method makes unnecessary some of the assumptions required in the application of the elastic theory, particularly the omission of the influence of shear, and of the unknown distribution of stresses around corners in frames.

2. It gives an independent check upon analyses made by the elastic theory and permits further easy and rapid analyses which, on account of the time involved, would not be practicable with the elastic theory.

3. It eliminates elaborate mathematical formulas and laborious computations.

4. The method is largely self-checking because the components of the reactions obtained by model deflections may be readily checked by using the three equations of static equilibrium, which have not been previously used in the solution of the problem.

5. Difficult problems may often be more readily solved by models.

6. The use of models permits greater freedom in the choice of structural forms which one might hesitate to use because of the difficulty or impossibility of analysis by usual methods.

An important use of these methods in analyzing open spandrel arches is to determine the influence of the superstructure on the strength of the arch-barrel. This effect has generally been disregarded in design, although elaborate studies were made in connection with the La Balme Bridge (see Table, Art. 34) by the use of a plate-glass model and polarized light.' (Cornell Civ. Eng., Vol. 32, p. 17.) In general, the study of such structures by models shows that the superstructure acts to strengthen the arch-barrel in supporting direct loads, which may be taken advantage of by saving material in the arch itself. However, the increased stiffness produced by the integral superstructure may result in greatly increased temperature and rib-shortening stresses, both in the arch-barrel and in the superstructure itself. (See Art. 40.) Fig. 127 shows the effect of a continuous superstructure upon the moments and thrusts of the arch, and also illustrates the stresses that may be produced in the superstructure itself due to its construction integral with the arch.

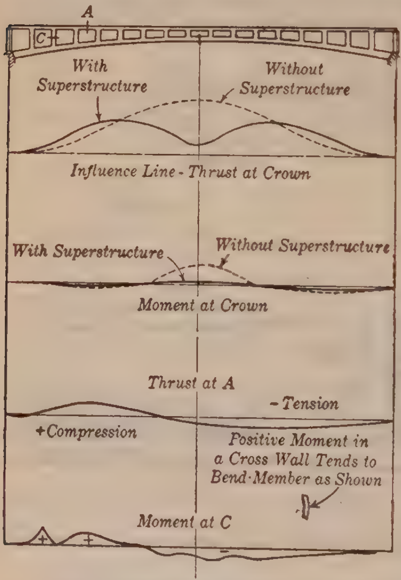

Fig. 127

In the design of the Arlington Memorial Bridge at Washington, D. C. (Fig. 136) the stresses in the arch and in the superstructure were studied by the use of models, the superstructure being designed to act integrally with the arch. In this bridge, the deck is supported by transverse walls resting on the arch. The ring stones are of granite ashlar, and the spandrel walls are concrete faced with granite. The weight of this heavy spandrel wall is transferred to the concrete arch-sheeting by the transverse walls, and the effectiveness of these walls for this purpose was also studied by means of a three-dimensional model. (See description by John Nagle, Military Engineer, Vol. 20, p. 154.)

The use of models is not limited to masonry structures. This method may be applied effectively to the study of indeterminate structures of many types and materials. (See also Art. 33, "Arched Dams.") For an application to reinforced concrete frames, see article by A. G. Hayden, Eng. News-Rec., Vol. 96, p. 686.

43. Construction and Erection

Materials of Construction. In selecting the material of which the arch is to be built, the designer must be governed by the available materials in the local market, due consideration being given to labor conditions. If cement, sand, and broken stone are cheaper than cut stone, the arch should be built of concrete, provided, however, architectural conditions do not demand stone. For arches over 150 ft. in span the stone arch may be cheaper than the concrete arch, but usually this will not be so. Occasionally when labor rates of cutting and setting stone are low and stone can be quarried at abnormally low rates, the stone arch may be cheaper for all spans

If the foundations are compressible the reinforced-concrete arch with 1% of steel is preferable, as it can better withstand deformation without failure. It is not correct to figure the reinforcement as carrying the total bending moment at all joints as is occasionally done, while the concrete is assumed to take the thrusts only. Such assumptions result in an absurdly high percentage of steel. However, when the cost of falsework is abnormally high, as for an arch of large span over a deep gorge, the percentage of reinforcement may be made high so as to reduce the amount of concrete and therefore the load upon the falsework. In such cases the cost of the falsework governs the design. As steel can never be stressed higher than 15 times the maximum compression in the concrete, or about 7500 lb. per sq. in., a large percentage of steel is not generally economical nor is a steel of high strength advantageous.

In a large work where the amount of arch construction is small, it is often better to build arches of stone, as they may not get the inspection care necessary for concrete. When stonecutters and setters are first-class and concrete labor poor, the stone arch is the safer arch to build, although if first-class inspection can be had, concrete work can be well done under nearly all conditions.

In order to decrease the cost of work at the quarries, it is common practice to make the voussoirs of a stone bridge of the same depth from the crown to the springing line, and to haunch the arch with concrete or rubble. When this is done the arch should generally be designed regarding the haunching as load and indirectly as a factor of safety. By bonding this haunching with stone voussoirs, however, they may be regarded as acting together and the combined masonry may be analyzed as an arch, in which case it is suggested that the safe working unit compressive stresses be taken as 70% of those recommended in the tables of Art. 16 for the weaker material.

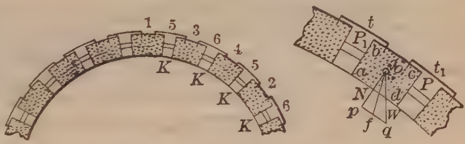

Fig. 128. Concrete Voussoirs

For arches over 100 ft. in span it is not good practice to use cut ring stones with the arch sheeting of rubble, concrete or brick, due to the great difference in the moduli of elasticity. Where large concrete arches, which should be built in alternate sections, are faced with stone voussoirs, the difficulties of erection are much increased.

The Architectural Details for all masonry bridges should be simple and logical. The accentuation of the roadway by an ornamental but simple coping and parapet, the accentuation of the ring stones and springing blocks by projection and simple ornamentation, the apparent strengthening of the abutment adjacent to the arch by projection, all tend to enhance the appearance of the bridge. The paneling and ornamentation of the spandrels, more commonly seen in concrete bridges, injure the appearance of the structure and lower the magnitude of its scale. No amount of ornamentation will relieve the awkward appearance of a bridge where spans and arch curves have been illogically selected. The ornamentation of a bridge depends upon its location. Where appearance is of paramount importance, a bridge should be designed so as to be in harmony with the surrounding landscape, present and future, whether it be rural or formal.

Drainage. The roadway of a masonry bridge should have drains at either side of the roadway at intervals of 30 to 40 ft., for a level roadway, and 100 ft. when the roadway is on a grade. These drains should have a minimum diameter of 2 in. and preferably 3 in. The minimum area of a drain in square inches should be $a = A/200$, where A = area of the surface drained in square feet. If a drain is placed at every 40 ft. of each gutter for a bridge 50 ft. wide, $A = 50/2 \times 40 = 1000$ sq. ft. and $a = 1000/200 = 5$ sq. in. If the drains are at 100-ft. intervals, $A = 50/2 \times 100 = 2500$ and $a = 2500/200 =$

12.5 sq. in. The drains should be designed with an intake trap, and the entire drainage system carrying the water to the ground should be so designed as to permit of easy cleaning.

In an arch with solid spandrels, the extrados of the arch sheeting should be waterproofed so as to prevent seepage of water through the masonry or concrete, and resultant discoloration of the soffit. This precaution may be advisable even where the roadway is properly drained, as there is always a possibility of rain water leaking from the roadway to the interior of the bridge.

Falsework. Arches are generally built upon temporary falsework called centers or centering, which may be of timber or steel. Timber centering is generally more economical and less subject to deformation from temperature changes, but it deforms due to changes in moisture content. The deflection of steel centering due to loads is about the same as for timber centering. The actual deflection of any type of centering does no harm, however, provided the amount of settlement can be estimated in advance and occurs prior to final closure of the arch. (For the design and construction of timber centering, see Sect. 9, Art. 13.)

Steel centers are generally more economical than timber when they can be used over again about four times, either by moving them transverse to the bridge or to several different arches of the same span length. They may be desirable where a clear opening is required under the arch during construction, for traffic, or to leave adequate water way. If the necessary foundations are provided the cost of steel centers will be approximately as follows:

For	Cost per cubic yard of arch concrete
40-foot span	\$4.00
80-foot span	6.00
150-foot span	8.00

Steel centering, however, is not usually feasible unless the steel sections can be handled by means of derricks.

Steel centers are generally constructed as 3-hinged trussed arches. They may be designed for unit stresses 10 to 15% higher than are customary for permanent structures, the loads being nearly static. It is advisable to make the general designs of the centering before the bridge piers are built, because usually the reactions of the centering can best be carried by masonry offsets near the top of the piers. This means of support saves the cost of building additional foundations to take the centering loads. (See Fig. 136.) The design of the offset must be predicated upon the design of the centering.

Provision also must be made to take the horizontal thrust of the centers at their supports. If the span is short, a horizontal tie rod can be used for this purpose, with turnbuckles for adjustment. If the arch is flat and of long span, the horizontal thrust of the centers must be taken directly by the pier, by the use of wood or steel wedges. Steel wedges are better than wood, and should be planed. The horizontal tie rod should also be provided, however, in order to facilitate lowering and moving the centering.

Provision must be made to enable lowering the centering after the arch is closed. This may be done by sand boxes (Sect. 9, Art. 13) or by wedges. Sand boxes are excellent but require more expert care, and generally steel wedges are best for this purpose. As steel centers are affected by temperature changes, the concrete should generally be placed in alternate sections, with keyways. The final closure should not be made at a time when a sudden drop in temperature is expected, for the resulting contraction of the centering might cause the fresh concrete to carry practically the entire dead load of the arch ring. (For comments on steel centers, see Eng. Rec., Vol. 65, p. 478.) Fig. 128a shows steel centers for the Arlington Memorial Bridge.

Concrete arches have been built using structural steel ribs as the reinforcing arch steel and to support the forms and green concrete during construction. This may be economical for a single narrow and short span, but not where the steel centers may be used several times.

Methods of Construction. All arches must be built symmetrically. That is, the centering must be loaded equally on either side of its middle. Stone arches under 75 ft. in span may be built continuously from springing line to crown, but unless the centering is abnormally unyielding for spans of more than 40 ft. hair-line cracks will occur at one or more joints, showing that the tensional value of the mortar is destroyed. Where the span is over 75 ft., these cracks may amount to 1/8 in. As a result, when the centering is struck

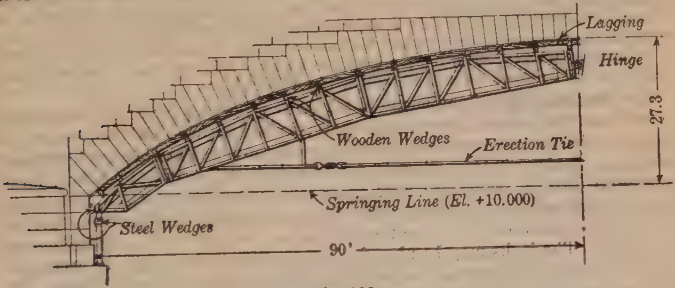

Fig. 128a

there will be a settlement of the crown of at least one inch. Therefore for spans of more than 75 ft., the masonry work should be laid up in alternate sections as shown in Fig. 128. The sections are numbered in the general order in which they should be built. The sections last built, called the keying sections and marked K, should be as small as will permit the men to work. The length of the larger sections should not exceed about 15 ft. In arches built of voussoirs each of which is composed of more than one stone, the masonry blocks should be "racked back." This is not shown in the figure.

Plain and reinforced-concrete arches under 40 ft. in span should be built as continuous work between umbrella points if possible. Arches of plain concrete over 40 ft. and under 75 ft. may be built continuously from the springing line to the crown; if over 75 ft. the alternate block system should be used.

Reinforced-concrete arches over 40 ft. and under 100 ft. in span may be built in longitudinal ribs 3 or 4 ft. wide, so arranged as to incorporate two or more ribs or lines of reinforcing steel. If so built the centering should be made very stiff, so that having one rib complete, the adjacent rib will not so deform the center as practically to strike the center under the first rib before the concrete of that rib is hardened. If built in ribs, transverse reinforcement should be used to tie the ribs together. Reinforced-concrete arches over 100 ft. in span would better be built in alternate blocks extending transversely across the bridge because of the danger of an adjacent longitudinal rib striking the centering under the completed ribs. The longitudinal rib method, however, has been successfully used in spans over 100 ft. As all centers settle and deform, the steel reinforcement becomes more or less buckled in construction and therefore will not be found in its theoretical position. In the construction of large arches it appears better to have the reinforcing steel in lengths not exceeding 30 ft., the length to be spliced after the large blocks have been placed. The splice may be an overlap, a bolted or a riveted joint. In concrete arches the concrete should be laid in horizontal courses or, where the inclination of the soffit is not too great, in courses parallel to the soffit. If alternate concrete blocks are used, the size of each block should be such that it can be completed as continuous work. Several keying blocks can usually be made in a day. The use of construction keyways also permits shrinkage due to settling and drying to take place without developing additional stresses in the concrete.

When arches are built in alternate sections the large blocks must be supported by stone, concrete or steel piers or columns until the key block masonry is in place (Fig. 128), or tie rods may be used as shown. The stresses in these piers or tie rods may be computed by resolving the weight of the blocks normal and tangent to the soffit (Fig. 128) and deducting the friction. $W = oq$ = weight of block. $N = op$ = normal thrust against the centering. $T = pq$ = tangential component. of is a line making an angle with N = the angle of friction of masonry upon wood. Then fq is the total stress in the pier P, due to the weight of block $abcd$. When the angle poq = or $<$ pof, the block exerts no pressure upon P. The upper strut P_1 may bring additional load upon P, due to the tendency of the upper blocks to slide down the arch centering. If tie rods are used, the stresses are found in a similar manner, but in that case the accumulated stress in the tie rod t is due to the lower blocks. As the arch centering settles or deforms, the block above the pier P rotates about the foot of the pier P and in consequence the pressure at the top and bottom of the pier is applied close to the edge. It is therefore suggested that when stone or concrete piers are used the unit compressive stress be taken at 40% of those given in Art. 16.

The Method of Rib-Compensation has been developed by French engineers to facilitate the construction of long-span concrete arches. In this method, a keyway is left at the crown until after the arch concrete has attained its proper strength. Jacks are then placed at intervals in this keyway, and a large horizontal force is applied to each half-arch through the jacks. This force may be made sufficiently large to raise the arch slightly, at the crown, thereby relieving the centering of its load and avoiding the difficulties of striking the centering. The jacks may be placed in any position relative to the arch axis, so as to bring the resistance line under dead load to the desired location. By this method it is possible to compensate for stresses due to rib-shortening under dead load. After the desired pressure has been applied, the spaces between the jacks are filled in with concrete, and subsequently the jacks are removed. Special provision must be made to properly strengthen the concrete of the arch at the crown in order to sustain the high unit pressures developed by the jacks. (See article by J. F. Brett, Jour. West. Soc. Engineers, Sept. and Oct. 1296; also Eng. News-Rec., Vol. 93, p. 463.) This method has been used on the St. Pierre du Vauvray, Villeneuve, Veurdre, Elorn and Boutiron bridges (see table, Art. 34).

Striking or Lowering of the Centering should be done gradually. The wedges or sand boxes should be lowered symmetrically, beginning at the crown and working to the springing lines. In a series of arches the centering between abutments or abutment piers should be struck simultaneously. The centering, which should be designed to carry the load of the arch, only, may be struck before the portion of the bridge above it is built, if the arch is stable under its own weight. If this is not done, expansion joints should be provided in the upper masonry, otherwise this masonry will crack, should there be any settlement of the crown of the arch, upon striking the center. Fig. 129a shows such joints for an earth-filled bridge, the expansion joints being marked jj, and 129b is a cross-section of one of these joints. Fig. 130 shows expansion joints in arched spandrels; they need only be left open, the spandrel arch centering remaining in place, until the large arch is struck. As the rise and fall of an arch, due to temperature, has a similar tendency to crack the masonry above the arch, such expansion joints are desirable to prevent temperature cracks. The joints of Fig. 130, when made permanent, should be about 1 in. wide, and the spandrel arches should be reinforced with steel so as to act as beams and cantilever beams. The spandrel expansion joints of the Walnut Lane Bridge, described in Trans. Am. Soc. C. E., Vol. 65, p. 423, are of excellent design. Expansion joints should extend from the back of the arch to the top of the parapet.

In an open spandrel bridge, if the crown of the arch is close to the roadway, the deck structure and arch will be joined together for a short distance on each side of the crown, forming a "saddle." In this case, no expansion joints need be provided adjacent to the saddle, the only joints required in the deck being near the ends of the arch above the skewbacks. Measurements of the action of expansion joints were made on a multiple-span open spandrel bridge at Danville, Ill. (Bulletin No. 174, Eng. Exp. Sta. Univ. of Illinois), which lead to

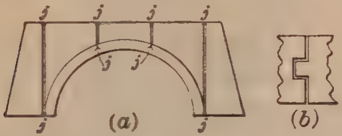

Fig. 129

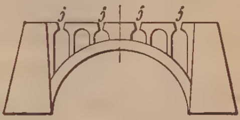

Fig. 130

the following conclusions: " There was practically no movement at the expansion joints adjacent to the saddles. These expansion joints are not needed to relieve the temperature stress in the deck, and they seem to weaken the structure by localizing the temperature deformation in the rib at the ends of the saddle."

In a three-hinged arch with permanent hinges, an expansion joint must be provided in the spandrels and deck over the crown hinge, as well as over the end-hinges.

The permanent paving of earth-filled bridges should not be laid for two years after the earth fill is placed, as the settlement will crack and warp the pavement. The filling should be spread in layers and thoroughly rammed to decrease the amount of settlement.

44. Large American Masonry Arches

Cabin John Bridge at Washington, D. C., completed in 1864, is the longest stone arch and the one having the largest ratio of span to width of bridge in America. It is further notable as the first American example of the use of hollow or cellular abutments. The arch was built up continuously from springing line to crown. The clear span is 220 ft. and the rise is 57.3 ft.

Walnut Lane Bridge at Philadelphia, Pa. (Fig. 131), completed in 1908, is the largest masonry arch in America. The main span consists of two detached parallel plain concrete arch ribs each supporting spandrel arches upon which rest low spandrel walls. These walls support steel I beams encased in concrete and the concrete jack arches of the floor. The main arch was built in alternate blocks.

The Edmondson Avenue Bridge at Baltimore, Md. (Fig. 132), completed in 1909, has piers and arches of plain concrete. The spandrels and floor system are of reinforced concrete. The order of building the large arch in alternate transverse blocks is shown in the sectional elevation.

The Bellefield Bridge at Pittsburgh, Pa. (Fig. 133), is a stone arch completed in 1900. It is the only large masonry bridge in America built with longitudinal spandrel arches. The necessary great width of the outside walls which must resist the spandrel arch thrust limits this type of construction to special

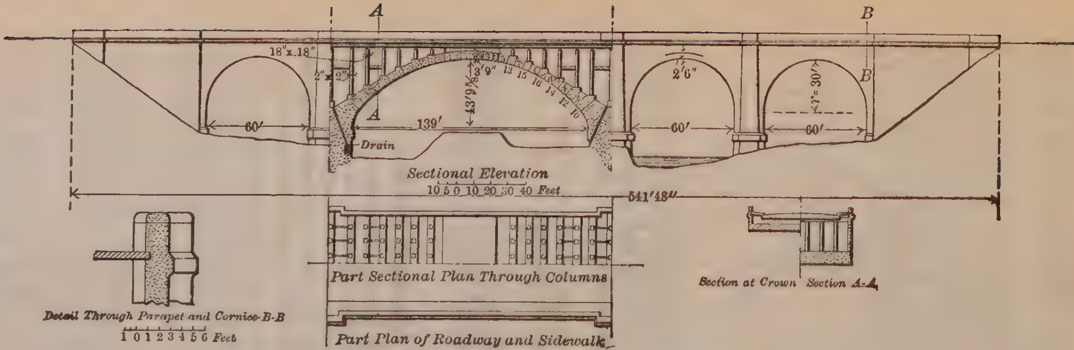

Fig. 132. Edmondson Ave. Bridge, Baltimore, Md.

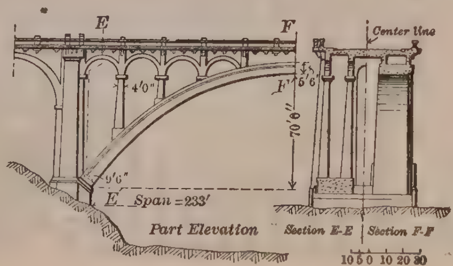

Fig. 131. Walnut Lane Bridge, Philadelphia, Pa.

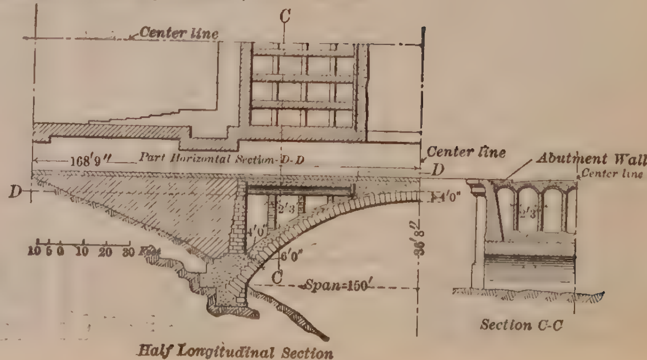

Fig. 133. Bellefield Bridge, Pittsburgh, Pa.

cases. The face wall in section *C-C* is marked abutment wall. The Bellefield arch was built continuously from springing line to crown.

The Pennsylvania R. R. Bridge at New Brunswick, N. J. (Fig. 134), consists of a series of stone arches having spans between 51 ft. and 72 ft. Two of these arches are shown in the figure.

Connecticut Avenue Bridge, Washington, D. C. (Fig. 135), was completed 1907. It consists of five 152-ft. spans and two 82-ft. spans. It is built of

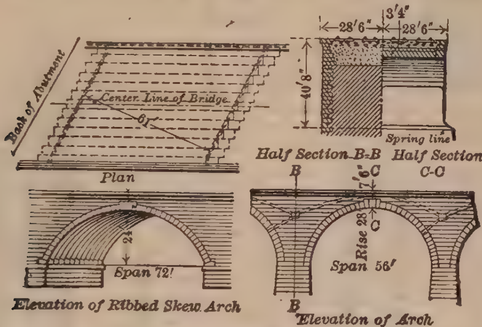

Fig. 134. Railroad Bridge, New Brunswick, N.J.

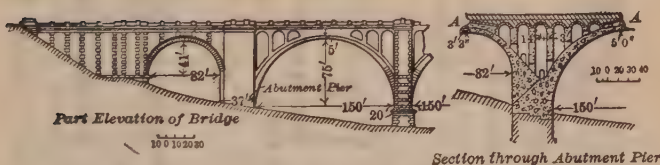

Fig. 135. Connecticut Ave. Bridge, Washington, D. C.

plain concrete. The coigns, belt courses, copings and other ornamental details were cast upon the ground, dressed and set in place as ashlar blocks. These details are indicated, in part, in the figure. Each spandrel arch nearest a pier and nearest the crown of the main arch has an expansion joint at its crown. These spandrel arches are therefore not true arches, and were reinforced with steel so as to act as simple and cantilever beams.

The Arlington Memorial Bridge, Washington, D. C. (Figs. 128*a* and 136), was under construction in 1928. This bridge, which is of monumental character, crosses the Potomac River, and consists of eight reinforced-concrete fixed arches and one steel-truss double-leaf bascule span. The clear arch spans vary from 166 ft. to 180 ft., and rises vary from 22.56 ft. to 27.38 ft.; crown thickness is 2.25 ft. The ring stones are of granite ashlar, and support a solid concrete spandrel wall faced with granite. The deck is supported by transverse walls spaced about 10-ft. centers, both deck and supports being reinforced concrete.

The Cappelen Memorial Bridge, Minneapolis, Minn. (Fig. 137), was completed in 1923. This bridge has the largest span of any concrete bridge in the United States (400 ft.) and with two side spans of 199 ft. The arches are fixed, and consist of two ribs, with open spandrels and beam-and-slab deck construction. The main arch reinforcement consists of latticed steel trusses.

45. Piers and Abutments

Engineers interested in design of bridge piers should consult "Hydraulic Laboratory Practice," edited by John R. Freeman, and published in 1929 by the Am. Soc. Mech. Engineers, New York.

Location of Bridge Piers should be based on (a) keeping the combined cost of superstructure and substructure a minimum, (b) securing a stable foundation, and (c) causing a minimum disturbance to stream flow and navigation. The cost of a pier does not vary greatly with the length of span. Topographical conditions, however, or the depth of water and the vertical distance to rock at various points of the river materially affect the cost of the piers and therefore the economical span length. The minimum cost for a steel bridge may be approximately attained if the cost of one river pier equals the cost of the main and lateral trusses of one span. (See " Roofs and Bridges," by Merriman and Jacoby, Part III, Art. 9.)

Piers should be located approximately parallel to the direction of the current so as not to cause (1) a shift in the river channel, (2) currents that may interfere with navigation, (3) erosion of the foundation bed, or (4) unnecessary obstruction to the flow of the stream resulting in increased backwater upstream in times of flood and possible damage and lawsuits. In order that the axes of piers may be approximately parallel to the direction of the current, it may be necessary to build skew spans. As skew spans result in higher cost of design and bridge fabrication (both of steel and masonry), they should not be adopted unless freshet and ice conditions and the direction of the current make them mandatory.

In navigable rivers the location of piers must be approved by the Secretary of War. The most important considerations in this case are: (a) Location of crossing relative to current and to river traffic requirements, (b) type of span over navigable channel, and (c) clear width of channel opening. (See paper by C. E. Smith, Proceedings, Am. Railway Eng. Assoc., Vol. 14, p. 185 of appendix.) If a movable span is undesirable because of its cost or the operating expense, or if the river banks are high, it may be desirable to build a high bridge. The War Department will generally approve a height that will clear shipping, which height on important streams may be 150 ft. or more above high water.

Dimensions of Piers. Height is usually determined by design of superstructure and required clearances above high-water level. With non-navigable streams, 10 ft. clearance above high water is usually sufficient to pass drift and ice. The pier top should be wide enough to allow a clearance of 1 to 1-1/2 ft. outside of bridge pedestals. Width under coping should be not less than 4 ft., and at least 1 ft. wider than the pedestals. Length under coping should be not less than distance out-to-out of pedestals plus 1-1/4 times the width of the pier. The coping thickness usually varies from 1 to 2-1/2 ft. The sides of the pier are usually battered, for stability and to improve the appearance. For tall piers, on rock or solid foundations, use a minimum batter of 1 : 48 or 1/4 in. per foot; for piers of ordinary height the usual batter is 1 : 24 or 1 : 12.

Forces Acting on a river pier may include:

(1) **End loads** of two adjacent bridge spans, including all dead load, and live load on either one or both spans. Impact of live load is generally omitted. Eccentricity of pier loading must not be overlooked where the two adjacent spans differ widely in length.

(2) **Wind Load,** generally assumed as 300 lb. per sq. ft. of exposed vertical surface of the pier and of both trusses and train, or 150 lb. per linear foot of bridge for both the upper and lower lateral systems applied at the panel points, and 300 lb. per linear foot of train applied 7 ft. above the base of rail. If end of pier is rounded, use 20 lb. per sq. ft. for wind on end of pier.

(3) **Traction Force of Train,** for which is used from 10 to 20% of the live load on one track applied at top of bearing. In determining the stability of a pier this force must be used with a good deal of discretion because of the indeterminate factors resulting from the continuity of the roadbed (the ballast and rails) and the friction in the roller bearings, all of which tend to transmit this force over more than one pier if there are a series of piers. Moreover, with a long train it is improbable that all the brakes will act simultaneously.

(4) **Centrifugal Force,** which occurs only when the track is on a curve, and which equals $0.00001167\ WV^2D$, where W = weight of train on track supported by the pier, V = velocity of train in miles per hour and D = degree of curvature of track. V may be taken as $60 - 2\text{-}1/2\ D$. Centrifugal force will be applied about 6-1/2 ft. above the rail and acts horizontally and in the direction of the radius of the curve away from the center of curvature.

(5) **Impact of Floating Debris and Ice,** which must be considered, as it may occur, but its value can only be conjectured. Unless it is liable to be considerable, it may generally be neglected. For small river piers it would be well to add to the normal pier thickness to guard against floating ice if records show probable large floes of ice. There are a few records of piers having been moved by floating ice.

(6) **Pressure of Flowing Water and of Solid Ice.** Ice pressure may usually be neglected. There are records, however, of piers having been moved by solid sheets of ice. This was believed to be partly due to the uplift of rising water and ice expansion. Therefore in designing small river piers in cold climates make them somewhat heavier than normal and have smooth masonry between high and low water. (See Art. 30, for pressure of ice against masonry dams.) Pressure of flowing water may be computed by the formula: $P = KWV^2/64.4$, where P = pressure in pounds per square foot, V = velocity of current in feet per second, W = weight of a cubic foot of water, and K is a constant. Greiner gives value for $KW/64.4$ as 1.5 for flat surfaces and 0.75 for rounded surfaces and minimum value for P as 150 lb. per sq. ft. for flat surfaces subjected to freshets and 50 lb. per sq. ft. for flat surfaces in tidal streams.

(7) **Forces Exerted by Expansion or Contraction of the Superstructure.** If the expansion support is a sliding plate, this force may be the reaction of the superstructure multiplied by the coefficient of friction; where suitable roller or rocker supports are used, the force will be much less than this maximum.

(8) **Weight of the Pier Itself.** If the foundation is pervious, the weight of that portion of the pier below water level should be reduced by 62.5 lb. per cu. ft.

Stability. A pier should be stable (based on the forces given in the preceding paragraphs) as to: (1) sliding downstream, (2) sliding parallel to the axis of the bridge, (3) overturning about the downstream toe, (4) overturning in the direction of the axis of the bridge. The maximum unit pressure at the downstream toe and at the side should not exceed the allowable masonry or foundation pressure (Art. 16). The stability should be examined under various combinations of track, wind and water loads.

Determination of stability consists of computing the point of action of the resultant reaction of the foundation, and the maximum unit pressure exerted on the foundation. In a plane through the pier at right angles to the bridge axis (see Fig. 138, sect. AA), let M_x = sum of the moments of all forces (vertical and those horizontal and transverse to the bridge) about the center line of the footing, O_1. In a plane through the pier parallel to the bridge axis (sect. BB), let M_y = sum of moments of all forces (vertical and those horizontal and parallel to the bridge) about the center O_2. W = sum of all vertical loads, that is, the reaction or the magnitude of the resultant; x = longitudinal eccentricity; and y = transverse eccentricity of the reaction. Then $\mathbf{x} = \mathbf{M_x/W}$ and $\mathbf{y = M_y/W}$. These coordinates therefore locate the point where the resultant intersects the pier base. With W and x and y known, the maximum and minimum unit stresses on the rectangle base are computed by the formulas of Art. 22. The stability against sliding of the pier on its foundation should also be considered, using the frictional coefficients given in Art. 16. Except upon firm and rough rock, the ratio of the sum of the horizontal loads to the vertical, $\frac{\Sigma P}{W}$, should not be greater than 0.36, and the departure of the resultant from the vertical should not exceed 20 deg. if friction alone is to be depended on. On rock the horizontal loads or pressures may be entirely taken by cutting the rock into steps, or by cutting depressions in the rock into which the masonry may be keyed.

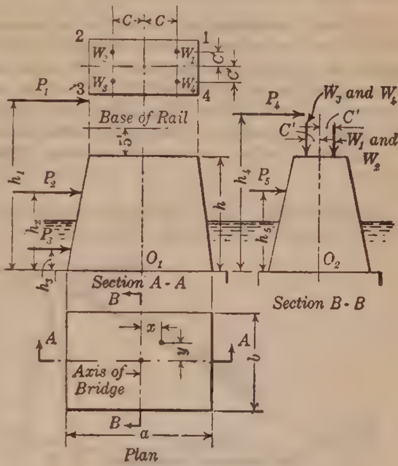

Fig. 138

For example, let the vertical loads W_1 and W_2 of the larger span (Fig. 138) include live load, W_3 and W_4 of the smaller span being dead load only. Assume two double-track spans, one 400 and the other 300 ft. long, dead load being 2000 lb. per linear foot of track and live load 4000 lb. per linear foot of track. Then $W_1 = W_2 = 600$ and $W_3 = W_4 = 150$ short tons. Lateral wind pressure is 300 lb. per lin. ft. (150 lb. per linear foot of top and bottom lateral systems) on truss and 300 lb. per linear foot of train. Wind reaction on pier from long span = 30 tons on truss applied 25 ft. above top of pier (the distance of the middle of the truss above the top of pier) and 30 tons on train applied 12 ft. above top of pier; wind reaction on pier from short span = 22.5 tons applied 20 ft. above top of pier. Hence resultant wind reaction is P_1 = 82.5 tons, and is applied 18.9 ft. above top of pier.

Dimensions of pier are a = 26 ft., b = 18 ft., h = 21 ft. Weight of pier (approximated) = 360 tons, after subtracting weight of displaced water; c = 6 ft., c' = 2.5 ft. P_2 = wind on end of pier (approximated) = 2 tons. P_3 = pressure of current (150 lb. per sq. ft.) = 10 tons. P_4 = traction force of train (taken as 10% of live load reaction of one track only) = 0.1 × 400 = 40 tons. P_5 = wind on side of pier = 0. (For very high piers a check computation should be made with the wind 30 lb. per sq. ft. in this direction and 0 parallel to the length of the pier.) h_1 = 39.9 ft.; h_2 = 14 ft.; h_3 = 4 ft.; h_4 = 21 ft. (All h's are approximate in this example.)

Then $\mathbf{M_x = P_1h_1 + P_2h_2 + P_3h_3 = 3360}$ **ton-ft.**

$\mathbf{M_y = P_4h_4 + (W_1 + W_2)c' - (W_3 + W_4)c' = 3090}$ **ton-ft.**

$\mathbf{W}$ **= sum of vertical loads =** $\mathbf{1500 + 360 = 1860}$ **tons**

Then $\mathbf{x = M_x/W = 1.81}$ **ft.**

$\mathbf{y = M_y/W = 1.66}$ **ft.**

By the formulas of Art. 22, the stress at corner 1 of the base of the pier $= S_1 = \frac{W}{ab}\left(1 + 6\frac{x}{a} + 6\frac{y}{b}\right) = 7.84$ tons per sq. ft., compression; and at the opposite corner $S_3 = 0.12$ ton per sq. ft., compression. The resultant lies within the kern of the base, hence compression everywhere prevails.

Tendency to slide or rotate may be diminished, when the pier is on a rock foundation, by the use of anchor bolts (Art. 22). If the current is very strong, or if it is probable that the river may become choked with ice, round dowel rods, extending for at least 40 diameters into both rock and pier, may be used, as seen in pier F of Fig. 139. This figure illustrates the forces which act on the piers of a bascule bridge, which may include wind on the open bascule leaf in the direction of the bridge axis in addition to the forces discussed above.

Shape of Pier. The rectangular shape is the cheapest, but causes greater interference with the current. Experiments by F. A. Nagler at the University of Michigan led to following conclusions (Trans. Am. Soc. C. E., Vol. 82, p. 334): (1) Best practical form of nose is either the half-round or the semi-elliptical, these being better than the pointed nose. (2) Backwater may be appreciably reduced by using an efficient tail. Best practical form of tail is either half-round or pointed. (3) The 90-deg. nose is not satisfactory; best angle for a pointed nose is 45 deg. or less. (4) For piers of same design upstream and downstream, the half-round shape gives least backwater. Where the nose is pointed and circular segments are used, the curves should be tangent to sides of the pier and the radius should be greater than half the pier thickness.

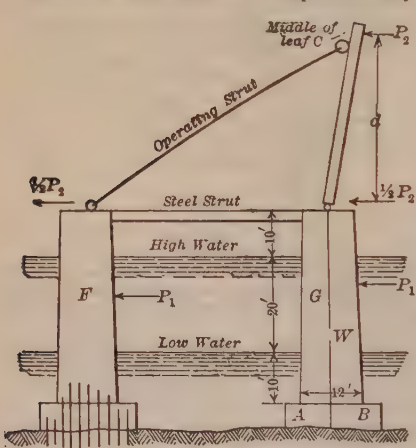

Fig. 139. Piers of Bascule Bridge

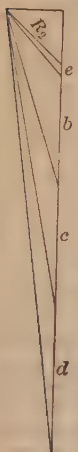
Piers of Arch Bridges are subject to horizontal thrust from the skew-backs of the adjacent spans, and the difference of these acts at the top and causes an overturning tendency. The ordinary arch pier should be analyzed for one adjacent arch without live load and the other adjacent arch with live load over the whole span. It is not necessary to consider thrust due to temperature or rib shortening except when two reinforced concrete arches of widely different spans rest upon the same pier and the larger arch has a rise of less than 1/6 the span; even then the consideration of these thrusts may be an unwarranted refinement. If the pier is an abutment pier it should be analyzed for either arch standing and the other arch removed and for both arches standing. Every third or fourth pier in a series of arches should be built wider than the others so as to act as an abutment in case of failure of one or more of the arches.

Fig. 140 shows graphic analysis for an abutment pier for the case of the left arch standing and the right arch removed. The pier is arbitrarily divided into horizontal courses for the purpose of analysis. The resultant pressures are shown for each joint, and the resistance line passes through the points where the resultants cut the joints. For each joint the distance *e* from the middle to the resistance line is measured and then the maximum stresses may be found from the formulas of Art. 21. The resistance line should lie within the middle-third of all joints. The inclination of the resultant thrust at each joint and at the foundation should be noted and the safety factor against sliding be determined.

Abutments for Arches. The method of analyzing the portion of an arch abutment which takes the arch thrust is similar to that used for piers, except that for an earth-filled bridge the earth pressure against the abutment should be combined with the other forces. In the case of a railway bridge the pressure produced by the earth fill behind an abutment should be increased by a surcharge of 800 lb. per sq. ft. For a single span, the cost of the abutments often exceeds the cost of the arch. The U abutment, Fig. 141, is uneconomical except for a very wide or very low bridge. If built upon a compressible foundation a crack *cc* will usually form at the junction of the transverse and longitudinal walls. This may be prevented by steel rods *rr* or by providing an expansion joint at *ee*.



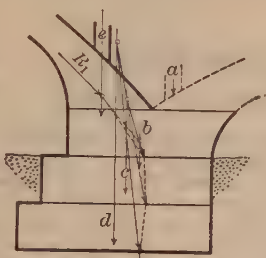


Fig. 140

In the design of U abutments the earth pressure against the back of the longitudinal walls may be less than against an ordinary retaining wall, since the wedge of earth which exerts pressure against the back of the wall is smaller. At the approach end of the abutment, the earth at the outside of the wall is effective in resisting the earth pressure at the back of the wall. It is not believed advisable, however, to decrease materially the masonry at the approach end on this account, as the outside fill may be disturbed by future excavation. As an additional factor of safety against rotation, the longitudinal walls may be tied together by steel rods.

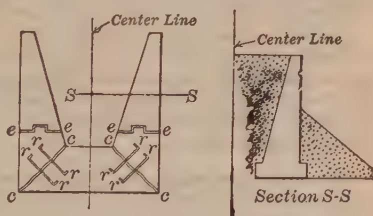

Fig. 141

A good type of abutment is shown in Fig. 142 for the case where the earth pressure is against the outside of the walls. The interior is cellular as shown in the plan or horizontal section *bb*. The earth thrust is taken by the interior walls acting as buttresses, *ss* being a line at the top of the outside earth-filled slope. The cells below *ss* may be partially filled with earth to help resist the pressure of the outside earth. Above this line the masonry walls may be changed to columns, as they carry only vertical loads of the roadway. The abutment may be built of stone, plain concrete, or reinforced concrete. If built of stone or plain concrete, the masonry should be arched as shown by dotted lines in the sections *aa* and *bb*; if built of reinforced concrete the arches may be changed to flat slabs as shown in full lines.

Owing to lack of knowledge regarding the material that may be deposited behind abutments by contractors, no very definite computations regarding earth thrust can generally be made. Probably a horizontal pressure equal to one-third of that of water will be sufficient for most cases.

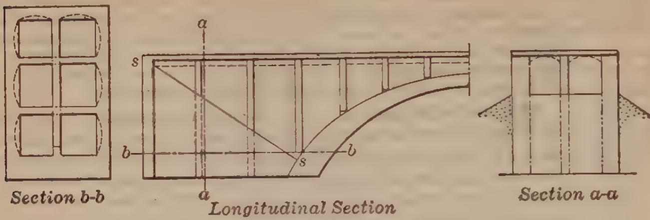

Fig. 142. Cellular Type of Abutment

DOMES OF MASONRY

46. General Data for Domes

Definitions. A dome (Fig. 143) is a spherical or spheroidal vault, a solid of revolution with vertical axis. The section of the inner surface of the dome (soffit) may be **semicircular** (Fig. 144), **pointed** (Fig. 145) or **segmental** (Fig. 146); in the last case the dome is also termed a " cupola." Domes may be closed, as that shown in Fig. 149, or open on the summit (Fig. 143), the opening being termed the " eye " of the dome. The rim of the eye frequently supports a structure called a lantern (Fig. 147). The section of the outer surface (extrados) is usually similar to that of the soffit, but may have a different curve. The solid bounded by the soffit and extrados is the **shell** of the dome. The bed joints are conical. Annular parts of the shell between bed joints (true or imaginary) are called **crowns.** In Fig. 143 the points *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, inclose one-fourth of a crown. **Voussoirs** are parts of the crown included between meridian joints, that is, vertical planes passing through the axis of the dome.

The plan of the dome is always a circle; it may be supported on a circular wall (drum) or carried over a square or polygonal area, resting upon walls or arches whose plan circumscribes the plan of the dome. The vaulted areas between the arches or walls and the base of the dome are called **pendentives** (Fig. 148). The joint between the shell of the dome and the supporting walls is the springing joint.

Data and Precedents. The dome is a remarkably stable form of structure; it can be shown analytically to be stable with a uniform thickness of 23/1000 of its diameter, which is less than 1/3 of the necessary thickness of a semicircular masonry arch of uniform thickness, carrying only its own weight. If the thickness of the shell is tapered from the springing joint toward the summit, it need only have a volume of 9/16 of the thinnest uniform dome of the same span. If enough steel bands are provided at the springing joint, the upper portion of the shell extending down 26 deg. from the summit can be made abnormally thin and yet be stable. The dome of the Cathedral of St. John The Divine, in New York City, built by Gustavino, is an excllent example of this. It has a diameter of 110 ft. and is built of tile, having a thickness of 4 in. for 29 deg. from the summit or 3/1000 of the span. For the next 19 deg. it is 6 in., and from there to the springing line 12 in. thick.

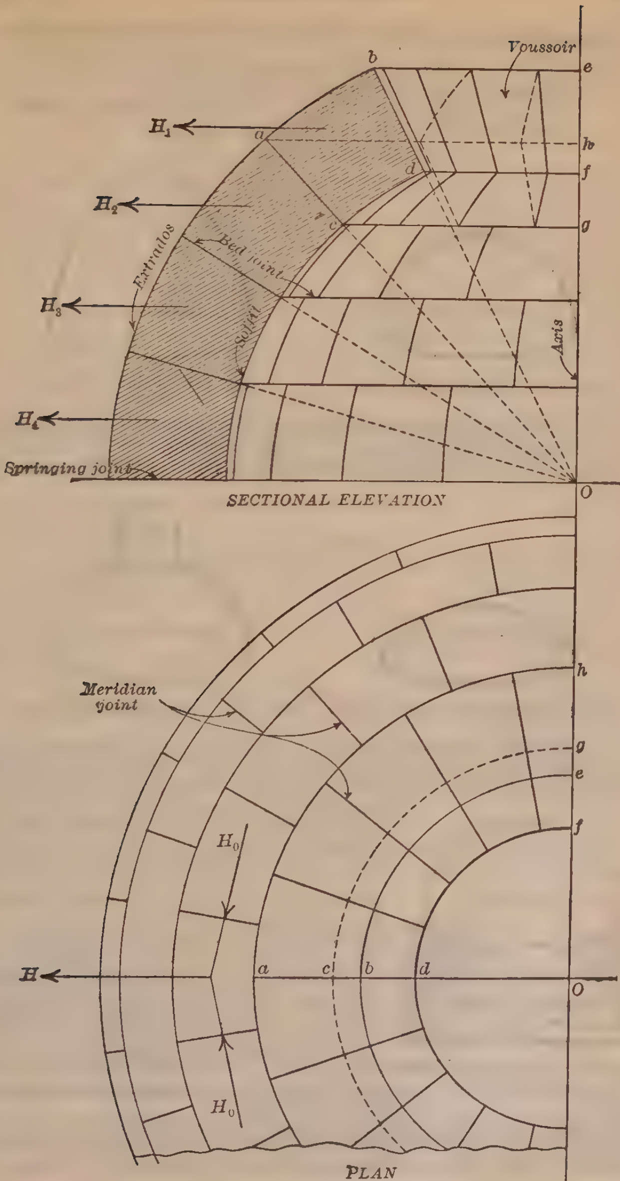

Fig. 143. Plan and Elevation of a Dome

According to Rondelet the following thicknesses are usually given to domes built of brick:

For spans up to 13 ft., a uniform thickness of 4 in.
For spans from 13 to 20 ft., a uniform thickness of 8 in.
For spans from 20 to 25 ft., 12 in. at the springing, 8 in. at the summit.
For spans from 25 to 35 ft., 16 in. at springing, 8 in. at the summit.

Fig. 144. Hemispherical Dome

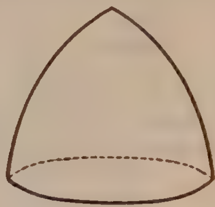

Fig. 145. Pointed Dome

Pointed domes are generally stronger than hemispheres; a dome generated by the revolution of an equilateral arc (60 deg.) requires, to be self-supporting, a thickness of only 5/8 of that of a hemispherical dome of the same span.

Fig. 146. Segmental Dome (Cupola)

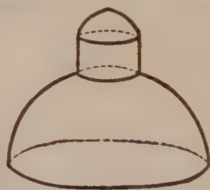

Fig. 147. Open Dome with Lantern

The dome of the Pantheon in Rome, built about A.D. 112, is the largest existing hemispherical dome of masonry, its diameter being 142 ft. It rests on a circular wall nearly 20 ft. thick which, however, is interrupted by 8 large and 8 small niches. The dome is open on the top, the "eye" being about 30 ft. in diameter. The lower courses of the dome, built of Roman tile, were all laid horizontal up to about 40 deg. from the springing line. Above this the construction is not known but is said to consist of tile arches and ribs of concrete. The outside of the dome shows a strong masonry backing beginning at the springing line and extending about half-way up.

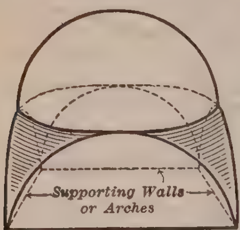

Fig. 148.—Hemispherical Dome and Pendentives

The dome of Santa Sofia in Constantinople, built by Justinian, A.D. 532–537, from the designs of Anthemius of Tralles and Isidorus of Miletus, has a diameter of 104 ft. and is carried on pendentives over a square area. The shell consists of 40 stone ribs and the space between same (about 6 ft. at the springing line) is filled with brick masonry. The dome is closed at the summit and has 40 windows between the ribs.

The dome of St. Peter's Cathedral in Rome, built by Michelangelo, has an inside diameter of 140 ft. and is built of brick. The lower quarter of the shell is of solid construction 9 ft. thick. The upper three-quarters of the height consists of a double shell.

The outer shell, which carries a lantern, is raised higher than the inner one and the two shells are connected by 16 stone ribs. St. Paul's Cathedral in London, designed by Sir Christopher Wren, has three shells; the innermost is hemispherical, open at the summit, the middle one is conical and carries the lantern, the outer dome is framed in timber and covered with lead

47. Conditions of Stability

The dome is usually built without centering, by constructing the crowns in succession, beginning at the springing joint. Every complete crown is self-supporting; consequently open domes may be stable. This stability is the result of tangential pressures acting normally on the meridian joints (H_0 in Fig. 143). Pressures of this character do not exist in simple arches. In Fig. 149, two meridian planes are shown in plan making a small angle ϕ with each other. They cut from the dome two lunes having contact only in a line at O, or, if the dome were open at the summit, the lunes would have no common point at all. The difference between the stability of the arch and the dome is manifest. The arch for its stability depends upon the balancing of the horizontal thrust of each half on either side of the crown or summit. In case of the dome the contact of symmetrically opposite sections (lunes) is in a line without area and incapable, therefore, of transmitting horizontal thrust which would counteract the tendency of the opposing sections to fall into the space below. Therefore the stability of the lunes must be the result of tangential forces or forces acting upon their sides (that is, upon the meridian joints), and normal to them.

These forces, called crown thrusts, are horizontal and act upon both sides of each voussoir (H_0 in Fig. 143). They result in the forces H or H_1, H_2, etc., which act radially outward in a horizontal direction. The forces H are termed resultant crown thrusts. Consider first the uppermost crown of a dome. To insure stability, in other words to prevent the voussoir from rotating or sliding upon its bed joint, the magnitude of H_1 must be such that if it is combined with the weight of the voussoir W_1, the resultant force P_1, called the meridian thrust, shall cut the bed joint ac and its direction shall not be inclined to the normal to the bed joint by more than the angle of friction of masonry upon masonry, say 30 deg. The meridian thrust acting upon the bed joint ac of the first voussoir will be transmitted to the crowns below, and at each voussoir new forces H_2, H_3, etc., must exist to maintain stability. In the case of domes having a high rise there will be found a bed joint called the joint of rupture below which no additional forces H occur, the above requirements of stability (as to the resultant) being fulfilled without the action of such additional horizontal forces. From this joint downward, the dome can be treated as a simple arch.

48. The Line of Pressure

Crown Thrust. In the analysis of stresses in domes of masonry it is assumed that the least horizontal force which is sufficient to keep the voussoirs from rotating and sliding will be the resultant crown thrust H (Fig. 143) if its combination with the weight of the voussoir, the meridian thrust, does not cut the bed joint so close to the edge as to crush the masonry or, due to the elasticity of the masonry, cause the joint to open on the opposite side.

The Meridian Thrusts, P_1, P_2, etc., in Fig. 149, result from combining weight W of the voussoir and the resultant crown thrust H. In order to make the latter a minimum, H must be applied as near to the extrados as possible and P must cut the bed joint as near the soffit as possible, consistent with the foregoing requirements. This may readily be proven graphically by assuming any other point of application of these forces. Theoretically, in order that no

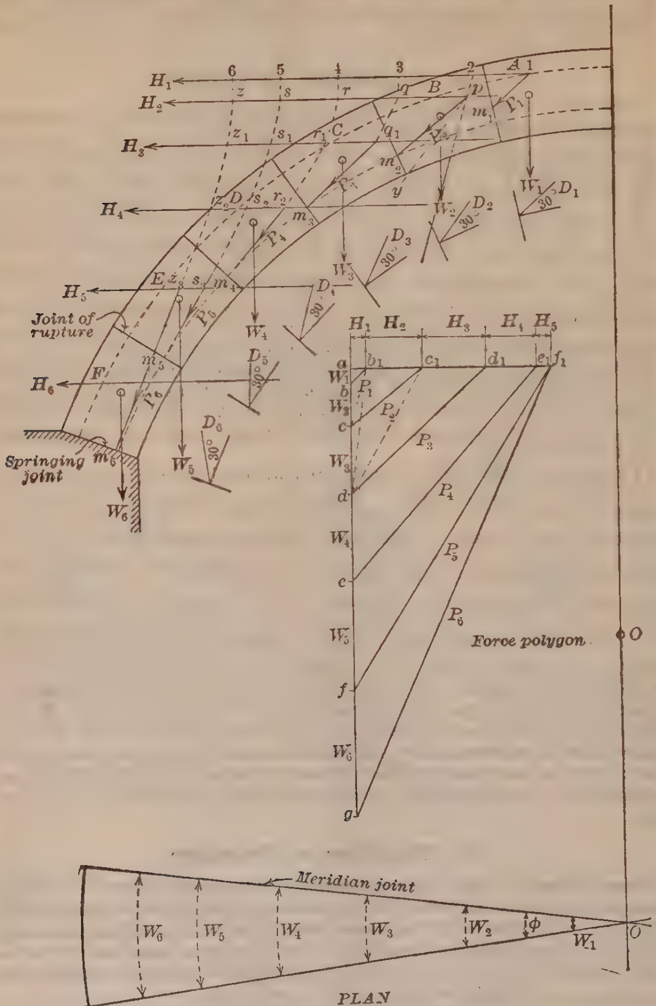

Fig. 149. Graphic Analysis of a Dome

joint may open, the resultant force upon any joint shall not lie outside the kern or the middle-third (Art. 21 and 22). In the case of domes, however, investigation of domes which have been standing for centuries shows that the limits of the middle half of the meridian and bed joints can be safely used as points of application for both crown thrust and meridian thrust. The use of these limits furnishes smaller dimensions than the use of the middle-third points and is here recommended for practical design. Therefore the point of application of the minimum force H should be taken at the upper middle half limit of the shell and the meridian thrust should be applied at the lower middle half point of the bed joint, provided that the condition of stability against sliding permits this location of the meridian thrust. If with the help of the so-found forces H a line of pressure can be drawn that will be within the middle half of the shell, the dome will be stable, provided that the unit stresses on both the meridian and the bed joints are not excessive.

49. Graphic Analysis

In Fig. 149 are shown a plan of a lune and a meridian half section of a cl sed dome. The soffit of the dome is segmental, the radius of the soffit being 8 ft. and its rise 5 ft. The central angle ϕ of the lune is 15 deg. The shell of the dome is 1 ft. 3 in. thick throughout. The section is divided by full radial lines into voussoirs 1 ft. 9 in. long on the center line. These radial lines form the bed or conical joints. The middle half limits of the shell are shown by the dotted curves and their intersections with the bed joints give the middle half limits of these joints. The weight of each voussoir acts at its center of gravity, which may be taken, with sufficient accuracy, as coincident with the geometrical center of the voussoir, except at the topmost wedge-shaped one in which the center of gravity is taken at the lower third. The weights of the voussoirs, including the superimposed loads if any, may be determined graphically or analytically. In the example given (Fig. 149) the weights of the voussoirs, W_1, W_2, W_3, etc., are proportional to the lengths of the arcs W_1, W_2, etc., of the plan which pass through the geometrical centers of the voussoirs. The lengths of these arcs are used directly in the force polygon to represent the weights of the voussoirs. The true magnitude of all the forces shown on the force polygon will therefore be found by measuring their lengths to the same scale as that of the plan of the dome, and multiplying these scaled lengths by the length of the voussoir $\times$ the thickness $\times$ the weight per unit volume of the masonry. W_1, W_2, to W_6 show on the section the lines of action of the vertical force.

The lines of action of the horizontal resultant crown thrusts H_1, H_2, etc., are assumed to be and are shown as applied at points A, B, C, D, E, and F, which points are located at the upper limit of the middle half of the shell and on the same radii as the centers of gravity of the corresponding voussoirs. The lines of action of the combined weights $W_1 + W_2$, $W_1 + W_2 + W_3$, etc., may be determined graphically or analytically and are shown in Fig. 149 as passing through points 2 to 6, inclusive. For example, the line of action of combined loads $W_1 + W_2 + W_3 + W_4$ passes through point 4. At D_1, D_2, etc., the limiting directions of the meridian thrusts (which must not be inclined to the normal of any bed joint by more than 30 deg.) are shown for every conical joint.

Point 1 is the intersection of the weight W_1 of the first voussoir and of the resultant crown thrust H_1. The resultant of these two forces must pass through this point and its direction, if the dome is to be stable, must be such that it will intersect the first bed joint between the middle half points, and it must not be steeper than the limiting direction D_1. Draw $1m_1$ (in section) and also bb_1 (force polygon) parallel to D_1; bb_1 is the probable magnitude of the meridian thrust P_1, because if its direction were steeper it would not fulfill the condition necessary to prevent sliding; if it were less inclined, it would require a greater resultant crown thrust than the minimum. Therefore, m_1 is a point of the probable line of pressure and ab_1 (force polygon) is the magnitude of the resultant crown thrust H_1 acting on the first voussoir.

The combined weight of voussoirs 1 and 2 passes through point 2. If no additional crown thrust were present the meridian thrust on the second bed joint would be obtained by combining H_1 and $W_1 + W_2$, in other words by drawing line $2\,x$ through 2 parallel to b_1c (force polygon). This line $2\,x$ falls outside the second bed joint and is too steep for stability against sliding. Therefore, at point p (the intersection of $2\,x$ and H_2) an additional horizontal force acts, if the dome is stable. If through point p, a line py parallel to the limiting direction D_2, is drawn, this line is also seen to fall outside the joint. The minimum resultant crown thrust H_2 acting at the second voussoir and consistent with the requirements of stability, will therefore be such as to make the meridian thrust pass through the lower middle half limit m_2 of the second bed joint.

Draw pm_2, in which m_2 is a seond point of the line of pressure; and draw cc_1 (force polygon) parallel to pm_2. Then cc_1 is the magnitude of the meridian thrust P_2 and b_1c_1 the magnitude of the resultant crown thrust H_2.

A similar construction is carried out for the other voussoirs to determine meridian thrusts P_3, P_4, P_5, and the resultant crown thrusts H_3, H_4, H_5. At voussoir 6 it is found that the sum of the horizontal forces H_1 to H_5 is sufficient to insure the stability of the voussoir and therefore the value of H_6 reduces to zero. Bed joint 5 then is the joint of rupture of this dome.

The magnitude of the crown thrust H_0 (the normal force acting on the meridian joints (Fig. 143) can be calculated by the formula: $H_0 = H/(2\sin \phi/2)$ or if ϕ is small $H_0 = H/\phi$, ϕ being measured in radians and H being the value of H_1, H_2, etc., for the voussoir in question. After the magnitudes of both the crown thrusts and meridian thrusts have been determined, the maximum unit stresses upon the bed joints and the meridian joints can be obtained by the methods given in Art. 21 and Art. 22.

It is sometimes necessary, in order to insure the stability of a dome or its supporting walls, to eliminate the transmission of the resultant crown thrust either at the joint of rupture or at the springing joint. This may be done by hoops of iron or steel. The magnitude of the tension for which these hoops must be figured can be determined by the above equation, where, in this case, H_0 denotes the tension in the band (hoop tension) and H denotes the sum of the values H_1, H_2, etc., at and above the joint in question.

Numerical Example. How large is the crown thrust H_0 acting on the meridian joint of voussoir 3 (Fig. 149) and what is the maximum compressive stress on this joint? By scaling (force polygon) H_3 is found to be 1.0 ft., the length of the voussoir is 1.75 ft., its thickness is 1.25 ft., and the weight of the masonry is 165 lb. per cu. ft. Then

$$H_3 = 1 \times 1.75 \times 1.25 \times 165 = 360 \text{ lb.}$$

ϕ being 15 deg., $H_0 = 360/0.262 = 1385$ lb.

By Art. 22, $$S_{max} = 2\,H_0/3\,rb,$$

where $r = 1/4 \times 1.25$ and $b = 1.75$ ft. for the case here discussed.

$$S_{max} = 8 \times 1385/3 \times 1.25 \times 1.75 = 1740 \text{ lb. per sq. ft.}$$

What is the required section of iron bands necessary to take the hoop tension at the springing joint so as to make the thrust at the springing vertical? $\Sigma H = 3.15$ (force polygon) $\times 1.75 \times 1.25 \times 165 = 1135$ lb. $H_0 = 1135/0.262 = 4335$ lb. If the allowable unit stress for iron is 8000 lb. per sq. in., the iron section required $= 4335/8000 = 0.54$ sq. in.

In a Conical Dome, if the base is kept from spreading by friction on a firm abutment or by means of a hoop, tension is nowhere exerted from the summit down.

CONCRETE AND REINFORCED CONCRETE

BY

ARTHUR G. HAYDEN, M. Am. Soc. C. E.

DESIGNING ENGINEER, WESTCHESTER COUNTY PARK COMMISSION

NEW YORK

PLAIN CONCRETE

1. Factors Controlling Quality of Concrete

Concrete is a comparatively new major structural material and the technique of its manufacture is subject to constant revision as we learn more concerning it by experience and scientific research. Present-day opinions regarding such effects as that of curing temperature, of prolonged mixing (such as several hours in a mixer-conveyor), of re-tempering and of other conditions may later be modified. Some recent investigations seem to indicate this. Caution should be exercised, however, in accepting the results of practical experimenting. Deviation from the rules of established practice may be permissible under one given set of conditions and not under another set of conditions. Practical experiments give results that are sometimes apparently contradictory. Established practice should then be discarded only after research by persons accustomed to separate and recombine effects and deduce general principles thereby, and not on the strength of ordinary observation. The rules set down in this section are intended to be in accordance with what is now considered good practice.

The essential factors in proper control of concrete manufacture are: Selection of good materials, correct proportioning of all ingredients, and proper technique in manipulation. The neglect of any one factor will offset to a great degree the good results anticipated by observance of the other factors. Adequate discussion cannot be given here; only the high points will be touched upon, and the reader is referred to standard treatises for detailed discussion.

Concrete is a physico-chemical mixture of cement, water and aggregate (sand and stone). The cement and water combine by a process known as hydration of the cement which binds the particles together. Insufficient cement paste in concrete to fill the voids in the aggregate will weaken the product. More water in the cement paste than is necessary to hydrate the cement remains uncombined and leaves minute water voids in the concrete, which weakens it structurally and leaves it pervious to the passage of water. Only about 2-1/2 gal. of water is necessary to hydrate a bag of cement and anything in excess of this produces water voids. With this minimum amount of water, however, it is not possible to produce a mixture that can be manipulated. A considerable amount of water in excess of this minimum is required to give mixtures suitable for placing. "Workability" is an essential requirement. Fortunately workable mixes can be made, with quantities of water so limited that the water voids are negligible in effect and the concrete strong, durable and impervious.

It is obvious that another essential requirement for a good concrete is structural uniformity throughout the mass. The water and cement must be intimately incorporated so that all the cement will be hydrated and unavoidable water voids uniformly distributed; the cement paste must be uniformly distributed throughout the mass of aggregates so that no portion of the mass will be impoverished; the fine and coarse aggregates must also be uniformly mixed and thoroughly coated with the cement paste. Thorough mixing is therefore essential.

After mixing, the material must be transported and deposited in the forms so that the results of good mixing will not be vitiated by subsequent segregation before the concrete has set. All these requirements may be classified under the general head of proper manipulation.

The chemical changes incident to setting and hardening do not take place at once but, after hydration of the cement, continue over a considerable period of time in the presence of water. This process is called "curing" and therefore concrete should be kept wet, after it has set, for as long a period as is practicable. Curing not only increases the strength of concrete and therefore its structural value, but is a necessity for the production of watertight and durable concrete. Excess mixing water damages concrete by producing water voids in the concrete but a plentiful supply of curing water is essential.

The essential requirements for making good concrete may therefore be summarized as follows, each item being treated in detail later in this section:

(1) Proper selection of materials
- (a) Cement
- (b) Water
- (c) Aggregate

(2) Correct proportioning
- (a) For strength and durability
- (b) For workability

(3) Proper manipulation
- (a) Mixing
- (b) Transporting
- (c) Depositing

(4) Continued curing to increase strength and durability.

2. Physical Properties of Concrete

The physical properties of concrete vary widely depending upon the quality and proportion of the ingredients and the technique of manufacture. Concrete is characterized by a relatively high compressive strength, increasing with age, a relatively low tensile strength (about 10% to 12% of the compressive strength) and a true shearing strength (as distinguished from the combined shear and tension action in the webs of beams) of about one-half the compressive strength. (It is on the basis of the combined action that web shear is sometimes given as 1-1/2 to 2 times the tensile strength.) The modulus of rupture as determined by transverse bending tests on plain concrete beams is about twice the tensile strength.

From the above general comparisons it is seen that plain concrete is suitable only for structures not subject to tension, either direct or in bending; such as foundations for structures, piers and abutments, dams, gravity retaining walls and small arches in which the pressure line can be kept within the middle third of the section for all conditions of loading and all ranges of temperature For structures subject to tension in transverse bending, such as floor slabs, beams, large arches, etc., the deficiency in tensile strength is supplied by reinforcing steel. Reinforced concrete will be discussed later.

In the discussion immediately following, the classes of concrete are designated by the proportions of the dry ingredients — cement : fine aggregate : coarse aggregate, as for example 1 : 2 : 4, 1:2-1/2 : 5 and so on.

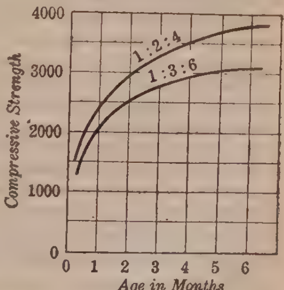

Fig. 1

The principal element affecting the strength of the concrete is the amount of mixing water relative to cement. The approximate variation of compressive strength with the water-cement ratio $\frac{W}{C}$ is shown in Fig. 5, Article 6. The strength of concrete increases with age. Fig. 1 shows typical curves for a particular set of laboratory conditions.

The ratios of compressive strength, tensile and shearing strength and modulus of rupture to each other vary considerably; the values depending upon the kind and age of the concrete and upon the methods used in their determination The ratios given at the beginning of the article are approximate.

Elastic Properties. Concrete does not possess such perfect elasticity as steel and many other metals. In a **compression** test, for example, small permanent deformations or set occur at comparatively low loads and the stress-strain curve is slightly curved almost from the beginning. If the load is not excessive, however, repeated loading causes the material to become more perfectly elastic and the stress-strain curve will approach a straight line up to the amount of stress which is repeated, as illustrated in Fig. 2. The elastic limit

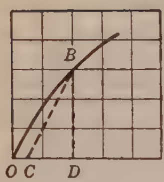

Fig. 2

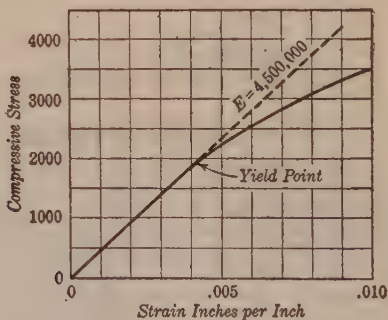

Fig. 3

is, for the reasons stated above, not well defined. There appears, however to be a limit to the stress which can be repeated indefinitely without continuing to add to the deformation and this limit may for all practical purposes be taken as the elastic limit. It is about one-half the ultimate strength; above this point the rate of deformation increases rapidly as the stress increases as indicated in Fig. 3. Since concrete is not perfectly elastic, the true modulus of elasticity is a variable depending upon the degree of stress existing at the time the increments of stress and strain are assumed to be measured. The stress-strain curve being nearly straight, however, within working limits of stress the modulus may be calculated on the basis of the working stress and the corresponding total deformation. In this regard there is some disagreement in method of experimenters; some calculating E as the ratio of total stress to corresponding total deformation (B D ÷ O D in Fig. 2); others calculating it as the ratio of total stress to the total deformation minus the permanent set occurring when the specimen experimented upon is first stressed; that is $\frac{BD}{OD - OC}$. The modulus also varies with the different kinds of concrete and with the age. Typical values are given in the table at top of next page.

The moduli for tension and compression are about equal.

Coefficient of Expansion. Tests show little variation in the coefficient of

Name of concrete	Modulus of elasticity, lb. per sq. in.		
	Based on elastic deformation		Based on total deformation
	At 114 lb. per sq. in.	At 570 lb. per sq. in.	At 570 lb. per sq. in.
1 : 2-1/2 : 5 (broken stone)........	4 660 000	3 590 000	3 440 000
1 : 2-1/2 : 5 (gravel)............	3 170 000	2 520 000	2 200 000
1 : 3 : 6 (broken stone)..........	3 870 000	2 990 000	2 570 000
1 : 3 : 6 (gravel)................	3 000 000	2 240 000	2 110 000

Kind of concrete	Modulus of elasticity between loads of 100 and 600 lb. per sq. in. based on elastic deformation		
	7 to 10 days	1 month	2 months
1 : 2 : 4......................	2 090 000	2 620 000	3 650 000
1 : 3 : 6......................	1 970 000	2 590 000	3 210 000

expansion, which may be assumed as 0.0000065 per degree Fahrenheit or about equal to that of steel.

Contraction after Hardening. The shrinkage of concrete after setting and hardening and drying may be assumed as 0.02% to 0.04% for 1 : 2 : 4 concrete.

Weight of Concrete. Average concrete weighs about 145 lb. per cubic foot. Reinforcing steel may be assumed to add 5 lb. per cubic foot, giving the usual figure of 150 lb. used in calculating dead loads.

3. Cement, Cement Testing

Natural Cement is the finely pulverized product resulting from the calcination (dehydration) of an argillaceous limestone at a temperature below fusion, which, when mixed with water, hydrates again into a solid. The proportions of lime and clay in the raw material vary considerably, depending upon the source, and therefore natural cement is not so uniform in quality as the artificial product known as **Portland cement.** It sets quicker, hardens more slowly, attains less strength—approximately 1/3 that of portland cement, and varies more in strength. For "Early Strength Cements" see page 158, Section 20.

Portland cement, which has almost entirely displaced natural cement for all structures, is an artificial mixture of calcined argillaceous and calcareous materials having more definite chemical and structural qualities. The proper control of the chemical composition in the process of manufacture determines its structural value.

The composition and method of manufacture of cement are discussed briefly in Appendix 1.

Testing. Cement being the active ingredient of concrete should be tested if it is to be used on important work, although there is little danger in using a well-known brand without testing, particularly if the engineer has used it in previous work within a reasonable period of time and knows its qualities. The results of tests depend largely upon the methods employed. Tests should therefore be made by experts who specialize in this work and in accordance with the methods standardized by the American Society for Testing Materials.

The usual tests made for portland cement are: (1) For fineness, (2) for soundness, (3) time of setting, (4) tensile strength.

Chemical tests are sometimes required on important work. The methods of testing are described in Appendix 2 and the requirements under tests are as given in Appendix 3.

Sampling. The above tests are to be made on samples selected, in accordance with A. S. T. M. standard methods, by the engineer or under his supervision as follows:

Sampling. 1. Tests may be made on individual or composite samples as may be ordered. Each test sample should weigh at least 4 lb.

2. (a) *Individual Sample.* If sampled in cars one test sample shall be taken from each 50 bbl. or fraction thereof. If sampled in bins one sample shall be taken from each 200 bbl.

(b) *Composite Sample.* If sampled in cars one sample shall be taken from one sack in each 40 sacks (or 1 bbl. in each 10 bbl.) and combined to form one test sample. If sampled in bins or warehouses one test sample shall represent not more than 200 bbl.

3. Cement may be sampled at the mill by any of the following methods that may be practicable, as ordered:

(a) **From the Conveyor Delivering to the Bin.** At least 4 lb. of cement shall be taken from approximately each 100 bbl. passing over the conveyor.

(b) **From Filled Bins by Means of Proper Sampling Tubes.** Tubes inserted vertically may be used for sampling cement to a maximum depth of 10 ft. Tubes inserted horizontally may be used where the construction of the bin permits. Samples shall be taken from points well distributed over the face of the bin.

(c) **From Filled Bins at Points of Discharge.** Sufficient cement shall be drawn from the discharge openings to obtain samples representative of the cement contained in the bin, as determined by the appearance at the discharge openings of indicators placed on the surface of the cement directly above these openings before drawing of the cement is started.

4. Samples preferably shall be shipped and stored in airtight containers. Samples shall be passed through a sieve having 20 meshes per linear inch in order to mix the sample thoroughly, break up lumps and remove foreign materials.

4. Gaging Water

Certain impurities in mixing water will seriously impair the quality of concrete. If it is necessary to use water from a stream liable to pollution from sewage or manufacturing wastes, tests should be made. It is customary to specify that mixing water shall be free from oil, acids, alkalis and organic impurities.

Oil may be detected by the iridescent film which it forms on quiet water. Oils of organic origin are very injurious to concrete. Mineral oils in small quantity lower the compressive strength but only to a slight degree.

Acids or alkalis may be detected by litmus paper, which may be procured at a drug store. Blue litmus paper changing to red when dipped in the water indicates the presence of acid. Red litmus paper changing to blue indicates the presence of alkali. If the color changes are rapid and decided, dangerous amounts of acid or alkali are indicated. If the color changes are slow and the resulting color faint, the water is safe to use.

Turbidity of the water indicates impurities, that may or may not be injurious, held in suspension. Investigation should be made to determine whether such matters comes from sewage or manufacturing waste or whether it is natural silt.

The use of sea water for mixing is generally prohibited, though very limited tests indicate that it is not injurious to concrete. Further investigation is needed to determine its effects definitely, especially its effects upon reinforcing steel.

The action of sea water on finished concrete structures seems to be physical rather than chemical. Marine structures of a dense concrete, manufactured under rigorous control, are durable. The destructive effect of sea water other than direct physical damage seems to be the disruptive effect of crystallization within the pores of concrete, in which excess mixing water has been used, or the action of frost within the voids of concrete which has been improperly transported or deposited; or similar causes.

5. Aggregates. Test for Aggregates

The aggregates — stone or gravel and sand—are the inert ingredients of concrete but their quality and grading affects the quality of the concrete. All aggregates should be structurally sound; the particles should not be soft nor friable. Aggregates consisting of flat or elongated particles do not make good concrete. Trap, granite and gravel are generally the best aggregate; some limestones are their equal; in particular, those having a high coefficient of wear. Soft limestones and, in general, sandstones and shale are weak. Blast furnace slag used with care makes a strong concrete, but sulphur should have been removed by two or three years' weathering to prevent subsequent deterioration of the concrete. Also in proportioning mixing water the absorption of slag should be measured, otherwise the mix is likely to be harsh.

Aggregates containing mica should be rejected. Even small amounts of mica in the aggregate will seriously reduce the strength of the concrete.

Aggregates can usually be obtained from sources supplying materials of known quality; so that tests are unnecessary. If there is doubt as to the quality of the aggregates offered, compression tests should be made on concrete cylinders as described in Appendix 6, to determine their suitability. The aggregates may be provisionally accepted on the 7-day test subject to satisfactorily passing the 28-day test also.

Pre-mixed Aggregates. Aggregates are often placed upon the market as "pre-mixed," containing about the correct proportions of fine and coarse materials for making good concrete. The fine and coarse materials tend, however, to segregate in the cars, or barges, so that earlier batches of concrete may vary considerably from later batches. It is considered better practice by some engineers to store fine and coarse aggregates separately on the job so that, although the finer particles in each may settle to a degree, correction may be made as the work progresses by varying the proportions of fine to coarse so that uniformity of the mixed materials may be maintained. The use of pre-mixed aggregate, however, decreases the cost of the concrete. If properly graded in the first instance and if segregation is not invited by long transportation in cars or in rehandling, there is no disadvantage in its use.

Size Classification. Fine aggregate (sand, fine gravel or stone screenings) is defined as material that will pass a No. 4 screen (4 meshes to the inch, or 3/16-in. square spaces between wires). Coarse aggregate (gravel, broken stone or slag) is the material retained on the No. 4 screen. Coarse aggregates are designated by the largest sized particles as measured by the clear space between the sides of the smallest opening through which 95% by weight of the material can be passed; thus we have 3-in. coarse aggregate, 2-1/2-in., 2-in., 1-1/2-in., 1-in., 3/4-in., 1/2-in.

Grading of Aggregates. Fine aggregate should be graded from fine to coarse within the following limits:

Passing 3/8-in. sieve (3/8-in. square openings)........	100%
Passing No. 4 sieve (4 meshes to the inch)...........	85% to 100%
Passing No. 16 sieve (16 meshes to the inch)..........	45% to 80%
Passing No. 50 sieve (50 meshes to the inch), not more than.....	30%
Passing No. 100 sieve (100 meshes to the inch), not more than...	5%

Coarse aggregate should be graded from fine to coarse; from 40% to 75% passing a sieve with square openings the side dimension of which is one-half the size classification of the aggregate. Not more than 10% should pass the No. 4 sieve.

Sampling Aggregates. The engineer should select stock samples of both fine and coarse aggregate from which to obtain the smaller samples for making the various tests to determine structural soundness, proper grading, presence or absence of organic impurities, amount of clay and silt, etc., as described elsewhere. A 50-lb. sample of fine aggregate and 100-lb. sample of coarse aggregate should be obtained, selection being from various locations in the supply. Bear in mind the tendency of the larger particles to roll to the bottom and outside of stock piles.

The small samples for the various tests to be made should be selected from the stock sample as follows in order that they too shall be representative:

Place the stock sample on a square of canvas or oilcloth and mix thoroughly. Spread the mixed material in the form of a circle 3 or 4 in. thick. Quarter the circle and discard opposite quarters. Re-mix the remainder and repeat the operation until the sample is of the required size for the test that is to be made.

Natural Sand. The selection of a natural sand for the fine aggregate requires particular attention since many sand pits have become impregnated with organic impurities of a humus nature from the overlying soil. The presence of silt or clay is not a necessary indication of organic impurity in the sand; neither is its absence an indication that there are no organic impurities. A clean-looking sand may contain organic impurities in the nature of a thin coating on the grains that will result in a very inferior concrete. Only 10% of organic loam may decrease the strength of concrete 50% or more. On the other hand, the presence of as much as 5% weight of clay or silt is not seriously detrimental if it is free from organic matter. The effect of organic matter on the strength of concrete is illustrated in Fig. 4.

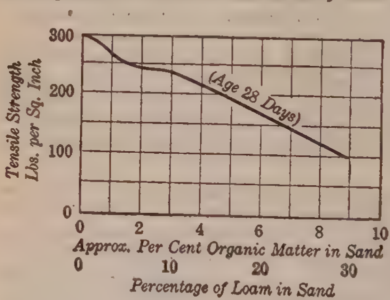

Fig. 4

Colorimetric Test for Organic Impurities. The detection of organic impurities in sand may be accomplished by the colorimetric test devised by Professor Duff A. Abrams and Oscar Harder, formerly of Lewis Institute, Chicago. Obtain a 12-oz. graduated prescription bottle and a stock of sodium hydroxide from a drug store. Make a 3% solution of the hydroxide by dissolving 1 oz. of it in 32 oz. of water. Fill the bottle to the 4-1/2 oz. mark with a representative sample of the sand to be tested, and add enough of the sodium hydroxide solution to bring the mixture to the 7-oz. mark after shaking thoroughly. If after 24 hours the liquid above the sand is colorless or of a light yellowish color, the sand may be considered safe in so far as organic impurities are concerned.

A standard color solution with which to compare the color of the test sample may be made as follows: Make a 2% solution of tannic acid in 10% alcohol. Add 2.5 c.c. of this to 97.5 c.c. of a 3% solution of sodium hydroxide, place in a 12-oz. prescription bottle, stopper it, shake and allow to stand 24 hours. This will give the standard light yellowish color. Any sand which by the colorimetric test produces a color darker than this should be subjected to strength tests in mortar or concrete to decide its suitability for making concrete. Washing sand will remove organic impurities but re-tests should be made afterward.

Structural Qualities of Sand. Tests to determine the structural value of sand are also of importance when the sand is obtained from a source where the quality of the product is unknown. The grains of some sands are soft and friable, which renders the sand unsuitable for making concrete. The structural value of a sand may be determined by making the standard tensile or compressive tests on specimens made with the sand and comparing with similar tests of specimens made with standard Ottawa sand. The standard tests are given in Appendices 2 and 6. The standard sand generally used for test comparisons is that obtained from a natural sand bank in Ottawa, Ill.

Clay in sand is sometimes beneficial and sometimes slightly detrimental. Lean concrete—a mixture of aggregate and lean mortar—is improved up to the point where the voids in the sand are completely filled by the cement and clay. The strength of richer concretes, in which the voids of the aggregate are filled due to careful proportioning and the addition of sufficient cement, is somewhat reduced by the presence of clay which reduces cohesion without increasing density. The effect of 5% of clay is not particularly harmful if it is finely divided and well distributed in the mass, although the American Society for Testing Materials' standard specification for fine aggregate limits the amount to 3%. The determination of the amount of clay and silt in sand or fine aggregate may be made by the Decantation test devised by the American Society for Testing Materials or by the approximate Sedimentation test as follows:

Fill a 32-oz. graduated prescription bottle to the 14-oz. mark with the sand or fine aggregate to be tested. Add clear water to the 28-oz. mark, shake vigorously and allow to settle one hour or more. If more than one ounce of sediment appears above the aggregate, the aggregate should be rejected or else it will require washing. Re-tests should always be made after washing.

6. Proportioning of Concrete

Theoretically the best concrete as to both quality and economy would be that in which the mixed aggregate is so graded that the minimum percentage of voids results and in which the voids in the aggregate are completely filled with a cement paste containing just enough water to hydrate the cement completely so that absolutely no water voids would be formed in the concrete to weaken it structurally. Practically, ideal conditions cannot be realized, for reasons stated at the beginning of the section. Some sacrifice of strength and density must be made by the use of more water than is necessary merely to hydrate the cement, in order to obtain workable mixes economically; but beyond a certain range the use of excess water is extremely damaging to concrete even as a practical structural material.

Evidences of this are on every hand in many structures. Unnecessary excess water is the cause of "**day's work**" **planes**—planes indicating the interruption of the depositing of concrete. This is due to laitance carried

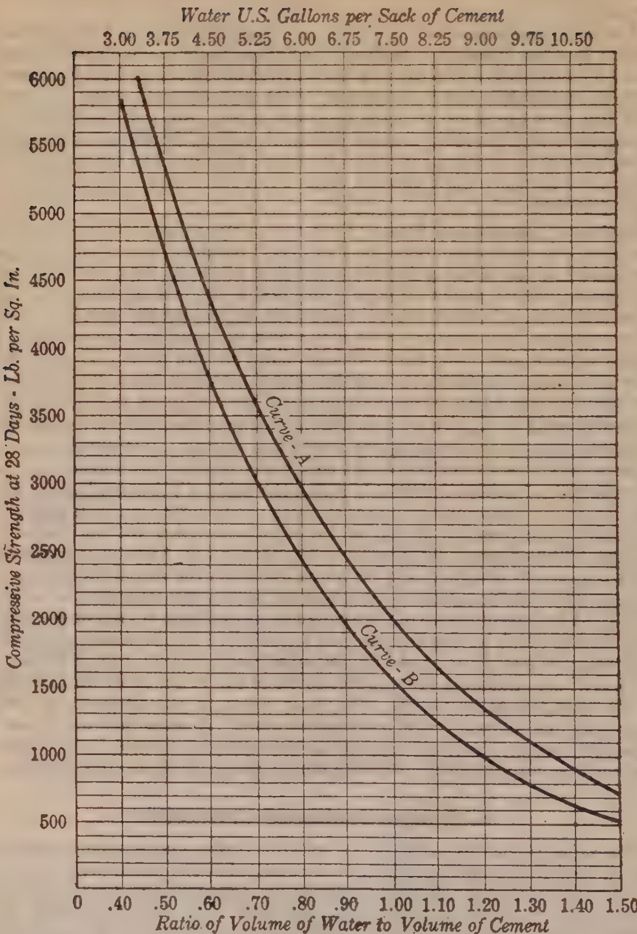

Fig. 5

Effect of quantity of mixing water on the strength of concrete. Curves based on average values from nine series of tests made over a period of four years. Curve *A* to be used for design where the water-cement ratio is carefully controlled by accurate measurement of quantities of water, cement and aggregate, with proper correction for water carried by the aggregate. Curve *B* to be used for design where the water-cement ratio is indifferently controlled and where only rough methods are used for measuring quantities of materials. These are curves developed by Duff A. Abrams.

by the excess water, which forms a structurally weak deposit as soon as concreting ceases and prevents the new concrete from bonding to the old. A pervious stratum is formed through which moisture percolates carrying along the solubles and forming a disfiguring chalky efflorescence. Within the body of the concrete, too, the minute water voids cause structural weakness not at first evident to the eye. The formation of minute frost particles due to the percolation of water or the physico-chemical formation of crystals in the minute voids exerts a tremendous disruptive force which causes the disintegration of many concrete structures. Such a condition is very unfortunate because entirely avoidable.

A prime requisite for making good concrete is therefore the strict limitation of the amount of water in the mix relative to the cement. Strength and durability are a direct function of the water-cement ratio $\left(\frac{W}{C}\right)$, other factors being constant, as shown in Fig. 5. For work requiring concrete that will develop a given strength in a given time as determined from Fig. 5, the relative amounts of water and cement must be kept constant. If it is found necessary

Classes of Concrete for Different Degrees of Exposure

From "Design and Control of Concrete Mixtures," Portland Cement Association.

Class of concrete (expected strength at 28 days lb. per sq. in.)	Maximum quantity * mixing water U. S. gallon per sack of cement (94 lb.)	Type of structure or degree of exposure
3000	6	Roadways, piles, pressure pipe and tanks. Thin structural members in severe exposure. Walls, dams, piers, etc., where exposed to severe action of water and frost.
2500	6-3/4	Sewers, bridges, walls, dams, piers, etc., for all weather conditions and moderate action of water and frost.
2000	7-1/2	Ordinary enclosed reinforced-concrete buildings. Bridges and retaining walls of heavy sections in moderate exposure.
1500	8-1/4	Mass concrete, basement walls, etc., protected from water or severe weather conditions.

* Free water or moisture carried by the aggregates must be included as part of mixing water.

to increase workability so that the concrete can be properly manipulated in the forms and around reinforcing steel, the proportion of cement paste to aggregate may be increased but **relative amounts of water and cement must not change.** The unit of field measurement of cement being the bag (94 lb., or about one cubic foot), the proportions of cement paste and aggregate may best be varied by changing the amount of aggregate per batch.

From the above it is seen that classification of concrete by arbitrary proportions has no real significance with respect to quality and is only a general indication (subject to modification) of the workability required for particular classes of work, hence, the approximate amount of cement paste relative to aggregate. A relatively stiff mix can be properly placed and compacted en masse as in abutments or gravity retaining walls and the mix may approach

1 : 3 : 5 or 1 : 3 : 6. The placing of concrete around steel reinforcement in the bottoms of deep beams or in thin vertical walls requires more workability and the concrete may approach 1 : 1-1/2 : 2 or 1 : 1-1/2 : 3. Above the reinforcement in the beams where the concrete can be more effectively manipulated, it may approach 1 : 2 : 3 or 1 : 2 : 4. In any case, however, the water must not exceed the amount that will produce the required strength.

Aggregates stored in the field, particularly the fine aggregates, usually contain a considerable amount of moisture and this must be taken into account in preparing the mix. Fine aggregates in storage piles under ordinary conditions will contain 1/4 to 1/2 gallon of water per cubic foot, and after a heavy protracted rain may contain as much as a gallon. Coarse aggregate retains less—from 1/8 to 1/4 gal. Account of this in determining the quantity of water to be added to the mix may be taken by weighing samples of the aggregate before and after drying and converting the loss in weight into gallons of water per cubic foot of aggregate. Moisture content of storage piles will remain constant for two or three days under settled weather conditions Determination of the content may therefore be made at such intervals. After a rain a re-determination is necessary.

METHODS OF PROPORTIONING

Proportioning by Determination of Voids in the Aggregates.

Proportioning by Trial Method for Maximum Density.

These "rational" methods require considerable modification of the proportions determined by them, in order to obtain smooth workable mixtures and, in fact, resolve themselves in the final analysis into a method of judgment.

Proportioning by Fineness Modulus, as developed by Professor Duff A. Abrams, is based upon careful research and the results of numerous laboratory experiments, and is the most scientific and accurate method given uniform aggregates. Even this method requires some modification in the field, and further study is needed to adapt its rules to field conditions. The necessary procedure is complicated and has been the main obstacle to its general adoption. The presentation of the technique will therefore not be given here.

Proportioning by Arbitrary Proportions. The customary arbitrary proportions (1 : 1-1/2 : 3 or 1 : 2 : 4 for richer mixes, and 1 : 2-1/2 : 5 or 1 : 3 : 6 for leaner mixes) give fairly satisfactory results with well graded aggregates proportioned dry. Coarse aggregate measured loose contains from 30% to 55% voids, depending upon grading; dry sand from 30% to 40%. In a 1 : 2 mixture of fine and coarse aggregates, both reasonably well graded from coarse grains to fine, the fine aggregate would presumably fill the voids in the coarse aggregate with a little to spare as allowance for bulking of the coarse aggregate in the matrix. Aggregate under job conditions, however, contains moisture which causes it to bulk. This bulking is considerable for fine aggregate. Coarse aggregate bulks little from surface moisture. A very wet sand may bulk so that a measured quantity will contain only about 80% of the solid material measured dry. Therefore a 1 : 2 mix of fine and coarse aggregates measured under job conditions without allowance for bulking will sometimes be "undersanded" and result in a harsh mix. Modification of the standard proportions, according to the nature of the work and conditions on the job, is therefore necessary.

Proportioning by Judgment Based on Experience. On all ordinary work satisfactory results may be obtained by modifying arbitrary proportions as the work proceeds, according to the trained judgment of the engineer.

The following observations will be an aid to judgment:

(a) The larger sized aggregates, reasonably graded down from coarse to fine particles, will produce the more economical concrete, that is, one which will require less cement paste to make a concrete of given consistency or degree of workability. Thus a concrete of 1 part cement and 5 parts of mixed fine and coarse aggregate well graded down from particles 2 in. in diameter will have about the same consistency or degree of workability as a concrete of 1 part cement and 4-1/2 parts of mixed fine and coarse well graded down from particles 1 in. in diameter. In this connection it may be noted that the volume of mixed fine and coarse aggregates will be about 85% of the sum of the volumes of the separated aggregates.

(b) Larger ratios of coarse to fine aggregate may be used with the larger size aggregates; thus with a 2-in. coarse aggregate the fine and coarse may well be mixed in the proportion of 2 : 3-1/2 whereas a 1-in. coarse aggregate will require a larger proportion of the fine to make a smooth working mixture, say 2 : 3. Too little fine aggregate tends toward harshness and leads to the danger of honeycombing. Too much, on the other hand, will produce porous concrete of low density. The yield in cubic yards of concrete for a given quantity of cement is also less for mixes containing larger proportions of fine aggregate relative to coarse aggregate. The best proportion depends upon the grading and other characteristics of the aggregates.

Summary of Procedure. (1) Select coarse aggregate of the maximum size appropriate for the work, say 1/1-2-in. to 3-in. for exclusively mass work; 1-1/2-in. for heavy reinforced-concrete work (heavy reinforcing bars with at least 2-in. clear spacing); 1-in. for light reinforced-concrete work. (2) From Fig. 6 determine the water-cement ratio for the strength concrete required. For example, for a 2000-lb. concrete, and using curve B (if moisture contents of aggregates are estimated from tables instead of being determined by tests) we find the required water-cement ratio to be 0.9. Quantity of water per bag of cement (about 1 cu. ft.) $= 0.9 \times 7.5 = 6.75$ gal.

(3) Determine the water content of the aggregate by test as previously explained, or, approximate from the following table:

Sand, very wet	3/4 to 1 gal. per cu. ft.
moderately moist	about 1/2 gal. per cu. ft.
moist	about 1/4 gal. per cu. ft.
Coarse aggregate, moist	about 1/4 gal. per cu. ft.

Deduct such amount from the quantity determined above in (2) to obtain the quantity of added mixing water.

(4) Adopt tentative proportions of cements: fine aggregate: coarse aggregate as follows:

1 : 2 : 3-1/2 for maximum size aggregate 2 in. or over.

1 : 2 : 3 for maximum size aggregate 1 in.

and proportionately for intermediate or smaller sizes.

If it so happens that the aggregates are well graded and have been measured dry (stock piles containing little moisture) the proportion of coarse aggregate to fine may be increased without resulting in harshness. The yield in concrete per unit volume of cement will be slightly increased thereby.

If, however, the first trial mix proves, for some aggregates, to be harsh, the proportion of coarse aggregate to fine may be decreased until smoothness is reached. Avoid, however, excessive proportions of the fines, for reasons before stated. Smoothness may also be secured by increasing the cement content.

Vary the consistency or degree of workability required for various portions of the work by varying the quantity of total aggregate per unit volume of cement; but always maintain the predetermined ratio of water and cement.

An idea of the relationship between consistency, size of aggregate and water-cement ratio may be gained from the following table furnished by the Portland Cement Association:

Consistency	Trial mix, dry compact volumes for maximum size of aggregate indicated	
	1 in	2 in
Water-Cement Ratio, 5-1/2 Gals. per Sack		
Stiff	1 : 2 : 3	1 : 2 : 3-1/2
Plastic	1 : 1-3/4 : 2-1/2	1 : 1-3/4 : 3
Soft	1 : 1-1/2 : 2	1 : 1-1/2 : 2-1/2
Water-Cement Ratio, 6 Gal. per Sack		
Stiff	1 : 2-1/4 : 3-1/4	1 : 2-1/4 : 4
Plastic	1 : 2 : 3	1 : 2 : 3-1/2
Soft	1 : 1-3/4 : 2-1/2	1 : 1-3/4 : 3
Water-Cement Ratio, 6-3/4 Gal. per Sack		
Stiff	1 : 2-1/2 : 3-1/2	1 : 2-1/2 : 4
Plastic	1 : 2-1/4 : 3-1/4	1 : 2-1/4 : 3-3/4
Soft	1 : 2 : 3	1 : 2 : 3-1/2
Water-Cement Ratio, 7-1/2 Gal. per Sack		
Stiff	1 : 3 : 4	1 : 3 : 4-3/4
Plastic	1 : 2-1/2 : 3-3/4	1 : 2-1/2 : 4-1/4
Soft	1 : 2-1/4 : 3-1/2	1 : 2-1/4 : 3-3/4

Water-cement ratios indicated include moisture contained in the aggregate.

Proportions are given by **volume, aggregate dry** and **compact.** Thus 1 : 2 : 3-1/2 indicates 1 volume of cement, 2 volumes of sand and 3-1/2 volumes of coarse aggregate.

If the aggregates are to be measured in the **damp** and **loose** condition they will occupy greater volume than when dry and compact. Amount should be determined by test. Approximate average value for sand 20%, for coarse aggregate 6%.

For approximate proportions **by weight** add 15% to proportions of aggregate shown in the table.

Absorptive Aggregate. The particles of light and porous aggregates will absorb an appreciable amount of water and for such condition a corrective addition to the quantity of mixing water may be made. This correction may be determined by means of the absorption tests recommended by the American Society for Testing Materials (1920 Proceedings, Part 1, Appendix 2, Report of Committee C-9). A rough test may be made by thoroughly drying samples in an oven to expel all absorbed water, weighing the sample, immersing in water for about half an hour, then removing surface water by spreading out for a period in the air so that the surface water is evaporated, and then weighing. The difference between the two weighings will indicate the amount of absorbed water. Very light and porous aggregate may absorb as much as 25% by weight of water; porous sandstone 7%. Average sand, pebbles and crushed limestone particles will absorb about 1% by weight; trap rock and granite 1/2%, and for these no correction need be made.

Yield. The yield in concrete of a given mix may be easily determined due to the fact that the volume of concrete is equal to the sum of the absolute volume of its ingredients, which may be calculated from the weights per unit volume.

One sack of cement (assumed 1 cu. ft.) weight 94 lb. The specific gravity of cement being 3.1, the "absolute weight" of a cubic foot of solid particles would be $3.1 \times 62.5 = 194$ lb.

The specific gravity of the aggregates may be assumed as 2.65; hence the "absolute weight" of the material of which it is composed is $2.65 \times 62.5 =$ 165 lb.

For a concrete mixture of 1 sack cement, 2 cu. ft. fine aggregate, 3-1/2 cu. ft. coarse aggregate, and 7 gal. (0.93 cu. ft.) water, the yield in concrete would then be calculated as follows:

First $\begin{cases} \text{weigh 1 cu. ft. fine aggregate (say 110 lb.)} \\ \text{weigh 1 cu. ft. coarse aggregate (say 100 lb.)} \end{cases}$

Calculate:

From cement $\frac{94}{194}$ = 0.49 cu. ft.

From fine aggregate $\frac{110 \times 2}{165}$ = 1.33 cu. ft.

From coarse aggregate $\frac{100 \times 3\text{-}1/2}{165}$ = 2.11 cu. ft.

From water 0.93 cu. ft.

Yield in concrete.............. 4.86 cu. ft.

7. Field Measurement of Materials

The application of accurate proportioning necessitates accurate measurement of materials for the mixer. The measurement of the cement is easily done by counting the bags. On important work close measurement of the aggregates by means of calibrated bottomless boxes should be required. Attempts to measure the aggregates by calibrating the barrows, carts or buckets used to convey the materials to the mixer are not effective. Unless measuring boxes are used it is better to adopt arbitrary proportions (say 2 to 3 or 2 to 4) of fine to coarse aggregate and rely on struck loads.

Accurate measurement of water should be demanded on all structural work and rigid inspection at the mixer should be provided. Reliable water measuring devices are on the market and installation of an approved device tested by experience should be required of the contractor.

Of equal importance with correct proportioning are proper mixing, transporting, depositing and curing. Neglect of proper observance of any one element will vitiate the good results of observance of all the others.

8. Mixing

Mixing of the ingredients must be thorough, so that fine and coarse particles of aggregate will be uniformly distributed, so that the water and cement will be intimately incorporated to cause complete hydration of cement, so that the water voids caused by the unavoidable excess will be well distributed in the mass, and so that the aggregate particles will be completely coated with the cement paste. A minimum of one minute actual mixing, after all ingredients including the water, are in the mixer, should invariably be demanded.

A batch a minute from a batch mixer means a net time of mixing after all the materials are in, of little more than half a minute. Fig. 6 shows the effect of **time of mixing** upon the **strength of the concrete.** Thorough mixing also **increases the workability** of the mix and makes it easier to place in the forms. It is also essential for watertight construction. Speeding up a rotary mixer by increasing the revolutions per minute has little effect in reducing the time required to produce the desired results; it is the time element rather than speed element that is important in mixing. Time of mixing also affects **uniformity of product.** Test specimens made of concrete mixed 15 seconds may show a mean variation of 30% in strength whereas those mixed 2 minutes should vary less than 10%.

Machine Mixers are of two general types, (1) the batch mixer and (2) the continuous mixer. In the batch mixer the proper amounts of material for a single "batch" of concrete are placed in the mixer and the contents are then mixed either by means of moving paddles or blades, or by the rotation of the receptacle itself, in which are generally placed deflectors to aid in the mixing. In the continuous mixer the operation is continuous, more or less adequate provision being made for maintaining the proper proportions of materials.

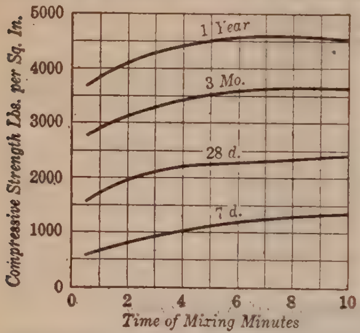

Fig. 6

The gravity mixer is a type of continuous mixer into which the material is introduced at the top and is mixed by striking various obstructions or deflectors in its descent. Continuous power mixers utilize some form of screw or paddle blades.

Although good results may be secured by either type, the correct proportions are more readily secured in the batch mixer and it is generally to be preferred, especially for small plants where the supervision is likely to be inadequate.

9. Transporting

The effect of methods of transporting concrete from the mixer to the forms upon the quality of the set concrete is of prime importance.

(1) Concrete should be transported quickly enough so that it will not get its initial set before its manipulation in the form has ceased. Since initial set should not occur within 45 minutes after mixing there is little danger from a violation of this principle except where there is a central mixing plant for several jobs and transportation is by truck. In such case avoidable delays by drivers may be prevented by a time checking system.

(2) The mode of transportation should prevent segregation or loss of materials. Buckets, chutes, belts of conveyors, etc., should be watertight so that the cement will not be lost from the mix. Chutes should be at such an angle (not less than 30 deg. with the horizontal) that the coarser materials will not be left behind. Continuous delivery from the chute will help to prevent segregation.

10. Depositing

The results of all previous care may be lost to a great degree by lack of care in depositing.

(1) Concrete must be deposited evenly in the forms in uniform layers and not allowed to pile up. Localized delivery causes the more liquid mortar to flow away from the aggregates and not only impoverishes part of the concrete but promotes the formation of laitance from the segregated cement and water, which has been discussed in Art. 6. In beam and slab floors the beams should be completely filled first; the concrete should not be dumped on the slab floor and allowed to flow into the beams thus causing segregation. The temptation to localize delivery from chutes, particularly in high walls, is very great.

(2) Concrete should be deposited so as to prevent as far as possible the entraining of air. Concrete should not be dropped from a height of more

than 5 ft. without the aid of a pipe or chute. It should be puddled or tamped so as to expel entrained air as well as to insure complete filling of the forms and close contact with reinforcing steel. In inaccessible forms as for thin walls, the outside of the forms should be tapped vigorously with automatic air hammers or with sledge hammers or mauls.

(3) Concreting should proceed without interruption so far as possible in order to prevent stoppage planes by the formation of laitance under initial set. Stoppage planes are only less pronounced than days' work planes.

(4) Concrete should not be deposited during freezing weather without special precautions, since it hardens very slowly at low temperatures. Freezing of the water while setting exerts a tremendous disruptive force which disintegrates the concrete and invariably causes failure although concrete frozen **before** setting will sometimes set up after thawing, with apparently little harmful effects.

If it is necessary to deposit concrete in cold weather, the aggregates throughout their mass and the water should be heated, but the water must not be so hot as to cause flash-set of the cement. The concrete should be delivered into place at a temperature above 50° F. but not over 100° F., and all materials should be heated to within these limits. A sheet-iron pipe or inverted trough buried in the aggregates and fired with wood is the usual method of heating small quantities of aggregates. Large quantities are sometimes heated by a network of steam pipes underlying the storage piles.

(5) Fresh concrete must be protected from the action of flowing water. In ordinary construction excavations should be unwatered. When ground-water is encountered, it is advisable to enlarge the excavations one or two feet in all dimensions, build the forms to dimension and surround them with a channel to lead the ground-water to a sump whence it may be removed without disturbance to the fresh concrete until it has set. Where springs are encountered, the water should be piped and led away from the area upon which concrete is to be placed.

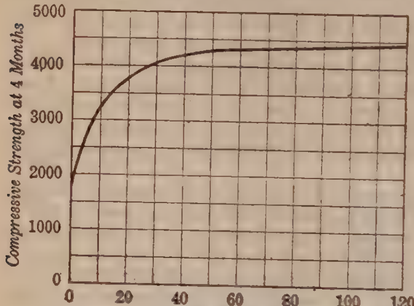
Under-water Concrete. In marine work proper, concrete may be lowered through the water by means of tightly closed buckets which may be opened at the bottom and discharged when in contact with the concrete already deposited; or, it may be deposited through a pipe or tremie. The latter method is usually to be preferred both on account of the better results obtained and on account of economy of operations.

Depositing by Tremie. Concrete may be placed under water through a tremie or watertight pipe 12 in. to 24 in. in diameter, having a conical shaped top the better to receive the charge of concrete. At the start of operations the mouth of the pipe is set on the bottom and the pipe filled with concrete. The pipe is then slowly raised, allowing the concrete to flow out as more concrete is poured in at the top, always keeping the pipe fully charged. It is essential, once the concreting operations are started, that the lower end of the pipe be kept buried in the concrete until the entire operation is completed. In this manner, washing out of the cement is prevented. The upper layer of concrete displaces the water, and laitance is kept at the surface of the concrete whence it may be finally and effectively removed. If at any time during the operations the bottom of the pipe loses contact with the concrete, the charge will be lost; therefore particular care must be taken in continuing operations not to stir up the fresh concrete in place. Tremie operations should be continuous until the structural unit has been completed.

Tremie concrete must be of a consistency that will permit it to flow readily and it therefore requires more cement and water than concrete placed in the dry.

11. Curing

Proper curing of concrete after setting is an important factor for successful work, as indicated in Art. 1. Excess mixing water is an evil. There is no danger from an excess of curing water. Fig. 7 shows graphically the value of proper curing. Keeping concrete wet for the first ten days after setting increases its strength and durability 75% over that which might be expected from its ordinary aging. Three weeks' curing shows 115% gain and four weeks' curing shows 145% gain. These results were observed from compression cylinder tests as follows: Specimens A were allowed to harden in air for four months and then tested — 1800 lb. per sq. in. Specimens B were cured in damp sand 3 days, kept in air the remaining 117 days and tested — 2100 lb. per sq. in. Specimens C were stored in damp sand 21 days, kept in air the remaining 99 days and then tested — 3900 lb. per sq. in. Specimens D were stored in damp sand the full 120 days and then tested — 4400 lb. per sq. in.



Storage - Days in Damp Sand Followed by Air Storage until Tested. Total Age 4 Months

Fig. 7

Concrete structures should be cured by adequate means. Drenching the forms with water before placing concrete will reduce absorption. Horizontal surfaces such as floors and pavements can be covered with damp sand the day after they are laid when they have hardened sufficiently to prevent pitting the surface, and kept damp by frequent sprinkling. Sometimes small dikes of clay are built around a section of floor or pavement, which is then flooded by water. Vertical surfaces can be kept damp by frequent sprinkling of the forms or exposed concrete. Sometimes walls are coverd with canvas or burlap which is drenched with water several times a day. In road work continuous drenching from sprinkler heads is something practical.

For like moisture-curing conditions, the time required for concrete structures to set and develop a given strength depends upon the external temperature maintained during the period of curing and also upon the rate of dissipation of internal heat generated by the chemical reactions of setting, as affected by massiveness. Fig. (8) shows graphically the effect of temperature upon the rate of strength increment of small test specimens for which the dissipation of internally generated heat would be rapid.

Measurements of the internal heat generated within massive structures have been made by embedding thermometers and making observations. Fig. 9 shows the results observed during the construction of the Arrowrock Dam by the U. S. Reclamation Service near Boise, Idaho (" Temperature Changes in Mass Concrete," by Chas. H. Paul and A. B. Mayhew, Trans. Am. Soc. C. E. 1915).

The resultant effect of external temperature, generation of internal heat and rate of radiation upon the curing of structures in general is largely a matter of guess. Massive structures will not require elaborate cold-weather protection to develop early strength. Structures having relatively thin sections, such as reinforced-concrete buildings and bridges, do require careful **cold-weather protection** to develop sufficient strength to permit early removal of supporting falsework. It is probable that many so-called inexplicable cold-

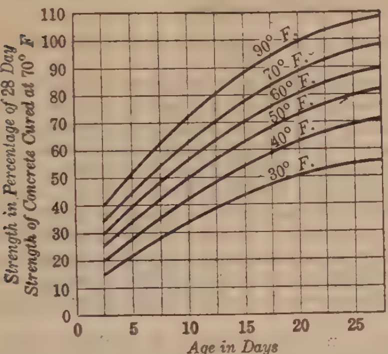


Fig. 8

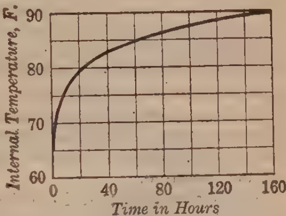

Fig. 9

weather failures are due to slow setting at low temperature or to actual freezing. In such construction cold-weather protection by enclosure and heating by salamanders may be necessary but this does not warrant dispensing with preheating the materials since the transference of heat through forms is slow.

12. Miscellaneous Notes

12a. Effect of Cold Weather Concreting

Although the rate of strength increment is slow at low temperatures, cold weather concreting need not be detrimental to the final quality of the product. If actual freezing is prevented during the setting process, and supports are left in place sufficiently long to permit the concrete to develop self-sustaining strength, there need be no concern as to the effects of low temperatures upon final quality. Supports for structures should not be removed, however, without making due time allowance for delayed rate of setting or until a sufficient period of warm weather has intervened.

12b. Construction Joints

Proper treatment of construction joints, stoppage planes or days' work planes is of vital importance and is too frequently neglected. Even in structures not required to carry a head of water, improperly treated joints permit percolation and disfigurement by efflorescence, besides being an element of structural weakness. An almost perfect joint can be made if mixing water is properly regulated to prevent excess, if the more liquid portions of the concrete are not allowed to segregate in transporting and depositing, if the surface of the concrete in place is thoroughly scrubbed with stiff wire brushes to remove laitance completely so that clean aggregates are exposed; and if the surfaces are again drenched before concreting proceeds and coated with a rich thin mortar, just before the fresh concrete is placed. The procedure may seem to be "fussy," but it is easy of execution and the results will pay both in avoiding unsightliness and planes of weakness. The formation of efflorescence on the surfaces of completed structures in which the concrete was not properly placed will appear sometimes promptly, sometimes after the lapse of considerable time.

12c. Payment for Concrete

Payment for concrete is usually by the cubic yard measured in place in the completed work.

Complete control of the proportions, however, is predicated on the use of sufficient cement to keep the water-cement ratio constant and at the same time give the required degree of workability. Since the contractor has necessarily based his bid upon the assumption of definite proportions, orders to increase cement content instead of merely adding water to increase workability will invariably lead to disputes, and as a matter of fact equity is on the side of the contractor, despite the technique in the matter. Specifications calling for strength concrete do not solve the question. No court would uphold orders to replace, extensively, structures for which the field tests of concrete indicated inferior quality. The real responsibility rests with the engineer, and the contractor is entitled to payment for the materials entering the construction in so far as is possible.

A separate payment item for the number of barrels of portland cement ordered to go into the concrete should be provided and payment for this amount should be made in addition to the number of cubic yards of concrete in the work. Cause for argument will be removed and responsibility for the quality of the product will be indisputably in the hands of the engineer where it belongs.

13. Admixtures

Various admixtures are sometimes used to increase workability; to increase impermeability or watertightness; to hasten setting; to facilitate curing; etc. In general the judicious use of such admixtures is not harmful and may be beneficial to the leaner mixtures; they are as a rule, however, palliatives and unnecessary in high-grade work.

Anti-freezing Admixtures. Admixtures to prevent freezing may be used with judgment in moderately cold weather to avoid expensive housing, but should not be relied upon when extremely cold weather is likely to follow.

Common salt (NaCl) is sometimes used to prevent freezing, though it retards the setting process and somewhat reduces the strength of the concrete. About 1% by weight to that of the mixing water is required to lower the freezing point each degree below 32° F. Up to 10% it is not particularly harmful to concrete if the tendency to reduction of strength is overcome by the addition of a little excess cement.

Calcium Chloride ($CaCl_2$) is used as an anti-freezing compound and also to accelerate setting and assist the curing process. It may be safely used up to 4% by weight to that of mixing water. With concrete cured at low temperatures a mixture of 2% calcium chloride and 9% common salt is more effective as an anti-freezing compound than common salt alone. 2% calcium chloride is effective as an accelerator for road concrete and permits opening the road to traffic in less time than ordinarily required.

Workability Admixtures. Neutral admixtures such as the diatomaceous earths (marketed under such trade names as diatomite and celite), kaolin and hydrated lime, are designed to increase workability and act as a void-filler to increase imperviousness. The amount of such admixtures that can be used beneficially depends upon the quality of the concrete and the character of the aggregate. It is more beneficial to the leaner mixes. Beyond the point of maximum of density these admixtures begin to decrease the strength by reducing cohesion. A rule for the " judicious use " of such admixtures as given by Pearson and Hitchcock, Proc. American Concrete Institute, Vol. 20, 1924, is as follows: percentages being by weight relative to the cement: For concretes leaner than 1 : 1-1/2 : 3 the maximum percentage of celite used should be equal to the index number for the coarse aggregate; of kaolin, to twice the same index number; of hydrated lime, three times the same index number. For example, for 1 : 3 : 6 concrete the maximum percentages would be 6 for celite, 12 for kaolin, 18 for hydrated lime. Some engineer-chemists claim that siliceous admixtures may be used to advantage in sea-water concrete to combine with the free lime of the cement into a calcium silicate and prevent the combination of the free lime with the magnesium sulphate and chloride of the sea water into a calcium sulphate which is expansive, soluble and destructive to concrete. Two pounds of a siliceous admixture per bag of cement is the usual proportion.

Clay. Clay acts much the same as lime. Finely divided and evenly distributed, it fills the voids of lean mixtures and improves quality, while reducing the cohesion of rich mixes.

Oils. Mineral oils are sometimes used in gaging concrete to increase workability and imperviousness. Up to 5% or 10% by weight of cement they lower the strength of ordinary concrete but little. In excess they are injurious. Some commercial oils for concrete contain oils of organic origin in addition to the mineral oils and are very detrimental. Rich mixes designed for imperviousness require no waterproofing compounds.

14. Watertight Concrete

The best concrete is watertight. Strict observance of the rules outlined in the preceding text will result in a strong, durable, impervious material without the use of waterproofing compounds. To obtain the required density for watertightness the water content of the mix should be kept low, say 6 gal. per sack of cement, which will require possibly a 1 : 2 : 3 or 1 : 1-1/2 : 2 mix for workability so that it will compact properly. Mix thoroughly, prevent segregation in transporting and depositing, spade or tamp 6 or 8-in. layers in the forms to break up stone pockets and expel entrained air, cure thoroughly. Tanks and other structures to be subjected to hydrostatic pressure should be thoroughly cured before the pressure is applied. If construction joints are unavoidable observe the rules for bonding new concrete to old, strictly. Abundant experience has shown that care will produce the desired results.

In tests conducted by the U. S. Bureau of Standards, thin slabs of a lean (1 : 6) portland cement mortar and 1 : 1-1/2 : 2 concrete were subjected to a water pressure of 60 lb. per sq. in. This pressure is equivalent to a 138-ft. head of water. Although water penetrated through 1-5/8-in. limestone slabs in periods ranging from 20 seconds to 20 minutes, it took 3-1/2 hours for water to penetrate through a 2-in. slab of 1 : 6 mortar, while at the end of 24 hours, when the test was terminated, the 2-in. slab of 1 : 1-1/2 : 2 concrete was still dry.

Hundreds of concrete tanks are being used for the storage of fuel oil, which is lighter than water, and these tanks are oiltight, and of course watertight. Concrete basements, pits, bridges, and tanks will also be watertight if proper care is taken in their construction. Experience and tests have shown that proper practice will make watertight concrete.

15. Follow-up Tests of Concrete

Field tests of concrete afford a means of determining the effectiveness of the field control of concrete. It is not to be expected that the tests on the standard compression-test cylinders sampled from mixes in the field would agree very closely with tests on blocks cut out from the completed structure, when such tests are made, or that they prove the exact quality of concrete in the work. Such factors as differences in curing conditions, differences in degree of compactness due to static head and a variety of other factors would be reflected in the results. Such tests are, however, an approximate indication of the quality of the concrete if the material in the form is representatively sampled and if a sufficient number of test specimens are made to reflect daily variation.

Since the test specimens are small, they should be made with strict observance of a rather elaborate technique, and should be stored and cured under standard conditions and tested in an exact manner in order to be of any value at all.

Appendix 6 describes the proper method of making and storing concrete test pieces.

If test cylinders are tested at 7 days' age, the 28-day strength may be approximately estimated by the following formula $S_{28} = S_7 + 30\sqrt{S_7}$.

Test cylinders should be cast in pairs; at least one pair for each 100 cu. yd. of concrete placed, or a minimum of two pairs for each day's work. The samples of concrete should be taken at the point of delivery and be as representative of the product as possible.

16. Forms for Concrete

General Requirements. Forms for concrete should be strong and rigid and should be tight enough to prevent leaking of the mortar. The material should be planed on one side and be of even thickness if a smooth face is desired. This is generally advisable for convenience in handling. Material which warps readily, such as hemlock or oak, is not desirable. Pine or spruce is commonly the best available material. For repeated use in built-up sections, tongued and grooved material is to be preferred.

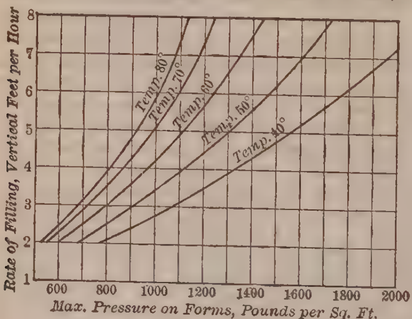

Fig. 10. Pressure of Concrete

Pressure of Concrete. The pressure of wet concrete, such as is frequently used, will be the full hydraulic pressure of a liquid weighing about 150 lb. per cu. ft., until initial setting begins. If the forms are to be filled before this occurs they must be designed for the full pressure. If setting begins while the work is in progress, then the maximum pressure will be less than the full hydrostatic pressure, this maximum limit depending upon the rapidity of filling and rate of setting of the concrete. It will therefore depend largely upon the existing temperature. Results of experiments made by F. R. Shunk on the maximum pressure of concrete are shown in Fig. 10. This diagram gives the maximum pressure which occurred for various rates of filling and at various temperatures. The tests were made by means of a pressure board 9.23 in. in diameter, set into the side of a form supporting a large mass of concrete. The concrete was made of 1 : 3 : 5-1/2 proportions and was very wet, the workmen sinking into it about 18 in. (Eng. News, Sept. 9, 1909.)

Design of Forms. Either 1-in. or 2-in. stuff is suitable for lagging but, excepting for small parts, 2-in. is preferable. One-inch stuff requires supports spaced 18 to 24 in. apart and 2-in. stuff a spacing of 4 to 5 ft. Studding or joists should be 2 in. by 4 in. to 2 in. by 5 in. for 1-in. lagging, and 4 in. by 6 in. up to 4 in. by 10 in. for 2-in. lagging. Forms for opposite faces of walls of ordinary thickness should be connected together by ties designed to take the full pressure. Thus connected, the outside bracing need be only sufficient to steady the forms as a whole while the concrete is being placed. Forms are conveniently connected by wire twisted into a sort of turn-buckle for adjustment. Iron rods fitted with nuts are more readily adjusted. These may be passed through small pipes cut slightly shorter than the thickness of the wall, which are afterwards filled with cement.

Where no cross ties are used the entire pressure must be borne by outside props placed, generally, as diagonal struts. Great pains must be taken to secure the ends of such struts from settlement. Rigidity is as important as strength, and deflections of forms should be limited to very small amounts.

Column Forms should be made of 2-in. plank and well clamped together to resist the heavy pressures involved. They are conveniently held together by wooden blocks connected by bolts and adjusted by wedges as shown in Fig. 11. Care must be taken to see that the bottoms of column forms are thoroughly clean before pouring concrete. To render this easy and certain it is advantageous to arrange a small removable panel at the base of the form.

Beam Forms are preferably made of 2-in. stuff. The bottoms should be well supported and the sides held together by wedges or clamps. Wedges are also conveniently used at top or bottom of the supporting struts.

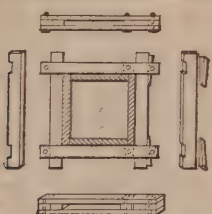

Fig. 11. Form for Column

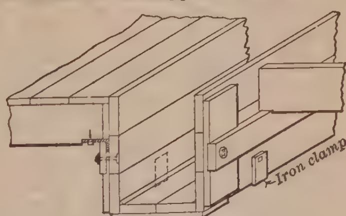

Fig. 12. Form for Beam

Slab Forms are made of 1-in. or 2-in. stuff. If the former is used it should be supported on joists spaced not more than 2 ft. apart. Joists are conveniently supported on 2-in. strips fastened to the sides of the beam forms or may be independently supported. Fig. 12 shows a typical arrangement of beam and slab forms.

Adhesion of Concrete to the forms can be prevented by oiling the forms with crude oil, soap or other greasy material. This aids also in preventing warping. If not oiled the forms should be thoroughly wet before placing the concrete. This is especially necessary in hot dry weather.

Wall Forms. Forms for thin walls are generally made to be supported by the concrete already in place. Fig. 13 shows a common arrangement. The bolts and slotted holes enable the sections to be raised conveniently as the work proceeds.

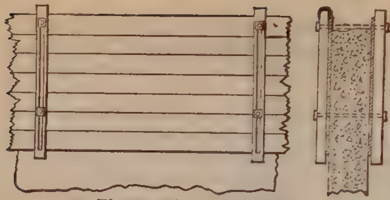

Fig. 13. Form for Wall

Removal of Forms should be done only under expert supervision. In warm weather column and wall forms can be removed in 2 to 4 days, slab forms in 10 to 15 days, and beam forms in 2 to 3 weeks. Low temperatures require much more time for hardening. Forms should be removed very carefully and gradually and the concrete examined before general removal is ordered.

17. Quantities of Material for One Cubic Yard of Compacted Concrete

(Without allowance for waste)

Based on 3.8 cu. ft. per bbl. of cement. Sand and stone measured loose

Proportions by volume			Ratio: Mortar / Stone	Quantities of material		
Cement	Sand	Stone		Cement, bbl.	Sand, cu. yd.	Stone, cu. yd.
1	1	1-1/2	0.98	3.10	0.44	0.65

REINFORCED CONCRETE

18. Reinforcement for Tension

Concrete having very little tensile strength must be reinforced with steel when subjected to bending stresses. In beams and slabs the usual amount of main tension steel is about 3/4% to 1% of the cross-sectional area of the beam; the size of the rods or bars depending upon the size (as to cross-section) of the beam; say 1/2-in. for thin floor slabs; from 3/4-in. to 1-1/4-in. for rectangular beams; structural shapes for very heavy girders. Plain round rods are sometimes used though the use of deformed rods (having depressions or projections) is general practice in order to increase the grip or bond between the concrete and steel. Four types of deformed bars are illustrated in Fig. 14.

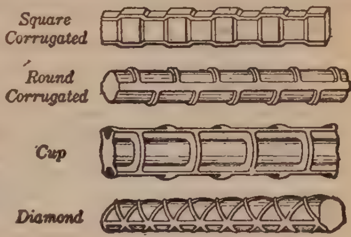

Fig. 14

Standard specification for reinforcing steel is given in Appendix 5.

Adhesion of Concrete to Steel. The grip or bond between concrete and plain rods (clean but not too smooth) depends somewhat upon the quality of the concrete — in general the stronger the concrete the higher the bond.

Bond stress is determined in two ways: (1) by direct pulling out of a rod embedded in a concrete block; (2) by embedding the two ends of a rod in a concrete beam (the middle of the rod being exposed by a recess in the beam) subjecting the beam to bending by loads and measuring the stress in the exposed middle portion of the rod by means of strain-gage readings. The latter method gives somewhat lower results than the former. Under test, initial slip of plain bars, indicating the destruction of pure adhesion, occurs at about 2/3 the maximum bond stress, after which frictional resistance comes into play until the maximum is reached. Maximum bond stress is in plain bars about 20% of the compressive strength of the concrete.

Deformed bars behave under test as do the plain rods up to the point of maximum bond of the plain rods. Beyond this point the bond of plain rods falls off rapidly up to failure, whereas the bond of the deformed rods continues to increase due to the abutting action between the concrete and the bar projections. Maximum bond of deformed bars at a slip of 0.05 in. is about 50% greater than the maximum bond of plain bars at a slip of 0.01 in.

Ordinary rust increases the bond. Mill or rust scale, however, destroys it.

Bond of flats is much less per square inch than the bond of square or round rods.

Right-angle bent ends do not affect initial slip but increase ultimate bond near the hook about 50%.

Hooked ends — 180° semicircular bends with a short length of straight beyond the bend — are more effective, increasing ultimate bond near the hook about 100%.

19. General Principles of Design

Use and Advantages of Reinforced Concrete. Steel is a material especially well suited to resist tensile stresses, and for such purposes the most economical form, the solid compact bar, is well adapted. A disadvantage in the use of steel in many locations is its lack of durability, thus rendering it necessary to add a protective covering to prevent corrosion and injury from fire. Concrete is characterized by low tensile strength, relatively high compressive strength, and great durability. It is a good fire-proof material and therefore serves both as a good inhibit of rust and as a good fire-proof covering for steel. A combination of steel and concrete constitutes a form of construction possessing in a large degree the advantages of both materials without their disadvantages.

For those structural members carrying purely tensile stresses steel must be employed, but it may be surrounded by concrete as a protection against corrosion and fire, or for the sake of appearance. For large and compact compression members plain concrete may be used. For more slender members, however, such as long columns, plain concrete is too brittle a material, and therefore too much affected by secondary and unknown stresses to be satisfactory; and for such members steel alone, or the two materials in combination, will preferably be used. For those structural forms in which both tension and compression exist, that is to say, in all forms of beams, the combination of the two materials is particularly advantageous. In this form the tensile stresses are carried by the steel and compressive stresses by the concrete.

Some of the most important types of construction in which reinforced concrete can be advantageously employed are the following: In buildings, for floors or for the complete structure; in foundations, especially where broad footings are required; in culverts and small beam bridges; in retaining walls, dams and abutments; in arch bridges; in bins and tanks for coal, grain and other material; in conduits and pipe lines subjected to low pressures; in chimneys and towers; and in separate structural forms such as piles, railroad ties, poles, etc.

General Assumptions in Calculations. In calculations of stresses and sections of reinforced-concrete structures the following general principles are usually followed:

(1) Calculations are made with reference to working stresses and safe loads rather than with reference to ultimate strength and ultimate loads, although some prefer to calculate ultimate loads and then apply a safety factor.

(2) Perfect adhesion is assumed between concrete and reinforcement. Under compressive stresses the two materials are therefore stressed in proportion to their moduli of elasticity. Under tensile stresses this relation also holds up to the ultimate strength of the concrete.

(3) Inasmuch as the extensibility of concrete is small, its tensile resistance is usually neglected and the entire tensile stress is assumed to be taken by the reinforcement. Where the stresses are very small, as frequently occurs in arches, the resistance of the concrete is sometimes considered. Certain beam formulas also take account of the tensile resistance of the concrete.

(4) Under working stresses the modulus of elasticity of concrete in compression is constant and the variation of compressive stress on a section of a beam is therefore rectilineal. The variation of tensile stress is also rectilineal and at the same rate. For ultimate loads a curvilinear law is usually assumed, the parabola being a convenient approximate curve to use.

(5) In beams, a plane section before bending remains plane after bending.

(6) Initial stress in the reinforcement due to contraction or expansion in the concrete is neglected.

20. Theory of Reinforced Beams

General Arrangement of the Reinforcement. The purpose of steel reinforcement is to carry the principal tensile stresses, the concrete being depended upon for the compressive and direct shearing stresses. If no steel were present the concrete would tend to rupture on lines perpendicular to the direction of maximum tension, as shown in Fig. 15, and hence we may conclude that the ideal tension reinforcement would require the steel to be distributed in the beam along the lines of maximum tension.

Fig. 15

Fig. 16

Fig. 16 shows by the dotted lines the lines along which failure of the concrete in a reinforced beam tends to occur. The inclined full lines show how the beam may be reinforced against such failures.

Where the shearing stresses exceed about 50 lb. per sq. in. some form of shear reinforcement is necessary. Fig. 17 shows various methods of arranging

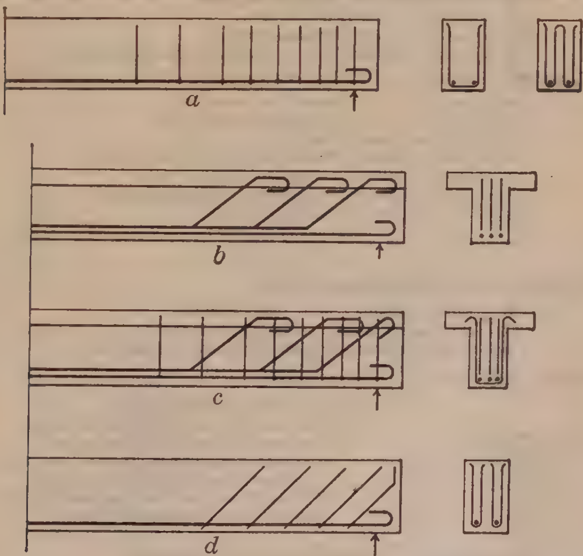

Fig. 17. Methods of Shear Reinforcement

such reinforcements. Figs. (*a*) and (*c*) show the use of vertical stirrups and Fig. (*d*) inclined stirrups. Inclined stirrups must be firmly fastened to the horizontal rods. For maximum strength form (*c*) or (*d*) should be used.

Methods of Failure. A reinforced-concrete beam tested to destruction will usually fail in one of three ways: (a) By the yielding of the steel at or near the section of maximum bending moment. (b) By the crushing of the concrete at the same place. (c) By a diagonal tension failure of the concrete at a place where the shear is large.

General Results of Tests. From the results of tests made by various experimenters the following general conclusions may be drawn:

(1) The elastic limit or, more strictly speaking, the yield point of the steel, may safely be taken as its ultimate strength in reinforced beams.

(2) The crushing strength of concrete as determined by tests on cylinders hardened under similar conditions will be fully realized in the beam.

(3) The usual shearing strength for beams reinforced with straight rods only is from 100 to 150 lb. per sq. in., but this can readily be increased by the use of proper web reinforcement to 300 or 400 lb. per sq. in.

(4) Steel used on the compressive side of beams is stressed in accordance with the usual assumptions.

Flexure Formulas for Working Loads. Assumptions: Rectilineal law of stress variation is assumed and the tension in the concrete is neglected. The notation used is as follows:

For Rectangular Beams:

$\mathbf{f_s}$ = tensile unit stress in steel.
$\mathbf{f_c}$ = compressive unit stress in concrete.
$\mathbf{E_s}$ = modulus of elasticity of steel.
$\mathbf{E_c}$ = modulus of elasticity of concrete.
M = moment of resistance, or bending moment in general.
$\mathbf{M_c}$ and $\mathbf{M_s}$ = moments of resistance with respect to the concrete and the steel.
A = steel area. b = breadth of beam.
d = depth of beam to center of tension steel.
t = total depth of beam.
k = ratio of depth of neutral axis to effective depth d.
z = depth of resultant compression below top.
j = ratio of lever arm of resisting couple to depth d.
jd = $d - z$ = arm of resisting couple.
$\mathbf{n} = Es/Ec$. $m = \dfrac{fs}{fc}$. $p = A/bd$.

For T Beams (in addition to preceding):

b = width of flange. b' = width of stem.
t = thickness of flange (see also t above).
p = steel ratio based on circumscribing rectangle bd.

For Beams Reinforced for Compression:

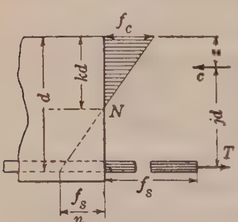

Fig. 18

$\mathbf{A'_s}$ = area compressive steel.
$\mathbf{p'}$ = steel ratio for compressive steel.
$\mathbf{f'_s}$ = compressive unit stress in steel.
C = total compressive stress in concrete.
C'' = total compressive stress in steel.
d' = depth to center of compressive steel.
z = depth to resultant of C and C'.

From Fig. 18 by proportion

$$\frac{k}{1-k} = \frac{f_cE_s}{E_cf_s} = \frac{n}{m} \qquad (1)$$

By composition

$$\frac{k}{k+(1-k)} = \frac{n}{m+n}\,nk = \frac{n}{m+n} \qquad (2)$$

From (2)

$$j = 1 - \frac{n}{3\,(m+n)} \qquad (3)$$

Since the total compression in the beam must equal total tension ($\Sigma H = 0$);

$$Af_s = \frac{bkdf_c}{2} = \frac{n}{m+n} \times \frac{bdf_c}{2}$$

from which
$$\frac{A}{bd} = p = \frac{n}{2\,m\,(m+n)} \qquad (4)$$

Assuming ratios for $m = \frac{f_s}{f_c}$ and $n = \frac{E_s}{E_c}$ equations (3) and (4) give all necessary solutions of a reinforced concrete beam. For $n = 15$ and $m = 24.5$ $\left(\text{as for example } \frac{16\,000}{650}\right)$ we have

$$j = 1 - \frac{5}{15 + 24.5} = \frac{7}{8}. \qquad p = \frac{15}{49 \times 39.5} = 0.0077$$

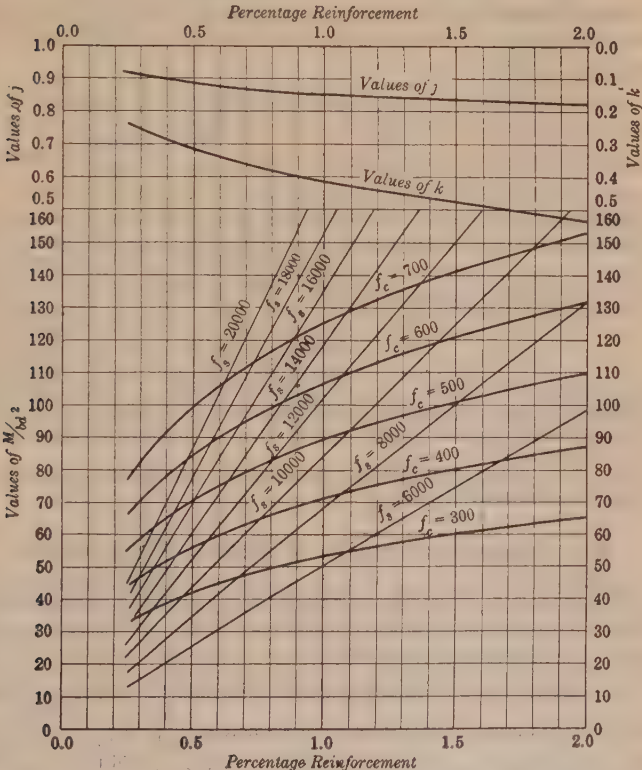

Fig. 19. Diagram for Reinforced Rectangular Beams. ($n = 15$)

The above values for j, p, m, n are usual values, hence for design calculations the moment of resistance of a beam

$$= 0.0077\,bdf_s \cdot \frac{7}{8}d = M \quad \text{or} \quad bd^2 = \frac{148\,M}{f_s}$$

Also (for n = 15), $bd^2 = \frac{10\,M}{f_c}$.

To design a beam for a bending moment of 416 000 in-lb. at 17 000 lb. in the steel and 700 lb. in the concrete $\left(\frac{17\,000}{700} = 24.5\right)$

$$bd^2 = \frac{148 \times 416\,000}{17\,000} = 3630. \quad \text{If } b = 12 \text{ in., } d^2 = 303 \text{ or } d = 17\text{-}1/2 \text{ in.}$$

$$\text{Cover} = \underline{\quad 2 \quad}$$
$$19\text{-}1/2 \text{ in.}$$

Use of Diagram Fig. 19. Fig. 19 gives values of k and j for various percentages of tensile reinforcement, also steel and concrete stresses for various values of $\frac{M}{bd^2}$ (for $n = 15$).

Assume a beam under bending moment 416 000 in-lb. to design for 16 000 lb. in the steel and 650 lb. in the concrete. At intersection of proper curves for unit stresses read to left $\frac{M}{bd^2} = 108$ or $bd^2 = \frac{M}{108} = \frac{416\,000}{108} = 3860$ and read to bottom $p = 0.77\%$. Various values of b and d will suit the case.

T-Beams. A T-beam may be treated as a rectangular beam $h\,w$ in Fig. 20 if the neutral axis as for a rectangular beam lies in the flange (at or above the bottom of the floor slab). In such case the T-beam is theoretically a rectangular beam with part of the neglected tension area of the concrete omitted, leaving sufficient stem to contain the reinforcing steel and resist longitudinal shear between the tension and compression flanges. If any considerable compression area of the enclosing rectangular unit is missing in the T-beam the structure will require special consideration. Derivation of formulas will not be given here.

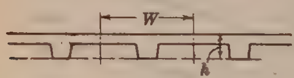

Fig. 20

Fig. 21 is a diagram for designing T-beams, the use of which will be illustrated in an example later on.

21. Over-reinforcement to Reduce Compression

From Fig. 19 it is seen that if the dimensions of a concrete section are for any reason limited, its moment of resistance may be increased (within limits) without exceeding allowable stresses by increasing the percentage of tension steel. The resulting steel stress will be low in order that the stress in the concrete may be kept within limits. For example, assume a beam 15 in. wide, 20 in. deep to carry a bending moment of 845 000 lb. without exceeding 16 000 lb. in the steel and 650 lb. in the concrete. $\frac{M}{bd^2} = \frac{845\,000}{15 \times 20 \times 20} = 141$. In diagram Fig. 19 find $p = 2\%$ for $f_c = 650$. f_s will then be a little less than 9000. Steel area $0.02 \times 15 \times 20 = 6$ sq. in.

It is usually considered better practice to keep the concrete stress within proper limits by over-reinforcement with tension steel as shown above, than by the use of compression steel. If, however, the compression steel is well tied into the concrete by inverted stirrups so as to make the compression flange in effect like the hooped column, it will be effective. The following discussion of beams reinforced for compression is therefore given:

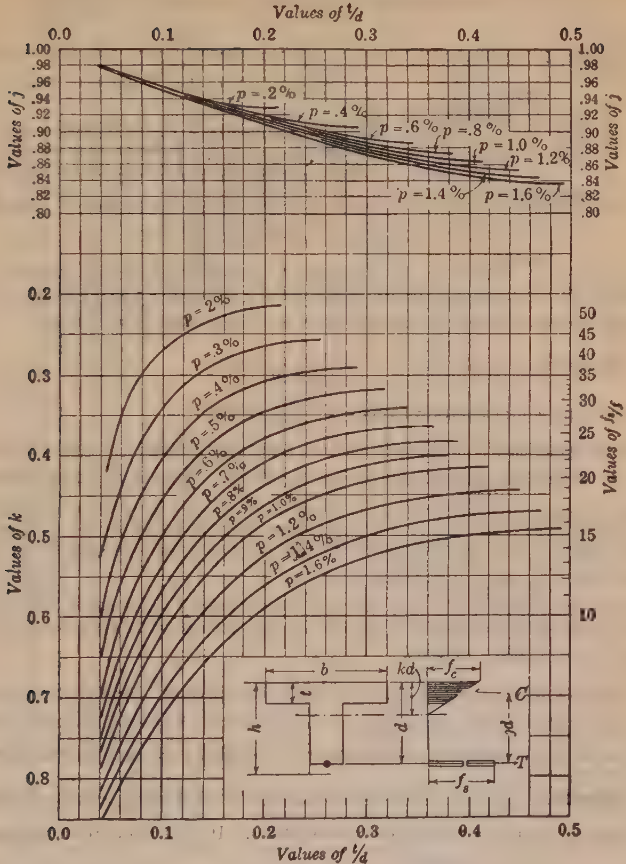

Fig. 21. Diagram for Reinforced T Beams. (n = 15)

22. Beams Reinforced for Compression

The normal capacity of a 15-in. × 20-in. beam for 16 000 lb. in the steel and 650 lb. in the concrete would be as follows: From Fig. 19 $\frac{M}{bd^2} = 108$; moment of resistance $= 15 \times 20 \times 108 = 648\,000$ in-lb.; $p. = 0.77\%$; $A_s = 15 \times 20 \times 0.0077 = 1.3$ sq. in. As in the above example a bending moment of 845 000 in-lb. is to be carried. 845 000 − 648 000 = 197 000 in-lb. to be carried by additional steel reinforcement. Compressive steel will be placed 2 in. from the upper face. From Fig. 19, $k = 0.38$; $kd = 7.6$ in.; therefore from Fig. 22 unit stress in compressive steel (for $n = 15$) =

$\frac{650 \times 15 \times 5.6}{7.6} = 7200$ lb. per sq. in. Required compressive steel $\frac{197\ 000}{18 \times 7200} = 1.5$ sq. in.

To maintain equilibrium of tension and compression forces, add tension steel $\frac{197\ 000}{18 \times 16\ 000} = 0.7$ sq. in. Total tension steel $2.3 + 0.7 = 3$ sq. in.

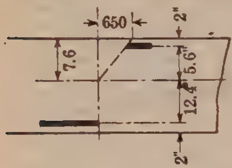

Fig. 22

Fig. 23 is a diagram for obtaining the arm z of the resisting couple and the ratio between the unit stress in tension steel and that in the extreme fiber of the compression flange. (Unit stress in the compressive steel will always be small.) The diagram is based on $n = \frac{E_s}{E_c} = 15$.

Example 1. Required the carrying capacity of a beam 15 in. wide, effective depth 20 in., having 3 sq. in. tensile steel and 1.5 sq. in. compressive steel placed 2 in from the top of the beam so that $\frac{d'}{d} = \frac{2}{20} = 0.1$.

Steel ratio p for tensile steel $= \frac{3}{15 \times 20} = 0.01$.

Steel ratio p' for compressive steel $= \frac{1.5}{15 \times 20} = 0.005$.

In the upper part of the diagram pass a straight-edge through $p = 0.01$ at left and $p' = 0.005$ at right and at its intersection with line for $\frac{d'}{d}$ read off $\frac{fs}{fc} = 24.5$. In lower part of diagram find in like manner $j = 0.88$. The moment value of the beam as determined by the tensile steel at a working stress of 16 000 lb. per sq. in. $= jdAsfs = 0.88 \times 20 \times 3 \times 16\ 000 = 845\ 000$ in-lb. The corresponding unit stress in the concrete $= fc = \frac{fs}{m} = \frac{16\ 000}{24.5} = 650$ lb. per sq. in.

If the allowable stress in the concrete were to be limited to say 600 or 1/27 of the stress in the steel, the moment value of the beam as determined by the concrete would be $\frac{24.5}{27} \times 845\ 000 = 766\ 000$.

Value of k may be found from the upper part of the diagram. From the intersection of the straight edge with the proper line for $\frac{d'}{d}$ follow the direction of the radial $\frac{fs}{fc}$ lines to the left hand ordinate, then horizontally to the scale for k. In the above example $k = 0.38$.

Example 2. A floor slab carries a moment of 12 000 in-lb. per inch of width. Design for unit stresses 16 000 lb. and 600 lb. If $\frac{fs}{fc}$ as found from the upper diagram is less than $\frac{16\ 000}{600} = 27$ the strength of the slab will be limited by the tension steel. Upper steel is to be 1-1/2 in. from the upper face. Assume $p = 0.01$ and $p' = 0.005$. Assume tentatively $\frac{d'}{d} = 0.15$. Find from upper part of diagram $\frac{fs}{fc} = 24$; then unit stress in steel must not exceed $\frac{24}{27} \times 16\ 000$ to give 600 in the concrete. From lower part of diagram find $j = 0.866$.

$$\frac{24}{27} \times 16\ 000 \times 0.01d \times 0.866d = 12\ 000$$

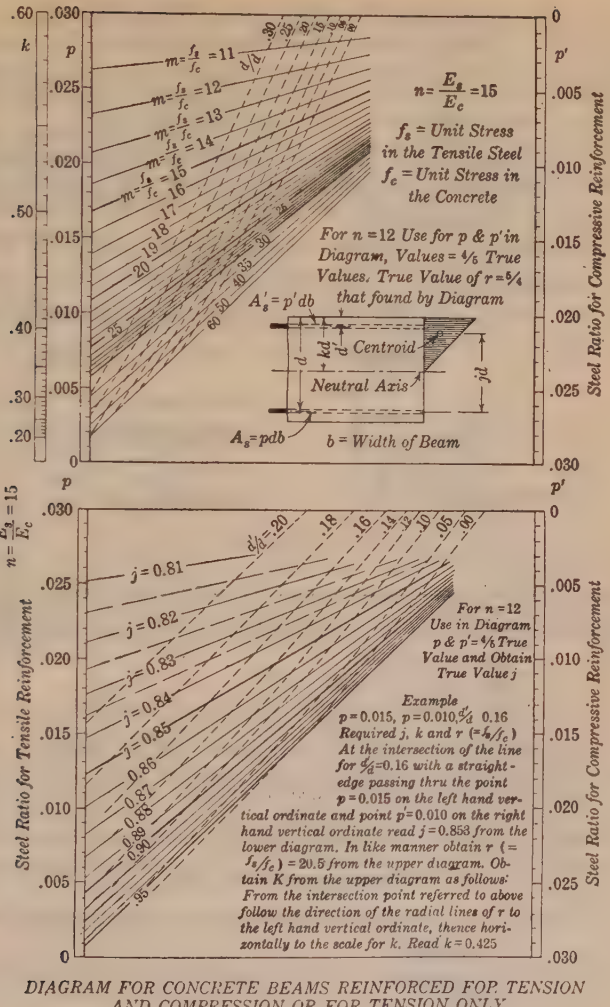

DIAGRAM FOR CONCRETE BEAMS REINFORCED FOR TENSION AND COMPRESSION OR FOR TENSION ONLY

Fig. 23

Solve for $d = \sqrt{97}$ = say 10 in.

Actual $\frac{d'}{d} = 0.15$, as assumed; hence no correction to the calculation is needed.

23. Combined Bending and Direct Stress

Case 1. Tension Over Part of the Section

As in the case of beam action alone, the compressive stress in the concrete may in case of necessity be kept within proper limits by increasing the percentage of tensile reinforcement or by adding compressive steel.

Assume that on a concrete section 1 ft. wide and 34 in. effective depth there has been calculated a bending moment of 113 000 ft-lb. and a direct thrust of 20 000 lb. acting along the axis of the structure or at the middle of the section. To avoid confusion reduce all figures to inch and pound units. $M = 113\,000 \times 12 = 1\,360\,000$ in-lb.

The bending moment and thrust are equivalent to a single force 20 000 acting a distance $\frac{1\,360\,000}{20\,000} = 68$ in. from the axis $= 84$ in. from the steel (Fig. 24). This is equivalent to a pure bending moment 1 680 000 in-lb.

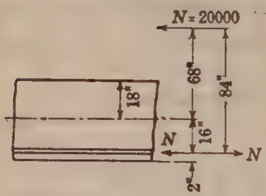

Fig. 24

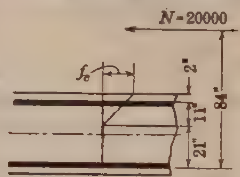

Fig. 25

acting on the section and a direct force $N = 20\,000$ lb. acting directly on the steel which will reduce the area of steel required for bending alone by $\frac{20\,000}{16\,000}$ $= 1.25$ sq. in. $\frac{M}{bd^2} = \frac{1\,680\,000}{12 \times 34 \times 34} = 121.$

From Fig. 19 for 16 000 lb. or 650 lb. limiting find $f_c = 650$; $f_s = 13\,000$; $p = 1.1\%$. Required $A_s = 0.011 \times 12 \times 34 - 1.25 = 3.25$ sq. in.

Since the concrete stress is limited, in the above example, compressive steel might have been used. Moment of resistance of normal beam 12 in. $\times$ 34 in. is $108 \times 12 \times 34 \times 34 = 1\,500\,000$ in-lb. with $f_s = 16\,000$ lb.; $f_c = 650$ lb.; $k = 0.38$; $kd = 13$ in.; $p = 0.77\%$; $A_s = 3.15$ sq. in. Balance of moment $1\,680\,000 - 1\,500\,000 = 180\,000$ in-lb. may be provided by additional compressive steel and tensile steel. (See Fig. 25.) Unit stress in compressive steel $= 650 \times 15 - 11/13 = 8250$ lb. per sq. in. Required compressive steel area $\frac{180\,000}{8250 \times 32} = 0.68$ sq. in. Required additional tensile steel (neglecting effect of direct stress) $\frac{180\,000}{32 \times 16\,000} = 0.35$ sq. in. Total tensile steel required $3.15 + 0.35 - \frac{20\,000}{16\,000} = 2.25$ sq. in.

Case 2. Compression Over Entire Section

The following construction is by E. H. Harder as published in the December 1927 number of "Concrete."

For a plain concrete section no tension exists if the direct force is within the middle-third as limited by the " core points," which are then situated a distance 1/6 t from the center of the section. If the section (as for a concrete arch, for example) is reinforced, the effect of the reinforcement is to move the " core points " outward. Ten per cent reinforcement may move the core points to a distance 1/3 t from the axis. An assumption of 1/4 t will in general lead to sufficiently accurate results without further approximation. Without generalizing a concrete example will illustrate the method of determining the stresses in the concrete and the steel for an eccentric direct thrust. Assume a section 12 in. × 30 in. acted upon by a thrust of 150 000 lb. and a bending moment of 840 000 in-lb. Eccentricity $e = \frac{840\,000}{150\,000} = 5.6$ in. Find the necessary reinforcement to keep compressive stress in the concrete within 600 lb. Refer to Fig. 26. Assume core points 30/4 = 7-1/2 in. from the center line, as indicated. Lay off $bf_c = 12 \times 600 = 7200$ to scale at the extreme compressive fiber and carry over to the direct force 150 000 lb. as indicated at a. Connect a with core points c_1 and c_2.

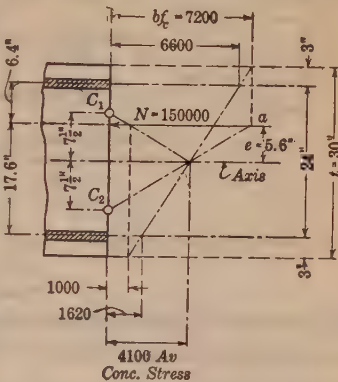

Fig. 26

Where line aC_2 cuts the axis, scale the average concrete stress = 4100. Load carried by concrete = N_c = 4100 × 30 = 123 000 lb. Remainder to be carried by steel = 150 000 − 123 000 = 27 000 lb.

$$\text{Carried by upper steel } 27\,000 \times \frac{17.6}{24} = 19\,800 \text{ lb.}$$

$$\text{Carried by lower steel } 27\,000 \times \frac{6.4}{24} = 7\,200 \text{ lb.}$$

At these steel areas the concrete stresses may be found by scale as follows:

$$\text{At upper steel } \frac{6600}{12} = 550 \text{ lb.}$$

$$\text{At lower steel } \frac{1620}{12} = 135 \text{ lb.}$$

$$\text{Required area of upper steel } (n = 15)\ \frac{19\,800}{15 \times 550} = 2.4 \text{ sq. in.}$$

$$\text{Required area of lower steel } \frac{7200}{15 \times 135} = 3.5 \text{ sq. in.}$$

24. Shear and Bond Stresses

Horizontal shear at any point in a beam is assumed as a measure of the diagonal tension for which secondary reinforcement may be required.

In Fig. 27 is indicated a small length x of beam with opposing compressive stresses on opposite sides indicated as C and C', opposing tensile stresses T

and T' and shear $= V$, no loads being assumed in the length x. The total horizontal shear above the steel and below the neutral axis is then $T' - T$ and **unit** horizontal shear

$$v = \frac{T' - T}{bx} \quad (1)$$

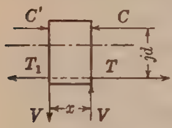

Fig. 27

in which b = width of beam. Taking moments with CC' as center,

$$(T' - T) = \frac{Vx}{jd} \quad (2)$$

From (1) and (2) find **unit** horizontal shear above the steel and below the neutral axis

$$= v = \frac{8\,V}{7\,bd} \quad (3)$$

Total horizontal shear per unit of length for the full width of beam

$$= \frac{8\,Vb}{7\,bd} = \frac{8\,V}{7\,d} \quad (4)$$

In that portion of the beam containing no other tension reinforcement than the horizontal rods, the horizontal shear $\frac{8\,V}{7\,d}$ per inch of length must be developed by the grip of the concrete on the rods. If $\Sigma 0$ = the sum of the perimeters of all the rods, the **bond** per square inch $= \frac{8\,V}{7d\,\Sigma 0}$.

In the above the approximate value of 7/8 for j was used and is correct within 1% or 2% for rectangular beams. For T-beams j may possibly vary from 0.85 to 0.95 and since the proportioning of T-beams usually necessitates the use of a diagram giving correct theoretic values of j, the correct value might as well be used.

25. Web Reinforcement for Shear

Fig. 28 represents a portion of a beam having some of the main rods bent up to resist diagonal tension which tends to open up cracks as indicated.

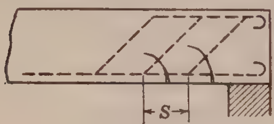

Fig. 28

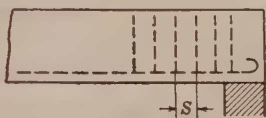

Fig. 29

Horizontal shear is taken as a measure of the diagonal tension. S = distance between bend-up of rods, and n rods each of cross-section A are bent up at any one point.

From equation (4) total horizontal shear in length $\mathbf{S} = \frac{Vbs}{bjd} = \frac{Vs}{jd}$ carried by concrete and bent-up rods. At 40 lb. per sq. in. allowable in the concrete, the concrete will carry 40 **bs** lbs. At 16 000 lb. per sq. in. in the steel, the steel will carry $16\,000\ \sqrt{2}nA$, assuming the rods bent up at 45 deg. Then

$40bs + 16\,000\,\sqrt{2}\,nA = \frac{Vs}{jd}$, from which the proper spacing s may be determined.

Fig. 29 represents a portion of beam having straight rods and **vertical** stirrups. If A' = area of stirrup rod and n = number of legs (2 for U-stirrup, 4 for W-stirrup, etc.) $40bs + 16\,000\,nA' = \frac{Vs}{jd}$.

26. Example: Complete Design of T-Beam for a Floor

Figs. 30 and 31. Span 40 ft. Dead load 1200 lb. per lin. ft. Moving live load concentration 9000 lb.

Assume floor slab to have been designed and required total depth $t = 8$ in. Working stresses $\left\{ \begin{array}{l} f_s = 17\,000 \\ f_c = 700 \end{array} \right\}$

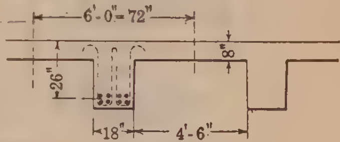

Fig. 30

Maximum dead load M at center $= 1/8 \times 1200 \times 40 \times 40 \times 12 = 2\,880\,000$ in-lb.
Maximum live load M at center $= 1/4 \times 9000 \times 40 \times 12 = 1\,080\,000$ in-lb.

3 960 000 in-lb.

Uniform dead and moving live loads give parabolic variation of maximum

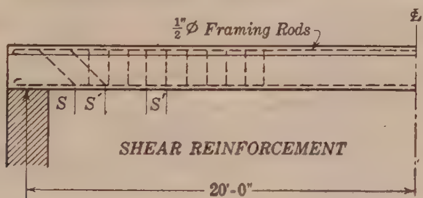

Fig. 31

moments from point to point as shown to scale on Fig. 32. Eight rods **1-1/4** in. round would give 10 sq. in. of steel.

For this area, approximate $d = \frac{3\,960\,000}{10 \times 17\,000 \times 7/8} = 26 \pm$ in.

For $d = 26$, $\frac{t}{d} = \frac{8}{26} = 0.31$ $\quad p = \frac{10}{26 \times 72} = 0.53\%$

From diagram Fig. 21 $j = 0.90$ $\quad \frac{f_s}{f_c} = 30$

Stress in steel $= \frac{3\,960\,000}{0.90 \times 26 \times 10} = 16\,900$ lb. per sq. in.

Stress in concrete $= \frac{16\,900}{30} = 540$ lb. per sq. in.

Moment value of each bar $= 1.23 \times 17\,000 \times 0.90 \times 26 = 495\,000$ in-lb. Plotting **twice** this moment value accumulatively on diagram for bending moment in the beam, Fig. 32, indicates where each pair of rods may be bent up for shear reinforcement.

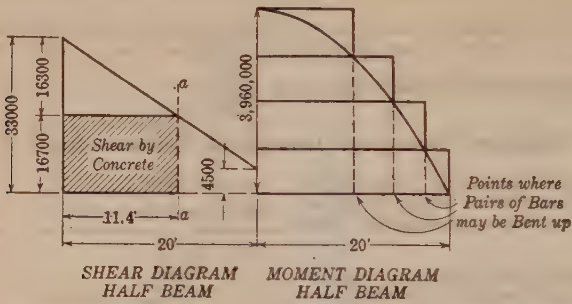

Fig. 32

Shear and Bond Stresses.

End shear. Dead load 1200 × 20 = 24 000 lb.
Live load 9 000 lb.

33 000 lb.

Center shear = 4500 lb. Plot shear diagram as shown.

Horizontal shear acts just above the rods in the stem of the beam; hence for shear and bond calculations b = 18 in. (not 72 in.).

Unit horizontal (longitudinal) shear above rods $\dfrac{33\,000}{18 \times 0.90 \times 26} = 79$ lb.

Allowable without shear reinforcement or special anchorage, as explained in Art. 29 = 40 lb. per sq. in.; hence shear reinforcement is required.

Circumference of 1-1/4-in round rod = 4 in. Four rods of upper layer will be bent up for shear reinforcement; hence at the end of the beam the maximum bond will act on 4 lower rods.

Bond $\dfrac{33\,000}{0.90 \times 26 \times 4 \times 4} = 88$ lb. per sq. in.

Shear capacity of concrete alone 18 × 0.90 × 26 × 40 = 16 700 lb.
Shear capacity of one rod bent up at 45 deg.

$$\frac{1.23 \times 17\,000 \times \sqrt{2} \times 0.90 \times 26}{S} = \frac{693\,000}{S}$$

Shear capacity of one 3/8-in. round vertical W-stirrup (4 legs):

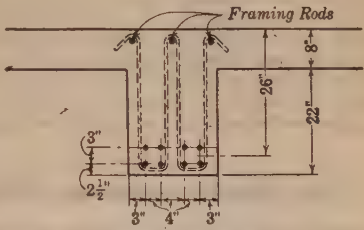
$$\frac{4 \times 0.11 \times 17\,000 \times 0.90 \times 26}{S} = \frac{175\,000}{S}$$

On the shear diagram plot shear capacity of concrete alone = 16 700 lb. Shear in excess of this must be supplied by bent-up rods and stirrups. To right of line $a - a$ shear is less than shear capacity of concrete and no shear reinforcement is needed. Shear carried by steel at first bend-up point is scaled 14 500. Hence S is calculated at $\dfrac{693\,000}{14\,500} = 48$ in., but should not exceed about 3/4 d = 20 in.

Shear just to right of bent-up rods is scaled 11 000. Hence S' at this point $= \dfrac{175\,000}{11\,000} = 16$ in. but should not exceed $1/2\,d = 13$ in. Bond stress in stirrups is assumed to be developed by grip of the concrete through half the depth of the beam.

$$\text{Bond} = \frac{17\,000\,A}{1/2 d \Sigma 0} = \frac{17\,000 \times 4 \times 0.11}{1/2 \times 26 \times 4 \times 1.2} =$$

120 lb. per sq. in.



STIRRUP DETAIL

Fig. 33

Space stirrups on 11-in. centers, reducing bond to 11/13 × 120 = 100 lb. per sq. in., unless reinforcement is provided with special anchorage as described in Art. 29.

27. T-Beams in Beam and Slab Construction

Total width of flange to be considered as effective width in design calculations not to exceed 1/4 span length of beam. Overhanging width on either side of stem to be considered as effective, not to exceed 1/2 clear distance to next beam nor 8 times the flange thickness. (See Fig. 34.)

For beams having flange on one side only, effective width in design not to exceed 1/12 span length of beam, and overhanging width not to exceed 1/2 clear distance to next beam nor 6 times the flange thickness.

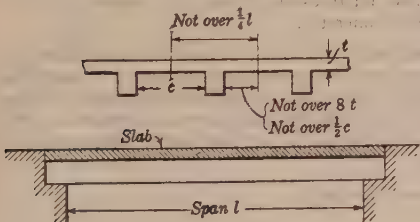


Fig. 34

Isolated T-Beams (designed to provide additional compressive area):

Flange thickness to be not less than one-half width of stem.

Total flange width to be not more than four times width of stem.

In all cases adequate shear and bond resistance must be provided between flange and stem.

The rules governing design as given in the following, Articles 28 to 33, are in agreement with the Joint Code of the American Concrete Institute and Concrete Reinforcing Steel Institute. Unit stresses mentioned in the text are for 2000-lb. concrete (that is, concrete that will develop an ultimate compressive strength of 2000 lb. per sq. in. as determined by tests in accordance with A. S. T. M. standards at age of 28 days.) For concrete of different strength the allowable unit stresses are in proportion.

28. Ordinary Anchorage of Main Reinforcement

In simple beams or free ends of cantilever beams, at least one-fourth of the positive reinforcement should extend along the tension face and beyond the face of the support a distance equal to at least 10 diameters of the bar.

In any span of a continuous, restrained or cantilever beam, the tensile negative reinforcement should have a length of anchorage beyond the face of support sufficient to develop full maximum tension at an average bond stress of 80 lb. per sq. in. for plain bars and 100 lb. per sq. in. for deformed bars (2000-lb. concrete assumed). At least one-third of the negative reinforcement should extend straight to or beyond the point of inflection and the remainder should be bent down not sharper than 45 deg. and overlapped with the positive reinforcement or anchored in a region of compression. Not less than one-fourth the positive reinforcement should extend along the same face into the support and be embedded at least 10 bar diameters beyond face of support.

29. Special Anchorage of Main Reinforcement

Tests show that beams in which the main bars and shear bars or web reinforcement (when required) are more securely anchored than as specified above have greater resistance against ultimate failure. In such beams, higher unit stresses in shear and bond may be allowed. The designer must determine whether it is more economical, in a particular case involving heavy shear and bond stresses, to use special anchorage to justify higher unit shear and bond, or to proportion the beam for the lower unit stresses with ordinary anchorage.

In simple beams or free end of continuous beams, at least one-half of the tensile reinforcement should extend along the tension face to provide anchorage beyond face of support for one-third the allowable working stress in tension at an average bond stress not to exceed 80 for plain bars nor 100 for deformed bars (based on 2000-lb. concrete).

In continuous and restrained beams, anchorage beyond points of inflection of at least one-third of the negative reinforcement and anchorage beyond face of support of at least one-third of the positive reinforcement should be provided to develop one-third of the allowable working stress in tension at average bond stresses not to exceed 80 for plain bars nor 100 for deformed bars (based on 2000-lb. concrete).

Figs. 35 to 38 illustrate types of anchorage.

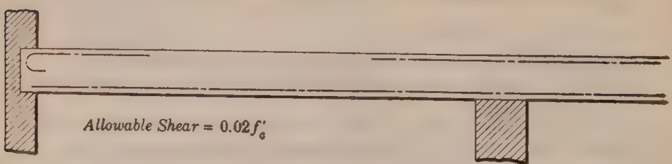

Fig. 35

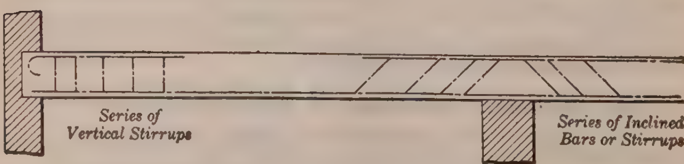

Fig. 36

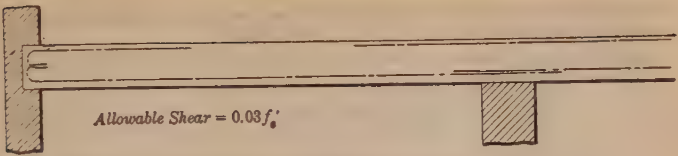

Fig. 37

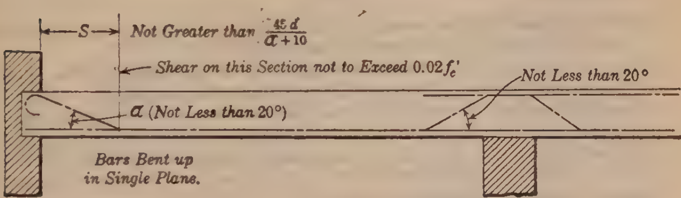

Fig. 38

30. Anchorage of Web Reinforcement

Web reinforcement shall be anchored at both ends by one of the following methods or a combination thereof, but only anchorage meeting the requirements of (a), (b) and (c) shall be used for shearing unit stresses in excess of 160 lb. per sq. in. (for 2000-lb. concrete).

(a) Providing continuity with the main reinforcement.

(b) Bending around the longitudinal reinforcement.

(c) A hook which has a radius at least 4 times the diameter of the web bar.

(d) A length of embedment in the compressive half (upper or lower) of the beam sufficient to develop the stress in the stirrup at bond stresses of 80 for plain bars or 100 for deformed bars (based on 2000-lb. concrete) and also provided that the other end of the stirrup is anchored as specified in (a).

The free end anchorage of a web member not bearing on the longitudinal reinforcement shall be such as to engage an amount of concrete sufficient to prevent the bar from pulling out. In all cases the stirrup should be carried close to the upper and lower surfaces.

31. Unit Stresses in Beams and Slabs

Allowable unit stresses for 2000-lb. concrete are, expressed in pounds per square inch:

Flexure. Extreme fiber stress in compression, 800 lb., excepting adjacent to the supports of continuous beams, 900 lb.

Shearing Stress. (a) Beams without web reinforcement and with ordinary anchorage of longitudinal bars, 40 lb.

(b) Beams without web reinforcement, and with special anchorage of longitudinal bars, 60 lb.

(c) Beams with properly designed web reinforcement and ordinary anchorage of longitudinal bars 120 lb.; the concrete being assumed to carry its share at 40 and the balance being carried by the web steel.

(d) Beams with properly designed web reinforcement and special anchorage of longitudinal rods 180 lb.; the concrete being assumed to carry its share at 60 and the balance being carried by the web steel.

Bond Stresses. Allowable bond stress between concrete and reinforcement for ordinary anchorage of main rods:

80 for plain rods.
100 for deformed rods.

In beams provided with special anchorage of main rods, the above values may be doubled.

Tension in Steel Reinforcement. Structural steel grade, 16 000 lb. per sq. in. Intermediate grade, hard grade or rail steel, 18 000.

Note. The Joint Code recommends 20 000 for the **intermediate** grade as the single standard for billet steel reinforcement conforming to the "Standard Specification for Billet-Steel Concrete Reinforcement Bars," (Serial Designation A15-14, of the American Society for Testing Materials) or for "Rail Steel Concrete Reinforcement Bars," conforming to the Standard Specification A. S. T. M. (Serial Designation A16-14.) See Appendix 5 for Specifications.

Ratios of Moduli of Elasticity, to be used as a basis for design calculations, are recommended as follows:

$$\frac{E_s}{E_c} = \begin{cases} 15 \text{ for 2000-lb. concrete at 28 days.} \\ 10 \text{ for 3000-lb. concrete at 28 days.} \end{cases}$$

and proportionately for other values; but not less than 10.

32. Calculation of Web Reinforcement

The calculation of web shear reinforcement consisting of bent-up main rods at 45 deg. and of vertical stirrups separately in different portions of the beam has been illustrated in the example of T-beam design. In more extreme cases a combination of bent-up rods and stirrups in the same region may be required. In such cases the total shearing resistance of the beam may be assumed as the sum of the shearing resistance of the concrete (at its proper value, 40 or 60 lb. per sq. in., see Art. 31) and the shearing resistances of each type of reinforcement, providing the total calculated resistance does not exceed the values given above (Art. 31). The effectiveness of an inclined bar or stirrup depends upon the angle of inclination (α) with the horizontal, expressed in degrees, and is assumed to be as follows:

When α is less than 45 deg.,

$$\frac{\text{Allowable total direct stress in bar}}{\sin \alpha}.$$

When α is between 45 and 90 deg.,

$$\text{Allowable total stress in bar} \times (\sin \alpha + \cos \alpha).$$

(See Fig. 39.)

Main bars bent up for shear should have an inclination not less than 15 deg.

Inclined stirrups should have a minimum inclination of 30 deg. (from 30 to 90 deg.).

When the total unit shearing stress is less than 120 lb. sq. in. (for 2000-lb. concrete) the distance from edge of support to the first stirrup or first bend-up point of main rod or between stirrups or bend-up rods shall not exceed $S = \frac{45\,d}{\alpha + 10}$, in which d = effective depth of beam.

When the total unit shearing stress exceeds 120 lb. sq. in. (for 2000-lb. concrete) S shall not exceed $\frac{30\,d}{\alpha + 10}$.

When the web reinforcement consists of bars bent-up at a single plane (see Fig. 38) the point of bending and shear at point of bending must not exceed the values indicated, and the portion of the total unit shear on the concrete assumed to be carried by the steel should not exceed 75 lb. per sq. in.

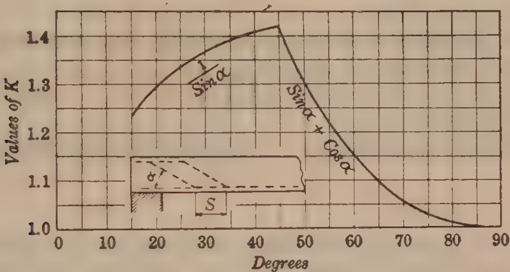

Fig. 39

33. Practical Points of Design

Minimum clear spacing between reinforcing bars:

(a) Unanchored bars: { 1-1/2 times diameter of round bars. / 1-1/2 times diagonal of square bars.

(b) Anchored bars (see Sect. 29) { One diameter of round bars. / One diagonal of square bars.

(c) Never less than 1 in. or 1-1/3 times maximum size of aggregate.

Maximum spacing of **principal slab reinforcement** in other than flat slabs and ribbed floor construction should be 3 times the slab thickness.

Minimum clear distance between bar and side of beam or other member should be equal to bar diameter but not less than 1 in.

Minimum protective cover of reinforcement in fire-resistive construction; 1 in. for slabs and walls, 1-1/2 in. for beams, girders and columns; in ordinary construction 3/4 in. for slabs and walls, 1 in. for beams, girders and columns.

When concrete is deposited directly on the ground, reinforcement near the ground should have 3-in. protection. At other surfaces of concrete exposed to the ground or weather, 2-in. protection should be provided.

Splices. Splicing by over-lap of bars:

(a) Preferably at other points than those of maximum stress.
(b) Splices of adjacent bars to be staggered.
(c) Minimum spacing between laps, as given for separate bars.
(d) Amount of overlap to be sufficient to transfer stress between bars by shear and bond; in general a minimum of 40 diameters of the bar.

Span Length (assumed for design purposes):

Simple beams; center to center distance of supports, but not more than clear span plus depth of beam.

Continuous or restrained beams built to act integrally with supports; clear distance between supports.

Unsupported Length of compression flange of a beam should not exceed 24 times width of flange.

Reinforcement against Shrinkage and Temperature Stresses. Reinforcement normal to the principal reinforcement in roof and floor slabs reinforced in one direction only should be from 0.2% to 0.3%; but in no case should bars be spaced more than 5 times the slab thickness nor more than 18 in.

34. General Notes on Building Construction

Floor Slabs. Reinforced-concrete floors are well adapted to use where the framework is of steel columns and beams, as well as where the entire structure is of concrete.

Fig. 40

Fig. 41

Figs. 40 to 43 illustrate various designs of floors supported on steel I-beams. In Figs. 40 and 41 the reinforcement may be of small rods or a metal fabric of some sort, the latter being convenient for short spans. In Figs. 42 and 43

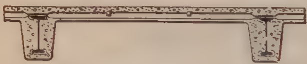

Fig. 42

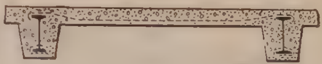

Fig. 43

the reinforcing bars are hooked around the flange of the beam, thus providing anchorage.

Fig. 44 illustrates floor arch construction in the case of a very heavy floor to support a load of 1500 lb. per sq. ft. In this case the shearing stresses were

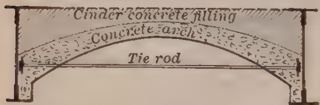

Fig. 44

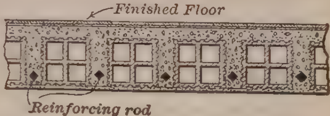

Fig. 45

so great that a sufficient bond strength could not readily be obtained without anchorage. When such anchorage is used it changes the beam to an arch, and enables the thickness of the concrete to be greatly reduced near the center of the span. Fig. 45 shows a common form of floor construction in which terra-cotta tile is used with concrete. The ribs of concrete form essentially small T-beams.

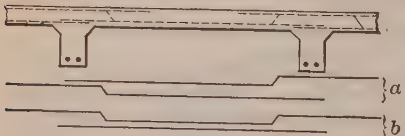

Fig. 46

Where concrete beams are used the slab and beam are built simultaneously. For short spans a metal fabric is convenient, as in Fig. 41. For longer spans, Fig. 46 shows common arrangement of reinforcement, the negative moments being provided for by bending up a part of the rods as in (*a*) or (*b*). The result may also be arrived at by using separate short straight rods over the support.

T-Beams. Beams and girders are usually designed as T-beams, utilizing a portion of the floor slab as a part of the beam. The proportions of the beam below the slab will be determined by considerations of strength, economy, requirement of head-room, and space for reinforcing material. Generally the ratio of depth to width will vary from 1 to 3 as extreme values, the larger ratio being suitable for very large beams. Deep beams are economical of concrete, but cost more for forms than shallow beams. An effective bond should be provided at the junction of the beam and slab. When the principal slab reinforcement is parallel to the beam, transverse reinforcement should be used extending over the beam and well into the slab.

If designed as continuous, the beam will be a rectangular beam at the support and will require strengthening at that point by compressive reinforcement, or by increase of depth. An increase of compressive stress at the support, amounting to 10 or 15%, is often permitted. Fig. 47 illustrates the main features of beam and girder design.

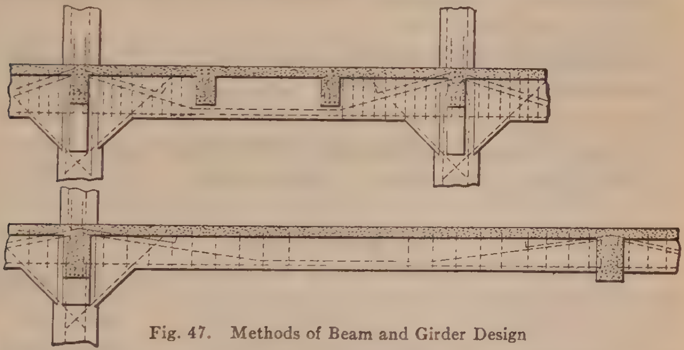

Fig. 47. Methods of Beam and Girder Design

Walls and Partitions

Concrete or Reinforced Concrete is well adapted to the construction of all walls where considerable strength is desired. For walls supporting light loads, such as curtain walls between the framework of a reinforced-concrete building, or partitions, the requirements of strength are met by the use of very thin walls, but such walls become relatively expensive on account of the cost of forms and do not make a dry or warm construction.

Walls of Double Thickness. Concrete walls are often made of double thickness with an air space enclosed, each part being 3 to 4 in. thick. The air spaces are formed by core boxes which are drawn up with the outside forms as the work proceeds. Cheap pipe of thin metal may also be used and left in place.

Brick Facing. Walls of single thickness are often finished with a single layer of face brick, with satisfactory results both in appearance and dryness.

Reinforcement of walls should be sufficient to prevent cracks. unless the wall is to be faced. A small amount of reinforcement is desirable in any case to insure adequate strength.

Partitions may be made as thin as 2 or 3 in., if the concrete is slightly reinforced. Hollow concrete tile or metal lath and plaster will, however, generally be more economical for partitions than poured concrete.

Roofs

General Design. Reinforced-concrete roofs are designed and constructed in the same manner as floors. For steep slopes the concrete in the slabs must be laid quite dry, or else top forms must be used to retain the concrete. The latter method is slow and expensive. Cinder concrete may frequently be used to advantage as the loads are relatively light.

Imperviousness. Concrete roofs may be designed merely as the supporting area for a roof covering of other material, or may be designed to be imvious and complete without such covering. To secure absolute imperviousness requires special precautions, and a maximum amount of reinforcement against shrinkage cracks (0.5 to 1.0%). If designed to support a separate roof-covering, the construction is much simplified and the design can be made very economical. To support the roof covering nailing strips of wood are embedded at suitable intervals.

Adaptability. Reinforced concrete is well adapted to roof construction where a fireproof construction is desired. To support the roof, beams may be employed for spans up to 40 or 50 ft. and trusses for still longer spans. The arch type of construction can also be readily carried out in reinforced concrete. Domes have been built of reinforced concrete in several instances. The stresses are resisted chiefly by circumferential tension rods and by the compressive stress in the concrete in a radial direction.

Girder Bridges, Trestles

Beam or Girder Bridges are designed in the same manner as other heavy concrete floors. Spans up to 20 or 30 ft. may well be made in the form of a simple slab of uniform thickness spanning the opening. For railroad structures the loads are relatively so large that shearing stresses will usually require careful attention. For longer spans a gain in economy will result by the use of main horizontal girders of relatively great depth, with a floor supported by the girders and reinforced transversely. The bridge may be made either a "through" or "deck" girder, according to the requirements of the case, the latter being the more economical. The details are arranged in a variety of ways, but the calculation and design of the reinforcement to meet the given conditions require no special consideration. The proper allowance for impact is an important point in this connection. Durability is an important factor favorable to the use of reinforced concrete for bridge floors.

Trestles. Where several short spans are required and concrete is used for both the girders and the piers, the latter may usually be made of comparatively small cross-section—much smaller than possible if ordinary masonry is used. The structure then approaches the ordinary floor and column construction in the relation of its parts. The piers may generally consist of two or more columns connected by a suitable portal. Where the piers are small, as here assumed, they must be built rigidly in connection with the girders of one or more spans, as are the columns in a building. The girders must be designed with proper reference to their continuity, and the piers must be reinforced somewhat near the top to enable them to resist a part of the bending moment due to the continuity of beams and piers.

Expansion joints should be provided at intervals not exceeding 75 to 100 ft., otherwise the movement due to contraction and expansion will be concentrated at the ends of the structure, resulting in severe stresses in the end columns. Fig. 48 illustrates the general arrangement of a large concrete trestle. Low trestles may be made without longitudinal bracing, the bending resistance of the columns giving the necessary stability. The end piers or abutment must be designed to act also as retaining walls.

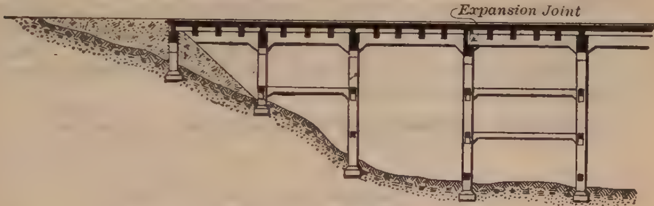

Fig. 48. Concrete Trestle

Pile Trestles, in which reinforced-concrete piles are used, are advantageous in many locations. They are somewhat more expensive than wooden trestles, but are durable and are well adapted to ballast floor construction. In their construction the concrete piles are driven into place and then caps of reinforced concrete are molded about the heads of the piles. On the caps are then placed slabs, forming the supporting floor for ballast.

35. Two-Way Reinforcement

Reinforcement of Slabs in Two Directions. If the length of a slab supported on all 4 sides exceeds 1.5 times its width the entire load should be carried in the short direction. Square slabs may well be reinforced in both directions. The exact distribution of load on square and rectangular slabs, supported on four sides and reinforced in both directions, cannot readily be determined. The following method of calculation will give results on the safe side. The distribution of load is to be determined by the formula

$$r = \left(\frac{l}{b} - \frac{1}{2}\right)$$

in which r = proportion of load carried in the short direction, l = length, and b = breadth of slab. For various ratios of l/b the values of r are:

l/b = 1.0	1.1	1.2	1.3	1.4	1.5
r = 0.50	0.6	0.7	0.8	0.9	1.0

Using the values above specified each set of reinforcement is to be calculated in the same manner as slabs having supports on two sides only. The spacing of rods so determined may safely be increased somewhat for the portions of the slabs between the edges and the quarter points.

Beams and Girders. The arrangement of columns, girders and beams is determined according to the same principles as in steel construction. Where the spacing of girders is not large (12 to 15 ft.) and where cross beams are not needed to secure lateral stiffness, the latter may be entirely omitted or used only at columns so as to form a panel which is square or nearly so. Reinforcement in two directions is not economical for oblong panels. Generally where cross beams are used they should be spaced from 5 to 8 ft. apart.

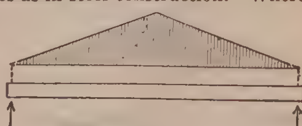

Fig. 49

If the panels are square or nearly so, the distribution of load on the beam may be assumed in accordance with Fig. 49. Under this assumption the bending moment at the center is equal to $wl^3/12$, where w = load per square foot and l = length of beam. Strictly speaking, the distribution is somewhat more uniform than here indicated, so that the bending moment given by this formula is somewhat on the safe side.

36. Effect of Continuity in Floors

Continuity of beams and slabs over their supports affects the moment factors that may be used in design. The following are the usual approximate rules for equal spans. For unequal spans special analysis is required. Beams and slabs built to act integrally with beams, girders or other **slightly** restraining supports and carrying uniform loads:

Single span: Maximum possible moment near center $= \dfrac{Wl^2}{8}$

Two spans: (Fig. 50)

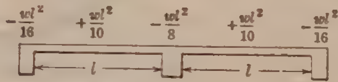

Fig. 50

More than two spans: (Fig. 51)

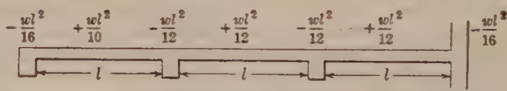

Fig. 51

For beams and slabs built to act integrally with columns, walls or other restraining supports and assumed to carry uniform loads, the customary approximate moment factors depend upon the relative stiffness factors of beam and supports: that is relative $\dfrac{I}{l} = \dfrac{\text{moment of inertia}}{\text{length of member}}$

Refer to Fig. 52

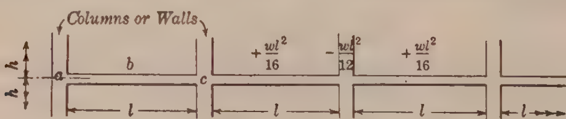

Fig. 52

Case 1. $\dfrac{I}{l}$ for beam $< \dfrac{1}{2} \times \dfrac{I}{l}$ for col. $\begin{cases} M_a = -\dfrac{wl^2}{12} \\ M_b = +\dfrac{wl^2}{12} \\ M_c = -\dfrac{wl^2}{12} \end{cases}$

Case 2. $\dfrac{I}{l}$ for beam $\gtreqless$ $\dfrac{I}{l}$ for col. $\begin{cases} M_a = -\dfrac{wl^2}{16} \\ M_b = +\dfrac{wl^2}{10} \\ M_c = -\dfrac{wl^2}{10} \end{cases}$

For moment and shear factors in continuous beams for particular conditions of loading see Sect. 7, Art. 14.

37. Distribution of Concentrated Loads in Floor Slabs

Various tests by Ohio State Highway Commission and the University of Illinois show that a slab having a width at least twice the span length and simply supported will distribute a point load at the center in such manner that the bending moment produced will be the same as for an independent slice of the slab having a width equal to 2/3 the span length and supporting the load as a line load across its width. From this it may be concluded that a load concentrated on a line parallel to the supports (Fig. 53) will be distributed over an "effective width" equal to the length of line plus 2/3 span length. Thus for a 5000-lb. load on a line 2 ft. long parallel to supports of a slab of 9-ft. span, "effective width" $= 2/3 \times 9 + 2 = 8$ ft. and bending moment $= \frac{5000}{8} \times \frac{9}{4} = 14\,000$ ft-lb.

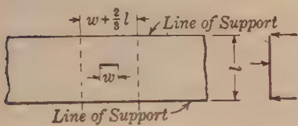

Fig. 53

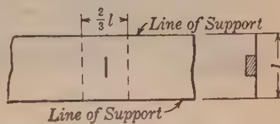

Fig. 54

A center load concentrated on a line perpendicular to supports (Fig. 54) may be considered as distributed along the length of line in direction of span and across the width of a slab having a width equal to 2/3 span length.

Theoretical considerations indicate that for a point-load off center the "effective" lateral distribution at each support will be $4/3 \times$ distance to support. In calculating moment due to such a load the effective width at load may be assumed to be the average of the lateral distribution at both supports or $2/3\,l$ as for center load. (See Fig. 55.)

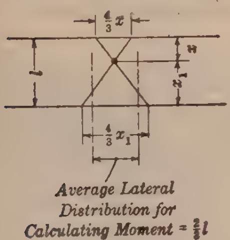

Fig. 55

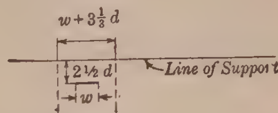

Fig. 56

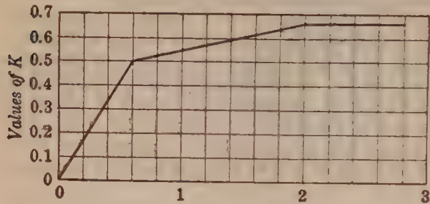
Critical shears for a concentrated load approaching a support have not been determined experimentally but existing data indicate that a slab properly designed for moment in accordance with the above will fail by punching shear rather than by diagonal tension. In the absence of more definite experimental data it may be safer to follow one of the rules adopted as good practice. The specification of the American Railway Engineering Association is as follows: Calculate shear at support by placing the load a distance from support equal to 2-1/2 times effective depth of slab and assume lateral distribution equal to 4/3 this distance as indicated in Fig. 56.

It is usually the case that rules for shear control the proportioning of the slab and require thickening the slab as designed for moment, or haunching at the supports which increase the cost of formwork. Experiments are now under way at Iowa State College, Ames, Iowa, to determine more definitely the laws of load distribution in floor slabs in relation to shear as well as moment and the results may lead to considerable economy in the design of floor slabs for moving concentrated loads.



Ratio = $\dfrac{\textit{Width of Slab}}{\textit{Span Length}}$

Lateral Distribution of Point Load at Mid Span = Kl

Fig. 57

For narrow slabs (width less than twice span length) the following rules are supported by experimental data, tests being made for point center load at middle of width. If width is 0.6 span length, "effective width" = half span length. Straight line variation of "effective widths" may be assumed for intermediate widths between this case and $\frac{w}{l} = 2$, and between this case and $\frac{w}{l} = 0$. (See Fig. 57.)

38. Flat-Slab Floors

The flat-slab floor is a type of floor in which a slab is supported directly upon the columns without the use of beams and girders, the slab acting as a continuous plate built into the column supports. Three general arrangements of slab reinforcement are in common use as illustrated in Figs. 58, 59

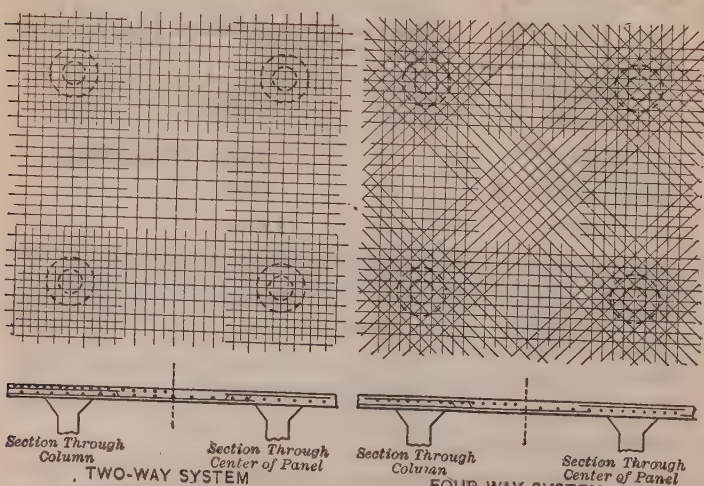


Fig. 58 Flat Slab Reinforcement Fig. 59

and 60. Columns are usually enlarged at the top into capitals. "Dropped panels" are often formed by thickening the slab in the vicinity of the columns as shown in Fig. 62.

Bending moments in the slab are approximated. When not governed by municipal building codes, the Joint Code of the American Concrete Institute and Concrete Reinforcing Steel Institute may be followed as quoted in part in the text following.

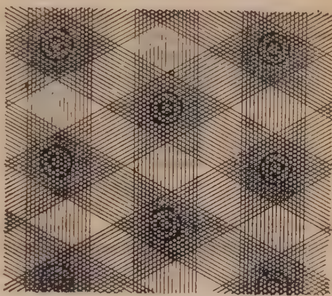

Fig. 60

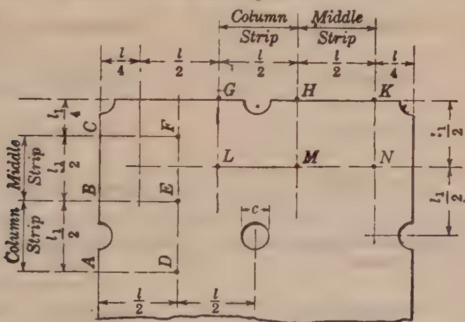
Fig. 61 shows the sections for the critical moments given in the table for the interior panels of a slab having three or more rows of panels in each direction, and in which the panels are approximately uniform in size.

Dropped panels should have a length or diameter b not less than 0.35 of the panel length l in that direction and a thickness t_2 not greater than 1-1/2 times nor less than 1-1/4 times the thickness t_1 of the slab proper.

In calculating reinforcement all bars crossing the section are considered effective. For diagonal bars in 4-way reinforcement the effective area is taken as the cross-sectional area multiplied by the sine of the angle between the bar and the section on which moments are figured.



Column Head Sections AB and GH Follow the Circumference of the Column Capital

Fig. 61

Due attention must be paid to bending moments at sections intermediate to the critical sections. The lines of inflection may be assumed as follows, distances being measured from center lines of panel:

	Without drop	With drop
Column strip................................	$0.33\ (l - c)$	$0.3\ (l - c)$
Middle strip................................	$0.33\ l$	$0.3\ l$

Allowance for shifting of points of inflection due to varying loads is made by carrying **all** bars in rectangular or diagonal bands, each side of sections of critical positive or negative moment, to a line at least 20 diameters beyond the lines of inflection. At least 0.4 of all bars in each band provided for positive moment should extend continuously in either direction to act as reinforcement for the opposite critical sections for negative moment. At least 1/3 of bars for positive moment in the column strip should extend into the dropped panel at least 20 diameters of the bar, or, if there are no dropped panels, to a point not more than 1/8 l from the center line of the column or support.

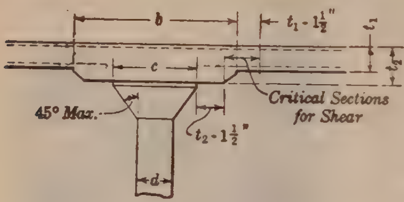


Fig. 62

DE	$+0.018\,Wl\left(1-\frac{2}{3}\frac{c}{l}\right)^2$	$+0.0171\,Wl\left(1-\frac{2}{3}\frac{c}{l}\right)^2$
EF	$+0.018\,Wl\left(1-\frac{2}{3}\frac{c}{l}\right)^2$	$+0.0171\,Wl\left(1-\frac{2}{3}\frac{c}{l}\right)^2$

For moments on GH, HK, LM and MN substitute l_1 for l in the above moment factors for AB, BC, DE and EF respectively.

For square panels $l_1 = l$.

The numerical sum of positive and negative moments for the column strip and middle strip in each direction is the same for all cases, namely,

$$0.09\ Wl\left(1 - \frac{2}{3}\frac{c}{l}\right)^2 \quad \text{and} \quad 0.09\ Wl_1\left(1 - \frac{2}{3}\frac{c}{l_1}\right)^2.$$

The ratio of $\frac{l}{l_1}$ should not exceed 4/3.

In wall panels and other panels in which the slab is discontinuous at edge of panel, the maximum positive moments on the strips perpendicular to the discontinuous edge should be calculated as 25% greater than those given in the table for interior panels, and all positive moment reinforcement should extend to the discontinuous edge and be embedded into the supports. The negative moments at the discontinuous edge are assumed as follows: in the column strip 90% of that for interior panels and in the middle strip, 5/8 of that for interior panels.

In panels having a marginal beam on one edge or two adjacent edges, the beam should be designed to carry at least the directly superimposed loads, exclusive of panel load. A marginal beam having a depth greater than 1-1/2 times minimum slab thickness should be designed to carry, in addition, a uniformly distributed load equal to at least 1/4 the total load for which the adjacent panel or panels are designed. Slabs supported by marginal beams on opposite edges should be designed as freely supported slabs for the entire load.

Minimum thickness t_1 of slab without drop

$$= 0.038\left(1 - 1.44\frac{c}{l}\right)l\sqrt{w} + 1\text{-}1/2,$$

in which w equals total load in pounds **per square foot.** Minimum thickness of dropped panel $t_2 = 0.02\ l\sqrt{w} + 1$. In addition, the slab thickness t_1 or t_2 should not be less than $\frac{l}{32}$ for floor slabs or $\frac{l}{40}$ for roof slabs (based on 2000-lb. concrete).

Shearing Stresses. Let r = proportional amount of total negative reinforcement in the column strip which directly crosses the dropped panel; or if there is no drop, the proportional amount directly crossing the column capital. Unless the slab is reinforced for shear, the unit shearing stresses calculated on the critical sections indicated in Fig. 61 should not exceed 40 $(l + r)$ or 60 lb. per sq. in., whichever governs (2000-lb. concrete being assumed).

Three-Way System. In 3-way systems, negative amount on the column head sections may be assumed as $0.032\ Wl\left(1 - \frac{2}{3}\frac{c}{l}\right)^2$ for each sextant strip around the column, and positive moment midway between the columns as $0.016\ Wl\left(1 - \frac{2}{3}\frac{c}{l}\right)^2$ for each sextant. l = distance center to center of columns and W = the total load on the **parallelogram panel.**

39. Reinforced-Concrete Columns

The rules of design below follow the Joint Code of the American Concrete Institute and Concrete Reinforcing and Steel Institute and may be used when building codes do not govern.

Concrete Columns may be: (a) reinforced by longitudinal bars (at least 4 having a minimum diameter of 5/8 in.) and separate hoops or ties. Longitudinal bars should have an effective cross-sectional area not less than 0.5% nor more than 2% of the total area of the column, and be embedded at least 2 in. clear from the face. The hoops or lateral ties should be not less than 1/4 in. in diameter spaced not more than 12 in.

(b) reinforced by longitudinal bars (at least 6 having a minimum diameter of 1/2 in.) and closely spaced continuous spirals enclosing a circular core the diameter of which may be measured c. to c. of the wire. The longitudinal bars should have an effective cross-sectional area not less than 1% nor more than 6% of that of the core. The spiral reinforcement should be not less than 1/4 the volume of the longitudinal reinforcement and the spirals spaced not more than 1/6 the diameter of the core nor more than 3 inches. Spirals should be evenly spaced and held by at least 3 vertical spacer bars.

Notation

n = ratio modulus of elasticity, steel to concrete.
p = steel ratio (area of steel to area of concrete core) for spirally reinforced column.
A_s = effective cross-sectional area of longitudinal reinforcement.
A'_c = net area of concrete in columns without spiral reinforcement (total column area less area of steel).
A = area of concrete core of spirally reinforced column.
$A_c = A(1 - p)$ = net area of core of spirally reinforced column.
f_c = allowable compression in concrete not to exceed $0.225 f'_c$.
f'_c = the ultimate strength at 28 days.

(a) Safe axial load for reinforced concrete columns without spiral reinforcement $= (A'_c + A_s n) f_c$.

(b) Safe axial load for spirally reinforced columns

$$= (A_c + npA) \times [300 + (0.1 + 4p) f'_c].$$

The above safe loads are for columns having a ratio of length, h, to radius of gyration, R, less than 40.

If the ratio exceeds 40 the safe load should be reduced, as follows: P being the safe load for the shorter column:

Safe load for long columns $= P\left(1.33 - \frac{h}{120\,R}\right)$, R for spirally reinforced columns should be calculated for the radius of gyration of the core.

Columns subjected to bending should be designed for the combined stresses, and additional reinforcement may be added to provide for the bending. For columns without spiral reinforcement the allowable compressive stress on the concrete may be increased 50%. The total amount of reinforcement considered in the calculations should not exceed 4% of the total column area.

For spirally reinforced columns the allowable compressive stress on the concrete core may be increased 20% over that shown in the bracket of the formula for safe axial load.

Principal columns in buildings should have a minimum diameter or thickness of 12 inches. Posts that are not continuous from story to story should have a minimum diameter or thickness of 6 inches.

Composite Columns. Safe load on composite columns in which a structural-steel or cast-iron column is thoroughly encased in a circumferentially reinforced concrete core may be based on the allowable unit stress of the metal column plus a unit stress of $0.25 f'_c$ on the area within the spiral core. The diameter of a cast-iron section should not exceed half of the diameter of the spiral core. Spiral reinforcement should be not less than 0.5% of the volume of the core.

40. Column and Wall Footings

Reinforced Concrete is especially well suited for the construction of footings for walls and columns and the foundations of any structure where the bearing area must be considerably larger than the superstructure resting thereon, such as towers, chimneys, lighthouses, arches, and, frequently, bridge piers and abutments. To secure the necessary bearing area by the use of plain concrete or other masonry requires great depth of foundation, increasing the expense and, often in the case of buildings, occupying much valuable space. Grillage foundations, consisting of steel I-beams protected by concrete, are more expensive than slabs of reinforced concrete, as they do not utilize the compressive resistance of the concrete; generally, therefore, the reinforced slab is to be preferred. Reinforced concrete is also used extensively for bearing piles and also for sheet piling, caissons, and other forms of foundation work.

Footings. The problem of the design of reinforced-concrete footings is in general the same as that of floors. For single footings of ordinary size a single square slab is most convenient. For larger footings and for footings carrying more than one column, a combination of beam and slab, similar to floor construction, is often most economical. For very soft soils this may need to spread as a floor over the entire foundation area, forming a monolithic structure.

For a **square slab** (Fig. 63) the pressure should be carried as directly as possible from the extremities to the center. Two sets of main reinforcing rods aa' and bb' should be used, as shown in the figure. The reinforcing of the remaining corners can best be done by sets of diagonal rods dd'. If these do not cover the area, then a few short cross-rods may be used. Reinforced in this way the total pressure on the area $ABCD$ may be assumed to be carried to the line BC, where the bending moment and shear will be a maximum. Figured as a free cantilever the resulting stresses will be higher than actually exist. If the entire square is reinforced by rods in two directions only, as ee', then a considerable part of such rods in the corners of the square are ineffective.

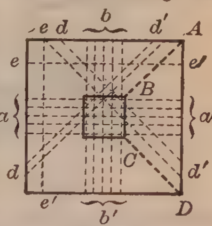

Fig. 63

In **cantilever beams,** used as footings, the maximum shearing stress is near the base of the wall where the moment is large. Shear cracks tend to form on the dotted lines a, a, Fig. 64. Bent rods, if used, should be bent just outside the column base, and not at the end of the beam, and stirrups must be spaced closely at this point. The beam being short the bond stress may require special attention. The shearing stresses in the concrete are likely to be high and exceed the limit generally allowed for beams. In this case, since the depth of the beam is relatively great, the dangerous section will be some distance from the face of the well. This distance may be taken equal to the effective depth of the beam and the rules for maximum shear then applied.

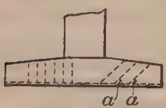

Fig. 64

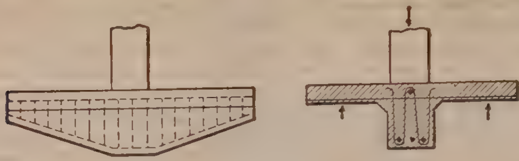
For large **individual footings** a beam and slab may be economical. To secure the benefit of a T-section and to give a flat upper surface the beam may be placed under the slab as shown in Fig. 65. This arrangement requires some attention to the connection of slab to beam, as the upward pressure against the slab tends to pull it away from the beam. The use of a horizontal rod in the top of the main beam, bonded by stirrups, will give a thoroughly good anchorage for the transverse rods of the slab. For still larger areas a system of girders and beams may be adopted, constituting a floor reversed as



(a) (b)

Fig. 65. Large Individual Footings

to loads. For **wall footings** a simple slab construction with transverse reinforcement is suitable.

Stresses in Footings Eccentrically Loaded. If for any reason (eccentric load, earth pressure, wind pressure, etc.) the resultant of the forces acting above the foundation level intersects that level eccentrically, the pressures upon the earth below are not uniform but vary in intensity from a minimum at one edge to a maximum at the other. It is customary, and sufficiently accurate for the purpose, to assume that in such a case the pressure varies uniformly from one side to the other. In Fig. 66 let e = eccentricity of resultant pressure, l = length of base, W = total vertical load per lineal foot on founda-

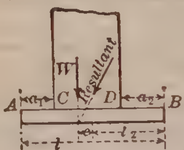


Fig. 66

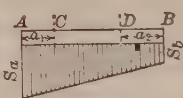

Fig. 67

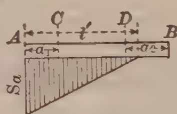

Fig. 68

tion, and S = pressure per unit area at any point. Then for rectangular areas, if e is less than $1/6\ l$, the variation in pressure is as represented in Fig. 67. The values of the intensity of pressure at A and B are as follows:

For edge A, $$S_a = \frac{W}{l}\left(1 + \frac{6e}{l}\right)$$

For edge B, $$S_b = \frac{W}{l}\left(1 - \frac{6e}{l}\right)$$

If e is greater than $1/6\ l$ the pressure is distributed as in Fig. 68 over a length l'_1 equal to $3\ (1/2\ l - e)$, and the pressure at A is $S_a = 2\ W/l' = 4\ W/3\ (l - 2e)$. The bending moments at C and D are then given by the formulas:

For Fig. 67, $$M_C = \frac{W}{2\,l^3}(l^2 + 6\,el - 4\ ea_1)\,a_1^2$$

and $$M_D = \frac{W}{2\,l^3}(l^2 - 6\,el + 4\,ea_1)\,a_1^2$$

For Fig. 68, $$M_C = \frac{2\,Wa_1^2}{3\,(l - 2\,e)^2}(9\,l - 18\,e - 2\,a_1)$$

and $$M_D = \frac{W}{54\,(l - 2\,e)^2}(2\,a_2 + 1 - 6\,e)^3$$

41. Arch Bridges

In ordinary masonry or concrete arches tensile stresses are not permissible. The ring must therefore be designed so that the line of pressure will not pass outside the middle-third. In reinforced arches this limitation does not exist. The arch rib is a beam, and if properly reinforced it may carry heavy bending moments involving tensile stresses in the steel. Besides this advantage, reinforcement renders an arch a much more secure and reliable structure, it greatly aids in preventing cracks due to any slight settlement, and by furnishing a form of construction of greater reliability makes possible the use of working stresses in the concrete considerably higher than those used in plain masonry. Furthermore, in long-span arches where the dead load constitutes by far the larger part of the load, any increase in average working stress counts greatly towards economy. It affects not only the arch itself but also the abutments and foundations.

Since the arch is a beam subject to either positive or negative bending moment it is essential that it should be reinforced on both sides, but the shearing stresses due to beam action are relatively small, so that little is needed in the way of web reinforcement. It is desirable, however, that the inner and outer reinforcements be tied together, somewhat as in a column, although in this case the necessity therefor is much less.

Technical terms are illustrated in Fig. 69. Abutment, pier, arch ring are the main parts of the structure. Soffit, back, and skewback are surfaces,

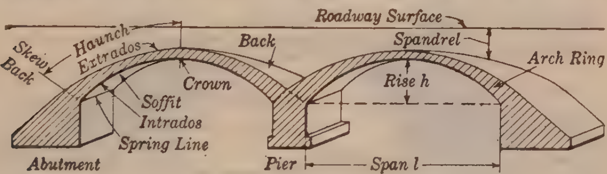

Fig. 69

the skewback being the surface of the abutment or pier from which the arch ring proper springs. Intrados and extrados are the lines on a longitudinal section, being the intersection of the cutting plane with the soffit and back respectively. The spandrel is the space between the back of the arch and the roadway over. The application of other terms is self-evident. "Span" and "rise" may also be applied to center-to-center distances on the neutral axis of the longitudinal section. The rise-ratio is ratio of rise to span $= \frac{h}{l}$.

The several types and sub-types of arch structure are as follows:

(1) **Solid barrel arch** in which the arch ring is continuous for full width of bridge.

(a) Spandrel filled (Fig. 69). The roadway is carried over the bridge on earth fill placed over the arch. Spandrel retaining walls at the two sides of arch retain the roadway fill.

(b) **Open Spandrel** (Fig. 70). The arch ring supports small spandrel arches or transverse walls or columns which in turn carry the floor system.

(2) **Ribbed Arches** consist of a number of relatively narrow arch ribs springing from the abutments and piers, supporting small spandrel arches or columns which in turn support the floor system.

Classification by Static Condition. A second classification of arches may be made with reference to their static condition, namely, three-hinged arch (statically determinate), two-hinged arch (indeterminate to first degree), and fixed or hingeless arch (indeterminate to third degree). The single hinge arch (hinge at crown) is rarely used.

The three-hinged arch is unaffected by temperature change, as regards stresses — excepting in a minute degree due to slight change in rise-ratio caused by rise or fall at the crown. Temperature stresses in a two-hinged arch of large rise-ratio are relatively small and may sometimes be neglected altogether. As the rise-ratio decreases temperature stresses become more important. Temperature stresses in the fixed arch are relatively large and increase in proportion as the rise-ratio decreases; the minimum rise-ratio may be determined by the temperature stresses.

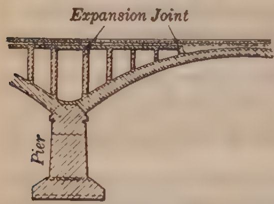

Fig. 70

The above considerations are important in selecting the type of structure, particularly for grade crossing elimination when it is necessary to keep distance from roadway under to roadway over at a minimum both on account of limitations of grades and cost of approaches. In such cases the **rigid-frame** bridge, to be discussed later, is preferable to either the arch or beam type structure.

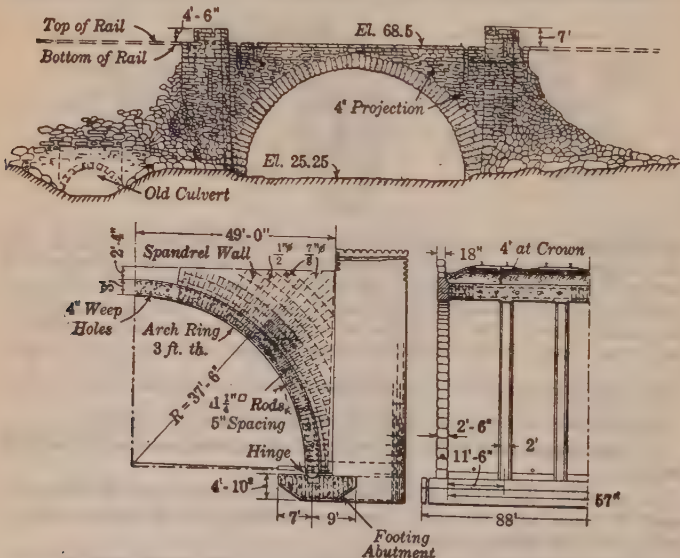

Fig. 71

Fig. 71 shows a two-hinged solid barrel reinforced-concrete arch designed to carry railroad traffic on an existing high embankment over a highway cut through the embankment.

Hinges. One type of hinge for concrete arch, designed for the above bridge, is shown in Fig. 72. Several other types of hinge are illustrated in Fig. 73.

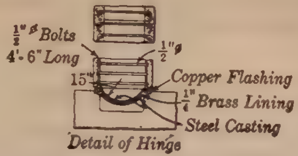

Fig. 72

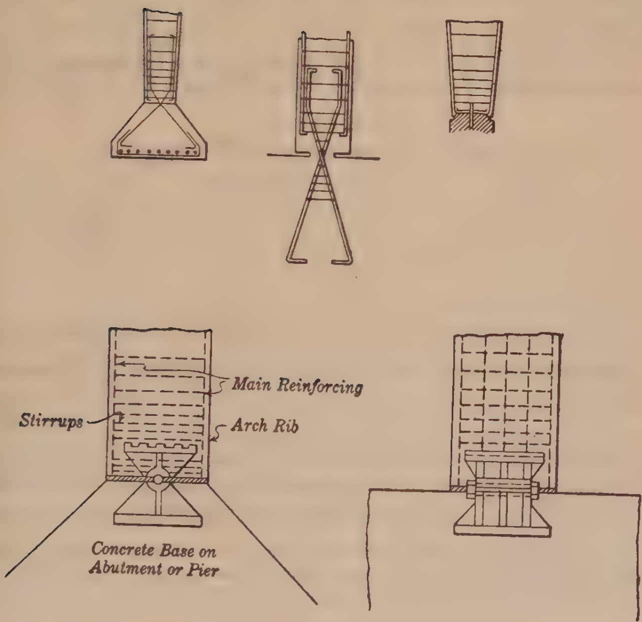

Fig. 73

42. Details of Design

The various parts of the arch structure should be well bonded together to resist temperature changes. All walls should be reinforced both vertically and horizontally with 0.1% to 0.2% of steel in order to prevent contraction cracks. Spandrel retaining walls should be provided with expansion joints above or on each side of the pier or at the edge of abutment to prevent cracking due to rise and fall of the crown caused by temperature changes.

Arches may safely be constructed on a good earth foundation that is not too compressible and that offers good resistance to sliding; also on pile foundations if the piles are driven to proper resistance and batter piles are driven to take the horizontal thrust. If the driving of the piles indicates uneven bearing capacity, the arch and abutments should be well reinforced transversely and any construction joints should be well keyed. Transverse reinforcement is a safeguard to any arch not built on ledge rock.

43. Intrados Curves

The intrados curves of arches should be true curves; preferably circular segments, elliptical segments, or (for "full-centered" arches) semicircles, or semi-ellipses. Parabolic and transformed catenary curves and their intermediates are not so pleasing and their use is justified only for structures of large size when strict economy is urgent. The use of "multiple-centered" curves invariablyde tracts from the appearance of the structure.

Clearance requirements as in the case of an arch over a highway sometimes require a modification of the elliptical curve as indicated in Fig. 74. The lower

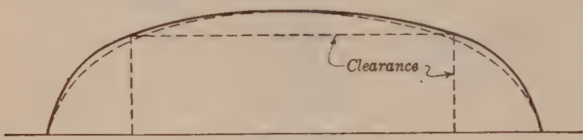

Fig. 74

curve is a true ellipse of equation form $\left(\frac{x}{a}\right)^2 + \left(\frac{y}{b}\right)^2 = 1$. In which a and b are respectively semi-major and semi-minor axes and coincident with the axes of reference. The upper curve has the equation $\left(\frac{x}{a}\right)^{2.2} + \left(\frac{y}{b}\right)^{2.2} = 1$ and provides more clearance at the sides of the roadway under, and, as it is a truly mathematical curve, irregularities are avoided. Different results may be obtained by applying different fractional exponents to the equation $\left(\frac{x}{a}\right)^m + \left(\frac{y}{b}\right)^n = 1$. Such curves may be rapidly calculated by use of the log. slide rule, and have been used for bridges of the Westchester County (New York) Parkways with pleasing effect in contrast with nearby bridges having multiple-centered curves or "spline" curves.

44. Preliminary Design

The design of the two-hinged and fixed arch is ordinarily a process of approximation being the mathematical analysis of a predetermined arch section. Various methods of direct design have been developed which are useful for large structures, notably that of Whitney described in Trans. Am. Soc. C. E. 1925. For small and moderate span bridges the methods of analysis illustrated by examples following are simpler. Various formulas for determining crown thickness for preliminary design have been derived but are not particularly useful as different formulas give different results. Judgment based on experience will enable the designer to lay out a section for analysis that will not require a re-analysis.

45. Three-Hinged Arch

The three-hinged arch is merely a truss frame *abc* (Fig. 75) in which the stress in the omitted tie member *ac* is replaced by thrust *H* at the abutments. Loads may be applied along the curved members *ab* and *bc* which act as beams transferring their reactions to the joints of the truss frame. Thus in Fig. 75 the vertical component of reaction of *bc* at $b = \frac{Pa}{1/2l} = \frac{2\,Pa}{l}$. Taking moments about b, $\frac{V_L\,l}{2} = \frac{Pa}{l} \times \frac{l}{2} = Hh$ from which $H = \frac{Pa}{2h}$. Further discussion of analysis is unnecessary.

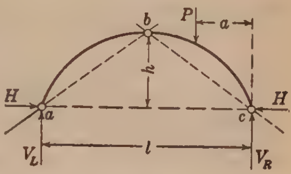

Fig. 75

46. Theory of Indeterminate Reinforced-Concrete Structures

The reader is referred to textbooks for a general discussion of the criteria for statical determinateness or indeterminateness of structure. In statically indeterminate structures the direction and magnitude, or direction, magnitude and points of application of the reactions cannot be found by the laws of statics alone, but depend also upon the relative elastic properties of different parts of the structure itself. There are no evident lever arms of the reaction from which the bending moments in the structure can be determined.

The methods explained in this section for attacking the problem depend upon a few simple fundamental laws of flexture which are illustrated, in the pages immediately following, by a few simple examples in beam deflection. The treatment is not rigorous. Shear and direct stress deformation is neglected in the development although correction for direct stress deformation may be made as " rib-shortening " as indicated for the arch. Other approximations are made to which attention will be called, but for all practical purposes the methods shown are sufficiently accurate for the design of the structures illustrated. Involved in these calculations are quantities which are a measure of the elastic properties of the structure, all containing values for moment of inertia. In such cases gross moments of inertia should be used, although the unit stresses are finally calculated on the occasional " cracked section," neglecting tension in the concrete.

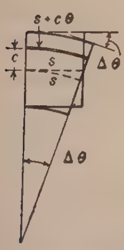

Fig. 76

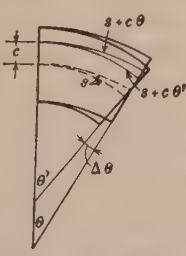

Fig. 77

Assume a very small length *s* of a beam originally straight as indicated in Fig. 76. After strain due to flexure alone, the change in length of a fiber distant *c* from the neutral axis will then be (in circular measure): $s + c\Delta\theta - s = c\Delta\theta$, $\Delta\theta$ being the measure of the change in direction of the tangents at the two ends of *s*. The strain (change in length) of this fiber may also be expressed as $\frac{Mc}{EI}$ in which $\frac{Mc}{I}$ is the stress on the fiber, due to the moment M of all external forces acting on the beam, as determined by the well-known beam formula. Comparing the two equations above, $\Delta\theta = \frac{Ms}{EI}$. The change in direction of the tangent between any two points will be the sum of the small changes for all the small lengths s between the points considered, or $\Sigma \frac{Ms}{EI}$.

Assume next a small length s of the neutral axis of a beam originally curved and subtending an angle θ before flexure and θ' after flexure (Fig. 77). The change in length of a fiber distant c from the neutral axis (due to flexure alone) will then be $(s + c\,\theta') - (s + c\,\theta) = c\,\Delta\theta$. The strain (change in length) of this fiber may also be expressed as $\frac{f(s + c\,\theta)}{E}$ in which f is the **unit** stress on this fiber due to the external moment M on the section. We then have $c\,\Delta\theta = \frac{f\,(s + c\,\theta)}{E}$ from which $\mathbf{f} = \frac{\mathbf{c\,\Delta\theta\,E}}{\mathbf{s + c\theta}}$. If a = the cross sectional area of this fiber, the moment of the stress about the neutral axis $= fac = \frac{ac^2\,\Delta\theta E}{s + c\theta}$.

Summing over the entire cross-section, $\mathbf{M} = \Sigma\,\mathbf{fac} = \frac{\Sigma \mathbf{ac^2\,E\Delta\theta}}{\mathbf{s + c\,\theta}} = \frac{\mathbf{IE\Delta\theta}}{\mathbf{s + c\theta}}$ from which $\Delta\theta = \frac{\mathbf{M\,(s + c\,\theta)}}{\mathbf{EI}}$. For the curvature occurring in ordinary arches, $s + c\,\theta$ may be assumed equal to s. Hence $\Delta\theta = \frac{\mathbf{Ms}}{\mathbf{EI}}$ approximate. Summing over any given length of the axis the change in direction of the tangents at the end of such length $= \Sigma\Delta\theta = \theta = \Sigma \frac{Ms}{EI}$.

Fig. 78 represents a straight cantilever beam supporting a load. Assume origin of coordinates (**at the point where displacements are to be measured**) in this case at a. The angle between the tangents at the ends of any small division s of the axis after flexure is $\Delta\theta = \frac{Ms}{EI}$ in which M is the bending moment (due to the external loads) at such point. The deflection at a contributed by the flexure in s is in circular measure, $x\Delta\theta = \frac{Mxs}{EI}$. The total angular change θ is the sum of effects of all the small divisions between the points considered; that is, $\Sigma \frac{Ms}{EI} = \frac{I}{E} \Sigma \frac{Ms}{I}$; E being placed outside the summation sign if the beam is homogeneous; that is of constant E. Likewise the total displacement δ between the points considered, is $\Sigma\,x\,\Delta\theta = \frac{1}{E} \Sigma \frac{Mxs}{I}$. The length considered may be from the support to any other point or between any two points away from the support. In the numerical example following, the total deflection of point a from a line perpendicular to the support is measured.

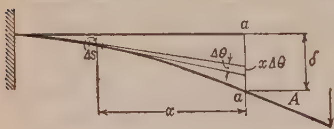

Fig. 78

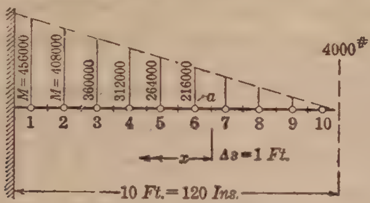
In this example also s is constant and could have been placed outside the sign of summation, but was retained to illustrate the method when it is convenient to vary the lengths of divisions. Moments of inertia I and bending moments at centers of divisions are as indicated. (Fig. 79.)



x is Measured from the Point at which Displacements are to be Figured, to the Centers of Divisions

Fig. 79

Point	M	s	I	x	$\frac{Ms}{I}$	$\frac{Mxs}{I}$	$\frac{M}{EI}$
1	456 000	12 in.	200	66 in.	27 400	1 810 000	.0000760
2	408 000	12 in.	180	54 in.	27 200	1 470 000	.0000756
3	360 000	12 in.	160	42 in.	27 000	1 135 000	.0000750
4	312 000	12 in.	140	30 in.	26 700	800 000	.0000743
5	264 000	12 in.	120	18 in.	26 400	475 000	.0000733
6	216 000	12 in.	100	6 in.	26 000	156 000	.0000720
Σ	....	....	....	....	160 700	5 846 000	

$E = 30\,000\,000$ (steel beam assumed). Approximate angular change from support to $a = \Sigma \frac{Ms}{EI} = \frac{160\,700}{30\,000\,000} = 0.00535$ radian. Approximate deflection at $a = \Sigma \frac{Mxs}{EI} = \frac{I}{E} \Sigma \frac{Mxs}{I} = \frac{5\,846\,000}{30\,000\,000} = 0.2$ in. The smaller the divisions, the closer will be the approximation.

From what precedes it is seen that the angular change will be the area of the $\frac{M}{EI}$ diagram plotted to scale as **indicated** in Fig. 80 although not here reproduced to scale. Also the deflection will be the moment of the $\frac{M}{EI}$ diagram about the point of displacement A.

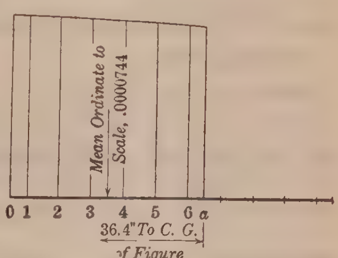


Fig. 80

Angular change 0 to $A = .0000744 \times 6 \times 12 = 0.00535$ radian.

Deflection at $A = 0.00535 \times 36.4 = 0.2$ inch.

The Curved Cantilever Beam. (Fig. 81.) The angular change contributed by the flexure of any division s of the axis of a member may be measured by the change in angle between the tangents at the ends of the division or between the radii or between any lines straight or broken, attached to the ends of the divisions. Making use of this geometric principle the deflection of a point in any desired direction may be readily calculated as shown. Assume as before, origin of coordinates at the point a whose calculated displacements are desired. From the figure it is seen that the vertical displacement of point a contributed by the flexure in s is $x\,\Delta\theta = \frac{Mxs}{EI}$ and the horizontal displacement is $y\,\Delta\theta = \frac{Mys}{EI}$ in which M is the bending moment on division s due to the loads acting on the beam. Summing the effects of all points on the axis (from support to a) total vertical displacement $= \Sigma\,\frac{Mxs}{EI}$ and total horizontal displacement is $\Sigma\,\frac{Mys}{EI}$. Likewise the total angular change (from support to a) is $\Sigma\,\frac{Ms}{EI}$. Note that in the expressions $\frac{Mxs}{EI}$ above (for straight or curved cantilever beams) x is the moment on the several divisions s due to **vertical unit load placed at the point where vertical displacements are to be measured.** Whence the expressions for vertical deflections may be written $\Sigma\,\frac{MM_as}{EI}$, in which M_a is the moment on the several divisions s due to unit vertical load at a,

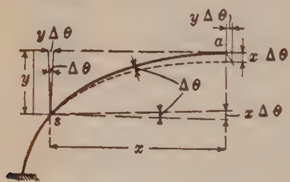

Fig. 81

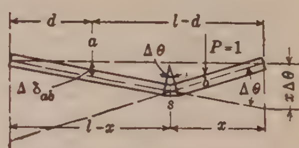

Fig. 82

likewise for horizontal deflection at a in the curved beam, $\Sigma\,\frac{Mys}{EI}$ may be written $\Sigma\,\frac{MM'_as}{EI}$, in which M'_a is the moment on the several divisions due to unit **horizontal** load at a.

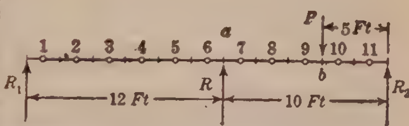
Simple Span Beam. (See Fig. 82.) For simplicity of demonstration the flexure contributed by a small length s only is shown to exaggerated scale in the figure. It will be convenient in what follows to find the constants for a load unity (say 1 lb.). Let δ_{ab} indicate deflection at a due to unit load at b and indicate the increment of deflection contributed by s as $\Delta\,\delta_{ab}$. By geometry $\Delta\,\delta_{ab} = \frac{x\Delta\theta d}{l}$. From what has preceded $\Delta\theta = M_b\frac{s}{EI}$ in which M_b = moment on s due to unit load. Then $\Delta\,\delta_{ab} = \frac{xd}{l}M_b\frac{s}{EI}$. Summing the effects of flexure on all elements s we have $\delta_{ab} = \Sigma M_b\frac{s}{EI}\cdot\frac{xd}{l}$. For load P greater than unity we have of course $P\,\delta_{ab} = P\Sigma M_b\frac{s}{EI}\cdot\frac{xd}{l}$. Note now that the expression $\frac{xd}{l}$ is the same as for moment on s due to unit load at $a = M_a$. The equation for deflection may then be expressed as $P\delta_{ab} = P\Sigma M_a M_b \frac{s}{EI}$. It is obvious from the form of this equation that $P\delta_{ab} = P\Sigma M_a M_b \frac{s}{EI} = P\delta_{ba}$. (Maxwell-Mohr's Theorem of Reciprocal Displacements.)

Application. Find R for the continuous beam shown in Fig. 83. If there were no reaction R the downward deflection at a for the 22-ft. span beam would be $P\delta ac = P\Sigma M_a M_b \frac{S}{EI}$. The upward deflection at a due to R acting on the 22-ft. span beam (that is $R\delta aa = R\Sigma M_a M_a \frac{S}{EI}$) must be equal and opposite; whence

$$R = \frac{P\,\delta ab}{\delta aa} = \frac{P\Sigma M_a M_b \frac{S}{EI}}{\Sigma M_a M_a \frac{S}{EI}}$$

In the numerical calculation I is, for simplicity of demonstration, assumed constant and equal divisions of 2 ft. are taken. $\frac{s}{EI}$, being constant, may then be placed outside the sign of summation and appearing in both numerator and denominator, it will cancel out. The method is just as simple for variable I and unequal divisions excepting that these quantities would be retained in the summations as illustrated in the example for the cantilever beam. The results are accurate to within 1%.

Point	M_a	M_b	M_aM_b	M_aM_a
1	0.45	0.23	0.10	0.20
2	1.36	0.68	0.93	1.85
3	2.27	1.14	2.59	5.16
4	3.17	1.59	5.04	10.05
5	4.09	2.05	8.39	16.70
6	5.09	2.50	12.72	25.85
7	4.90	2.95	14.45	24.00
8	3.81	3.41	13.00	14.51
9	2.72	3.86	10.50	7.40
10	1.64	2.32	3.81	2.69
11	0.54	0.77	0.42	0.29
Σ	....	....	71.95	108.70



$$R = \frac{71.95}{108.7} = 0.66\,P \qquad R_1 = \frac{5\,P - 6.6\,P}{22} = -\,0.07\,P$$

$$R_2 = 0.41\,P$$

Fig. 83

Referring to Fig. 83 and the equation above for R, note that $M_b = \frac{x'x}{l}$. Then $P\delta_{ac} = P\Sigma\left(\frac{M_a s}{EI}\cdot\frac{x}{l}\right)x' = P$ multiplied by the moment at the load point b of all the quantities $\frac{M_a s}{EI}$ considered as loadson the beam in their proper position as shown in Fig. 84.

The quantities $\frac{M_a s}{EI}$ when used in this way are termed "elastic" loads and the moments due to them will be designated by m. M_a in all cases is the moment on any division s due to a unit load acting at the point where the displacement is to be measured and in the direction in which the displacement is required.

Applying this principle to the continuous beam, influence line for the reaction $R = \dfrac{P\Sigma \frac{M_a s}{EI} \cdot \frac{x'x}{l}}{\Sigma M_a M_a \frac{s}{EI}}$ may be calculated as the load P moves over the span as illustrated in the numerical example. In this example $\frac{s}{EI}$ being constant, may be placed outside the summation sign, and appearing in both numerator and denominator it cancels out.

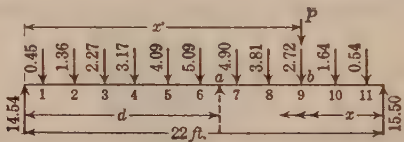


Fig. 84

M_{11} = 15.5	P at 11	$Ra = P\,(15.5 \div 108.7) = 0.14\,P$
M_{10} = 45.4	P at 10	$Ra = P\,(45.4 \div 108.7) = 0.42\,P$
M_9 = 72.0	P at 9	$Ra = P\,(72.0 \div 108.7) = 0.66\,P$
M_8 = 93.3	P at 8	$Ra = P\,(93.3 \div 108.7) = 0.86\,P$
M_7 = 107.8	P at 7	$Ra = P\,(106.8 \div 108.7) = 0.98\,P$
Ma = 108.7	P at a	$Ra = P\,(108.7 \div 108.7) = P$
M_6 = 110.6	P at 6	$Ra = P\,(110.6 \div 108.7) = 1.01\,P$
etc.	etc.	etc.

47. Two-hinged Arch

Refer to Fig. 85. Assume a curved beam resting on rollers at one end and simply supported at the other. Flexure in any small division s of the beam will cause a horizontal displacement at the free end $= y\Delta\theta = \frac{Mys}{EI}$ in which M is the bending moment on the division s due to the external loads neglecting the horizontal thrust H. The total displacement due to flexure in all the divisions $s = \Sigma \frac{Mys}{EI}$.

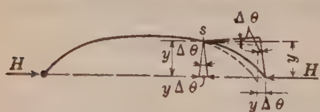

Fig. 85

Now assume a horizontal thrust applied to the end of the beam sufficient to counteract the horizontal displacement. New moments Hy are introduced acting on the individual divisions and we have: Total horizontal displacement due to thrust $= \Sigma y\Delta\theta = \Sigma \frac{(Hy)ys}{EI} = \Sigma \frac{Hy^2s}{EI}$. The horizontal displacement due to external loads and that due to the thrust being equal and opposite we have

$$\Sigma \frac{Mys}{EI} = \Sigma \frac{Hy^2s}{EI}, \quad \text{or} \quad \frac{I}{E}\Sigma \frac{Mys}{I} = \frac{H}{E}\Sigma \frac{y^2s}{I}.$$

From which $H = \dfrac{\Sigma \dfrac{Mys}{I}}{\Sigma \dfrac{y^2 s}{I}}$ for a curved beam hinged at the ends but ends fixed in location. (Two-hinged arch.)

In the above equations y is also an expression for moment in the several divisions due to unit horizontal load acting like H. Whence the expression for H may be written $\dfrac{\Sigma M M_a \frac{s}{I}}{\Sigma M_a M_a \frac{s}{I}}$ in which M_a is the moment in the several divisions due to such unit load.

Temperature Stresses. c = coefficient of expansion (0.0000065). t = temperature change in degrees Fahrenheit. l = span length. E = modulus of elasticity of concrete.

$$\Sigma y \Delta\theta = ctl = \frac{H}{E}\Sigma\frac{y^2 s}{I}; \text{ from which } H = \frac{Ectl}{\Sigma\frac{y^2 s}{I}}$$

Rib Shortening. fc = approximate average stress on the concrete throughout the arch due to thrust from the dead load.

$$\Sigma y \Delta\theta = \frac{fcl}{E} = \frac{H}{E}\Sigma\frac{y^2 s}{I}; \text{ from which } H = \frac{fcl}{\Sigma\frac{y^2 s}{I}}$$

48. Rigid-Frame Bridges

The rigid-frame bridge developed by the Westchester County (New York) Park Commission, A. G. Hayden, Designing Engineer, has proven its advan-

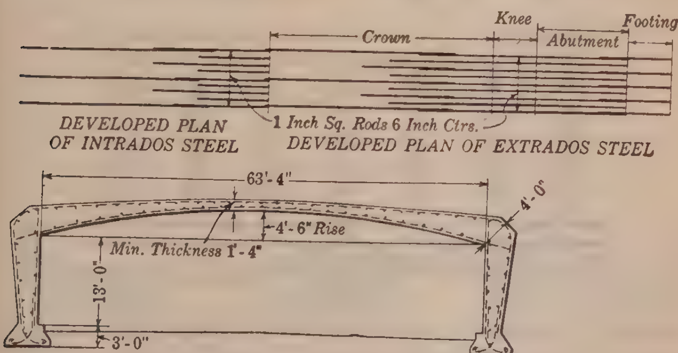

Fig. 86

tages both from an economic and architectural point of view and is peculiarly adapted to structures separating intersecting highways.

Fig. 86 shows typical details of a single-span solid-section frame; Fig. 87, two-span solid-section frame. Fig. 88 shows a ribbed type frame consisting of a series of 5 rigid frames supporting a floor slab and having a reinforced-concrete cutoff wall at each end to retain the approach fill. Although certain effects of skew exist in the skewed ribbed type frame and were accounted for in design, it was used for heavily skewed bridges before other effects had been

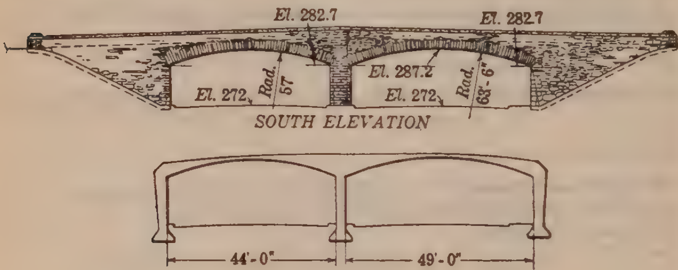

Fig. 87

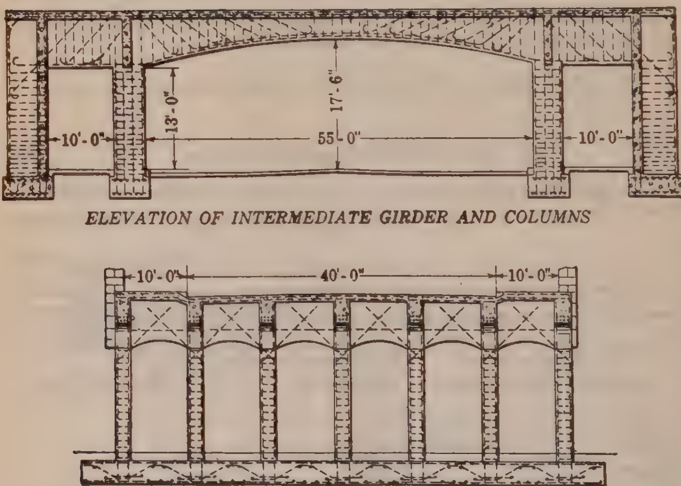

Fig. 88

evaluated. The complete solution of problems of design relating to skewed arches and frames of solid section now makes it possible to design such structures with certainty and supersede the ribbed type. Fig. 89 shows the adaptation of rigid-frame design to structural steel, which will not be treated in this section.

The intrinsic economy of the rigid-frame bridge lies in the fact that the external work and therefore equivalent internal work done under load is less for the rigidly connected structure than for the beam separately supported on its abutments. Moreover, the entire structure is effective for resisting this smaller amount of external work. There are no idle members. Still further, the horizontal loads due to earth pressure counteract to a degree the effect of the vertical loads.

In design, the structure may be made safe as a self-supporting unit discounting earth pressure. Passive earth pressure developed by flexure in the structure may also be taken into account though this must be assumed. Stresses are easily calculated for an assumed uneven settlement of the footings.

In addition to the intrinsic economy of the frame bridge further economy is realized in the approaches since the distance from roadway under to roadway over may be made less than for other types on account of the slender proportions of the structure. The fixed arch of like span and equal area-way requires greater rise in order to reduce temperature stresses. Temperature stresses in frame bridges of the proportions illustrated are negligible, although in special cases they should be examined.

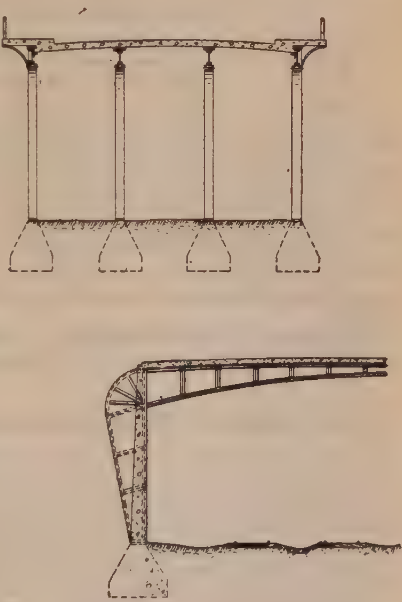

Fig. 89

Methods of Design. Frame bridges of the Westchester County Parkways have been designed by a variety of methods, some entirely new, but all giving the same results. Later methods have been greatly simplified. It is beyond the scope of this work to do more than indicate the line of attack which will be illustrated by a partial design of

Fig. 90

a double-span solid-section reinforced-concrete rigid-frame bridge by the influence-line method.

Before proceeding with the illustrative example some general observations will be made. The calculation given is based on the assumption of hinged condition at the bottom of the footings. Fixed condition might as well have been assumed although for a structure resting free on the soil such condition could not be realized. The absence of a definite hinge at the bottom of the footing does, however, introduce a small amount of restraint here which may be taken into account as follows, though this is generally unnecessary. Fig. 91 shows one type of base, resting free on the soil. It is obvious that the resultant reaction cannot come at either edge, since this would presume infinite soil pressure at these points. If it could suddenly come very close to the edge causing extremely high local pressure, slight yielding of the soil would automatically throw it inward again. There is, therefore, a reasonable range on the base within which the resultant reaction must come, and theoretical critical positions controlling the stresses in any region of the frame may be easily determined for any particular case. Detailed discussion, however, is beyond the scope of this work. It is usually sufficient for all practical purposes to make analysis as for hinge at a, since the footing reinforcement extending upward into the leg and the uncalculated soffit reinforcement will adequately provide for uncalculated restraint.

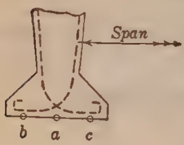

Fig. 91

If the structure is seriously restrained at the footings, as by embedded piles, calculation for both hinged and fixed conditions will cover all contingencies.

49. Design of Double-Span Continuous Frame

If the statically indeterminate structure shown in Fig. 92 is designed for hinged conditions at the footings (resting free on the soil) there will be, for any system of loads, six unknown horizontal and vertical components of reactions as shown. These cannot be solved by the laws of statics. Suppose the supports are arbitrarily altered by the removal of redundant reactions C, D and F as shown in Fig. 93. This "transformed" structure is statically determinate and for any given condition of loading all the stresses and therefore all the deflections can be found by statics. The problem resolves itself into finding in Fig. 93 the vertical and horizontal deflections at (2) and horizontal deflections at (3), due to the load P by the methods indicated in the preceding text, and then finding what unknown forces C, D and F will bring these deflections back to zero; that is, what reactions will restore the conditions to those shown in Fig. 92 when the problem will be solved. When C, D and F have been determined, the application of them to the structure in Fig. 93 causes reaction in the direction of H_1, V_1, and V_3 which, added to the latter, gives the final reactions A, B and G as will be shown.

Let δ_{cp} = deflection in direction and at point of application of C due to unit load applied like P.

δ_{cc} = deflection in direction and at point of application of C due to unit load applied like C.

δ_{cd} = deflection in direction and at point of application of C due to unit load applied like D.

δ_{cf} = deflection in direction and at point of application of C due to unit load applied like F.

Then the deflections in the direction and at point of application of C due to the actual loads and unknown reactions are

$$P\delta_{cp}, \quad C\delta_{cc}, \quad D\delta_{cd}, \quad F\delta_{cf}$$

Since the reactions C, D and F must be such that the deflection $P\delta_{cp}$ caused by the load P in the transformed structure (Fig. 93).

$$P\delta_{cp} + C\delta_{cc} + D\delta_{cd} + F\delta_{cf} = 0$$

By like reasoning we have also the following equations:

$$P\delta_{dp} + C\delta_{dc} + D\delta_{dd} + F\delta_{df} = 0$$
$$P\delta_{fp} + C\delta_{fc} + D\delta_{fd} + F\delta_{ff} = 0$$

As demonstrated for the simple beam, the quantities δ_{cp}, δ_{cc}, δ_{cd}, δ_{cf} and so on, are equal to $\Sigma M_c M_p \frac{s}{EI}$, $\Sigma M_c M_c \frac{s}{EI}$, $\Sigma M_c M_d \frac{s}{EI}$, $\Sigma M_c M_f \frac{s}{EI}$ and so on in which M_p is the moment on any division s due to the load P and M_c, M_d, M_f (and so on) are moments on any division s due to load unity acting like the reaction components. Whence we have the final equations

$$-P\Sigma M_c M_p \frac{s}{EI} = C\Sigma M_c M_c \frac{s}{EI} + D\Sigma M_c M_d \frac{s}{EI} + F\Sigma M_c M_f \frac{s}{EI}$$
$$-P\Sigma M_d M_p \frac{s}{EI} = C\Sigma M_d M_c \frac{s}{EI} + D\Sigma M_d M_d \frac{s}{EI} + F\Sigma M_d M_f \frac{s}{EI}$$
$$-P\Sigma M_f M_p \frac{s}{EI} = C\Sigma M_f M_c \frac{s}{EI} + D\Sigma M_f M_d \frac{s}{EI} + F\Sigma M_f M_f \frac{s}{EI}$$

When the coefficients of C, D and F have been determined numerically, the above three equations may be solved for the three unknown components of reactions C, D and F. If there is more than one load on the structure M_p is the moment on any division s due to the system of loads.

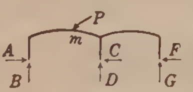

Fig. 92

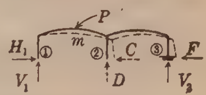

Fig. 93

This method of determining the redundant reaction components C, D and F is well adapted for cases where a fixed loading is being considered, as was illustrated in the example of the 2-span beam. If, however, moving load is to be considered and influence lines for the redundant reaction components are desired the method of placing the "elastic loads" on the structure may be used as was illustrated for the 2-span continuous beam in the **text preceding.** The labor of calculation is thereby reduced. For example, the expression $P\Sigma M_c M_p \frac{s}{EI}$ above may be put $P\Sigma\left(M_c \frac{s}{EI}\right) M_p$ in which M_p is the moment on any particular division s of the transformed structure, due to load $P = 1$, that is $\frac{xd}{l}$ (l being total span of transformed structure) and $M_c \frac{s}{EI}$ is a quantity pertaining to such division. The arithmetical process in calculating $M_c \frac{s}{EI} M_p$ a is the same as calculating the moment at P due to the quantity $M_c \frac{s}{EI}$ acting as a load on its particular division; and $\Sigma M_c \frac{s}{EI} M_p$ is the moment at P due to the several quantities $M_c \frac{s}{EI}$ in their appropriate positions. It follows that the calculation of moments at all points of the transformed structure under such loading will give a complete influence line for the influence load unity moving over the span.

If we designate moments due to the quantities $M_c\frac{s}{EI}$ treated as loads by the symbol m_c we have as the final equation

$$Pm_c = C\Sigma M_c M_c\frac{s}{EI} + D\Sigma M_c M_d\frac{s}{EI} + F\Sigma M_c M_f\frac{s}{EI}$$

Likewise

$$Pm_d = C\Sigma M_d M_c\frac{s}{EI} + D\Sigma M_d M_d\frac{s}{EI} + F\Sigma M_d M_f\frac{s}{EI}$$

and

$$Pm_f = C\Sigma M_f M_c\frac{s}{EI} + D\Sigma M_f M_d\frac{s}{EI} + F\Sigma M_f M_f\frac{s}{EI}$$

The use of these equations will be illustrated in the example following:

Nomenclature: Terms not defined in the text or indicated on the figures are:

M_E and N_E: Moment and thrust at any point in the structure due to earth pressure.

N_p, N_c, N_d, N_f: Thrusts at any point in the structure due to the loads and reactions P, C, D and F.

M_t and N_t: Movement and thrust at any point in the structure due to temperature change.

t = total depth of section of arch ring or frame.

In the following calculations the divisions s are all 5 ft.; s and E (modulus of elasticity) being constant cancel out of all equations, excepting temperature equations.

Fig. 94 shows the structure to be analyzed and Figs. 95*a*, 95*b*, 95*c* and 95*d* show the method of calculating M_c, M_d, M_f and M_p used in the equations.

Calculation for Reactions C, D and F

From equations heretofore derived (p. 1085) but canceling out s and E which are constant:

$$Pm_c = C\Sigma\frac{M_cM_c}{I} + D\Sigma\frac{M_cM_d}{I} + F\Sigma\frac{M_cM_f}{I}$$

$$Pm_d = C\Sigma\frac{M_dM_c}{I} + D\Sigma\frac{M_dM_d}{I} + F\Sigma\frac{M_dM_f}{I}$$

$$Pm_f = C\Sigma\frac{M_fM_c}{I} + D\Sigma\frac{M_fM_d}{I} + F\Sigma\frac{M_fM_f}{I}$$

Substituting the numerical valves for terms that have been calculated in the table we have for $P = 1$:

$$m_c = 15903\ C + 9031\ D = 15485\ F$$

$$m_d = 9031\ C + 11446\ D + 18062\ F$$

$$m_f = 15485\ C + 18062\ D + 30971\ F$$

Solving these equations,

$$C = -\ 0.00006115\ m_f + 0.00012235\ m_c$$

$$D = -\ 0.00063834\ m_f \qquad\qquad + 0.00109462\ m_d$$

$$F = -\ 0.00043514\ m_f - 0.00006115\ m_c + 0.00063834\ m_d$$

In the table that follows the values of m_c, m_d amd m_f are substituted and reactions C, D and F obtainéd.

Temperature Stresses

c = coefficient of linear expansion = elongation per unit length per degree Fahrenheit rise in temperature.

t = temperature change in degrees Fahrenheit.

l = span length.

Table of moments and thrusts gives values for 50° rise.
For 50° drop in temperature, the signs will change.

Fundamental equations already derived are:

$$P\delta_{cp} + C\delta_{cc} + D\delta_{cd} + F\delta_{cf} = 0$$

$$P\delta_{dp} + C\delta_{dc} + D\delta_{dd} + F\delta_{df} = 0$$

$$P\delta_{fp} + C\delta_{fc} + D\delta_{fd} + F\delta_{ff} = 0$$

in which $P\delta_{cp}$, $P\delta_{dp}$ and $P\delta_{fp}$ are deflections of points in the transformed system. An increase of temperature causes deflection of these same points in like directions and these temperature deflections may be substituted for the deflections $P\delta_{cp}$, $P\delta_{dp}$ and $P\delta_{fp}$ in the above equations. Substituting the proper flexual equivalents in the remaining terms and multiplying through E/s, we have

$$-\frac{E}{s}lct = C\Sigma\frac{M_c M_c}{I} + D\Sigma\frac{M_c M_d}{I} + F\Sigma\frac{M_c M_f}{I}$$

$$0 = C\Sigma\frac{M_d M_c}{I} + D\Sigma\frac{M_d M_d}{I} + F\Sigma\frac{M_d M_f}{I}$$

$$-\frac{E}{s} \times 2\,lct = C\Sigma\frac{M_f M_c}{I} + D\Sigma\frac{M_f M_d}{I} + F\Sigma\frac{M_f M_f}{I}$$

After substituting numerical values in these equations and solving

$$C = 0.$$

$$D = -\ 0.00063834\frac{E}{s} \times 2\,l \times ct.$$

$$F = \ 0.00040457\frac{E}{s} \times 2\,l \times ct.$$

$$\frac{E}{s} \times 2\,lct = \frac{144 \times 2\,500\,000}{5} \times 100 \times 0.0000065 \times 50 = 2\,340\,000.$$

Then $C = 0$ $\quad D = -\ 1.494$ kips. $\quad F = 0.947$ kip.

In center post $M_t = 0$. $N_t = -\ 1.49$ kips.

In end posts $N_t = -\frac{D}{2} = +\ 0.75$ kip.

In top (horizontal member) $N_t = F = +\ 0.95$ kip.

Live load: Bridge is designed for uniform live load of 70 lb. per linear foot width of structure and in addition a single concentration of 3300 lb. per foot width of structure.

Uniform live load on a 5-ft. division = 5 × 70 = 350 lb. = 0.35 kip.
Concentration as above 3.30 kips.

The following calculations are for the design of section at Point 11. Moment and thrust due to earth pressure are brought forward from the calculation sheet for "earth pressure." Dead load and live load moments and thrusts for actual loads are derived in the following table. Column 1 shows the load point. Columns 2 and 3 tabulate respectively the influence line ordinates for moment and thrust as scaled from the influence diagram for point 11. Column 4 tabulates the actual dead loads at the various points as shown on the structure diagram. Column 5 tabulates the live loads with concentration placed at Point 9 for negative moment and at point 11 for positive moment. Actual dead and live load moments and thrusts are obtained by multiplying across columns 2 × 4, 2 × 5, 3 × 4 and 3 × 5 to obtain results in columns 6 to 11. The summations at the bottom give total effect of all the loads on the structure.

Moments in kip-ft. (1000 ft-lb.)
Thrusts in kips (1000 lb.)

Summary of Maximum Forces Acting on Section at Point 11

Note. Forces have been calculated for the various sections due to earth pressure acting at the right end of the structure. Forces at any section due to earth pressure left will be the same as forces on a symmetrically placed section in the other span due to earth pressure right. For example, forces at point 11 for earth pressure left will be the same as forces at point 17 calculated for earth pressure right. The sum of the calculated forces for points 11 and 17 will therefore give the forces due to balanced earth pressure for either point.

	Moment kip-ft.	Corresponding thrust, kips
Dead load	−17.7	+5.3
Earth pressure, right	+ 7.3	+0.3
Earth pressure, left	− 3.4	+1.6
Sub total	−13.8	+7.2
Live load	−14.2	+2.0
Sub total	−28.0	+9.2
Temperature	− 7.1	−1.0
Total	−35.1	+8.2

Having the maximum moment and thrust acting on the section, the required area of reinforcing steel and the stresses in the concrete may be calculated by the methods described elsewhere in this Section or by any other convenient method.

Similar calculations needed for all other parts.

50. Analysis of a Symmetrical Fixed Arch

The symmetrical fixed arch is statically indeterminate to the third degree. The analysis is therefore similar to that of the two-span rigid frame given above.

One-half of the transformed structure used in this analysis is shown in Fig. 98. The problem is to find the redundants B, C and D, such that under applied loads or deformations the ends of the two cantilevers formed by cutting the arch at the crown will coincide. To simplify this problem, the redundants are applied at the end of a rigid bracket directly below and at z distance from the crown. The equations taken directly from the previous analysis express the conditions here:

$$\delta_b = B\delta_{bb} + C\delta_{bc} + D\delta_{bd} + \Sigma P\delta_{bk} = 0$$
$$\delta_c = B\delta_{cb} + C\delta_{cc} + D\delta_{cd} + \Sigma P\delta_{ck} = 0$$
$$\delta_d = B\delta_{db} + C\delta_{dc} + D\delta_{dd} + \Sigma P\delta_{dk} = 0$$

From the condition of symmetry $\delta_{bd} = \delta_{db} = \Sigma\dfrac{xs}{EI} = 0$ and $\delta_{cd} = \delta_{dc} = \Sigma\dfrac{xys}{EI} = 0.$

In addition, $\delta_{bc} = \delta_{cb} = \Sigma\dfrac{ys}{EI} = 0$ when $Z = \dfrac{\Sigma y''s/I}{\Sigma s/I}$. (See Fig. 98.)

The equation then becomes:

$$B\delta_{bb} + \Sigma P\delta_{bk} = 0$$
$$C\delta_{cc} + \Sigma P\delta_{ck} = 0$$
$$D\delta_{dd} + \Sigma P\delta_{dk} = 0$$

Temperature and rib shortening effects are determined by substituting, for the loading deflections, the corresponding deflections due to temperature change and shortening of the arch caused by axial thrust. The equations become:

Temperature	Rib Shortening
$B\delta_{bb} = 0$	$B\delta_{bb} = 0$
$C\delta_{cc} - ctL = 0$	$C\delta_{cc} + \dfrac{f_c}{E}L = 0$
$D\delta_{dd} = 0$	$D\delta_{dd} = 0$

The minus sign in the temperature equation expresses the fact that for a rise (positive) in temperature, the movement of point O is opposite to the direction of C.

In the rib shortening formula, f_c = thrust at the crown divided by area of crown cross-section. This method for determining the effect of rib shortening is approximate, but the results are sufficiently near those determined by more accurate analysis to make the design safe for the usual arch under live load.

The solution of a problem is shown. A load of unity is applied (see Fig. 98) and the redundants determined. Any system of loads in the plane of the arch axis can be applied and B, C and D determined in the same manner. The remaining reactions can be determined by laws of statics.

This method applies equally to concrete or to steel structures, the only difference being in the calculation of I.

Influence lines are particularly useful in presenting a problem clearly and a systematizing of computations will save time and labor.

General Equations

Loads: $B\delta_{bb} + \Sigma P\delta_{bk} = 0$

$C\delta_{cc} + \Sigma P\delta_{ck} = 0$

$D\delta_{dd} + \Sigma P\delta_{dk} = 0 \qquad M_b = 1$

Temperature: $B = 0 \qquad M_c = y$

$C\delta_{cc} - ctl = 0 \qquad M_d = x$

$D = 0$

$$z = \frac{\Sigma y''\frac{s}{I}}{\Sigma\frac{s}{I}} = \frac{104.5}{20} = 5.23$$

M = moments due to load P

$$C = \frac{288\,000\,000 \times .000006 \times 40 \times 100}{1215.8} = \pm\ 5700$$

51. Integral Arch Action

In the design of open spandrel reinforced-concrete arches it has been customary to design the arch rib as carrying the dead load of the spandrel columns or walls and the floor system without being otherwise affected by the superstructure, and to design the superstructure as such without being affected by the action of the arch rib. Recent investigations both analytical and experimental in connection with structures in service show that large discrepancies, not always on the safe side, are introduced by neglecting in design the continuity of the structure. Reinforced-concrete does not lend itself to a complete segregation of the parts, and the usual assumptions made in

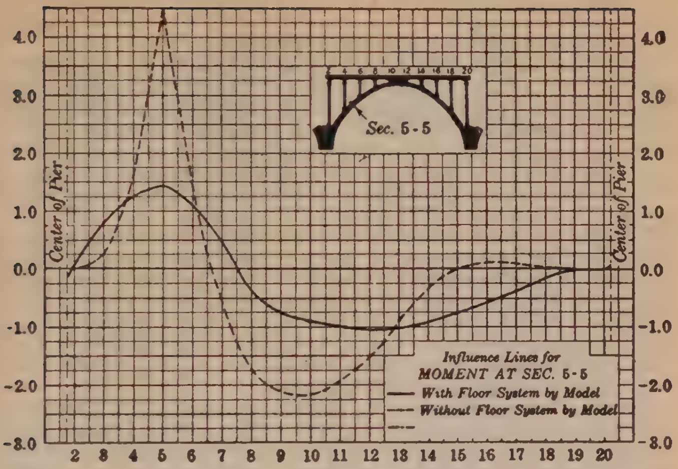

Fig. 99

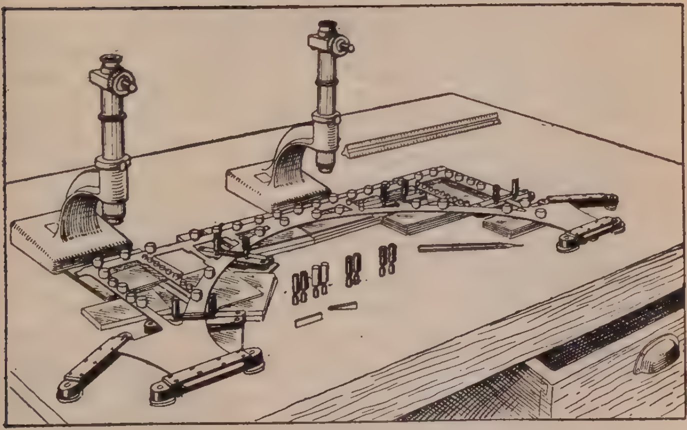

Fig. 100

design are often at serious variance with the conditions realized in construction. This caution is introduced here, without detailed discussion of the correct methods of design, in order that certain important points shall be recognized and proper means taken for their solution.

Fig. 99 shows a comparison of the calculated influence line for moment near the quarter point of an arch rib for the two cases. The solid line is the influence line obtained by assuming the entire structure to act integrally as usually constructed; the dotted line is that obtained by assuming the arch rib to carry the superstructure as dead load without inter-action between the two. Comparisons for thrust and shear at this point and for moment, thrust and shear at other points show like discrepancies, not always on the safe side.

The influence lines were obtained by the deformeter method of Professor George E. Beggs of Princeton University. This is a process of obtaining a ratio between an indeterminate reaction or between the stress in a member of an indeterminate structure and the load producing it, by measuring, in a celluloid or cardboard model of the structure, the relation between an arbitrarily imposed displacement at the section under consideration and the resulting displacement at the point of application of the load and in the direction of its application as described in Sect.

The structure for which the above comparisons are given is the Ashtabula Viaduct in Ohio as analyzed by D. H. Overman, Bridge Designer, Ohio Department of Highways, of which J. R. Burkey is Chief Engineer of Bridges. Fig. 100 shows Professor Beggs's deformeter apparatus mounted over the celluloid model of this structure. The model is shown weighted down upon small ball-bearings resting upon plate glass to reduce friction acting against free motion in the model.

52. Skewed Arches

Demonstration of methods of analysis for the skew arches beyond the scope of this book but a brief general discussion is pertinent.

The failure of many skewed reinforced-concrete arch bridges and concern for the safety of others have led many engineers to condemn such construction. The rapid growth of automobile traffic, however, and the economic pressure for elimination of grade crossings have brought this problem to the fore. It is doubtful if the public with its growing appreciation of esthetics in bridge construction will tolerate the construction of old-time girder and truss types for the many over-passes and under-passes that will have to be built in the near future, and the nature of modern traffic precludes kinking one highway, crossing another, in order to avoid the construction of a skewed arch or frame structure. The Arch Committee of the American Society of Civil Engineers has gone far toward a solution of this problem, taking advantage of the mathematical researches of Professor J. Charles Rathbun of the South Dakota School of Mines * and the investigations of Professor George E. Beggs of Princeton University by deformeter methods of mechanical analysis.

Fig. 101 shows graphically the principal forces acting on a skewed single span arch like structure (rigid-frame bridge) that do not exist in the "right" structure. A comparison of Figs. 102 and 103 shows the effect, on the principal system of reinforcing, of the forces introduced by the skew. The transverse rods in Fig. 102 are merely tie-rods whereas the transverse rods in Fig. 103 are principal reinforcement. This is sufficient evidence of the importance of accounting for structural effects of skew in the safe design of important structures.

53. Retaining Walls

Forms of Walls built of reinforced concrete are made such that advantage is taken of the weight of the material supported to increase the stability of the wall against overturning. Fig. 104 represents in outline the usual type of reinforced wall. It consists of a vertical wall AE attached to a floor DC. For low walls the upright part of AE may act simply as a cantilever; and likewise the parts EC and ED. For higher walls the part AE is tied to EC at intervals by back walls, AEC, in the form of thin transverse walls with tension reinforcement. The projecting portion ED may still act as a cantilever, or it, also, may be connected to the vertical wall AE by means of buttresses. In either case the earth pressures act in essentially the same manner, and the necessary width of base is found

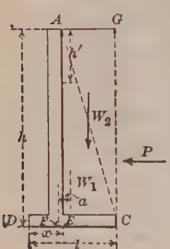

Fig. 104

in the same way. The first type is adapted to heights of 12 to 18 ft. For higher walls the second type will be more economical.

Stability of Wall. The stability of a retaining wall is usually determined with reference to its overturning. For safety in this regard the common requirement is that the resultant line of pressure shall intersect the base within the middle-third. This gives a distribution of pressure such that there is some compression over the entire section. Besides stability against overturning, the pressure on the foundation must be investigated and if found excessive the footings must be extended until the pressures are reduced to safe values.

In Fig. 104 let h = height of wall, l = width of base, x = distance from toe to back of wall AE, $k = x/l$, P = total horizontal pressure of earth against the vertical section GC, w = weight of earth filling per cubic foot, W_1 = weight of masonry per lineal foot, W_2 = weight per lineal foot of earth above the floor EC, a = lever arm of W_1 about point F, the edge of the middle-third. Then in order that the resultant pressure shall cut the outer edge of the middle-third the value of l is given by

$$l = \sqrt{\frac{2\,Ph - 6\,W_1a}{wh\,(1 + 2\,k - 3\,k^2)}}$$

If the moment of the masonry, W_1a, be neglected the value of k which will give a minimum value of l is 1/3. Using this value of k and taking w = 100 lb. per cu. ft. the value of l becomes $l = 1/8\,\sqrt{P}$ in which l is to be expressed in feet and P in pounds.

For other values of x/l, or k, the width of base must be increased over that required for k = 1/3 by the following percentages:

For $x/l = k$ =	0.5	0.25	0.15	0.10	0.0
Per cent increase =	2	2	4	6	15

Compared to masonry walls the reinforced wall with l/h = 1/4 to 1/3 has about the same stability as a solid masonry wall of the same width of base, and of the common type in which the outer face is battered 1 to 2 in. per foot. Under ordinary conditions a width of 0.4 to 0.5 the height will be required.

Foundation Pressures. If the pressures on the foundations need to be considered the value of these pressures is obtained as described for footings, after first determining where the resultant of W_1, W_2 and P cuts the base. This feature of the design is too often neglected and most of the failures of retaining walls have been due to excessive pressures at the outer toe. The pressure can be reduced to safe limits by widening the foundation or the foundation may be strengthened by means of piles.

Stresses in the Wall. Form (1), Fig. 105 or 106. The bending moment at the base of the upright portion AE is $Ph/3$. At any other section, F, it is $P'h'/3$, where P' is the pressure for depth h'.

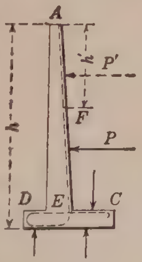

Fig. 105

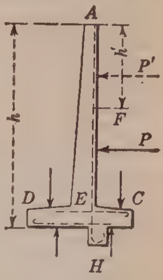

Fig. 106

Only a portion of the reinforcing rods need be carried up the full height. At the base the vertical rods must have sufficient anchorage to develop their full strength.

The cantilever DE must be treated in the same manner as the upright cantilever. The pressures will be much heavier and the shear and bond stress may need attention. The cantilever EC is acted upon by an upward and a downward force as shown in the figure. The maximum moment will be at E and will be negative. It is provided for by reinforcement as shown, which may be bent around into the toe DE or down into the projection EH if such is necessary to prevent sliding. The bending moments in DE and EC, due to upward earth pressure, can be readily found by means of the moment formulas given under the subject of footings for foundations.

Form (b), Fig. 107. The external pressures are practically the same as in the case previously considered. The pressure against the longitudinal wall AE is carried laterally for the most part and given over to the inclined back

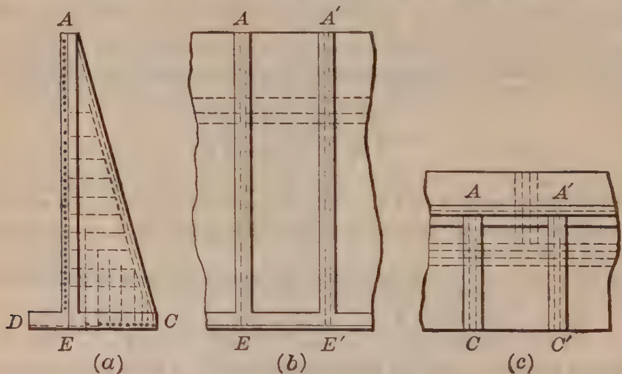

Fig. 107. Retaining Walls

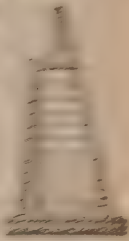
walls. The wall AE must therefore be designed as a slab supported along the lines AE, $A'E'$, and EE', Fig. (b).

The floor EC is supported by the back wall AEC and is therefore reinforced longitudinally as a floor slab in accordance with the resultant pressure at any point. The back wall ACE acts as a cantilever beam anchored to the floor. It is also a T-beam, the flange being the longitudinal wall AE. The tension along the edge AC is carried by rods near the edge, whose stress at any point is found with sufficient accuracy by an equation of moments taken about the center of the front wall. The maximum stress will be at the bottom. The main tension rods in AC should be well anchored in the reinforcing rods of the floor EC. A few additional vertical rods should also be put in to insure thorough bonding of floor to wall.

A horizontal beam may be made of the coping at A, thus giving some support to the wall AB along its upper edge. A downward projection may be necessary at the toe D, or at some other point in the base, in order to increase the resistance against forward sliding.

To prevent unsightly cracks, long walls must be provided with expansion joints at intervals of 50 to 75 ft., or must be reinforced longitudinally by 0.1 to 0.2% of steel. Long walls have thus been successfully built without expansion joints.

The form of retaining wall shown in Fig. 107 was extensively used on the Great Northern R. R. at Seattle, Wash. (Eng. News, Vol. 53, 1905). An estimate by C. F. Graff of the amounts of material per lineal foot required in reinforced and plain con-



is less likely to be injured in driving than a wooden pile. Where the bearing capacity depends largely upon frictional resistance the strength of the concrete pile may be taken the same as that of the wooden pile. Tapered piles appear to have a bearing capacity in soft material considerably greater than a straight pile of the same average diameter.

In the construction of piers in sandy beaches molded piles having an enlarged base have been very successfully used. These have been jetted into place. The same form is well adapted generally to foundations in sand where the jet process can be used.

In driving molded piles a driving head is used in which a cushion of sand, rope, or some other convenient material is interposed between a driving block of wood and the concrete. Experience indicates that any injury caused in driving rarely extends more than a few inches from the base of the pile. The jet process may often be used as in the case of wooden piles. In this case the end of the pile is preferably made square in order to provide a maximum of bearing surface. Where piles of considerable length are required the lower portion may often be advantageously made of wood and the upper portion of concrete doweled to the wooden pile. A considerable saving in cost is thus possible. In open water a hollow concrete pile driven over a wooden pile and to a firm bearing into the ground has given very satisfactory results.

The cost of concrete piles is generally from two to four times as much as that of wooden piles, so that the former are not likely to be economical where the conditions are favorable to the life of the wooden pile.

Sheet piling may also be made of concrete to advantage wherever it is desirable to leave it in place as a part of the permanent structure.

Repairs to Wooden Pile Structures have been successfully made by enclosing the upper portion of the wooden pile within a concrete box constructed of slabs of reinforced concrete.

55. Pipe and Box Culverts

Pipe and Box Culverts. For small openings the monolithic pipe or box form is very advantageous. Considerable settlement, as a whole, may be permissible, and hence solid foundations may not be needed. The cross-section may be circular, eliptical or rectangular. Theoretically, the elliptical form is the best, as it corresponds more nearly to the requirements for resisting the earth pressure. The circular is practically as good for small openings, whereas for large openings the rectangular form will often be the best on account of its simplicity and the smaller head-room required. Where the culvert is manufactured at a shop and transported to the site, the circular or the elliptical form will usually be the most advantageous.

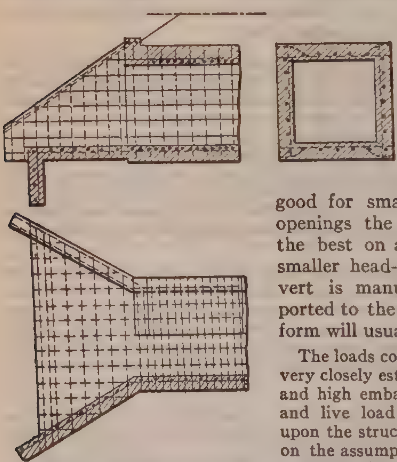


Fig. 109. Standard Box Culvert

The loads coming upon such structures cannot be very closely estimated, but except for small spans and high embankments the entire weight of filling and live load is usually assumed to act directly upon the structure. The stresses may be calculated on the assumption that this load acts vertically and is uniformly distributed over the width or diameter of the culvert. The lateral pressure should not be considered as an aid in supporting the vertical load. On this basis the maximum bending moment in a circular culvert is given by $M = 1/16pd^2$, where M =

bending moment at crown and at center of base for a unit length of culvert, p = load per unit area and d = diameter of culvert. For rectangular culverts the bending moments may be taken as for a simply supported beam, and in the vertical walls the moments may be calculated for a lateral pressure equal to 1/8 the vertical load.

Reinforcement of Culverts. In the circular form a wire mesh is convenient, especially for small diameters. A single mesh is sufficient, placed near the extrados at the sides and crossing the central axis at about the quarter point. In the rectanglar form, if reinforcement for negative moments at the corners is omitted, then the four sides will act as simple beams.

Longitudinal reinforcement should be provided to some extent. Where foundations are good a very small amount will be sufficient, but if settlement is likely to occur the longitudinal reinforcement becomes of importance. The entire culvert will act as a beam subjected mainly to positive bending moments. Most of the reinforcement should therefore be placed along the bottom of the culvert. Fig. 109 is a standard design for a rectangular box railroad culvert.

Tests of reinforced culvert pipe by A. N. Talbot showed that under concentrated loads the actual strength was fully equal to the theoretical strength; and that under a load distributed by means of a sand box the actual effective strength was relatively somewhat greater than for concentrated loads. Complete failure in the latter tests was generally prevented by lateral support from the sand box.

56. Dams

Two Types of Reinforced-Concrete Dams are shown in Figs. 110 and 111. The first is suitable for locations where little or no water passes over the crest, the second is designed to act as a spillway. In both cases the dam consists

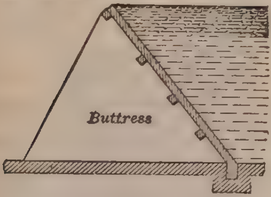

Fig. 110

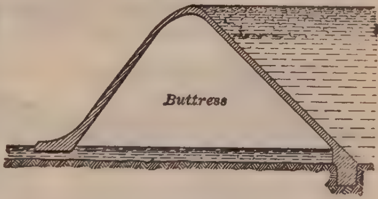

Fig. 111

of a water-tight reinforced floor on the upstream side, supported by solid buttresses placed 10 to 15 ft. apart and 12 to 24 in. thick. The upper wall may be supported directly on the cross walls and reinforced with longitudinal rods, or longitudinal beams may be used as shown and the slab supported on these. The pressure on the foundation is determined by considering the resultant of water pressure and weight of dam. The buttresses or cross walls are subjected to compressive stresses only. Ample longitudinal reinforcement should be provided to bind the structure together thoroughly.

Where the foundation is solid rock the buttresses may rest directly upon it, but where a pile foundation is required a continuous floor should be provided under the entire structure and covering the heads of the piles. If well bonded together a reinforced-concrete dam is exceedingly strong and stable and must fail as a unit if at all. Great care must be exercised in securing a thorough connection between the foundation and dam by means of a deep concrete connection at the upper toe. When founded on piles all seepage of water underneath the dam must be cut off by a line of sheet piling at the upper toe. This piling should be well covered by the concrete. To prevent upward pressure on the floor, or upon the lower face, drain openings should be provided connecting the interior with the tail-water level.

57. Dock and Harbor Walls; Breakwaters

Forces to be Considered. Dock and harbor walls not subjected to wave action are designed as retaining walls subjected to the earth pressure on the land side with surcharge due to loads on docks or quays. The action of heavy ice may require consideration, both with respect to its pressure and its wearing effect. In the case of outer protecting works, such as breakwaters, piers or jetties, the action of the waves is the principal force to be considered.

Force of Waves. The pressure or force exerted by waves depends upon the velocity of the impinging water and its depth. The former depends upon the exposure, wind velocity, depth of water and shape of bottom. The velocity in shallow water is approximately proportional to the square root of the height of wave and the depth of water. The pressure due to impact is proportional to the square of the velocity and therefore is also approximately proportional to the height of wave and depth of water.

Pressures due to impact of high waves have been measured in several cases. For waves 10 ft. high, pressures of 1800 to 3000 lb. per sq. ft. have been observed, and for extremely high waves of 25 to 30 ft. pressures of 6000 to 7000 lb. per sq. ft. have been noted. In exposed locations large blocks of concrete weighing 3000 tons have been moved, requiring an estimated average pressure of over 2 tons per sq. ft. The maximum intensity occurs at about the mean water level, is zero at the crest and gradually diminishes towards the bottom. The impact of waves on either vertical or sloping walls causes large masses of water to be thrown upward which, on falling, strikes severe blows upon the upper surface of the wall or breakwater, tending to rupture it.

Breakwaters are constructed in various ways. Timber cribs filled with stone are suitable for moderate wave action. The same construction, capped

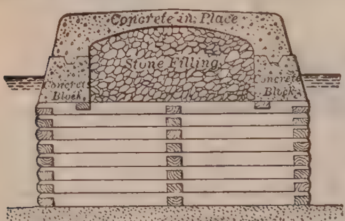

Fig. 112

Fig. 113

with concrete, as shown in Fig. 112, forms a strong combination. The structure is built to above the water-level by the use of large concrete blocks. The whole is then capped with mass concrete. Fig. 113 illustrates the same general type in which the mass is built of mass concrete deposited under water within temporary frames. Separate concrete blocks are often dovetailed or clamped together to give additional stability.

Foundations for Breakwaters, not located on solid rock, are commonly prepared by first depositing a broad layer of rubble stone at a flat slope and leveling up the top by the aid of careful soundings or by means of divers. Piles are also used, which are cut off below water level and protected by heavy riprap. Bags of cement have also been frequently employed for the purpose.

The Reinforced-Concrete Caisson furnishes perhaps the most satisfactory method of construction yet devised. Fig. 114 illustrates such a form used by W. V. Judson on Lake Michigan. The caisson is built at shore and towed to place. It is then sunk by filling one or more compartments with stone, and the whole is capped with concrete, sufficiently reinforced to preserve the monolithic character of the structure. Similar caissons have been employed for quay walls and breakwaters in European works. At Rotterdam, caissons were employed of dimensions 131 ft. × 32 ft. and 43 ft. high. These were built in dry docks, towed to place and brought into alinement by means of a tongue-and-groove joint. Some cells were filled with concrete, others with sand or rock. Reinforced concrete possesses great advantages for

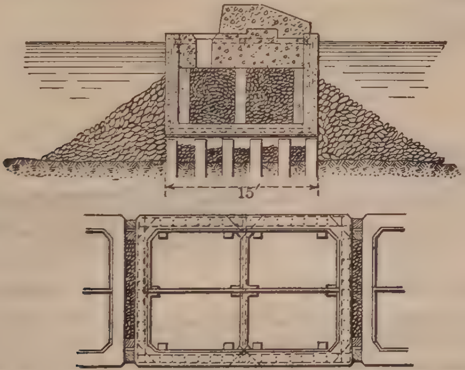

Fig. 114. Reinforced-Concrete Caisson

construction of this sort over ordinary masonry or concrete construction by reason of its monolithic character.

Concrete sheet piling, fitted with tongue and groove, has been used successfully for breakwaters. Two rows of such piling are driven, after which the intervening space is filled with sand and the whole capped with a superstructure of reinforced concrete.

Sea Wall. Fig. 115 illustrates the Galveston sea wall. It is founded on piles and constructed of mass concrete, but this is reinforced near the front face, as shown.

Dock and Harbor Walls are built, in the main, like ordinary retaining walls. Frequently a pile foundation is necessary. If the piles are driven in soft mate-

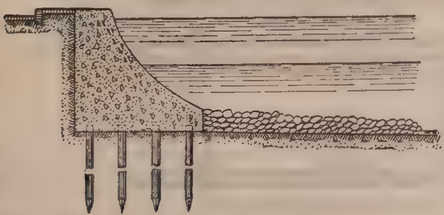

Fig. 115. Galveston Sea Wall

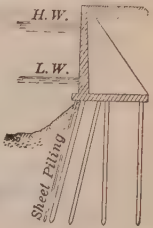

Fig. 116

rial, one or more rows should be driven at a considerable inclination in order to resist the horizontal component of the pressure. The walls are commonly constructed of concrete, either in loose blocks of mass concrete, plain or reinforced. Where the wear from ice is heavy a concrete wall may well be faced with granite or with other hard stone. Reinforced concrete possesses the same advantages in this type of wall as for ordinary retaining walls and is built of the same general form. Fig. 116 shows the essential features.

Anchored walls of reinforced concrete are often advantageous, especially in the construction of new walls along a river front where anchorage is readily secured. Fig. 117 illustrates such a construction as carried out at Berne, Switzerland. The wall consists

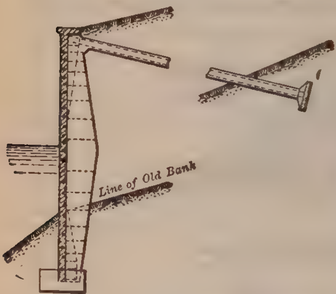

Fig. 117. An Anchored Wall

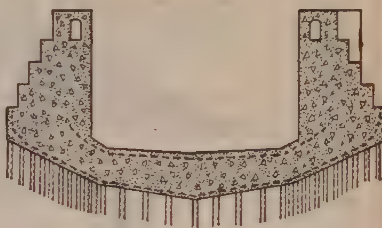

Fig. 118. Canal Lock

of a series of anchored beams connected by slab construction. The stability of the wall is measured by the stability of the entire mass between the wall and the anchorage.

Dry Docks and Canal Locks. In this construction reinforced concrete is of advantage, not only in the construction of the walls, but also in the floors, enabling them to be readily designed against upward pressure and in one piece with the walls. Fig. 118 is a section through the lock on the Charles River, Boston, showing this feature.

58. Reservoirs, Tanks, Bins

For Covered Reservoirs reinforced concrete is very well adapted. The rectangular form with flat cover is usually the most convenient; its design involves the same features as building design with the additional one of imperviousness. Fig. 119 illustrates a typical design of this kind for Indianapolis (Eng. News, Oct. 15, 1908). Especial care is required in such structures to prevent contraction cracks by the use of a liberal amount of reinforcement.

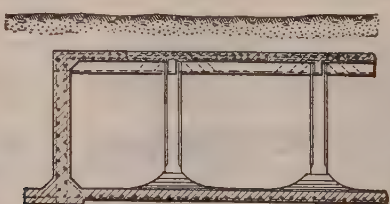

Fig. 119. Covered Reservoir

Fig. 120 illustrates the general form of construction used in a large elevator at Baltimore. The walls of the bins are 8 in. thick and are reinforced with vertical rods of 1/2-in. round steel, spaced 3 ft. apart, and with horizontal bars 3/8 in. by 1 to 1-3/4 in. spaced 12 in. apart. The hopper bottoms, the tunnels for the conveying machinery and the foundation floor resting upon the piles are all of reinforced concrete. (Eng. Record, Feb. 20, 1909.)

Elevated towers and tanks may also be made of concrete, but high pressures are difficult to deal with. Bins and coal pockets are structures for which concrete is well adapted. For the storage of coal bins of unprotected steel are not durable, but reinforced concrete furnishes an almost ideal material, lending itself readily to the necessary form for strength and furnishing the desired durability.

Reinforced concrete is advantageously used in other minor forms of structures and structural elements. Noteworthy among such uses is its employment for fence posts and poles for various purposes. In building construction it is found that sills, lintels, steps and staircases are usually cheaper in reinforced concrete than in stone or metal.

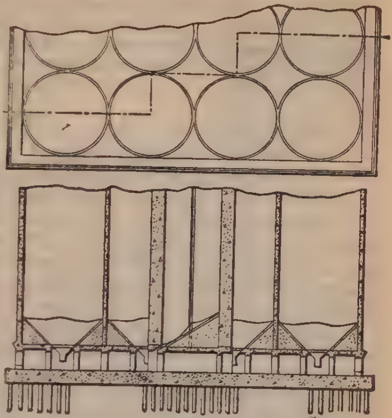

Fig. 120. Grain Elevator

59. Conduits, Sewers, Pipes

For Conduits not under pressure, large sewers and the like, reinforced concrete lends itself to convenient and economical construction. As to the analysis and design, these structures are only special cases of the monolithic pipe or box which was discussed in Art. 55. The character of the foundation and

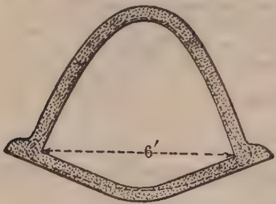

Fig. 121

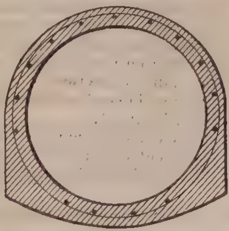

Fig. 122

convenience in construction will lead to various modifications of design. Fig. 121 is a typical cross-section of a large sewer for Harrisburg, Pa. A mesh of expanded metal is used for reinforcement, arranged to resist positive moments excepting at bottom and corners. Fig. 122 illustrates a design of a circular pipe or conduit molded in place.

Reinforced concrete has also been used to some extent for pipes under pressure, but it is very difficult to secure imperviousness under heads of considerable magnitude.

In pressure pipes the tensile stress is entirely taken by the steel, the concrete furnishing merely for the impervious layer and resisting bending due to earth loading.

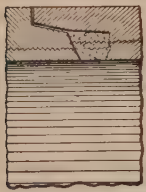

Fig. 123

Pipes of reinforced concrete separately molded in sections have been successfully used for moderate pressures with a considerable economy over metal. The joining of such pipes is accomplished by overlapping of the reinforcement. One method of doing this is illustrated in Fig. 123.

60. Chimneys

General Design. A reinforced-concrete chimney consists of the outer main shell, the inner shell or lining, and the base. The outer shell is made 4 to 6 in. thick at the top and 8 to 12 in. at the bottom, depending upon the height and diameter. The inner shell is generally made 4 in. in thickness, and of concrete or fire brick, the latter being preferable for high temperatures. The amount of reinforcement required is small, as the load is purely vertical and of small amount. Half-inch rods spaced 1 to 2 ft. apart are ample. The lining is generally carried up about one-third the height, but the large amount of cracking which has occurred in some chimneys just above the lining indicates the desirability of more extensive linings. The outer shell is designed to resist wind pressure and also with some reference to the temperature stresses. The base must be of such an area that the maximum earth pressure due to vertical load and wind pressure will not exceed safe limits. The thickness is then determined with reference to the bending and shearing stresses which are caused by these pressures.

Wind Stresses. The stresses at any given section, distance h below the top, will be determined. The notation is as follows:

A = area of chimney section under consideration.
A_s = total area of steel sections.
W = weight of superincumbent portion of chimney.
P = wind pressure on that portion.
M = bending moment at the section.
e = distance from the center of the section to where the resultant of the weight and wind pressure cuts the section (" eccentric distance ").
f_c = unit stress in concrete adjacent to the steel at lee side.
f_c' = unit stress in concrete adjacent to steel at windward side.
h = distance from top to section considered.
r = mean radius of section.
f_s = unit stress in steel at the windward side.
p = steel ratio, A_s/A.
m = a coefficient such that $f_c = mW/A$.
m' = a coefficient such that $f_c' = m'W/A$.
n = ratio of modulus of elasticity of steel to that of concrete, taken at 15.

The value of e is first to be determined by the formulas:

$$M = 1/2\ Ph \qquad e = M/W = Ph/2\ W$$

If e is greater than $1/2\ r$ there will be tension on the windward side. In this case it is assumed that the steel will carry all the tension. If the tensile stress is small, however, the concrete will not be overstressed and it may be desirable to calculate its stress on this assumption. Two cases will therefore be considered: (1) Where the stresses are all compressive, or the tension on the windward side is small (less than 50 lb. per sq. in., say), and (2) where there are large stresses on the windward side and the concrete is neglected.

Case 1. Having found e as above described the unit stresses are found by

$$f_c = \frac{1 + 2\,e/r}{1 + np}\,\frac{W}{A}, \quad \text{and} \quad f_c' = \frac{1 - 2\,e/r}{1 - np}\,\frac{W}{A}$$

Case 2. Practical formulas for this case cannot be stated, but the curved lines in Fig. 124 give values of m for different values of e/r and of p. Then

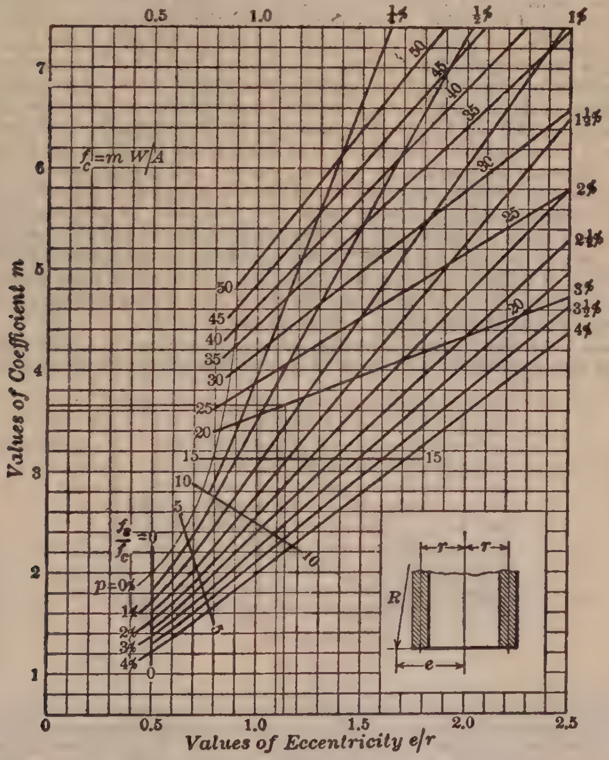

Fig. 124. Diagram for Reinforced-Concrete Chimneys

$f_c = m\,W/A$. The straight lines give the ratio of $\frac{f_s}{f_c}$ for the given value e/r and p; from this ratio the value of S_s is determined.

The maximum concrete stress is slightly greater than the values calculated by the above formulas, as these give the stress adjacent to the steel. The results are, however, sufficiently accurate.

The Wind Pressure commonly assumed is 25 to 50 lb. per sq. ft. on the projected area, but this is probably higher than necessary. Experiments made at the Eiffel Tower and at the National Physical Laboratory of England show that the pressure per square foot on square, flat surfaces, from 10 to 100 sq. ft. in extent, is 0.0032 times the square of the wind velocity in miles per hour. Taking the velocity at 100 miles per hour and the pressure on a cylindrical surface at 2/3 that on the projected plane, a value of 20 lb. per sq. ft. is deduced, which should be ample.

Temperature Stresses. Both theoretical considerations and evidence from practice indicate that temperature stresses are likely to be high, especially near the top of the lining. They occur in direction both vertically and circumferentially and are due to the high temperature of the interior as compared to the exterior. Both vertical and horizontal cracks of the exterior are of frequent occurrence and are doubtless due to this cause. Assuming the coefficient of expansion to be the same at all temperatures, a theoretical analysis indicates that for 1% of circumferential reinforcement the compressive stress in the concrete on the interior is as much as 350 lb. per sq. in. for each 100° difference in temperature between exterior and interior surfaces; the corresponding stress in the steel is about 5000 lb. per sq. in. Approximately the same stresses are caused in the vertical reinforcement. The stresses in the concrete increase somewhat with increase in reinforcement, but decrease in the steel; they are proportional to the differences in temperature of outer and inner surfaces. A difference in temperature of 200° will therefore bring the compressive stress well up to safe limit. So far as temperature stresses are concerned it is advantageous to use a small amount of steel.

Bases. The bases of chimneys are designed in the same manner as column footings. In this case, however, the earth pressures must be determined with reference to the

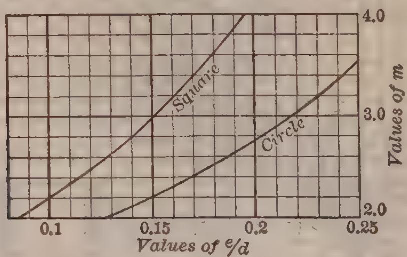

Fig. 125

effect of wind pressures and vertical load combined. The resultant of the wind pressure, the weight of chimney, the earth filling above the base and the base itself is to be first determined. Suppose the resultant cuts the base at a distance e from the center. Let W = total vertical load, M = wind moment at bottom of base, A = area of base, d = maximum diameter of rectangular base, or diameter of circular base, and p = maximum pressure on foundation per unit area. Then $e = M/W$. The values of p are as follows:

For rectangular bases, wind acting in the direction of the diagonal, and for values of e less than $d/12$, $p = W/A + 12\,M/Ad$. For circular bases, and values of e less than $d/8$, $p = W/A + 8\,M/Ad$. For either rectangular or circular bases, and values of e greater than the limits above given, $p = mW/A$, in which m is to be taken from Fig. 125.

APPENDICES

The American Society for Testing Materials (1926)

Appendix 1. Cement Manufacture

Cement. In engineering literature the term cement is understood to mean the finely pulverized product obtained by the burning of a suitable mixture of argillaceous and calcareous materials, or by an artificial mixture of such materials after burning, which will possess the property of hardening into a solid mass when mixed with water. The essential ingredients in the manufacture of cement are calcium carbonate ($CaCO_3$), silica (SiO_2) and alumina (Al_2O_3); the last two, combined in various proportions, constitute the argillaceous material. The characteristic property of cement is that of hardening by the addition of water, and therefore its ability to harden when excluded from the air.

Portland Cement is the finely pulverized product resulting from the calcination to incipient fusion of an intimate, artificial mixture of properly proportioned argillaceous and calcareous materials. It has a definite chemical composition varying within comparatively narrow limits. There are three distinct stages in the process of its manufacture: (1) the preparation of the correct mixture by the selection, mixing and grinding of the ingredients, (2) the burning of the mixture to a clinker, and (3) the pulverizing of the burned clinker to a fine powder. Portland cement is distinguished by uniformity of quality and high strength which it rapidly acquires.

Portland cement should be used in structures where strength is of special importance, or where the structure is exposed to the action of the elements. It should be used invariably in reinforced concrete construction.

Manufacture of Portland Cement. A great variety of materials is available for the manufacture of portland cement. The principal combinations in use are as follows:

	Argillaceous.	Calcareous.
(1)	Argillaceous limestone (cement rock).	Pure limestone.
(2)	Clay or shale.	Pure limestone.
(3)	Clay or shale.	Chalky limestone or chalk.
(4)	Clay.	Marl.
(5)	Clay	Alkali waste.
(6)	Blas urnace slag.	Pure limestone.

Two general processes are used in the grinding and mixing of the raw material, the dry and the wet. In the dry process, the material is thoroughly dried and then finely ground, the latter stages of grinding being done after the mixing. Where slag is used it is first granulated by being run into water, which causes it to form into small, easily crushed particles. In the wet process the material is mixed and ground together into a " slurry " containing 60 to 70% of water. This slurry is then pumped directly to the burning kiln. The wet process is generally used with clay and marl.

After this preparation the material is burned to a clinker in a kiln of which there are two general types, the fixed vertical kiln and the continuous rotary kiln. The latter is used in most American plants, and to its development is due, largely, the growth of the cement industry in this country. From 100 to 200 lb. of coal are required per barrel of product, and the production per kiln is generally from 100 to 300 barrels.

The final grinding of the burned clinker is of the greatest importance. As it is only the very finest particles (the " flour ") that possess active properties, the advantage of fine grinding is obvious, this is done in two or three stages. The necessary calcium sulfate is generally added before the final grinding.

Natural Cement is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature below fusion. The proportions of lime and clay in the raw material may vary between much wider limits than in the case of portland cement. Natural cement does not develop its strength as quickly nor is it as strong or uniform in composition as portland cement. It is now little used in the United States.

Natural cement is suitable for use in structures where mass and weight rather than strength are the essential features. It is thus adapted for use in many underground structures, such as sewers, conduits, massive foundations and in the unexposed portions of large and massive structures above ground, such as dams, retaining walls, piers and abutments. Used alone, or mixed with lime mortar, it also makes a suitable mortar for ordinary brick and stone masonry.

Puzzolan or Slag Cement is the finely pulverized product resulting from grinding a mechanical mixture of fused argillaceous material and hydrated lime. The argillaceous substance may consist of natural puzzolanic material, such as volcanic ash, trass or allied igneous material, or of artificial materials, such as blast-furnace slag or burnt clay. Puzzolan cement is not as strong or reliable as portland or natural cement and is not extensively used in the United States. Its use should be confined to unexposed work where great strength is not required.

Appendix 2. Testing of Cement

Standard Cement Tests. In all important work the cement should be fully specified and regularly tested. For unimportant work, however, there is little danger to be feared in using well-known brands of cement without testing. Results of test depend largely upon the method of making them; it is hence very important that definite and uniform methods be used. The kinds of tests usually made are as follows: (1) Fineness. (2) Time of setting. (3) Tensile strength of neat cement and of sand mortar. (4) Soundness, or constancy of volume. A chemical analysis is also desirable on large work. Of much importance in securing uniform and reliable results are the methods of sampling, the consistency of the mortar, temperature of the material, character of sand used and of apparatus employed. The standard methods of testing given below have come into general use in the United States.

Standard Methods of Cement Testing devised and recommended by the American Society for Testing Materials (1926) are given here (chemical analysis omitted).

Fineness. Wire cloth for standard sieves for cement shall be woven (not twilled) from brass, bronze, or other suitable wire, and mounted without distortion on frames about 2 in. below the top of the frame. The sieve frames shall be circular, approximately 8 in. in diameter, and may be provided with a pan and cover.

2. A standard No. 200 sieve is one having nominally an 0.0029-in. opening and 200 wires per inch standardized by the U. S. Bureau of Standards, and conforming to the following requirements:

The No. 200 sieve should have 200 wires per inch, and the number of wires in any whole inch shall not be outside the limits of 192 to 208. No opening between adjacent parallel wires shall be more than 0.0050 in. in width. The diameter of the wire should be 0.0021 in. and the average diameter shall not be outside the limits 0.0019 to 0.0023 in. The value of the sieve as determined by sieving tests made in conformity with the standard specification for these tests on a standardized cement which gives a residue of 25 to 20% on the No. 200 sieve, or on other similarly graded material, shall not show a variation of more than 1.5% above or below the standards maintained at the Bureau of Standards.

3. The test shall be made with 50 grams of cement. The sieve shall be thoroughly clean and dry. The cement shall be placed on the No. 200 sieve, with pan and cover attached, if desired, and shall be held in one hand in a slightly inclined position so that the sample will be well distributed over the sieve, at the same time gently striking the side about 150 times per minute against the palm of the other hand on the up stroke. The sieve shall be turned every 25 strokes about one-sixth of a revolution in the same direction. The operation shall continue until not more than 0.05 gram passes through in 1 minute of continuous sieving. The fineness shall be determined from the weight of the residue on the sieve expressed as a percentage of the weight of the original sample.

4. Mechanical sieving devices may be used, but the cement shall not be rejected if it meets the fineness requirement when tested by the hand method described in Par. 3.

5. A permissible variation of 1 will be allowed, and all results in excess of the specified limit but within this permissible variation shall be reported as 22%.

Mixing Cement Pastes and Mortars. 6. The quantity of dry material to be mixed at one time shall be 500 grams for neat cement mixtures and 1000 grams for mortar mixtures. The proportions of cement or cement and sand shall be stated by weight in grams of the dry materials; the quantity of water shall be expressed in cubic centimeters (1 cc. of water = 1 gram). The dry materials shall be weighed, placed upon a non-absorbent surface, thoroughly mixed dry if sand is used, and a crater formed in the center, into which the proper percentage of clean water shall be poured; the material on the outer edge shall be turned into the crater by the aid of a trowel. After an interval of 1/2 minute for the absorption of the water the operation shall be completed by continuous, vigorous mixing, squeezing and kneading with the hands for at least a minute. During the operation of mixing, the hands should be protected by rubber gloves.

7. The temperature of the room, apparatus, materials and mixing water shall be maintained as nearly as practicable at 21° C. (70° F.).

Normal Consistency. 8. The Vicat apparatus consists of a frame bearing a movable rod weighing 300 grams, one end being 1 cm. in diameter for a distance of 6 cm., the other having a removable needle 1 mm. in diameter, 6 cm. long. The rod is reversible, and can be held in any desired position by a screw, and has midway between the ends a mark which moves under a scale (graduated to millimeters) attached to the frame. The paste is held in a conical, hard-rubber ring 7 cm. in diameter at the base, 6 cm. at the top, and 4 cm. high, resting on a glass plate about 10 cm square.

9. In making the determination, 500 grams of cement, with a measured quantity of water, shall be kneaded into a paste, as described in paragraph 6, and quickly formed into a ball with the hands, completing the operation by tossing it six times from one hand to the other, maintained about 6 in. apart; the ball resting in the palm of one hand shall be pressed into the larger end of the rubber ring held in the other hand, completely filling the ring with paste; the excess at the larger end shall then be removed by a single movement of the palm of the hand, the ring shall then be placed on the larger end on a glass plate and the excess paste at the smaller end sliced off at the top of the ring by a single oblique stroke of a trowel held at a slight angle with the top of the ring. During these operations care shall be taken not to compress the paste. The paste confined in the ring, resting on the plate, shall be placed under the rod, the larger end of which shall be brought in contact with the surface of the paste; the scale shall then be read, and the rod quickly released. The paste shall be of normal consistency when the rod settles to a point 10 mm. below the original surface in 1/2 minute after being released. The apparatus shall be free from all vibrations during the test. Trial pastes shall be made with varying percentages of water until the normal consistency is obtained. The amount of water required shall be expressed in percentage by weight of the dry cement.

10. The consistency of standard mortar shall depend on the amount of water re-

quired to produce a paste of normal consistency from the same sample of cement. Having determined the normal consistency of the sample, the consistency of standard mortar made from the same sample shall be as indicated in the table, the values being in percentage of the combined dry weights of the cement and standard sand:

Percentage of Water for Standard Mortars

Percentage of water for neat cement paste of normal consistency	Percentage of water for one cement, three standard Ottawa sand	Percentage of water for neat cement paste of normal consistency	Percentage of water for one cement three standard Ottawa sand
15	9.0	23	10.3
16	9.2	24	10.5
17	9.3	25	10.7
18	9.5	26	10.8
19	9.7	27	11.0
20	9.8	28	11.2
21	10.0	29	11.3
22	10.2	30	11.5

Soundness. 11. A steam apparatus, which can be maintained at a temperature between 98 and 100° C. is recommended.

12. A pat from cement paste of normal consistency about 3 in. in diameter, 1/2 in. thick at the center, and tapering to a thin edge, shall be made on clean glass plates about 4 in. square, and stored in moist air for 24 hours. In molding the pat, the cement paste shall be flattened on the glass and the pat then formed by drawing the trowel from the outer edge toward the center.

13. The pat shall then be placed in an atmosphere of steam at a temperature between 98 and 100° C. upon a suitable support 1 in. above boiling water for 5 hours.

14. Should the pat leave the plate, distortion may be detected best with a straight-edge applied to the surface which was in contact with the plate.

Time of Setting. 15. The following are alternate methods, either of which may be used as ordered:

16. The time of setting shall be determined with the Vicat apparatus.

17. A paste of normal consistence shall be molded in the hard-rubber ring as described in paragraph 8 and placed under the movable rod, the smaller end of which shall then be carefully brought in contact with the surface of the paste, and the rod quickly released. The initial set shall be said to have occurred when the needle ceases to pass a point 5 mm. above the glass plate in 1/2 minute after being released; and the final set, when the needle does not sink visibly into the paste. The test pieces shall be kept in moist air during the test. This may be accomplished by placing them on a rack over water contained in a pan and covered by a damp cloth, kept from contact with them by means of a wire screen, or they may be stored in a moist closet. Care shall be taken to keep the needle clean, as the collection of cement on the sides of the needle retards the penetration, while cement on the point may increase the penetration. The time of setting is affected not only by the percentage and temperature of the water used and the amount of kneading the paste receives, but by the temperature and humidity of the air, and its determination is therefore only approximate.

18. The time of setting shall be determined by the Gillmore needles.

19. The time of setting shall be determined as follows: A pat of neat cement paste about 3 in. in diameter and 1/2 in. in thickness with a flat top mixed to a normal consistency shall be kept in moist air at a temperature maintained as nearly as practicable at 21° C. (70° F.). The cement shall be considered to have acquired its initial set when the pat will bear, without appreciable indentation, the Gillmore needle 1/12 in. in diameter, loaded to weight 1/4 lb. The final set has been acquired when the pat will bear, without appreciable indentation, the Gillmore needle 1/24 in. in diameter,

loaded to weigh 1 lb. In making the test, the needles shall be held in a vertical position, and applied lightly to the surface of the pat.

Tension Tests. 20. The form of test piece shown in Fig. 126 shall be used. The molds shall be made of non-corroding metal and have sufficient material in the sides to

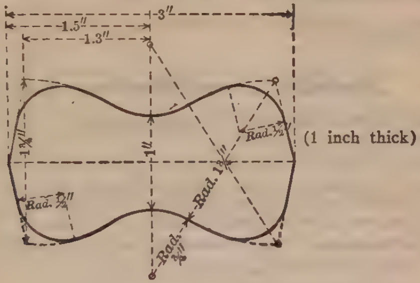

Fig. 126

prevent spreading during molding. Molds shall be wiped with an oily cloth before using.

21. The sand to be used shall be natural sand from Ottawa, Ill., screened to pass a No. 20 sieve and retained on a No. 30 sieve. This sand may be obtained from the Ottawa Silica Co., Ottawa, Ill.

22. This sand, having passed the No. 20 sieve, shall be considered standard when not more than 5 grams pass the No. 30 sieve after one minute continuous sieving of a 500-gram sample.

23. The sieves shall conform to the following specifications:

The No. 20 sieve shall have between 19.5 and 20.5 wires per whole inch of the warp wires and between 19 and 21 wires per whole inch of the shoot wires. The diameter of the wire should be 0.0165 in. and the average diameter shall not be outside the limits of 0.0160 and 0.0170 in.

The No. 30 sieve shall have between 29.5 and 30.5 wires per whole inch of the warp wires and between 28.5 and 31.5 wires per whole inch of the shoot wires. The diameter of the wire should be 0.0110 in and the average diameter shall not be outside the limits 0.0105 to 0.0115 in.

24. Immediately after mixing, the standard mortar shall be placed in the molds, pressed in firmly with the thumbs and smoothed off with a trowel without ramming. Additional mortar shall be heaped above the mold and smoothed off with a trowel; the trowel shall be drawn over the mold in such a manner as to exert a moderate pressure on the material. The mold shall then be turned over and the operation of heaping thumbing and smoothing off repeated.

25. Tests shall be made with any standard machine. The briquets shall be tested as soon as they are removed from the water. The bearing surfaces of the clips and briquets shall be free from grains of sand or dirt. The briquets shall be carefully centered and the load applied continuously at the rate of 600 lb. per minute.

26. Testing machines should be frequently calibrated in order to determine their accuracy.

27. Briquets that are manifestly faulty, or that give strengths differing more than 15% from the average value of all test pieces made from the same sample and broken at the same period, shall not be considered in determining the tensile strength.

Storage of Test Pieces. 28. The moist closet may consist of a soapstone, slate or concrete box, or a wooden box lined with metal. If a wooden box is used, the interior should be covered with felt or broad wicking kept wet. The bottom of the moist closet should be covered with water. The interior of the closet should be provided with nonabsorbent shelves on which to place the test pieces, the shelves being so arranged that they may be withdrawn readily.

29. Unless otherwise specified all test pieces, immediately after molding, shall be placed in the moist closet for from 20 to 24 hours.

30. The briquets shall be kept in molds on glass plates in the moist closet for at least 20 hours. After 24 hours in moist air the briquets shall be immersed in clean water in storage tanks of non-corroding material.

31. The air and water shall be maintained as nearly as practicable at a temperature of 21° C. (70° F.).

Appendix 3. Specifications for Cement

Standard Specifications for Portland Cement. American Society for Testing Materials, Standards, 1926.

Definition. Portland cement is the product obtained by finely pulverizing clinker produced by calcining to incipient fusion, an intimate and properly proportioned mixture of argillaceous and calcareous materials, with no additions subsequent to calcination excepting water and calcined or uncalcined gypsum.

Chemical Properties. The following limits shall not be exceeded:

Loss on ignition, per cent	4.00
Insoluble residue, per cent	0.85
Sulfuric anhydride (SO^3), per cent	2.00
Magnesia (MgO), per cent	5.00

Physical Properties

(1) **Fineness.** The residue on a standard No. 200 sieve shall not exceed 22% by weight.

(2) **Soundness.** A pat of neat cement shall remain firm and hard, and show no signs of distortion, cracking, checking, or disintegration in the steam test for soundness.

(3) **Time of Setting.** The cement shall not develop initial set in less than 45 minutes when the Vicat needle is used or 60 minutes when the Gillmore needle is used. Final set shall be attained within 10 hours.

(4) **Tensile Strength.** The average tensile strength in pounds per square inch of not less than three standard mortar briquets composed of one part cement and three parts standard sand by weight, shall be equal to or higher than the following:

Age at test, days	Storage of briquets	Tensile strength, lb. per sq. in.
7	1 day in moist air, 6 days in water	225
28	1 day in moist air, 27 days in water	325

7. The average tensile strength of standard mortar at 28 days shall be higher than the strength at 7 days.

Packages, Marking and Storage. 8. The cement shall be delivered in suitable bags or barrels with the brand and name of the manufacturer plainly marked thereon, unless shipped in bulk. A bag shall contain 94 lb. net. A barrel shall contain 376 lb. net.

9. The cement shall be stored in such a manner as to permit easy access for proper inspection and identification of each shipment, and in a suitable weather-tight building which will protect the cement from dampness.

Inspection. 10. Every facility shall be provided the purchaser for careful sampling and inspection at either the mill or at the site of the work, as may be specified by the purchaser. At least 12 days from the time of sampling shall be allowed for the completion of the 7-day test, and at least 33 days shall be allowed for the completion of the 28-day test. The cement shall be tested in accordance with the methods hereinbefore prescribed. The 28-day test shall be waived only when specifically so ordered.

Rejection. 11. The cement may be rejected if it fails to meet any of the requirements of these specifications.

12. Cement remaining in storage prior to shipment for a period greater than 6 months after test shall be retested and shall be rejected if it fails to meet any of the requirements of these specifications.

13. Cement shall not be rejected on account of failure to meet the fineness requirement if upon retest after drying at 100° C. for 1 hour it meets this requirement.

14. Cement failing to meet the test for soundness in steam may be accepted if it passes a retest using a new sample at any time within 28 days thereafter.

15. Packages varying more than 5% from the specified weight may be rejected; and if the average weight of packages in any shipment, as shown by weighing 50 packages taken at random, is less than that specified, the entire shipment may be rejected.

Standard Specifications for Natural Cement. Adopted by the American Society for Testing Materials, 1904; revised 1908, 1909:

Definition. 1. Natural cement is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas.

Physical Properties. 2. The residue on a standard No. 100 sieve shall not exceed 10%, and on a standard No. 200 sieve shall not exceed 30%, by weight.

3. Pats of neat cement about 3 in. in diameter, 1/2 in. thick at center, tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(a) A pat shall then be kept in air at normal temperature.

(b) Another pat shall be kept in water maintained as near 70° F. as practicable.

These pats shall be observed at intervals for at least 28 days, and, to satisfactorily pass the tests, shall remain firm and hard and show no signs of distortion, checking, cracking, or disintegrating.

4. The cement shall not develop initial set in less than 10 minutes, using the Vicat needle. Final set shall be attained in not less than 30 minutes nor more than 3 hours, using the Vicat needle.

5. The minimum requirements for tensile strength for briquets 1 sq. in. in cross-section shall be as follows, and the cement shall show no retrogression in strength within the periods specified:

Age	Neat cement	Strength
24 hours in moist air		75 lb.
7 days (1 day in moist air, 6 days in water)		150 lb.
28 days (1 day in moist air, 27 days in water)		250 lb.
	One part cement, three parts standard Ottawa Sand	
7 days (1 day in moist air, 6 days in water)		50 lb.
28 days (1 day in moist air, 27 days in water)		125 lb.

Packages, Marking and Storage. 6. The cement shall be delivered in suitable bags or barrels with the brand and name of the manufacturer plainly marked thereon. A bag shall contain 94 lb. net. A barrel shall contain 282 lb. net.

7. The cement shall be stored in such a manner as to permit easy access for proper inspection and identification of each shipment, and in a suitable weather-tight building which will protect the cement from dampness.

Inspection. 8. (a) Every facility shall be provided the purchaser for careful sampling and inspection at either the mill or at the site of the work, as may be specified by the purchaser. At least 10 days from the time of sampling shall be allowed for the completion of the 7-day test, and at least 31 days shall be allowed for the completion of the 28-day test.

(b) The cement shall be tested in accordance with the methods contained in the Standard Specifications and Tests for Portland Cement of the American Society for Testing Materials.

Rejection. 9. The cement may be rejected if it fails to meet any of the requirements of these specifications.

10. Cement failing to meet the 7-day requirements may be held awaiting the results of the 28-day tests before rejection.

Note. For specification for High-Early-Strength Cement see Appendix 7.

American Society for Testing Materials.

Appendix 4. Tentative Specifications for Concrete Aggregates

Serial Designation: C 33 — 28 T

This is a Tentative Standard, published for the purpose of eliciting criticism and suggestions, and as such is subject to annual revision.

Issued, 1921; Revised, 1923, 1926, 1928

Quality of Aggregates

It is recognized that for certain purposes satisfactory results may be obtained with materials not conforming to these specifications. In such cases the use of fine and coarse aggregate not conforming to these specifications should be authorized only under special provisions based upon laboratory studies of the possibility of designing a mixture of materials to be used on the job that will yield concrete equivalent to the specified mixture made with material complying with these specifications in all respects.

Fine Aggregate

General Characteristics. 1. Fine aggregate shall consist of sand or other approved inert materials with similar characteristics, or a combination thereof, having hard, strong, durable particles and shall conform to the requirements of these specifications.

Deleterious Substances. 2. (a) The maximum percentages of deleterious substances shall not exceed the following values:

	Per cent by weight
Removed by decantation	3
Shale	1
Coal	1
Clay lumps	1
Other local deleterious substances (such as alkali, mica, coated grains, sift and flaky particles)	—

Note. It is recognized that under certain conditions maximum percentages of deleterious substances less than those shown in the table should be specified.

(b) The sum of the percentages of shale, coal, clay lumps, soft fragments and other deleterious substances shall not exceed 5 per cent by weight.

(c) All fine aggregate shall be free from injurious amounts of organic impurities. Aggregates subjected to the colorimetric test for organic impurities and producing a color darker than the standard shall be rejected unless they pass the mortar strength test as specified in Sect. 4.

Grading. 3. (a) Fine aggregate shall be well graded from coarse to fine and when tested by means of laboratory sieves * shall conform to the following requirements:

* For detail requirements for these sieves, see the Standard Specifications for Sieves for Testing Purposes (Serial Designation: E 11) of the American Society for Testing Materials, 1927 Book of A.S.T.M. Standards, Part II, p. 917.

	Per cent
Passing a 3/8-in. sieve	100
Passing a No. 4 sieve	(85) to (100)
Passing a No. 16 sieve	(45) to (80)
Passing a No. 50 sieve	(2) to (30)
Passing a No. 100 sieve	(0) to (5)

Note. Figures in parentheses are suggested as limiting percentages but they may be altered within these limits to suit local conditions.

(b) In case the concrete resulting from a mixture of aggregates approaching the extreme limits for gradation is not of a workable character, or when finished does not exhibit a proper surface, due to an excess of particles approximately 1/8 to 1/2 in. in size, either a fine aggregate having a sufficiently greater percentage of fine material, or a coarse aggregate having a sufficiently smaller percentage of fine material must be used.

Mortar Strength. 4. Fine aggregates, when subjected to the mortar strength test, shall have a tensile or compressive strength at the age of 7 and 28 days of not less than (100)%* of that developed by mortar of the same proportions and consistency made of the same cement and standard Ottawa sand.

Coarse Aggregate

General Characteristics. 5. Coarse aggregate shall consist of crushed stone, gravel, blast-furnace slag, or other approved inert materials of similar characteristics, or combinations thereof, having hard, strong, durable pieces, free from adherent coatings and conforming to the requirements of these specifications.

Deleterious Substances. 6. (a) The maximum percentages of deleterious substances shall not exceed the following values:

	Per cent by weight
Removed by decantation	1
Shale	1
Coal	1
Clay lumps	1/2
Soft fragments	5
Other local deleterious substances (such as alkali, friable, thin, elongated, or laminated pieces)	..

Note. It is recognized that under certain conditions maximum percentages of deleterious substances less than those shown in the table should be specified.

(b) The sum of the percentages of shale, coal, clay lumps and soft fragments shall not exceed 5% by weight.

Grading. 7. (a) Coarse aggregate shall be well graded, between the limits specified, and shall conform to the following requirements:

		Per cent by weight
Passing ...... in. sieve † or screen	(maximum size)	not less than (95)
Passing ...... in. sieve † or screen	(intermediate size)	not less than (40)
	(one-half maximum size)	not more than (75)
Passing ...... in. sieve † or screen	(intermediate sizes)	not less than .....
	(as needed)	not more than ....
Passing No. 4 sieve or a 1/4-in. screen		not more than (10)

Note. Where a range is shown the engineer should use an appropriate figure within the limits recommended. The percentages in parentheses are recommended but may need to be altered to suit local conditions.

* Percentages in parentheses are recommended but they may be altered to suit local conditions.

† The question whether round or square openings shall be used for testing aggregates is now being studied by the Section on Coarse Screens of the Technical Committee on Size and Shape of Committee E-1 on Methods of Testing.

(b) In case the concrete resulting from a mixture of aggregates approaching the extreme limits for gradation is not of a workable character, or when finished does not exhibit a proper surface, due to an excess of particles approximately 1/8 to 1/2 in. in size, either a fine aggregate having a sufficiently greater percentage of fine material, or a coarse aggregate having a sufficiently smaller percentage of fine material shall be used.

Weight of Slag. 8. Blast-furnace slag that meets the grading requirements of these specifications shall conform to the following minimum weight requirements:

Base concrete.......................... 65 lb. per cu. ft.
Surface concrete (subject to abrasion)........ 70 lb. per cu. ft.

Durability. 9. Coarse aggregate shall pass a sodium sulfate accelerated soundness test, except that aggregates failing in the accelerated soundness test may be used if they pass a satisfactory freezing and thawing test.

Appendix 5. Reinforcing Steel

Excerpts from Specifications for Billet Steel Concrete Reinforcement Bars and Rail Steel Concrete Reinforcement Bars, American Society for Testing Materials Standards.

Billet Steel Bars

The material for billet steel bars may be made by the Bessemer or open-hearth process. The bars shall be rolled from new billets; no re-rolled material will be accepted.

Chemical composition: Phosphorus..... { Bessemer; not over 0.10%
Open-hearth; not over 0.05%

An analysis of each melt of steel shall be made by the manufacturer to determine the percentages of carbon, manganese, phosphorus and sulphur. The analysis shall be made from a test ingot taken during the pouring of the melt. The chemical composition thus determined shall be reported to the purchaser or his representative.

Analysis may be made by the purchaser from finished bars representing each melt of open-hearth steel and each melt or lot of tons of Bessemer steel.

One tension and one bend test shall be made from each melt of open-hearth steel and from each melt or each lot of 10 tons of Bessemer steel except that if material from one melt differs 3/8 inch or more in thickness or diameter, one tension and one bend test shall be made from both the thinnest and thickest material rolled.

Rail Steel Bars

Bars shall be rolled from standard section Tee-rails.

One tension and one bend test shall be made from each lot of 10 tons or less of each size of bar, rolled from rails varying not more than 10 lb. per yd. in nominal weight.

Billet Steel and Rail Steel Bars

Tension and bend test specimens for plain and deformed bars shall be taken from the finished bars, and shall be of the full thickness or diameter of bars as rolled; except that the specimens for deformed bars may be machined for a length of at least 9 in. if deemed necessary by the manufacturer to obtain uniform cross-section. Tension and bend test specimens for twisted bars shall be taken from the finished bars without further treatment.

Twisted bars shall have one complete twist in a length not over 12 times the thickness of the bar.

Properties considered	Tensile properties billet steel bars							Rail steel bars	
	Plain bars			Deformed bars			Cold twisted bars	Plain bars	Deformed and not twisted bars
	Structural steel grade	Intermediate grade	Hard grade	Structural steel grade	Intermediate grade	Hard grade			
Tensile strength, lb. per sq. in.	55 000 to 70 000	70 000 to 85 000	80 000 min.	55 000 to 70 000	70 000 to 85 000	80 000 min.	Recorded only	80 000	80 000
Yield point, min., lb. per sq. in.	33 000	40 000	50 000	33 000	40 000	50 000	55 000	50 000	50 000
Elongation in 8 in., min., per cent *	1 400 000 / Ten. str.	1 300 000 / Ten. str.	1 200 000 / Ten. str.	1 250 000 / Ten. str.	1 125 000 / Ten. str.	1 000 000 / Ten. str.	5	1 200 000 / Ten. str.	1 000 000 / Ten. str.

* See modification for thickness below.

The yield point shall be determined by the drop of the beam of the testing machine.

For plain and deformed bars over 3/4 in. in thickness or diameter, a deduction of 1/4% from the percentages of elongation specified shall be made for each increase of 1/32 in. in thickness or diameter above 3/4 in. For plain and deformed bars under 7/16 in. in thickness or diameter, a deduction of 1/2% from the percentages of elongation specified shall be made for each decrease of 1/32 in. in thickness or diameter below 7/16 in.

Bend-test Requirements. The test specimen shall bend cold around a pin without cracking on the outside of the bent portion, as follows:

Thickness or diameter of bar	Billet steel bars							Rail steel bars	
	Plain bars			Deformed bars			Cold twisted bars	Plain bars	Deformed and not twisted bars
	Structural steel grade	Intermediate grade	Hard grade	Structural steel grade	Intermediate grade	Hard grade			
Under 3/4 in.	180° $d = t$	180° $d = 2t$	180° $d = 3t$	180° $d = t$	180° $d = 3t$	180° $d = 4t$	180° $d = 2t$	180° $d = 3t$	180° $d = 4t$
3/4 in or over	180° $d = t$	90° $d = 2t$	90° $d = 3t$	180° $d = 2t$	90° $d = 3t$	90° $d = 4t$	180° $d = 3t$	90° $d = 3t$	90° $d = 4t$

Explanatory Note.— d = the diameter of pin about which the specimen is bent; t = the thickness or diameter of the specimen.

Appendix 6. Compression Tests for Concrete

Making and Storing Test Cylinders. The quality of the concrete in any portion of a structure should be based on the average of tests of not less than three cylinders, and better five. Test cylinders should be made and stored in accordance with the " Standard Methods of Making and Storing Specimens of Concrete in the Field " of the American Society Testing Materials, Serial Designation: C 31-21.

The concrete for testing must be taken from the forms immediately after placing, whenever possible. Shovel the concrete from the forms into a bucket and mix with a trowel before placing in the molds. If the concrete is being placed with buggies, the sampling should preferably be done by means of a " buggy sampler," designed especially for the purpose. This is a trough-shaped receptacle made of metal and provided with hooks at the ends which fit over the front and rear edges of the buggy. The top of the " trough " is partially closed by means of two inclined baffles converging upward and inward from the sides. Thus a long, narrow opening is formed which allows only a portion of the concrete entering the buggy to pass into the sampler. When the buggy is in position under the hopper or spout, the opening into the sampler takes a representative portion of the batch as it enters the buggy. This eliminates the inaccuracy of sampling the concrete with a scoop after the buggy has been filled, partial segregation of aggregates and cement making such procedure unreliable.

Breaking Test Cylinders. When the cylinders arrive at the laboratory they should be unpacked at once and stored in damp sand or in a moist room until broken. If the cylinders have not been capped on the job they should be capped upon arrival so that both ends shall be smooth, parallel and at right angles to the axis of the cylinder.

Compression tests should be made soon after removal of the specimens from the curing room, that is, while still in a damp condition.

The cylinders should be carefully placed in the testing machine so as to give an even bearing surface. The metal bearing plates should be placed in contact with the ends of the specimen.

The load should be applied through a spherical bearing block placed on top of the test piece. The diameter of the bearing block should be approximately the same as that of the test cylinder. The upper section of the bearing block should be kept in motion as the head of the testing machine is brought to a bearing on the test piece. The load should be applied smoothly and evenly, without shock. The moving head of the machine should travel at the rate of about 0.05 in. per minute.

Results of Compression Tests. In general, only the ultimate compressive strengths need be observed. The load indicated by the testing machine, at failure of the test piece, should be recorded and the unit compressive strength calculated in pounds per square inch, the cross-sectional area having been computed from the average diameters of the specimen. The type of failure and appearance of the concrete should also be noted.

Report Forms. A record of the investigation and design of the concrete mixtures together with the history and results of the concrete tests should be kept. Such report forms may be made to suit the particular requirements at hand.

From " Design and Control of Concrete Mixtures " Portland Cement Association.

Standard Method of Making and Storing Specimens of Concrete in the Field

Serial Designation: C 31-27. A. S. T. M.

1. The methods herein specified apply to molding and storing of test specimens of concrete sampled from concrete being used in construction.

2. The test specimens shall be cylindrical in form with the length twice the diameter. The standard shall be 6 by 12-in. cylinders where the coarse aggregate does not exceed 2 in. in size; for aggregates larger than 2 in. 8 × 16 in. cylinders shall be used; 2 by 4 in. cylinders may be used for mixtures without coarse aggregates.

3. (a) The molds shall be cylindrical in form, made of non-absorbent material, and shall be substantial enough to hold their form during the molding of the test specimens. They shall not vary in diameter more than 1/16 in. in any direction, nor shall they vary in height more than 1/16 in. from the height required. They shall be substantially water tight so that there will be no leakage of water from the test specimen during molding.

(b) Each mold shall be provided with a base plate having a plane surface and made of non-absorbent material. This plate shall be large enough in diameter to properly support the form without leakage. Plate glass or planed metal are satisfactory for this purpose. A similar plate should be provided for covering the top surface of the test specimen after being molded.

(c) Suggestions for suitable forms are shown in the accompanying figures.

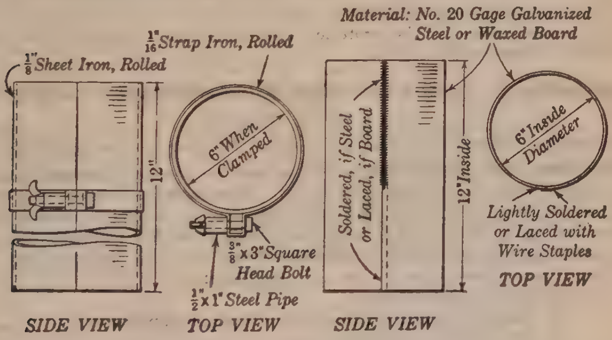

Fig. 127

4. (a) Concrete for the test specimens shall be taken immediately after it has been placed in the work. All the concrete for each sample shall be taken from one place. A sufficient number of samples — each large enough to make one test specimen — shall be taken at different points so that the test specimens made from them will give a fair average of the concrete placed in that portion of the structure selected for tests. The location from which each sample is taken shall be noted clearly for future reference.

(b) In securing sample, the concrete shall be taken from the mass by a shovel or similar implement and placed in a large pail or other receptacle, for transporting to the point of molding. Care shall be taken to see that each test specimen represents the total mixture of the concrete in that place. Different samples shall not be mixed together but each sample shall make one specimen.

5. (a) The pails or other receptacles containing the samples of concrete shall be taken as quickly as possible to the place selected for molding test specimens. To offset segregation of the concrete occurring during transportation, each sample shall be dumped into a non-absorbent water-tight receptacle and, after slight stirring, immediately placed in the mold.

(b) The test specimens shall be molded by placing the concrete in the form in layers approximately 4 in. in thickness. Each layer shall be puddled with 25 strokes with a 5/8 bar about 2 ft. long, tapered slightly at the lower end. After puddling the top layer, the surface concrete shall be struck off with a trowel and covered with the top cover plate which will later be used in capping the test specimens.

6. Two to four hours after molding, the test specimens shall be capped with a thin layer of stiff neat cement paste in order that the cylinder may present a smooth end for testing. The cap shall be formed by means of a piece of plate glass 1/4 in. thick or a machined metal plate 1/2 in. thick and of a diameter 2 or 3 in. larger than that of the mold. This plate is worked on the fresh cement paste until it rests on top of the form. The cement for capping should be mixed to a stiff paste some time before it is to be used in order to avoid the tendency of the cap to shrink. Adhesion of the concrete to the top and bottom plates can be avoided by oiling the plates or by inserting a sheet of paraffined tissue paper.

7. At the end of 48 hours the test specimens shall be removed from the molds and buried in damp sand except in case the molds shown in Fig. 3 are used; in this case test specimens may be buried in damp sand without removal of the mold, thus permitting shipping of the test specimens in the molds.

8. (a) The test specimens shall remain buried in damp sand until 10 days prior to the date of test. They shall then be well packed in damp sand or wet shavings and shipped to the testing laboratory, where they shall be stored either in a moist room or in damp sand until the date of test.

(b) Should a 7-day test be required, the test specimens shall remain at the work as long as possible to harden and then shall be shipped so as to arrive at the laboratory in time to make the test on the required date.

(c) Test specimens shall be protected from drying after removal from damp storage and before testing.

Appendix 7. Notes on High-Early-Strength Cements

By Duff A. Abrams

Director of Research, International Cement Corporation, New York City

High-Early-Strength Cements are being used for many varieties of concrete work where time is an important factor. The principal features of these cements are that concrete made from them may be placed in service after curing for 1 to 3 days. They have gained widespread recognition for construction of pavements, bridges, buildings, floors, concrete products, etc.

Three types of these cements are now available:

(1) True portland cement.
(2) Portland cement with certain chemical admixtures.
(3) High-alumina cements.

The specification for these cements has not been fully standardized. The Committee on Cement recently recommended to the American Society for Testing Materials a specification for High-Early-Strength Portland Cement which differs from the present " Standard Specification and Tests for Portland Cement " only in that the following requirements are substituted for tensile strength and SO_3 content:

Tensile Strength 1–3 Standard Briquets
24 hr. — 275 lb. per sq. in.
3 days — 375 1–3 Standard Briquets
SO_3 not more than 2.50%

One American manufacturer produces a high-early-strength portland cement by a double-burning process. Cements of this type are ground to such a fineness that 90 to 99% will pass the standard 200-mesh sieve.

For the use of high-early-strength cement in connection with concrete pavements see Sect. 20, Art. 17, p. 1158.

ROOFS AND BUILDINGS

1. Data for Roof Trusses

The constituent parts of a roof are the **covering** (including covering proper and any sheathing or slab that is used), the **purlins** and the **trusses**.

Roof Coverings are of many kinds, the most familiar being wood, slate, tin, sheet metal, tile, concrete, gypsum and the various composition roofings. It is highly important that the choice of covering be adapted to the slope of the roof or vice versa. The lack of this adaptation is a frequent cause of leaky roofs.

The **Slope** of a roof is the natural tangent of the inclination with the horizontal and is best expressed in inches of rise to one horizontal foot. The preferable slope for tar and gravel on sheathing is from 3/4 to 1-1/4 in. per ft.; reinforced cement tile of the "Bonanza" and similar types, 5 in. per ft.; corrugated sheet metal, 6 in. per ft.; slate, 7 in. per ft. The kind of waterproofing used on concrete and gypsum roofs will determine the slope.

Purlins are either wooden or steel beams extending horizontally from truss to truss and carrying the roof loads to the trusses. For long spans it is sometimes economical to space trusses far apart and to use deep purlins supporting intermediate beams called **jack rafters**.

Trusses are used to support roofs covering openings of from 20 to 200 ft., while for spans exceeding 200 ft. arches are generally used. A **truss** is an assemblage of bars, or members, which forms a structure to carry transverse loads and which under vertical loads has vertical reactions, the bars being so joined together at their ends that they bear only direct tension or compression when the external loads are applied at the joints. A **riveted truss** (Fig. 6) is one in which the members are connected together at the joints by being riveted to connecting steel plates, and a pin truss or **pin-connected truss** has the members joined together at their ends by means of one steel cylinder or pin at each joint. Purlins usually rest on the top surface of the upper chord, which is the upper bar of a truss, and should be placed directly over the joints whenever possible. In some roofs without jack rafters the purlins must be spaced so close together that some of them rest on the upper chord between the joints, thus causing the upper chord to act as a beam in addition to its direct stress.

A Panel of a roof truss is the space between two consecutive joints of the top chord, and a panel length is the distance from one of these joints to the next. A **bay** is the space between two adjacent trusses, and the bay length is the distance from center to center of trusses.

Forms of Trusses vary to suit the span length, outline of roof and clear head-room required underneath. The Fink and Warren trusses shown in Figs. 1 and 2 are suitable for spans up to about 120 ft. When the short web member of a Fink truss is replaced by two members, the Fink truss is converted into a fan truss as shown at (*a*) and (*b*) Fig. 2.

Loads on Roof Trusses are: dead, snow, wind; also ceilings, a crowd of people on a gallery or floor, or machinery suspended from the truss. Dead loads consist of weight of roof covering, sheathing rafters, purlins, trusses and suspended ceilings.

Weights of roofing per square foot of roof surface.

1. Coverings: wood shingles, 2 to 3 lb.; tin sheets or shingles, 1 lb.; corrugated steel, 2 to 3 lb ; slates, 7 to 10 lb.; tiles, 8 to 25 lb.; felt and gravel, 8 to 10 lb.; skylight glass 3/16 to 1/2 in., including iron frames, 4 to 10 lb.
2. Sheathing: spruce, white pine or hemlock boards, 1 in. thick, 3 lb.; Southern pine, 1 in. thick, 4 lb.
3. Rafters: wood, 2 by 4 to 2 by 8 in. spaced 16 to 24 in. on centers, 1.5 to 5 lb.
4. Purlins: wood, 1 to 3 lb.; steel, 1-1/2 to 5 lb.

5. Ceilings: plastered, 10 lb. per square foot of ceiling area.

6. Cinder concrete, 9 lb. per in. of thickness; stone concrete 12 lb. per in. of thickness.

Weights of Steel Trusses are often determined from empirical formulas, but such formulas are not trustworthy as they neglect many of the variable factors entering into the weights. The preceding tables are for the two most common forms of trusses:

The weights of ordinary Fink Trusses with slopes 5 in. and 4 in. on 1 ft. are from 5 to 15% more than those with 6 in. on 1 ft. given in the table.

Snow Loads on roofs vary with the latitude and slope of roof. The following values for weight of snow per horizontal square foot are commonly specified: New England and Michigan, 30 lb.; New York City and Chicago, 20 lb.; Baltimore, Cincinnati and St. Louis, 10 lb. Snow loads need not be used on roof surfaces having an inclination of 45 degrees or more from the horizontal, if there are no snow guards.

Wind Loads for roofs vary with the locality and slope of the roof and should be taken as acting horizontally at 30 lb. per sq. ft. on vertical surfaces of the most exposed structures and 15 to 25 lb. per sq. ft. on vertical surfaces of less exposed structures. On inclined surfaces only the normal component of the wind pressure need be considered, and this varies with the inclination of the roof.

Duchemin formula for wind pressure on inclined surfaces:

$$N = P\frac{2 \sin \theta}{1 + \sin^2 \theta}$$

in which N = normal pressure in pounds per square foot;
P = horizontal pressure on a vertical plane (taken at 20 lb. per sq. ft.);
θ = degrees of inclination to the horizontal.

θ	N	Slope	θ	N
5°	3.46	1 in. on 1 ft.	4° 45′ 49″	3.30
10°	6.76	2 in. on 1 ft.	9° 27′ 45″	6.39
15°	9.63	3 in. on 1 ft.	14° 2′ 10″	9.14
20°	12.25	4 in. on 1 ft.	18° 26′ 6″	11.50
25°	14.35	5 in. on 1 ft.	22° 37′ 12″	13.42
30°	16.00	6 in. on 1 ft.	26° 33′ 54″	14.88
35°	17.28	7 in. on 1 ft.	30° 15′ 24″	16.06
40°	18.20	8 in. on 1 ft.	33° 41′ 25″	16.95
45°	18.88			
to 90°	20.00			

For a pressure other than 20 lb. per sq. ft. the above values are to be changed proportionally.

The Total Load for an ordinary roof truss may be either

Dead + Wind + 1/2 Snow

or

Dead + 1/2 Wind + Snow

It is improbable that both the maximum snow and wind loads will be upon the roof at the same time. Sufficient accuracy is obtained in designing roofs up to 100-ft. span by assuming a total load per square foot of exposed surface large enough to include the dead, wind and snow loads. This combined load may be considered applied vertically. Unless governed by a local building code, for spans up to and including 90 ft. and in climates corresponding to that of New York, the total minimum uniform load in lb. per sq. ft. of roof surface for different kinds of covering may be taken as follows:

Corrugated metal on steel purlins	40
Gravel or composition on wood sheathing	50
Slate on boards	50
Tile on steel purlins	55
Gravel or composition on cinder concrete	65
on stone concrete	75
Slate or tile on cinder concrete	70
Fireproof buildings of the mill-building class when slope is less than 2 in. per ft.	90

For roof spans over 90 ft. the above cited loads should be increased 1% for every 2 ft. increase of span. For roofs in climates where snow is excessive 5 to 10 lb. should be added, and in climates where there is not liable to be snow 10 lb. may be deducted. Additions should be made for any special loads such as shafting, ceilings or trolleys carried by the bottom chord, and tanks, elevator supports or similar loads above the roof.

Stresses may be found by analytic or by graphic methods, the latter being usually employed. The analytic method can be profitably used as a check when advisable. For roof trusses the simplest analytic solution is by the method of joints or method of moments. In applying the **method of joints** a section is passed around a joint in such a manner as to cut all the bars meeting at that joint and then applying the relation from statics that the algebraic sum of all the vertical components meeting at the joint must = 0, or that the algebraic sum of the horizontal components meeting at the joint must = 0. Thus, by passing a section around joint A, Fig. 3, it is seen at once that the vertical component of P_1 = 3-1/2 W and therefore the stress in P_1 = 3-1/2 $W \sec\theta$, where θ is the angle the bar P_1 makes with the vertical. Similarly, the horizontal component of P_8, that is, stress in P_8 = horizontal component of P_1 = 3-1/2 $W \tan\theta$. The **method of moments** is that method of computing stresses in which a section is first passed through the truss, cutting in general not more than three members, one of which shall contain the stress desired; and then the equation of moments about the intersection of the other two bars cut is written and solved for the desired stress. Thus, in Fig. 3, to compute stress P_{10} by method of moments, pass a vertical section through P_4, P_{14}, P_{10} and consider the left side of this section. The equation of moments about B, the origin of moments for P_{10}, is $(3\text{-}1/2\ \mathbf{W})\boldsymbol{l}/2 - \mathbf{W}6\boldsymbol{l}/8 - P_{10}\mathbf{h} = \mathbf{0}$. In this equation P_{10} is assumed to be in tension, and since in the solution of the equation both sides are positive the bar P_{10} is in tension and its value $= Wl/h$. The section passed may be straight or curved, vertical or inclined. In Fig. 3 the dotted section for P_{12} is passed in such a way as to cut 6 bars, but by taking the origin of moments at B and writing the equation of moments of all forces above the section there results $-\mathbf{W}\boldsymbol{l}/8 + \mathbf{P}_{12}\,\mathbf{h}/2 = \mathbf{0}$; whence $\mathbf{P}_{12} = \mathbf{W}\boldsymbol{l}/4\,\mathbf{h}$.

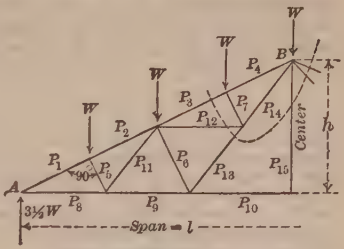

Fig. 3

By using the method of moments or method of joints the stresses in the Fink truss of Fig. 3 have been computed and the accompanying table prepared for a span of l, a height of h and a vertical load W at each upper joint. The load W is called a panel or apex load.

Coefficients for Stresses in Fink Truss. Fig. 3

Bar	Kind of Stress	$\frac{l}{h} = 3$	$\frac{l}{h} = 3.46$ 30°	$\frac{l}{h} = 4$	$\frac{l}{h} = 5$	$\frac{l}{h} = 6$
P_1	Comp.	6.31	7.00	7.83	9.42	11.07
P_2	"	5.75	6.50	7.38	9.05	10.75
P_3	"	5.20	6.00	6.93	8.68	10.43
P_4	"	4.65	5.50	6.48	8.31	10.12
P_5	"	0.83	0.87	0.89	0.93	0.95
P_6	"	1.66	1.73	1.79	1.86	1.90
P_7	"	0.83	0.87	0.89	0.93	0.95
P_8	Tension	5.25	6.06	7.00	8.75	10.50
P_9	"	4.50	5.19	6.00	7.50	9.00
P_{10}	"	3.00	3.46	4.00	5.00	6.00
P_{11}	"	0.75	0.87	1.00	1.25	1.50
P_{12}	"	0.75	0.87	1.00	1.25	1.50
P_{13}	"	1.50	1.73	2.00	2.50	3.00
P_{14}	"	2.25	2.60	3.00	3.75	4.50
P_{15}	"	0.00	0.00	0.00	0.00	0.00

The upper chord panel loads are equal. To obtain stress in pounds in any bar of the truss, multiply the coefficient by the panel load in pounds.

2. Design of Roof Trusses

Working Stresses. For designing the structural steel of roof trusses and buildings (when not governed by a local building code) the following unit or working stresses in lb. per sq. in. are recommended:

	(a) Acceptable Steel	(b) Standard Steel
Tension, net section, rolled steel	16 000	18 000
Axial compression, rolled steel and steel castings, short lengths	16 000	18 000
Bending: on extreme fibers of rolled shapes, built sections, girders, and steel castings	16 000	18 000
Bending, on extreme fibers of pins	24 000	27 000
Shear on power-driven rivets and pins	12 000	13 500
Shear on bolts and hand-driven rivets	10 000	11 200
Shear, average, on webs of plate girders and rolled beams, gross section	10 000	11 200
Bearing pressure on power-driven rivets and pins	24 000	27 000
Bearing on bolts and hand-driven rivets	20 000	22 500
Axial compression on gross section of columns and struts	16 000–70 l/r	18 000–80 l/r
With a maximum of	13 000	14 500

Where l = effective length of member in inches;
r = least radius of gyration of section in inches.

By " acceptable steel " is meant steel which is acceptable to the building official, but of which the origin and physical characteristics are not definitely determined. By " standard steel " it is meant that the steel to be used is guaranteed to conform to the American Society of Testing Materials Standard Specification for Structural Steel for Buildings (serial designation A9–24).

For combined stresses due to wind and other loads the above-mentioned unit stresses in column (a) may be increased 50%, provided the section thus obtained is not less than that required if wind forces are neglected. In column (b) they may be increased 33-1/3%.

The effective length of main compression members should not exceed 125 times their least radius of gyration, and those for wind and lateral bracing 200 times their least radius of gyration.

Any portion of the cross-section of a compression member may be neglected in computing the radius of gyration, provided this portion is neglected in the design of the member. Eccentricity, shock, rust, the bending of lateral struts due to their own weight, should all be considered.

Spacing of Trusses. Theoretically, the economic spacing of roof trusses is about one-quarter the span, but in practice the spacing may be governed by conditions peculiar to the structure under consideration. If the covering or sheathing rests on purlins a spacing of about 16 ft. is commonly used for spans up to 65 ft.; beyond that the spacing may be one-quarter of the span. Where plank sheathing rests directly on the trusses the spacing may be 6 to 8 ft. for 2-in. and 8 to 10 ft. for 3-in. tongued and grooved plank. If spans are of unusual length or roof loads are very heavy it may be found economical to use jack rafters resting on latticed or beam girders framed into the roof trusses. Sub-purlins can rest on top of the jack rafters or wood sheathing can extend from rafter to rafter.

Proportioning Purlins. Steel purlins are usually made of ∟'s, [’s or I beams, although for long spans they are made of truss form. Where the purlin is placed so as to deflect in the plane of the resultant load acting upon it, as when an I beam is set with its web vertical to carry a vertical load, the size of the purlin is computed by the formula, $\mathbf{M/S = I/c}$, where M is the maximum bending moment on the purlin in inch-pounds; S, the allowable unit stress in pounds per square inch; I, the moment of inertia about axis perpendicular to web; c, half depth of beam in inches. Having computed M, S is assumed, the value of I/c (called the section modulus) is found by dividing M by S, and the size of a beam having a section modulus equal to or slightly greater than this is chosen from a table giving properties of structural shapes.

If the purlin is placed so that the deflection is not in the plane of the resultant load carried by it, as when an I beam supports a vertical load and rests on an inclined chord of a truss, hence having its web inclined, a trial size of the beam is taken and the maxmum fiber stress in the outermost fiber is computed by the formula

$$\mathbf{S} = \frac{\mathbf{M_1c_1}}{\mathbf{I_1}} + \frac{\mathbf{M_2c_2}}{\mathbf{I_2}},$$

where S = maximum fiber unit stress, M_1 = bending moment due to that component of load which is normal to plane of roof, I_1 = moment of inertia of section of purlin about a gravity axis parallel to roof. c_1 = the distance from this axis to fiber on which stress is maximum, M_2 = bending moment due to component of load which is parallel to roof, I_2 = moment of inertia of section about a gravity axis normal to roof, and c_2 = the distance from this axis to fiber on which stress is a maximum. This method does not apply to purlins of ∟ section, but the moments must be resolved into the planes of their principal axes. By connecting the purlins together with sag rods running up both sides of a sloping roof to the same connection at the peak of the roof the second term of the preceding equation is negligible in the design of all purlins

Section Moduli in Plane of Vertical Loading of Angles and Channels Placed at Right Angles to Roofs as Indicated in Fig. 4

Purlin	Slope of Roof in Inches on 1 Foot

except the one or two at the peak carrying the pull from the sag rods. Sag rods are usually made 5/8 or 3/4 in. in diameter and are spaced 6 to 7 ft. apart. To prevent undue deflection the depth of a rolled beam purlin should not be less than **1/32** of its span length. For fiber stress not exceeding 10 000 it may be 1/40.

To determine the strength of the ordinary sizes of L's and ⊏'s for purlins without sag rods and free to bend in any direction, the section moduli can be taken from the preceding table and used in the fundamental formula for flexure.

It should be noted that L purlins set as in Fig. 4 are stronger than those of Fig. 5. This table is based on purlins being set as shown in Fig. 4.

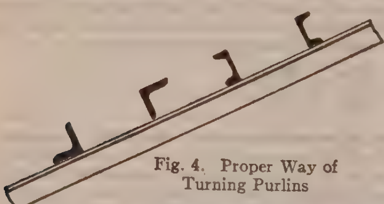

Fig. 4. Proper Way of Turning Purlins

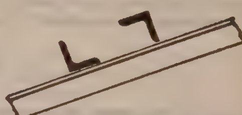

Fig. 5. Improper Way of Turning Purlins

Proportioning Tension Members. A tension member or bar of a truss, also called a tie, is one that carries a pull or tensile stress. For riveted trusses 2 L's, and for pin trusses 2 eyebars are commonly used for each tension member. For design of eyebars see Art. 27. In riveted trusses carrying light loads the 2 ∟'s should be placed side by side with a space between them equal to the thickness of the gusset plates, Fig. 6, and should have their vertical legs up. These ∟'s should be connected together at points from 2 to 3 ft. apart throughout their lengths by placing a circular steel washer between the ∟'s and driving a rivet through the 2 ∟'s and the washer. These rivets are called tack or **stay rivets,** and simply hold the ∟'s together during transportation and erection and make the ∟'s act together when under stress.

To proportion the cross-section of a tension member of 2 ∟'s divide the total stress in the member by the allowable unit tensile stress, thus obtaining the required net area of the 2 ∟'s, and then choose from a table of properties of ∟'s, 2 ∟'s of the same size, each having a net area equal to or slightly larger than 1/2 the required net area. The net area of an ∟ is found by deducting from the gross area of the cross-section the greatest sectional area cut out by rivet holes in any one section. In **computing net areas** the diameter of a rivet hole is assumed 1-8 in. larger than the diameter of the cold rivet before driving. An angle is sometimes connected to a gusset plate by rivets in one leg only, in which case there would usually be only one row of rivets in the connecting leg, and hence only one rivet hole area, equal to diameter of hole times thickness of piece, would be deducted from the gross section. Where there are two rows of rivets in the ∟ at one end the rivets should be staggered so that there would be only one rivet hole in any one section.

Proportioning Compression Members. A compression member or column in a truss is one which carries a compressive stress, and for roof trusses is made of one or two ∟'s, Fig. 6, two ∟'s with a plate between, or of two [’s. In light work one or two ∟'s are nearly always used for each member, while for heavy trusses the top chord is composed of two [’s or two or more ∟'s. To proportion the cross-section of a compression member subjected to compression only, the simplest way is to assume a trial cross-section and compare the actual average stress per square inch on this section with the allowable average stress per square inch as computed from a column formula. If the actual and allowable stresses are equal or if the actual is only slightly less than the allowable the section is used, but if the actual is greater than the allowable a new trial area is chosen and the process repeated.

The Actual Average Stress per square inch is found by dividing the total stress in the member by the gross area of the cross-section. The allowable average stress is found from the column formula of the specifications (see p. 1184).

The following example will illustrate the method of proportioning the inclined top chord of a Fink truss having a panel length along this chord of 7 ft., a direct compression of 46 500 lb., and made of 2 ∟'s spaced 3/8 in. apart for the gusset plates, the allowable unit stress being given by the formula $S = 16\,000 - 70\,l/r$. Assume two 4 by 3 by 5/16 in. ∟'s and place the 4 in. legs vertical and 3/8 in. apart. From a steel company's handbook (or p. 676), the area of the 2 ∟'s is found to be 4.18 sq. in. and the least radius of gyration that about the gravity axis parallel to the short legs. Dividing 46 500 lb. by the area 4.18, the actual average unit stress is found to be 11 120 lb. per sq. in., and by substituting $l = 84$ in. and $r = 1.27$ in. in the column formula the value of the allowable unit-stress, S, is 11 370 lb. per sq. in. Hence the 2 ∟'s assumed are of correct size. These ∟'s must be riveted together at intervals not exceeding $0.65 \times 84/1.27 = 43$ in.; 0.65 being the least radius of gyration of one ∟ and 1.27 the least for 2 ∟'s. It is customary to place tack rivets every 2 or 3 ft. apart throughout the length of these members.

Purlins resting between joints on the top chord of a truss cause **cross-bending** therein, which, in addition to the compression acting, must be considered in the design of the chord. In such cases the shortest method for designing the chord is to assume a section, usually two ∟'s or two ∟'s and a vertical plate for light trusses, and compare the maximum unit stress with the allowable. If the section thus assumed is too large or too small a new trial section

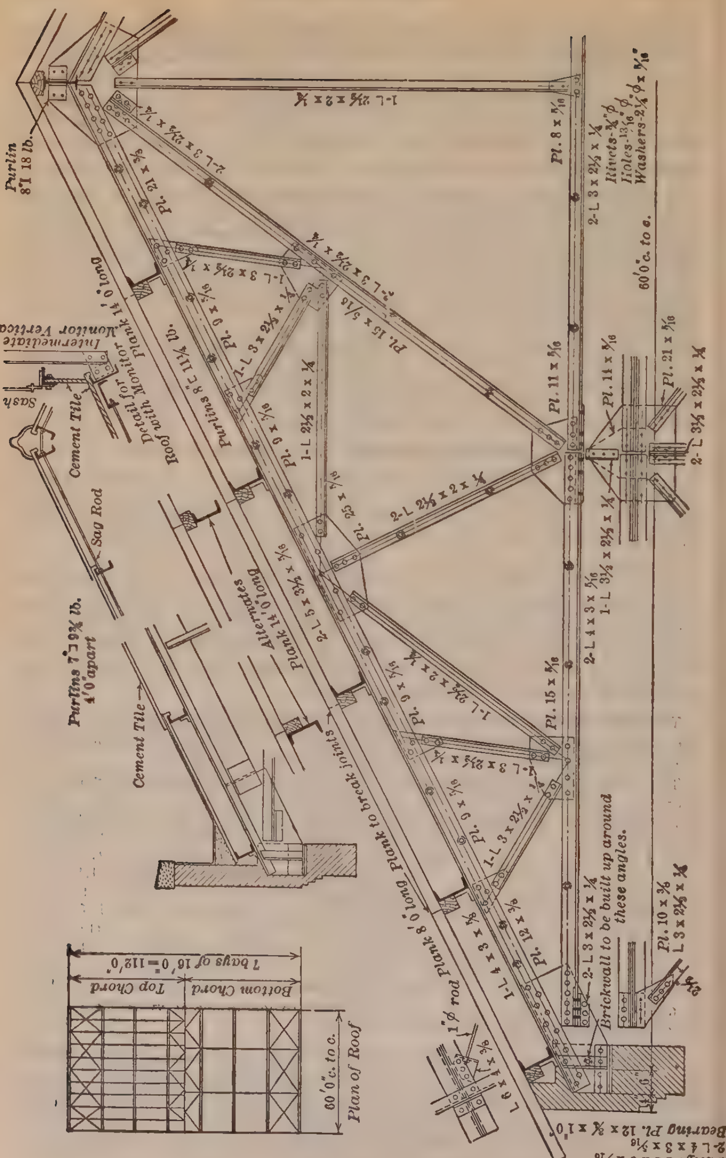

Fig. 6. Fan Roof Truss with Details

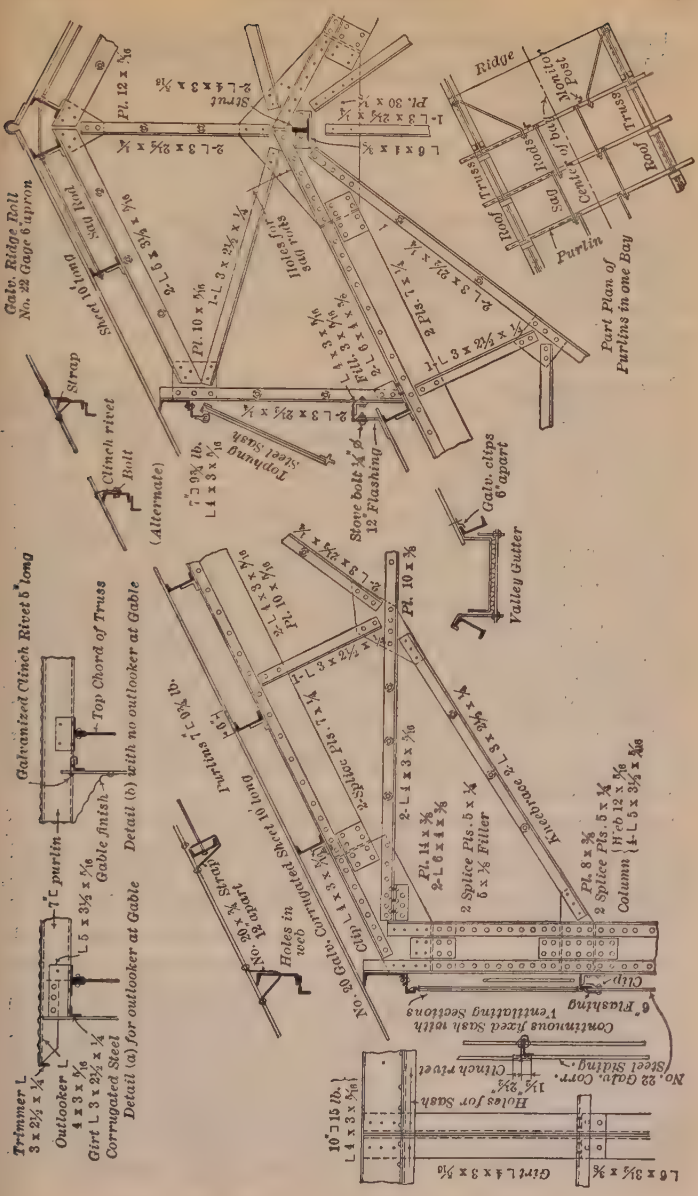

Fig. 7. Details for Corrugated Steel Covered Building

is chosen and the process repeated until the section is satisfactory. The maximum unit-stress in a continuous chord due to combined direct compression and bending is with sufficient accuracy given by

$$S = \frac{P}{A} + \frac{\frac{Mc}{I}}{1 - \frac{Pl^2}{10\,EI}},$$

where S is the maximum unit stress on the most strained fiber, in pounds per square inch; P the direct compressive load in pounds; A the area of cross-section in square inches; M the maximum bending moment on the chord acting as a beam of panel length l and continuous over the joints; c the distance from gravity axis to most strained fiber under consideration; I the moment of inertia of cross-section; E the modulus of elasticity, for steel say 30 000 000 lb. per sq. in.

Designing Joints. Since most roof trusses are of the riveted type, only riveted joints will be considered. For the design of pin joints see Art. 29. In laying out the members of the truss their center lines should meet at a point at each joint and should coincide with the truss diagram. It is the usual practice in roof work to use the gage lines of the angles for the center lines, instead of center of gravity lines. The error is negligible. Rivets should be placed in each member to transmit the stress from that member into the gusset plate. As an illustration of the method of computing the number of rivets, consider a member carrying a direct stress of 46 500 lb., and made of 2 L's 4 by 3 by 5/16 in., one on either side of a 3/8 in. gusset. The rivets connecting the L's to the gusset are in double shear, that is, they must be sheared on two sections before failure can occur; they are in bearing on the 3/8-in. gusset plate and in bearing in the oppostie direction on 2 thicknesses of 5/16 in. L. The **double shearing value** of one rivet is equal to twice the area of its cross-section multiplied by the permissible shearing stress per square inch, or, assuming rivets 3/4 in. in diameter, the double shearing strength is 2 × 0.44 × 12 000 = 10 560; the 12 000 being the permissible shear in pounds per square inch. The **bearing value** of a rivet on a piece is the product of the diameter of the rivet in inches, the thickness of the piece in inches and the permissible bearing pressure in pounds per square inch. In the case here assumed the bearing value of the 3/4-in. rivet on the 3/8-in. gusset plate is 3/4 × 3/8 × 24 000 = 6750 lb., and since this is smaller than either the double shearing value or the bearing on the two 5/16-in. L's, 6750 lb. is the allowable stress on one rivet; 24 000 being the permissible bearing strength per square inch. The number of rivets in the member at this joint is 46 500/6750, or 7.

The Permissible Unit-Stresses used in the problem just solved, namely 12 000 lb. per sq. in. for shearing and 24 000 lb. per sq. in. for bearing, are safe values for shop, that is, machine-driven rivets. For field rivets driven by hand, or for bolts, the safe shearing and bearing values are 10 000 and 20 000 lb. per sq. in., respectively. Allowable shearing and bearing values for rivets of different diameters are given in Art. 21.

Fig. 6 shows a fan roof truss with details.

Fig. 7 shows details of an ordinary steel building with covering of corrugated steel.

Details. Even though to make what is usually considered the design of a structure may be easy, to detail it may be difficult. The ideal draftsman is a designer, a designer of details. Seldom has a structure given way for lack of strength in the main members but faulty details have invited and brought disaster. Theoretically, in laying out the members of a roof truss the center of gravity lines should meet at a point at each joint and should coincide with the truss diagram. However, in practice the rivet lines are generally used. Details are thus simplified. Eccentric rivet connections should be reduced to a minimum. Economy will be gained by having as many duplicate parts as possible. Connections that induce secondary stresses should be avoided. Details should be designed in accordance with shipping facilities, cost of transportation and ease of erection. While it may lessen the cost of field work to fabricate trusses in few sections, the transportation charges may be enough larger to consume all saving.

Again, while it may lessen freight charges to ship a truss in many pieces, the cost of field riveting will be increased.

3. Steel Mill-Building Frames

Steel Mill-buildings in general are divided into three types. Those of the first type have steel frames carrying the roof loads as well as the weight of the walls which protect the frames; the walls being constructed of corrugated steel sheets or of concrete supported by the steel frames. The essential parts of the steel work are the roof trusses, columns and bracing; a truss together with the columns which support it constitutes a bent, of which Figs. 8, 9, and 10 represent typical cases. In the second type of steel mill-building the columns are braced principally by thin masonry walls, thus eliminating most

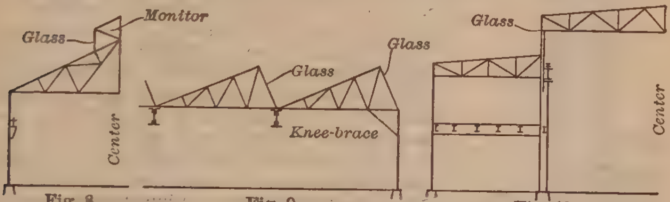

Fig. 8 Fig. 9 Fig. 10

Steel Mill-building Frames

of the steel bracing between columns, while in the third type the steel roof trusses are supported on masonry walls instead of on steel. Light is admitted to the interior of mill-buildings through windows in the side and end walls and in addition through skylights in the roof proper or in the monitor roof, or through windows in clerestory of the monitor. **A monitor,** (Fig. 8), is that portion of building extending above the main roof for the purpose of ventilating or lighting the interior of a building. Fig. 9 shows **saw-tooth** roof construction. Roofs of this form of construction are extensively used for wide areas. The glazed portions should of course face the north; a diffused light thus illuminates the floor below without casting shadows.

Columns should be proportioned to resist (1) direct stress due to roof, crane or other loads, (2) stress due to wind and (3) stress due to eccentric loads. A great number of column formulas have been suggested for the design of steel members in compression. The "straight-line" formula $\mathbf{S = 16\,000 - 70\, \mathit{l}/r}$, except where noted otherwise, is used throughout this section.

Rivets in tension should be avoided when practicable. Carrying the crane load on a column flange directly under the web of the runway girder is preferable to carrying it on a bracket. By connecting roof trusses to columns with gussets greater stiffness is obtained than by resting them on column caps. Various column details are shown in Figs. 11 and 12.

Girts, sometimes called side purlins, are beams, usually of angles or channels fastened to the columns to support the side covering and to resist wind pressure. For corrugated steel siding the wind pressure is the greater load and the longer leg of the angle or the web of the channel should be laid

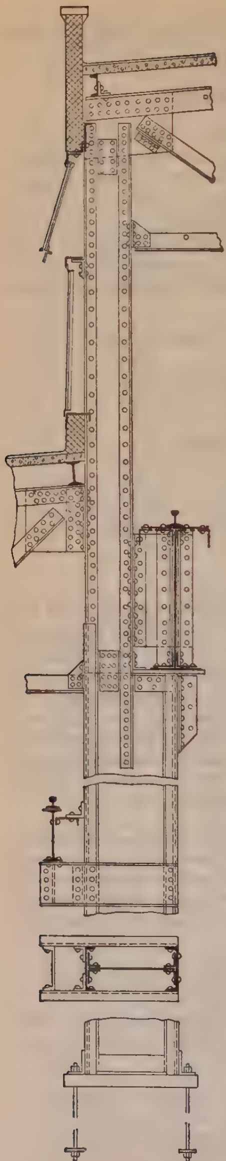

Fig. 11. Typical Column Details

horizontal. To prevent deflection sag rods 5 to 8 ft. apart fastened to the girts and running to the eave struts are used.

The Bracing of a mill-building should be so designed that wind and vibratory stresses are carried to the foundations. Diagonal bracing should be introduced into the plane of both top and bottom chords for stiffness as well as for calculated stresses. This applies also to roof trusses resting on brick walls. Adjustable rods may be used for top chord bracing, the purlins acting as struts, but the bracing of the bottom chord should be angles or other rigid shapes. Diagonals between the steel columns in each end of the building and in an occasional side bay are usually sufficient to carry the induced stresses to the foundations. When it can be done an excellent way is to carry the transverse thrust from the wind as well as that from the cranes to the ends of the building and thence by diagonals to the ground. The usual way is to design each bent as a unit for both the vertical and horizontal loads of one-half the adjoining bays. In such cases the kneebrace is an important member. A **kneebrace** is a short diagonal, usually a pair of angles, used to connect a truss or beam to a column. Traveling cranes running through a building often bar the use of transverse kneebraces. The gusset plates connecting the trusses to the columns should then be as large as possible and calculations made accordingly. Angles may be added to stiffen the edges of the plates. Kneebraces should be used between crane girders and their supporting columns.

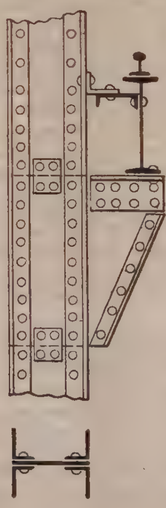

Fig. 12. Connection of Crane Bracket to Column

Electric Traveling Cranes are an important part of the equipment of most mill-buildings and are often the dominant factor in the design. Ten-ton cranes are the most common. Cranes of 50 short tons capacity and less are usually carried on a two-wheel carriage at each end. Those of 60 to 125 short tons capacity should have four-wheel carriages in order to avoid excessively concentrated loads on the runway girders. Cranes of 150 short tons capacity and more are built with end carriages of both four and eight wheels. The eight-wheel carriage reduces the concentrated load on the runway girders. The wheel bases, maximum wheel loads and clearance of cranes vary with the design of the maker. The figures given in the table on next page represent average values.

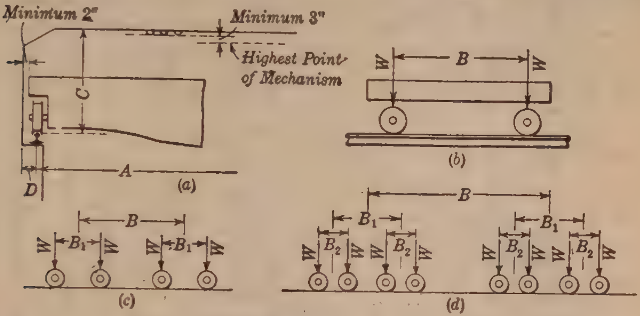

Fig. 13. Wheel Diagrams for Traveling Cranes

Stresses due to the wheel loads given in the table should be increased 25% for vibration and impact except for hand-power cranes, where 10% is sufficient. For two cranes in action on the same girder, no impact need to added provided the stress obtained is larger than the stress due to a single crane with impact. In addition to the vertical loads the top flanges of crane girders should be designed to resist a transverse horizontal thrust on each carriage, applied to the wheels, of 10% of the lifting capacity of the crane. The traction stress due to starting or stopping the crane should be assumed at 10% of each wheel load and may be considered as distributing itself along the entire length of the runway.

Floor Loads. Live Loads in pounds per square foot on floors of the mill-building class should not be assumed at less than the following:

Mold lofts, pattern and template shops	60
Machine shops, light machinery	120
Machine shops, heavy machinery	150 to 200
Factories	100 to 250
Foundries, charging floor	300 to 800
Power houses	200

It is important that industrial processes be understood sufficiently to make proper provision for their loads and stresses. Provision should also be made for the support of all engines, boilers, tanks or other concentrated loads carried by the steel construction.

The Working Stresses given in Art. 2 may be used in proportioning members.

Wind Stresses. For buildings not more than 25 ft. to the eave line a horizontal wind pressure should be assumed at not less than 15 lb. per sq. ft. on the sides and the corresponding normal component on the roof according to the Duchemin formula for wind pressure on inclined surfaces. For buildings more than 25 ft. to the eave line the horizontal pressure should be taken at not less than 15 lb. for the lower 25 ft., and 20 lb. for the side surface above 25 ft. and the corresponding normal component on the roof. The steel framework should be designed to carry wind pressure to the ground.

The stresses in the framework due to wind acting on the vertical and inclined sides of a building depend to a great extent on the manner of fixing the ends of the columns. If the ends are hinged, that is, free to turn, the

stresses throughout the frame are different from those existing when the ends of the columns are fixed. A **column is fixed** at the end when it is so rigidly held there that the axis of the column cannot change its direction at that point. In the case of a fixed-end column the point of **contra-flexure**, that is, the point where the direction of curvature changes, is taken halfway between the base of the column and the foot of the kneebrace. In light buildings the columns should not usually be assumed fixed at the bottom.

The case of an intermediate transverse bent of a kneebraced mill-building will be considered. The example taken will be a bent of 60-ft. span, height 18 ft. to foot of kneebrace, 24 ft. to bottom chord and slope of roof 6 in. to 1 ft. Trusses are 16 ft.

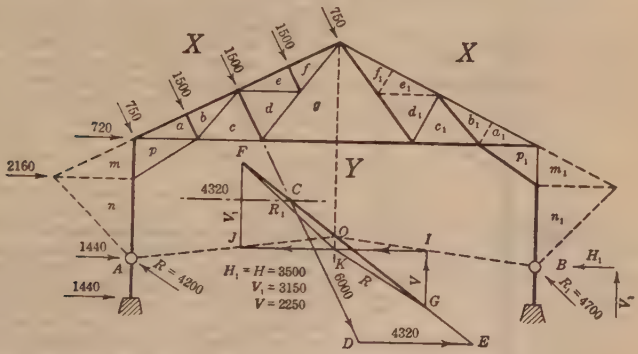

Fig. 14. Load and Reaction Diagram.

apart c. to c. The wind pressure will be taken at 15 lb. per sq. ft. perpendicular to the sides of the building and at 11.2 lb. (Duchemin formula, Table, Art. 1) normal to the roof. The columns are assumed partially fixed at the lower end, with the point of contra-flexure at one-third the distance between the lower end and the foot of the kneebrace; the upper ends are considered supported.

Fig. 14, the load and reaction diagram, shows the arrangement of the forces and the method of finding the reactions at the points of contra-flexure in the columns. The

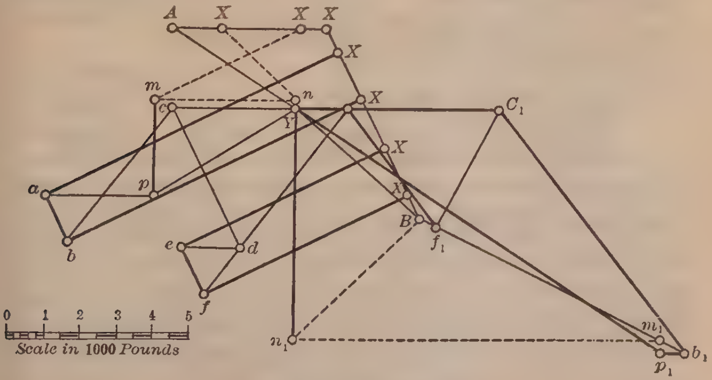

Fig. 15. Stress Diagram

wind shear is assumed to be divided equally between the two columns, making the horizontal reactions at A and B equal. CE is the resultant of CD and DE, the wind on the roof and the sides. The wind resultant is laid off, FG, so that it is bisected by the mid-vertical line at O. The perpendiculars dropped from F and G upon the dotted lines OA and OB gives the vertical components of the reactions at B and A respectively. Draw the horizontal line JI intersecting the mid-vertical at K. Then $KF = R_1$ and $GK = R$, the reactions at B and A respectively.

Fig. 15 is the stress diagram. The heavy lines indicate compressive and the light lines tensile stresses. Dotted lines indicate stresses in imaginary truss members which are inserted to make the stresses statically determinate. Removing these members will produce bending stresses in the columns but will not affect the stresses in truss members and kneebraces. The stress in any member can also be determined by the method of moments or sections. For instance, let S = required stress in the kneebrace. Take M (Fig. 15a) as center of moments and since the sum of moments of all forces about M = zero; $(4200 \times 15.0) - (4320 \times 9.0) - (S \times 5.0) = 0$ from which S = 4800 lb. tension. This checks with the stress obtained by the graphical method of Fig. 15.

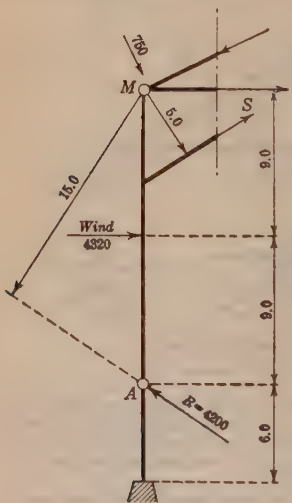

Fig. 15a. Stress in Kneebrace

The stresses in the columns due to wind are as follows: The direct stresses in the portion below the kneebrace are 2250 lb for the windward and 3150 lb. for the leeward column, being the vertical reactions V and V_1, scaled from the reaction diagram. The horizontal shear at the point of contra-flexure of each column scaled from the reaction diagram is 3500 lb. The direct stress in the portion of the windward column above kneebrace equals the vertical reaction V plus the vertical component of the kneebrace and in the leeward column the vertical reaction V_1, minus the vertical component of the kneebrace. The horizontal shear in the portion of the windward column above the kneebrace equals the horizontal component of the stress in the kneebrace (3960) + wind (4320) − H (3500) = 4780. The horizontal stress in the portion of the leeward column above the kneebrace equals the horizontal component of the stress in the kneebrace (10 200) − H_1 (3500) = 6700.

The bending moments in the columns are:

	Ft.-lb.
At foot of leeward column, 3500 × 6	= 21 000
At foot of leeward kneebrace, 3500 × 12	= 42 000
At foot of windward column (3500 × 6) + (1440 × 3)	= 25 320
At foot of windward kneebrace (3500 × 12) − (1440 × 12)	= 24 720

It is seen that the maximum bending moment is at the foot of the leeward kneebrace.

To Design a Mill-Building Bent proceed as follows: Determine stresses in truss due to a total uniform load over the entire roof surface, as in Art. 1. The total load includes the wind load which may be assumed at 10 lb. per sq. ft. for roofs of 3 in. slope and more and at 5 lb. for slopes of less than 3 in. Proportion the members for these stresses using the working stresses recommended in Art. 2. Then find the wind stresses due to the normal wind forces by the methods of Figs. 14 and 15. If the wind stress in any member from Fig. 15 is greater than the wind stress (obtained by interpolation) due to a vertical load of 10 or 15 lb. per sq. ft. over the entire roof surface, that member is proportioned for the maximum wind plus the stress from the uniform loads other than wind, using working stresses 50% more than in the first calculation, but in no case is a less section to be used than that first obtained. The members bc and b_1c_1 will generally need to be increased; often cd and c_1d_1; occasionally gd, gf, gf_1 and gd_1. Compressive stresses are noted in certain tension members, particularly b_1c_1 and the lower chord. The diagonals bc and b_1c_1 can be made of two angles instead of one as when designed for tension alone. The compressive stresses in the lower chord are overcome by the tensile stresses due to the dead load. The kneebraces have wind stresses only, and are proportioned for the larger working stresses.

The Columns may be designed as follows:

(1) Proportion for the direct stress from the specified total uniform load on the roof surface using the column formula specified. (See p. 1184.)

(2) Proportion for combined compressive and bending stresses using the formula of Art. 2,

$$S = \frac{P}{A} + \frac{\frac{Mc}{I}}{1 - \frac{Pl^2}{10\,EI}}.$$

S in this formula is the actual maximum fiber stress which should not exceed by more than 50% the S obtained from the column formula in (1). The direct stress, P, is that due to the roof loads (other than wind) and the vertical reaction from wind. For M the maximum bending moment due to wind is to be used.

The greater section obtained by (1) or (2) is to be used.

For example, if the roof of Fig. 14 be of corrugated steel, the total direct load on a column is 31 ft. × 16 ft. × sec 26° 34′ × 40 lb. = 22 200 lb. The column is proportioned for this load according to (1) above. As with truss members it may be assumed that 10 lb. of the 40 lb. uniform load is from wind leaving 16 650 lb. from loads other than wind. The reaction diagram shows a direct stress in the leeward column of 3150 lb. In proportioning the column according to (2) the value of P in the formula is therefore 16 650 + 3150 = 19 800 lb. The value of M is the maximum bending moment, 42 000 ft.-lb. = 504 000 in.-lb. The greater section in this particular case is that obtained by (2) and it should be used.

4. Tall Building Frames

The Steel Frames used in the construction of modern tall buildings such as office buildings carry the entire weight of walls, floors and, in fact, all dead and live loads. To these buildings have been given the name **skeleton construction.**

Columns should always be made of steel, although in cheap construction cast iron is sometimes used. Fig. 16 shows various common sections employed for columns in buildings. Where two [’s or four L’s are used to form a column they should be connected together by **lattice bars**, which are flat bars from 1-3/4 to 2-1/2 in. in width riveted first to one [or pair of L’s and then to the other. Columns made of L’s and plates must be riveted together with rivets in the body of the column spaced not over 16 times the thickness of the thinnest outside piece connected, the maximum distance used being 6 in. on centers. At ends of such columns the rivet pitch, which is the distance of rivets on centers, should not exceed four diameters of the rivet for a length equal to 1-1/2 times the greatest width of the member. Columns should be continuous over two stories, and splices should be placed just above the floor levels. Cast-iron bases or pedestals are often used under columns to distribute the load over the foundations, although rolled steel slabs are preferable in most cases and have come into quite general use. For heavy loads foundations are made of one or more tiers of grillage beams on concrete footings. All columns must be encased in concrete, terra cotta or other fireproof materials, Fig. 16, and no pipes should be placed within such casings. Two inches of concrete or 2 to 4 in. of terra cotta is the minimum thickness for casings, and the space between the terra cotta and the columns should be filled with concrete or other similar filling.

In tall buildings **wind bracing** is a prime requisite. No other feature of their design has called forth a greater variance of opinion. Dependence for bracing is often placed upon the walls, floors and partitions in buildings less than 100 ft. high where the height is not more than twice the minimum horizontal dimension. The columns are strongly spliced and secured to the floor framing. For greater limits the wind stresses are carried to the ground by the steel frame. This often presents a difficult problem. Kneebraces are excellent when they do not project into rooms and corridors. A system of diagonal bracing, ∟'s or ⊏'s, as shown in Fig. 17 (*a*), is ideal but it can seldom be used. In a system without diagonals the connections of floor girders and beams to columns must be designed to take bending stresses and at the same time come within prescribed architectural limits. Connections that have often been used are shown in Fig. 17 (*b*), (*c*), (*d*). For the lower floor connections details (*b*) or (*d*) are used and for the upper floors where wind stresses are light (*c*) is used.

See Art. 7. Wind Stresses in Tall Buildings.

Live Loads. Tall buildings are usually within the limits of a city and must be designed in accordance with the provisions of a municipal building code. When not governed by a building code the following loads and working stresses are recommended:

Minimum Live Load in Pounds per Square Foot of Floor Area

Dwellings (private residences) first floor	40
Dwellings (private residences) upper floors	30
Apartment houses, first floor	50
Apartment houses, upper floors	40
Hotels, first floor	80
Hotels, upper floors	40
Office buildings, first floor	100
Office buildings, upper floors	50
School buildings, class rooms	50
School buildings, assembly rooms	75
Churches and theatres	75
Places of public assembly where floors are used for drilling or dancing	120
Where not so used	100
Retail stores, ordinary	100
Private garages, pleasure vehicles only	60
Public garages, pleasure vehicles only	90
Garages, motor trucks 1 to 3 tons capacity	150
Garages, motor trucks 3-1/2 to 5 tons capacity	200
Warehouses	200 to 500

Every steel beam in any floor should be capable of sustaining a live load concentrated at its center of not less than 3000 lb. if used for business purposes; of 2000 lb. if used as a private garage storing pleasure vehicles only; of 3000 lb. if used as a public garage storing pleasure vehicles only; of 8000 lb.

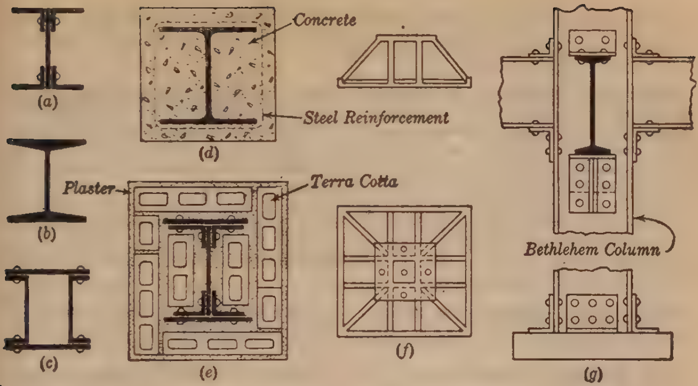

Fig. 16. Columns for Fireproof Buildings

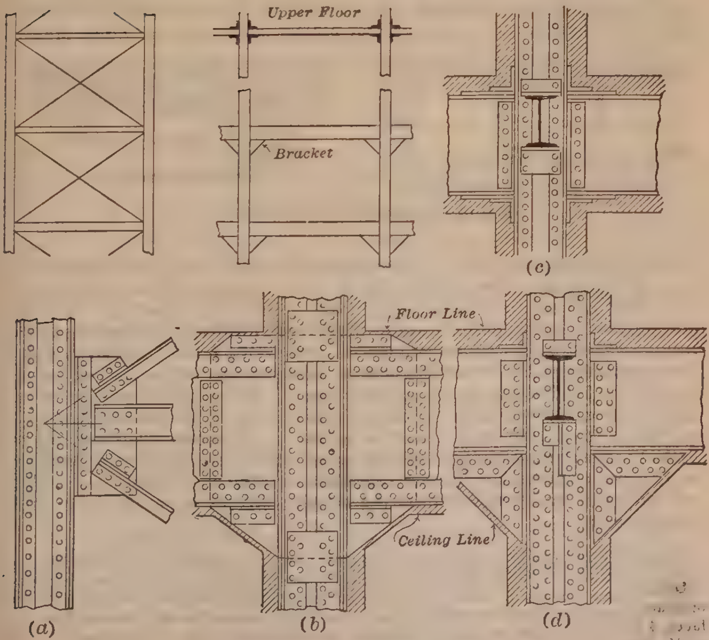

Fig. 17. Types and Details of Wind Bracing

rf motor trucks of 1 to 3 tons capacity are stored and of 12 000 lb. if motor trucks of 3-1/2 to 5 tons capacity are stored. The kind of material stored in a warehouse will determine the floor load.

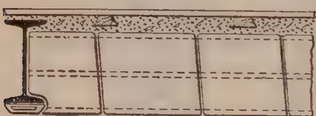
Reduction of Live Load. In computing stresses for columns in such buildings as warehouses and factories which are likely to be fully loaded on all floors simultaneously the full specified live load should be used. In types of buildings such as apartment houses and office buildings the specified floor loads may be reduced in computing column stresses as follows: for the roof the specified live load should be used, for the top floor 90% of the live load, for each succeeding lower floor the live load may be reduced by 5% until 50% of the live load floor loads is reached, when such reduced loads should be used for all remaining floors, except the first or ground floor for which the full specified live load should be used. Girders of office building type carrying more than 200 sq. ft. of floor may have the specified live load reduced 10%. Dead loads must be computed in all cases.

Wind Pressure should be assumed at not less than 20 lb. per sq. ft. on the sides of building and the corresponding normal component on the roof.

The Working Stresses given in Art. 2 should be used in proportioning, members.

5. Fireproof Floors

Floors for Steel Buildings consist of a wearing surface of wood, concrete marble or tile laid on hollow-tile blocks, brick or concrete arches which are carried by I beams, called joists or floor beams, spaced from 4 to 8 ft. apart,



Terra Cotta Arch (End Construction)

Reinforced Concrete

Fig. 18. Fireproof Floor Construction

though usually from 5 or 6 ft., depending on the kind of arches used and the span of the beams. Floor girders, that is, deep I beams or plate girders running from column to column, support the joists, and if between exterior columns, they also support the walls. **Hollow-tile blocks** made of porous terra cotta, and used as flat arches, are placed between the I-beam joists and set in cement mortar so as to cover the bottom flanges of the beams, thus affording protection of the beams against fire underneath. A layer of concrete is spread over the blocks, covering the top flanges of beams to a depth of about 2 in., and on this concrete the wearing surface is placed. **Concrete floors** are either arched or flat. In the latter case they consist of a slab in which steel netting or rods are embedded. The concrete surrounds the steel beams, and a flat ceiling is usually suspended from the beams. Fig. 18 shows details of fireproof flooring.

Dead or Fixed Loads on floors should be computed for each case. The following are ordinary values in pounds per square foot for fireproof flooring: wooden wearing surfaces, 4 to 6; screeds or nailing strips, 2; concrete filling, 15 to 30; arch or slab, 20 to 50; steel floor joists and girders, 8 to 12; ceiling construction and plaster, 3 to 10. The total dead weight of fireproof floors varies from 50 to 100 lb. per sq. ft. The accompanying table gives weights of hollow-tile floor arches.

Weight of Hollow-tile Flat Floor Arches

Exclusive of Weight of Steel, Filling or Wearing Surface

End Construction			Side Construction		
Depth of Tile, in.	Beam Spacing, ft.	Weight, lb. per sq. ft.	Depth of Tile, in.	Beam Spacing, ft.	Weight, lb. per sq. ft.
6	3 to 4	25	6	3.5 to 4.0	27
7	4 to 5	26	7	4.0 to 4.5	29
8	5 to 6	27	8	4.5 to 5.0	32
9	6 to 7	29	9	5.5 to 6.0	36
10	7 to 8	33	10	6.0 to 6.5	39
12	8 to 9	38	12	6.5 to 7.0	44

Reinforced Concrete Floor Slabs weigh about 9 lb. per sq. ft. per inch of thickness if of cinder concrete and 12 lb. if of stone concrete. Cinder concrete fireproofing around beams weighs from 40 lb. per lin. ft. for 8-in. to 170 lb. for 24-in. standard beams of light weight. These weights will be increased for beams of wider flanges.

The Spacing, or distance between centers of floor beams, varies with the type of fireproofing, the length of span of the beams and character of loading. After determining the live load and the type and weight of fireproofing the total live and dead load can be easily computed and the correct size and spacing of I beams for this loading and span can be taken from tables in steel companies' handbooks, or the spacing may be assumed and the proper beams to be used for the spacing is found by taking from pages 666 to 669 a size and weight having a section modulus which equals the value of I/c in the following formula:

$$\frac{I}{c} = \frac{3\,dwl^2}{2\,S},$$

where I/c is the section modulus in inch units, I being the moment of inertia and c the half depth of beam; d, the distance center to center of beams in feet; w, total live and dead load in pounds per square foot; l, span of beam in feet; S, allowable unit fiber stress in pounds per square inch. If a beam cannot be found with a section modulus close to that required, a slight change in the spacing may be advisable. In this case a beam may be chosen and the distance $d = \dfrac{2\,SI}{3\,cwl^2}$ computed. The heaviest section of a given depth of I beam should be avoided, as it is not as economical as a lighter beam of a greater depth. The size of a beam required to carry a uniform load may also be chosen by multiplying the load per running foot of beam by the span and selecting from a handbook a beam corresponding, and in case the load on the beam is concentrated at the center it can be reduced to an equivalent uniform load by multiplying it by two. For loadings not uniform or not concentrated at the center of the span the section modulus **I/c** must be found from the formula **I/c = M/S,** where M is the bending moment in inch-pounds and S the unit stress which is usually taken at 16 000 lb. per sq. in.

The Deflection of Floor Beams carrying plastered ceilings underneath should not exceed 1/360 of the span. For I-beams carrying uniform loads, simply supported at the ends and stressed to 16 000 lb. per sq. in., this limit of deflection will be exceeded if the ratio of span length to depth of beam exceeds 24.

Compression Flanges of I Beams or girders should be stayed laterally at distances not exceeding 12 times the flange width. If this ratio is exceeded the allowable unit stress should be found by the formula, $S = 19\,000 - 250\, l/b$, where S = allowable unit stress in pounds per square inch, l = unsupported length and b = width of flange. A corresponding reduction should be made in the tables of safe loads given in steel companies' handbooks. For example, the tabular allowable uniform load for an 18 in. 55-lb. beam 20 ft. long based on a maximum bending stress of 16 000 lb. per sq. in. is 47 000 lb. The beam length l, is 240 in. and the flange width, b, is 6 in. If the top flange is unsupported laterally the allowable unit stress is $19\,000 - 250\, l/b = 9000$ and the safe load is $9/16 \times 47\,000$ lb. = 26 500 lb.

Tie Rods from 5/8 to 7/8 in. in diameter are used to connect the webs of I beams in buildings to assist in construction, in bracing the beams laterally and to take the thrust from the floor arches. For uniformly loaded floor arches the horizontal thrust is given approximately by $T = 3\, wl^2/2r$, and the spacing of the tie rods by $l_2 = 10\,000\, ra/wl^2$, where T = thrust in pounds per linear foot of floor beam; w = total live and dead load per square foot; l = span of arch in feet; r = rise of arch in inches; l_2 = distance between rods in feet; a = net area of tie rods in square inches. For flat arches r is approximately 6/10 to 8/10 the depth of the arch.

The Safe Unit Shearing Strength of I-beam webs or of plate-girder webs for buildings is given by

$$S_s = \frac{12\,000}{1 + \dfrac{h^2}{3000\, t^2}}$$

where S_s is in pounds per square inch; d = depth of beam or web of plate girder, t = thickness of web, h = vertical distance between flanges of I beams, and for plate girders horizontal distance between stiffeners or vertical distance between flanges, whichever is the smaller. All dimensions are in inches. To obtain the total safe shearing strength V of a web multiply the above unit stress by the gross cross-sectional area of web, or $V = S_s dt$.

Safe Unit Shearing Strength of I-Beam Webs for Buildings

Pounds per Square Inch

$\frac{h}{t}$	S_s	$\frac{h}{t}$	S_s	$\frac{h}{t}$	S_s	$\frac{h}{t}$	S_s	$\frac{h}{t}$	S_s

6. Fireproof Walls and Partitions

Walls for Steel Mill Buildings are made of brick, concrete, tile, corrugated steel, hy-rib and concrete, metal lath and plaster, wood or metal sash. Two or more kinds of siding are often used in the same building. If corrugated steel is used for the roof the sides are often made of it also but of lighter weight. Less than No. 22 should not be used for roofs nor less than No. 24 for siding. For the roof the usual method of fastening is by straps to [purlins and for sides by straps or clinch rivets to [or L girts. Though more expensive, galvanized sheets are preferable to painted sheets. Walls between columns are usually made 12 in. thick if of brick and 8 in. thick if of tile or concrete. A greater thickness may be required when the walls carry all loads or when the columns are set free from the walls.

Where a **rectangular opening** is to be made in a solid masonry wall, and there are no windows or other openings in the wall above, one or more I beams placed side by side, and connected together by cast-iron or rolled steel ⊏ separators fitting between the beams, are used to support the masonry. Assuming that the beams carry a triangular portion of the wall having for its base the span and for its altitude 1/2 the span, the **section modulus of the combined beams** $= wtl^3/32\,000$, where w is the weight of the masonry in pounds per cubic foot; t = thickness of wall in feet; l = span of opening in feet. If there are windows above the opening, the entire weight vertically above the opening should be taken on the beam. In either case the beams should have a depth of not less than about 1/24 the span.

The question of lighting has been much discussed in recent years. It is important that natural light should be utilized to the best advantage. The location of windows as well as their area should be considered. The types of sash most used for mill buildings are the ordinary wooden sash and the rolled steel sash. The latter is more satisfactory and is used almost entirely for the best modern buildings.

Walls in Office Buildings having steel frames are made of brick, stone or terra cotta and are carried by girders or I beams at each floor level, thus separating the wall into parts each one story in height. The thickness of these walls is usually fixed by building laws, 12 in. being the minimum. Terra cotta facing with brick backing for exterior walls is good construction. Cement mortar should be used. Hollow-tile furring blocks, usually 2 to 6 in. in thickness, attached to the inside surfaces of exterior walls, are used as a protection against dampness and noise, and serve to hold the plaster. **A spandrel,** which is that part of an outside wall in an office building over a window and under the window vertically above, is carried on I beams, or on ⊏'s and ∟'s. The terra cotta blocks are anchored to the steel. Fig. 19 shows spandrel construction.

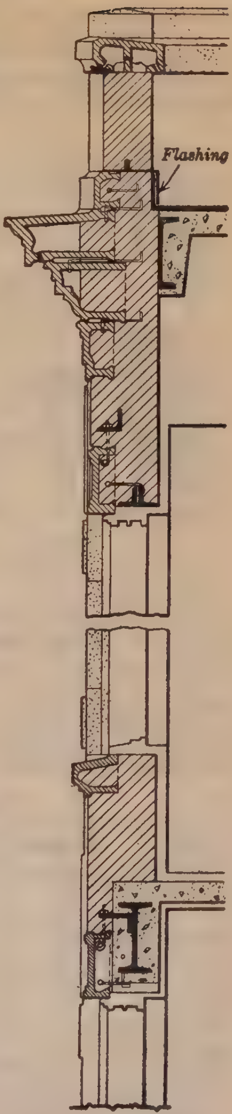

Fig. 19. Spandrel and Cornice Sections

Partitions in Fireproof Buildings, Fig. 20, are made of hollow terra cotta blocks, plaster, plaster block, brick and of various patented materials. Of these materials terra cotta hollow blocks are commonly employed. Partitions of this material are made from 4 to 12 in. thick, 4 in. being the usual thickness for the blocks, which for the body of the partition are 12 by 12 in. in size but for the top and sides are 6 to 8 by 12 in. to fit in with the square blocks. Terra cotta should be wet before being laid and also before being plastered, and should be laid in a mortar composed of one part lime-putty, two parts cement and two to three parts sand. **Plaster** on both sides of a terra cotta partition increases the thickness by about 1-1/2 in., that is, 3/4 in. per side Twelve feet for 3-in., 16 ft. for 4-in., 20 ft. for 6-in., are the usual heights for the thicknesses of partitions given. Solid plaster partitions are made from 2 to 4 in. thick and are supported on

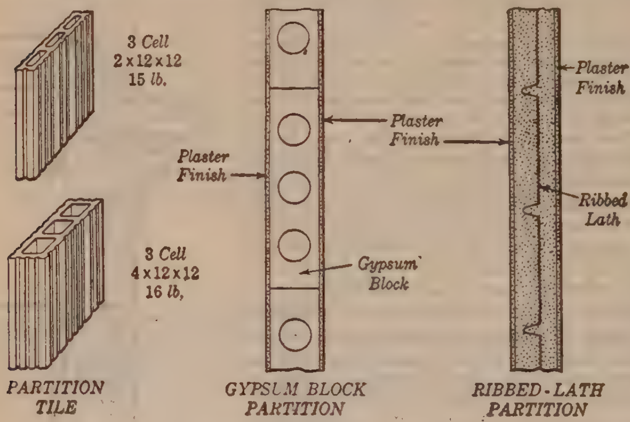

Fig. 20. Fire-resisting Partitions

wire lath on steel framework. For the 4-in. partitions a central body of cinder concrete supported between two such wire nettings is built, then plastered on both sides. **Hollow plaster partitions** consist of a steel framework of [’s to which metal lath is attached on each side, and to this the plaster is applied, leaving a hollow space between the two layers of plaster.

The accompanying table gives weights of various forms of partitions, the weight in each case of terra cotta and plaster blocks not including the plastered surfaces. For each plastered surface used add 5 lb. per square foot of surface. The weights given are per square foot of partition.

Weights of Partitions

Kind of Partition	Thickness, in.	Weight, lb. per sq. ft.	Kind of Partition	Thickness, in.	Weight, lb. per sq. ft.
Porous or hard-burned terra cotta	2	10 to 14	Solid plaster	2	20
	3	11 to 16		4	32
	4	12 to 19	Hollow plaster	4	22
	5	17 to 22	Plaster blocks	2	7
	6	22 to 24		4	12
	8	28 to 33		8	22

Wood stud and plaster partitions weigh from 80 to 150 lb. per lin. ft., depending upon height and thickness of plaster; gypsum block partitions may be assumed at 10 lb. per sq. ft. for 3-in. thickness with an increase of 2-1/2 lb. for each additional inch of thickness. To this should be added the weight of the plaster.

The question of whether partitions, especially those subject to relocation, should be considered as dead or live load is perplexing. An approach to a solution is to consider them equivalent to an addition of 15 lb. per sq. ft. to the dead load of the floor.

7. Wind Bracing in Tall Buildings

Wind Pressure for many-storied buildings when not specified by a building code should be assumed at not less than 20 lb. per sq. ft. on the sides of build-

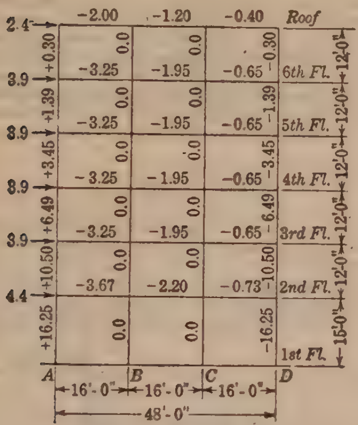

DIAGRAM OF LOADS AND AXIAL STRESSES
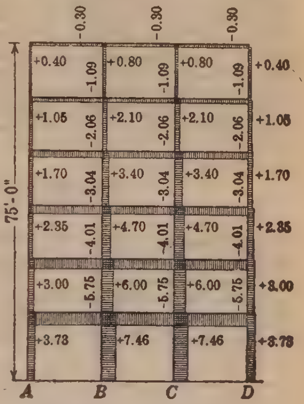
Loads and Stresses Given in Thousands of Pounds

Fig. 21*a*



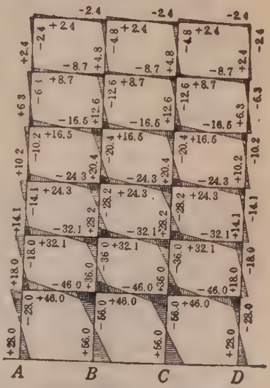
SHEAR DIAGRAM
Shears Given in Thousands of Pounds

Fig. 21*b*

ings and the corresponding normal pressure on the roof. The steel frame should be designed to resist the stresses caused by these pressures. It is inadvisable to allocate a certain amount of wind force to the walls, partitions, and floors, and the remainder to the steel framework.

The gusset-plate type of wind bracing is now used almost exclusively in the bracing of high tier buildings. The large bending moments in girders and columns do not make it economical with the use of steel. Its great advantage is that it interferes much less with the development of architectural features than other types. Different methods of calculating wind stresses have been proposed. A method in quite common use is the one here presented.

The three-aisle bent of a six-story building shown in Fig. 21*a* will be taken for illustration. Loads and direct stresses are given throughout. The shear diagram (Fig. 21*b*), gives shears and Fig. 21*c* gives bending moments for both girders and



MOMENT DIAGRAM
Moments Given in Thousands of Foot-Pounds

Fig. 21*c*

columns. It is evident that for horizontal wind pressure the bent is a cantilever beam or truss with fixed end at the foundation. Wind loads are assumed as given in the figure. It is also assumed that the point of contra-flexure of each column is at mid-height of the story, that the point of contra-flexure of each girder is at its center of span and that the joints are perfectly rigid.

The structure is regarded as equivalent to a series of independent portals. The total horizontal shear is divided equally between the number of aisles. An outer column thus takes but one-half the shear of an interior column. For equal transverse spacing of columns the direct or axial stress due to the overturning moment of the wind is taken by the outside columns. The interior columns belong to adjacent portal systems. The compressive stress from one portal balances the tensile stress from the other, making the resultant axial stress zero. The direct stress in the outer columns of any story is then equal to the wind moment at the point of contra-flexure divided by the width of the building. Numerically: in the fourth story outer columns the direct stress is

$$\frac{(2.4 \times 30) + (3.9 \times 18) + (3.9 \times 6)}{48} = 3450.$$

The difference in axial stress between any two abutting sections of an outside column acts as a shear at the point of contra-flexure of each of the row of girders of the abutting sections.

Considering in detail the fourth floor, Fig. 22, we have as the shear in each girder, 6487 − 3450 = 3037. The maximum bending moment in each girder is 3037 × 8 = 24 296 ft-lb. In the same way the maximum bending moment in a third floor girder

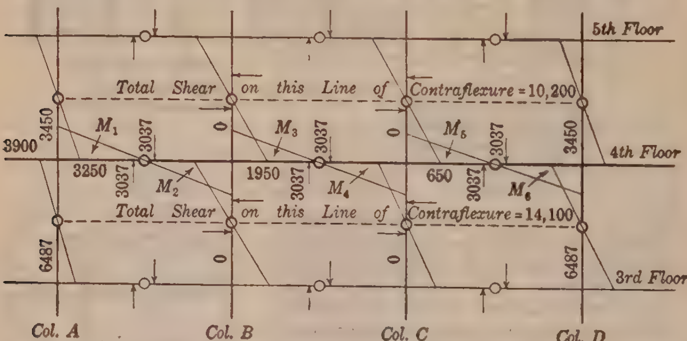


Fig. 22

is (10 500 − 6487) × 8 = 32 104. The bending moments in columns are the shears at points of contra-flexure multiplied by one-half the story heights.

Since panels are equal and each portal assumed to take one-third the shear, each leg of the portal takes one-sixth of the shear. The windward columns therefore reduce the panel loads by one-sixth, leaving five-sixths as the direct stress in the windward girder. The direct stress in the middle girder is further reduced by two-sixths, leaving the direct stress three-sixths. The leeward girder is further reduced by two-sixths, leaving a direct stress of one-sixth. Numerically: the direct compressing stesses in the fourth floor girders are, from A to B, $3900 - \frac{3900}{6} = 3250$; from B to C, $3250 - \frac{3900}{3} = 1950$; from C to D, $1950 - \frac{3900}{3} = 650$.

It will be observed that the bending moments in girders of the same floors are alike and equal to the sum of those in the outer columns above and below the girder. Their values are not affected by the width of the aisle. The bending in an outer column in any story equals the total shear in that story multiplied by the story height and the product divided by four times the number of aisles. The bending moment in an interior column equals twice that in an outer column. Of course the algebraic sum of the moments about any point is zero.

If the transverse spaces between columns are unequal, the wind shear taken by each aisle may be assumed proportional to its span. Though not theoretically correct, the direct stresses in columns will thus be brought to the outer rows. The bending moments at each end of a floor girder will be the same though they will not be alike for all the girders of a floor.

Column splices should be made in lengths of two or more stories and care taken that they are spliced sufficiently to make them continuous as retards transverse bending. Column splices and the connections of girders and beams to columns should be riveted. As a general rule unless the height of a building exceeds twice the least width the wind stresses require but little special consideration.

8. Cost Data and Building Laws

The following Costs are average values for buildings. The **cost of shop work** in cents per pound for light building work is as follows: roof trusses 1.25 to 2.50, hip and valley framing 2.50 to 5.00, beam work 0.50 to 1.00, columns from 0.60 for rolled sections to 1.75 for riveted plate and ∟ sections, plate girders 0.90 to 1.50. Steel mill-building frames, shop work about $35.00 per short ton including drafting. **Erection of Steel:** bolted work $16.00 to $24.00 per short ton, riveted work $18.00 to $30.00 for office buildings with riveted connections $20.00 per short ton is a common figure. **Corrugated steel** $12.00 to $18.00 per square, furnished and laid. **Roofs** per square: slate $15.00 to $20.00, three- or four-ply gravel, not including sheathing, $4.00 to $6.00. **Structural Steel** for building costs approximately from 5 to 8 cents per lb. in place complete, including painting. Two-inch cement mortar walls on metal fabric $2.00 to $3.00 per sq. yd.

Material. The " Standard Specifications for Structural Steel for Buildings " of the American Society for Testing Materials are in general use. Among required properties of structural steel mentioned in these specifications are: ultimate tensile strength, 55 000 to 65 000 lb. per sq. in. of cross-section; maximum phosphorus, 0.06%; minimum per cent of elongation in 8 in., 1 400 000 divided by the ultimate tensile strength, for material over 3/4 in. in thickness a deduction of 1 from the above percentage of elongation shall be made for each increase of 1/8 in. in thickness above 3/4 in. to a minimum of 18%, for material under 5/16 in. in thickness a deduction of 2.5 from the above percentage of elongation shall be made for each decrease of 1/16 in. in thickness below 5/16 in.; cold bends without fracture 180 degrees flat for plates shapes, and bars 3/4 in. or under in thickness, for thickness over 3/4 in. and including 1-1/4 in. around a pin the diameter of which is equal to the thickness of the specimen, and for material over 1-1/4 in. in thickness around a pin the diameter of which is equal to twice the thickness of the specimen.

Rivet steel shall have an ultimate tensile strength of 45 000 to 56 000 lb. per sq. in. of cross-section; maximum phosphorus, 0.06%; maximum sulfur, 0.045%; minimum per cent of elongation in 8 in., 1 400 000 divided by the ultimate tensile strength; cold bends without fracture 180 degrees flat.

Standard Specification for Steel Castings and for Gray Iron Castings have also been issued by the A. S. T. M.

Workmanship. All workmanship should be first-class in every respect and in accordance with practice followed by the best bridge shops. Before being worked, material should be thoroughly straightened by methods that will not injure it. Punching should be done accurately, but occasional inaccuracies in matching of holes may be corrected with reamer. The diameter of the punch should not be more than 1/16 in. larger, nor that of the die 1/8 in. larger than the diameter of the rivet. Rivets should be driven by pressure tools wherever possible. Abutting surfaces of compression members except where joints are fully spliced, should be planed to even bearing so as to giv close contact throughout.

Painting. Red Lead or Graphite Paints are commonly used for painting steel in buildings, one coat being applied at the shop and one after erection. Linseed oil may be used instead of paint for the shop coat. Red-lead paint should be mixed just before using and should be kept thoroughly stirred and should be applied with round, not flat, brushes. Painting should not be allowed in wet or freezing weather nor on any but clean surfaces.

Cast iron need not be painted until after erection. Steelwork for foundations to be entirely embedded in concrete need not be painted but should be free of dirt, grease or other matter which would impair the bond of the concrete.

Inspection. All inspection and tests are usually made at the option and expense of the purchaser, the contractor furnishing necessary test pieces and the free use of a testing machine.

Erection. Care should be taken that all steelwork be level and plumb before bolting or riveting and that proper provision be made for resisting stresses due to erection operations. Field connections are better when riveted than when bolted but specifications are often needlessly severe in calling for all connections to be riveted. Field connections may be bolted throughout for one-story buildings carrying no concentrated loads, shafting or cranes. Other buildings should have connections riveted for column splices, trusses, girders and beams to columns, chord splices of trusses and for bracing. In structures subject to heavy loads and vibrations rivets should be used throughout, except that purlins and girts that do not form part of the bracing may be bolted. Drift pins should be used only to bring parts together. Unfair holes should be made to match by reaming.

Building Laws. In the United States there are 80 or 100 cities having a population of over 100 000 each and about 200 cities with a population of from 30 000 to 100 000 each in which are located the great majority of buildings other than mill buildings requiring steel in their construction, the design of which must usually be in accordance with a municipal building code. The engineer should acquaint himself with these regulations before beginning

Allowable Live Loads for Floors According to Building Laws

Class of Building	Maximum Live Load, pounds per square foot

his work. As the data given in handbooks may have been superseded, all information should be obtained from the building code itself. When codes are incomplete, as many are, the engineer must supply lacking data from such authorities as he deems advisable.

Cast-iron Columns to be used in construction of buildings in New York City must not have diameter less than 5 in. or thickness of metal less than 3/4-in.; nor shall they have an unsupported length of more than 70 times their least radius of gyration or 20 times their least lateral dimension or diameter except by special permission or except as modified by column formula; top and bottom flanges, seats and lugs must

Allowable Unit Loads for Columns According to Building Laws

Material of Column	Allowable Unit-load, pounds per square inch			
	New York	Chicago	Philadelphia	Boston
Medium Steel......	$16\,000 - 70\frac{l}{r}$	$16\,000 - 70\frac{l}{r}$	$\dfrac{16\,250}{1 + \dfrac{l^2}{11\,000\,r^2}}$	$\dfrac{18\,000}{1 + \dfrac{l^2}{20\,000\,r^2}}$
Cast Iron..........	$9\,000 - 40\frac{l}{r}$	$10\,000 - 60\frac{l}{r}$	$\dfrac{11\,600}{1 + \dfrac{l^2}{400\,d^2}}$	$9000 - 40\frac{l}{r}$

l = length, r = radius of gyration, d = diameter or least side, all in inches.

be of ample strength reinforced by fillets and brackets, and shall be at least 1 in. thick when finished. Column joints secured by not less than 4 bolts of at least 3/4-in. diameter. The core of a column below a joint shall be not larger than the core of the column above and the metal shall be tapered down for a distance of at least 6 in., or a joint plate of sufficient strength may be inserted to distribute the load. If the core of a column shifts more than one-fourth the thickness of the shell, the strength shall be computed by assuming the thickness of metal all around equal to the thinnest part, and the column will be condemned if this computation shows the strength to be less than that required by the New York building code. Whenever blowholes or imperfections are found which reduce the cross-sectional area of the column more than 10 per cent, such column will be condemned. Posts and columns not having one open side or back to be drilled with 3/8-in. hole in shaft to show thickness.

Wind Bracing. Building codes vary greatly in their provisions for wind bracing. The **New York** code requires that all buildings over 150 ft. in height and all buildings or parts of buildings in which the height is more than four times the minimum horizontal dimension, be designed to resist a horizontal wind pressure of 30 lb. for every square foot of exposed surface measured from the ground to the top of the structure. When the stress in any member due to wind does not exceed 50% of the stress due to live and dead loads, it may be neglected. When such stress exceeds 50% of the stress due to live and dead loads, the specified working stresses may be increased by 50% in designing such members to resist the combined stresses. The **Chicago** code specifies that all buildings shall be designed to resist a horizontal wind pressure of 20 lb. per sq. ft. and allows the same increase of working stresses as the New York code. In **Philadelphia** a wind pressure of not less than 30 lb. per sq. ft. is called for on all buildings erected in open spaces or on wharves. On tall buildings erected in built-up districts the wind pressure is to be figured for not less than 25 lb. at tenth story, 2-1/2 lb. less on each succeeding lower story, and 2-1/2 lb. additional on each succeeding upper story to a maximum of 35 lb. at the fourteenth story and above. In proportioning members subject to stresses due to wind loads the working stresses may be increased 30%. The code of **Boston** requires on a structure a wind pressure of not less than 10 lb. per sq. ft. for the first 40 ft. in height above ground, a pressure of 15 lb. per sq. ft. for from 40 to 80 ft. and 20 lb. per sq. ft. for portions more than 80 ft. above ground. An increase of 20% in working stresses is allowed for wind loads combined with other loads.

Allowable Unit Stresses According to Building Laws

Kind of Material	Allowable Unit-stress, lb. per sq. in.			
	New York	Chicago	Philadelphia	Boston
Compression:

Under Philadelphia, the first value is for mild and the second for medium steel.

A number of provisions besides those for floor and wind loads affect the design of the steelwork. **Fireproofing around exterior columns** in New York must be 8 in. thick on the outer face while in Chicago 4 in. will answer. **Thickness of enclosure walls** when carried by the steelwork is specified as 12 in. for New York, Chicago and many other cities. A large number have a thickness of 12 in. for a top section of 75 ft. and a greater thickness for sections below. Still other variations are found.

Limitations upon the **heights of buildings** ranging from 120 to 250 ft. are placed in many cities. For fireproof commercial buildings 2-1/2 times the width of the adjoining street is quite common. A number of cities have limits of 150 to 175 ft. **Special requirements** must not be overlooked. One such, found in a few codes is that prohibiting the spacing of floorbeams of fireproof buildings more than 5 ft. on centers for stores, warehouses and factory buildings and 8 ft. on centers for other buildings. This eliminates "long-span" construction. Other requirements are confined to the individual code in which they are found. As stated previously, the structural engineer should be acquainted with the municipal code by which the construction of his building is governed.

GENERAL DATA FOR BRIDGES

9. Dead Loads

Simple Bridges include all beam, girder or truss bridges supported at both ends only. **Continuous** bridges include those which continue unbroken over two or more spans and which under vertical loads have vertical reactions. A cantilever beam is one that is fixed at one end and unsupported at the other and a **cantilever** bridge is therefore one having one or more cantilevers. An **arch** bridge may be defined as one which under vertical loads produces inclined pressures on its supports, thus including **suspension** bridges which have the end reactions outward as well as the more common forms of arched bridges which have reactions upward and inward.

The first important bridge of metal was a cast-iron arch of 100-ft. span built at Coalbrookdale in England in 1779, and the first iron truss bridge in the United States is believed to be the one built at Frankfort, N. Y., in 1840. The largest cast-iron bridge in America was built in 1866, in Chestnut St., Philadelphia, its longest span being an arch of 185 ft. Steel was first used in bridge construction in the arches of the Eads bridge at St. Louis in 1874. The modern steel truss span is the outgrowth of the wooden and the combination truss, the latter being a truss in which some members are of wood and some of iron.

A Deck Bridge is one in which the floor system is supported on or near the top chord of the trusses or girders, and a **through bridge** is one in which the floor is on or near the lower chord, but the depth of which is sufficient to permit the use of overhead bracing. A **half through** bridge is a **through** bridge which is so shallow, or whose floor is so near the top chord that no overhead bracing can be used. Bridges are **square** or **skew**, the former including those having the ends of the span at right angles to the length, hence having the trusses parallel and of the same length; while skew spans have one or both ends at oblique angles with the length and the trusses of a span may be of the same or different lengths.

Economical Types of simple bridges include rolled I-beam bridges for short spans up to 40 or 50 ft.; plate girders for longer spans up to 65 or 70 ft. for highway and up to 100 or 125 ft. for railway bridges: riveted half through trusses for highway bridges between 50 and 100 ft; riveted deck or through trusses up to about 150 ft. for highway, and to about 200 ft. for railway bridges; pin-connected trusses for longer spans.

Loads on Bridges include the dead or fixed, the live or movable, impact due to live loads, wind, and lateral dynamic forces due to irregularities of track, centrifugal force due to electric cars or trains moving on curved tracks, snow, longitudinal forces due to friction, and forces due to changes of temperature.

The Dead Load of railroad bridges includes the weight of the girders and trusses, of the top, bottom and transverse lateral bracing, and of the floor system which may be of either the open or solid type. The following weights are approximate only but are sufficient for use in preliminary designing and they should in every case be checked from the finished design. For ordinary open floors the weight of track is from 400 to 600 lb. per ft. for one track including rails, guard timbers, ties and all fastenings. The weight of steel per foot of span in single-track railroad bridges of the several types named below, having open floors and designed for Cooper's Class E-40, E-50 and E-60 loadings (Art. 10) in accordance with the American Railway Engineering Association Specifications, 1925, is approximately expressed by:

Deck plate girders. . . . . $w = k\,(13\,l + 100)$
Through plate girders. . . . . $w = k\,(15\,l + 500)$
Through pin-connected or riveted trusses . . . . $w = k\,(9\,l + 700)$

where l = length of span; k = 0.88 for E–40; k = 1.00 for E–50 and k = 1.12 for E–60 loadings.

The weight of steel in a double-track girder bridge is about 100% greater, and in a double-track truss bridge from 80 to 90% greater than for a similar single-track structure.

The Total Weight of Material in one single-track span is found by adding the weight of the track, 400 to 600 lb. per ft. to the weight of steel as given by the above formulas and multiplying by the span in feet. A **dead panel load** on one truss is the weight on one panel point from one panel length of truss and floor system. For a single-track bridge the panel load on one truss is found by multiplying the total dead load per foot of truss by the panel length. For example, if a single-track through bridge designed for a Cooper E–50 live load, has a span of 200 ft. divided into 8 equal panels of 25 ft. the above formula, $w = 9\,l + 700$ gives 2500 lb. per ft. as the weight of steel in the bridge. If the track weighs 450 lb. per foot of bridge the total load per foot of one truss = 1/2(2500 + 450) = 1475 lb., and the panel load per truss is 1475 × 25 = 36 875 lb. It is customary to assume two-thirds of the panel load on the loaded and one-third on the unloaded chord panel points, but a better method is to divide the weight of the truss equally between the upper and lower chords and apply the weight of track and floor after the latter has been obtained from the floor design at the loaded chord.

Highway Bridge Dead Loads include in addition to the weight of the sidewalks, if any, the weight of the roadway and the steel in the stringers, floor beams, trusses and bracing. Highway bridges vary greatly in size and design and no formula will give accurate results for the dead weight. The floor is designed first and its weight computed. The weight of the steel in the trusses or girders and the lateral system may be assumed. After the sections of the main members have been found for the live, impact and trial dead load, the assumed dead load may be checked, a percentage being added for details. More than one or two trials will seldom be necessary. After the bridge has been completely designed an accurate final estimate of the dead weight should be made and the sections corrected if necessary. For computing the loads on highway bridges the following **weights of materials** in pounds per cubic foot will be found useful: timber, creosoted, 60; oak, untreated, 54; pine, untreated, 48; concrete, 150; paving brick, 150; granite blocks, 160; asphalt, 135; macadam, 130; sand or earth, 100; stone ballast, 100; steel, 490; cast iron, 450. The following weights are in pounds per linear foot: ordinary latticed sidewalk railings, 30; rails and fastenings, street railway tracks, 100 per track; rails and fastenings, railroad tracks, 150 per track.

Snow Loads for railroad bridges are usually negligible, but for highway bridges in cold climates it is necessary to consider the snow load in some cases, especially for drawbridges when open. The maximum allowance is 20 lb. per sq. ft.

10. Live Loads

Live or Movable Loads ordinarily used for the design of railroad bridges consist of one or two locomotives followed by a uniform load representing the weight of the heaviest cars. To allow for future increase the weights specified by this loading should be greater than the heaviest locomotives and cars in service on the road for which the bridge is designed. Wheel spacings and weights of actual rolling stock are so variable that typical loads are largely used, those specified by Cooper being most common. Fig. 23 shows Cooper's

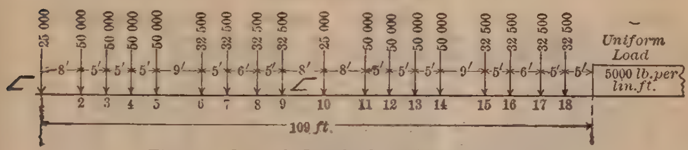

Fig. 23. Cooper's Standard Loading, Class E-50

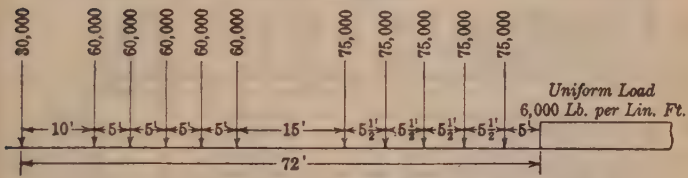

Fig. 23a. Class M-60

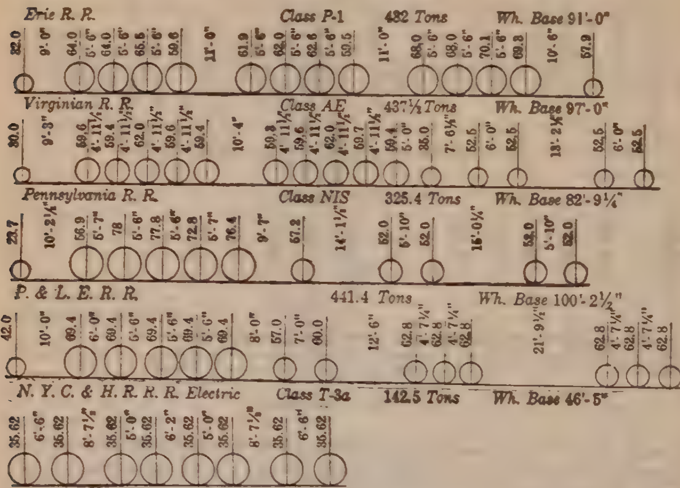
Class E-50 standard loading, consisting of two consolidation locomotives followed by a uniform load of 5000 lb. per lin. ft. The loads given are axle loads. Cooper's standards provide for heavier traffic by using Classes E-60 and E-55 and for lighter traffic by using Classes E-45, E-40, and E-30, each of which has the same wheel spacing as Class E-50, but the weights, and hence all functions of these weights such as reactions and stresses, are less, being proportional to the class number; thus the weights of E-60 are 12/10 those of E-50 and of E-45 are 9/10 those of E-50; E-40, 8/10 of E-50; E-30, 6/10 of E-50. At the present time, 1929, most of the important bridges on main lines are designed for E-60, and, in some cases, especially for floor systems, for as high as E-75 to E-90. In the latter case higher unit stresses than those ordinarily allowed are used.

The Cooper System of Loading was introduced about thirty years ago when the heaviest loads were represented by E-40. Since then there has been a continuous change in type, as well as in weight, of locomotives. Fig. 24 shows four of the heaviest existing locomotives arranged in the general order of their stress-producing effect. The first two are of the Mallet, or articulated, type, with 12 and 10 driver axles, respectively; the last two are the Santa Fé type, with 5 driver axles. No. 1 produces maximum stresses in spans above, roughtly, 150 ft.; No. 2 in spans between about 70 and 150 ft.; and No. 3 in shorter spans. The stresses produced by these locomotives differ from those obtained by the use of any single Cooper loading. Thus No. 1 will produce a center moment in a 100-ft. span equivalent to that from E-72; in a 200-ft. span, to E-66; in a 300-ft. span, to E-63; 400-ft. span, to E-62; 2000-ft. span, to E-60. Again, a 140-ft. span designed for No. 3 has ratings varying between E-54.8, for the center chord members, to E-69.5, for the center panel diagonals, and E-75 for the floor beams.

To overcome these inconsistencies, and more nearly to fit modern loading conditions, Dr. D. B. Steinman has proposed a new conventional wheel load diagram, M–60, (Fig. 23a), which very closely produces the same maximum stresses in all spans as those produced by the heaviest existing locomotives. This proposed loading is a composite of the first three locomotives shown in



All loads are in thousand pounds per axle.

Fig. 24. Wheel Diagrams of Heavy Locomotives in Service.

Fig. 24. While it is of the Mallet type, it conforms very closely, in stress-producing effects, with the Santa Fé, Decapod, and other heavy locomotives. As in the case of the Cooper E series, lighter or heavier loadings can be provided by using a different class number, such as M-50, or M–70, and changing weights and stresses proportionately.

Equivalent Uniform Live Loads which will give stresses as close as possible to those computed for actual wheel loads are sometimes used, the most common for computing chord stresses being the uniform load per foot which produces a moment at the center of the span equal to the maximum moment produced on the span by two locomotives followed by a uniform train load. The equivalent uniform load for computing web stresses is the uniform load per foot which produces an end shear equal to that produced by the locomotive loading. The table on p. 1165 gives for Cooper's E–50, maximum moments; end, quarter point and center shears; pier reactions for equal spans; and the equivalent uniform loads based upon center moments, end shears and pier reactions. The table on pages 1168 and 1169 gives the same data for M-10 loading. For M–60 multiply by 6.

The latest type of passenger **electric locomotives**, Class T–3a, used by the N. Y. C. & H. R. R. R., weighs about 285 000 lb. distributed nearly equally on 8 axles, as shown in the last wheel diagram in Fig. 24.

For span lengths L greater than 284 ft., max. moment = **5/16 L^2 + 2375.**
For span lengths L greater than 100 ft., max. end shear = **1.25 L + 90 − 2750/L.**
For span lengths L each greater than 142 ft., max. pier reaction = **2.5 L + 4750/L.**

Moments are in thousand pounds per foot; shears are given in thousand pounds; pier reactions are given in thousand pounds and are for piers between two spans each equal to the tabulated span; equivalent loads are in pounds per linear foot.

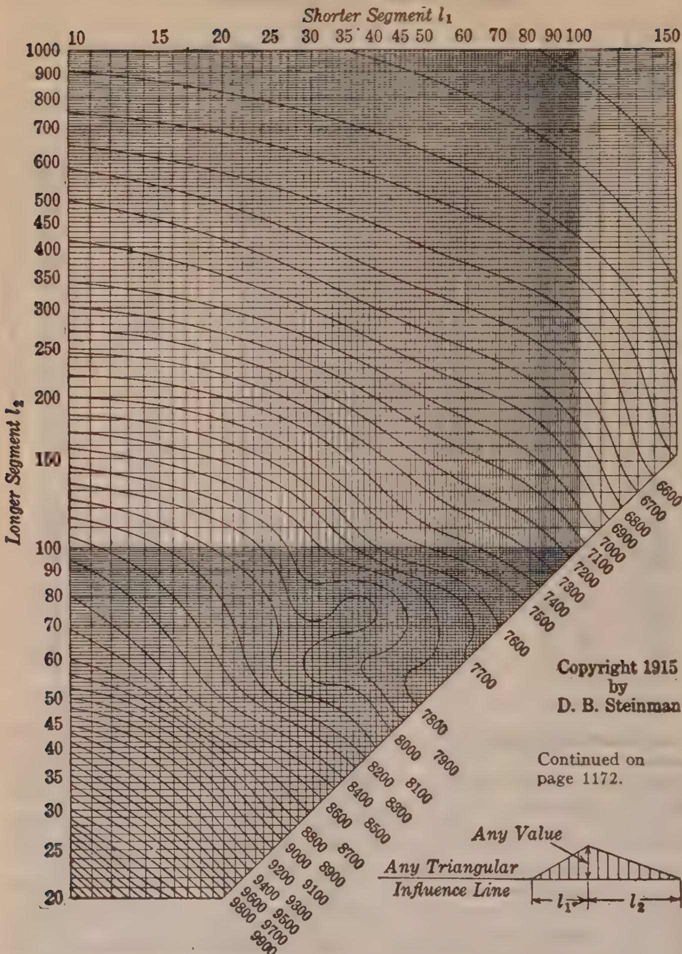
An Exact Equivalent Uniform Load is one which gives exactly the same stress in a member as the actual wheel loading. The following charts and tables, based upon Cooper and Steinman loadings, were constructed by Dr. D. B. Steinman. Fig. 25 is a chart from which may be obtained the exact equivalent load, based upon Cooper's E–60 loading, for any stress function having a triangular influence line the lengths of whose segments are l_1 and l_2. Since, for end reactions or intermediate shears in a girder without floor beams the influence diagram is a triangle with $l_1 = 0$, instead of extending the chart the values of the corresponding equivalent uniform loads are given in a separate table. Fig. 25*M* is a similar chart for the *M*–60 loading. Fig. 26 gives the governing wheel of a Cooper loading for maximum of any stress having a triangular influence line. Fig. 26*M* gives the same information for an *M* loading. The use of these charts will be explained in Arts. 17, 24, 25 and 26 in connection with stresses in girders and trusses.

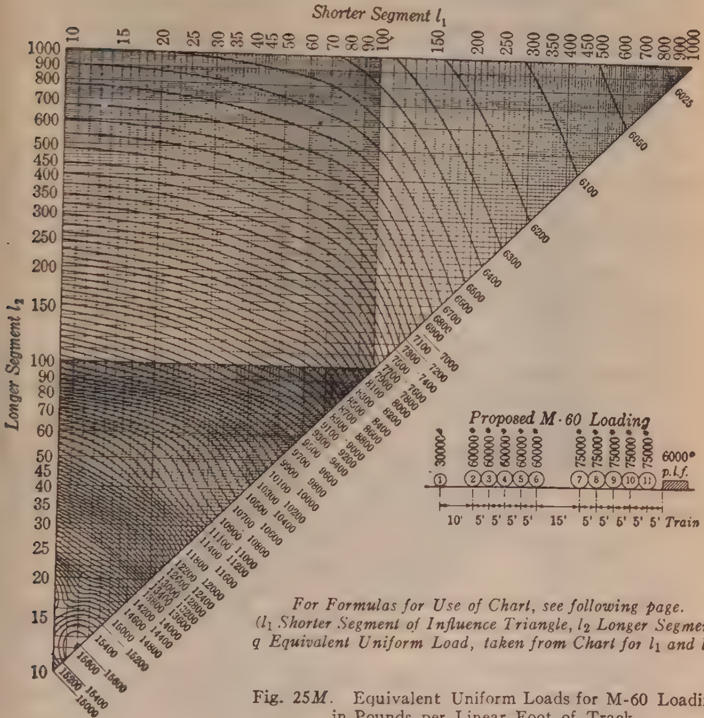
A **Conversion Table,** (Fig. 27*a*), is given on page 1175 by which stresses computed for an E loading may be compared with those for an *M* loading. Thus, for a 100-ft. span designed for E–60, the center moment is equivalent to an *M*



Continued on page 1172.

Fig. 25. Equivalent Uniform Loads for Cooper's E-60 in Pounds per Linear Foot of Track

(.776 × 60) = M–46.56; the end shear to an M (.858 × 60) = M–51.48. Conversely, if the span is designed for M–60, the center moment is equivalent to that from an E $\left(\frac{60}{.776}\right)$ = E–77.40; the end shear from E–70; the pier reaction from E–66. A still more useful conversion chart, applicable to any



For Formulas for Use of Chart, see following page.
(l_1 Shorter Segment of Influence Triangle, l_2 Longer Segment, q Equivalent Uniform Load, taken from Chart for l_1 and l_2)

Fig. 25*M*. Equivalent Uniform Loads for M-60 Loading in Pounds per Linear Foot of Track.
Continued on page 1174

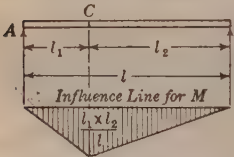
stress whose influence line is a triangle, is given in Fig. 27*b*. It is recommended that all stresses, whether from an E or an M loading, be computed from the equivalent uniform load corresponding to the shorter and longer segments, l_1 and l_2 respectively, of the influence line.

The Live Loads for a Highway Bridge should be chosen to correspond with the location of the structure, suitable provision being made for future traffic. Most of the large cities have their own specifications. In many states the design of highway bridges must conform with the specifications issued by the Highway Commissions of those states. The Final Report, 1924, of the Special Committee of the Am. Soc. C. E. on Specifications for the Design of

Formulas for Use of Fig. 25 and 25M

l_1 = Shorter segment of influence triangle.
l_2 = Longer segment.
q = Equivalent uniform load, taken from chart for l_1 and l_2.

BENDING MOMENTS
(and Chord Stresses)

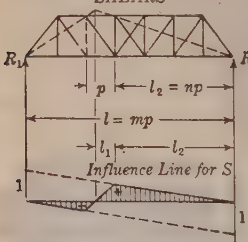


Max. Moment at C in Span AB.

$$M = 1/2\, q l_1 l_2$$

(l_1 and l_2 = The Two Segments of the Span)

SHEARS

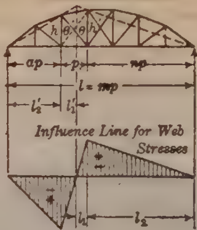


Max. Shear in Truss Panel:

$$V = \frac{1/2\, q l_1 l_2}{p}$$

$$\left(l_1 = \frac{l_2}{m-1}\right) \quad (l_2 = np).$$

WEB STRESSES



$$l_1 = \left(\frac{m}{ar + b} - 1\right) l_2 \qquad r = \frac{h'}{h}$$

For Member shown full:

Max. + Web Stress $\Big\}$ $= 1/2q\, l_1 l_2 \frac{\sec\theta}{rp}$;

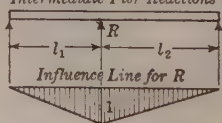
Max. − Web Stress $\Big\}$ $= 1/2\, q' l'_1 l'_2 \frac{\sec\theta}{p}$.

For Member shown dotted:

Max. − Web Stress $\Big\}$ $= 1/2\ q_1 l_2 \frac{\sec\theta'}{p}$;

Max. + Web Stress $\Big\}$ $= 1/2\, q' l'_1 l'_2 \frac{r.\sec\theta'}{p}$.

FLOORBEAM REACTIONS
Intermediate Pier Reactions

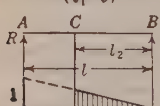


Max. Intermediate Reaction:

$$R = 1/2\, q\,(l_1 + l_2)$$

(l_1 and l_2 = The Two Adjoining Spans.)

$(l_1 = 0)$



Max. Shear at C: $\ {}^*V = 1/2\, q l_2 \frac{l_2}{l}$

Max. Reaction at A: $(l_2 = l)$.

$$R = 1/2\, q l$$

l_2	q	l_2	q	l_2	q	l_2	q	l_2	q	l_2	q	l_2	q	l_2	q	l_2	q

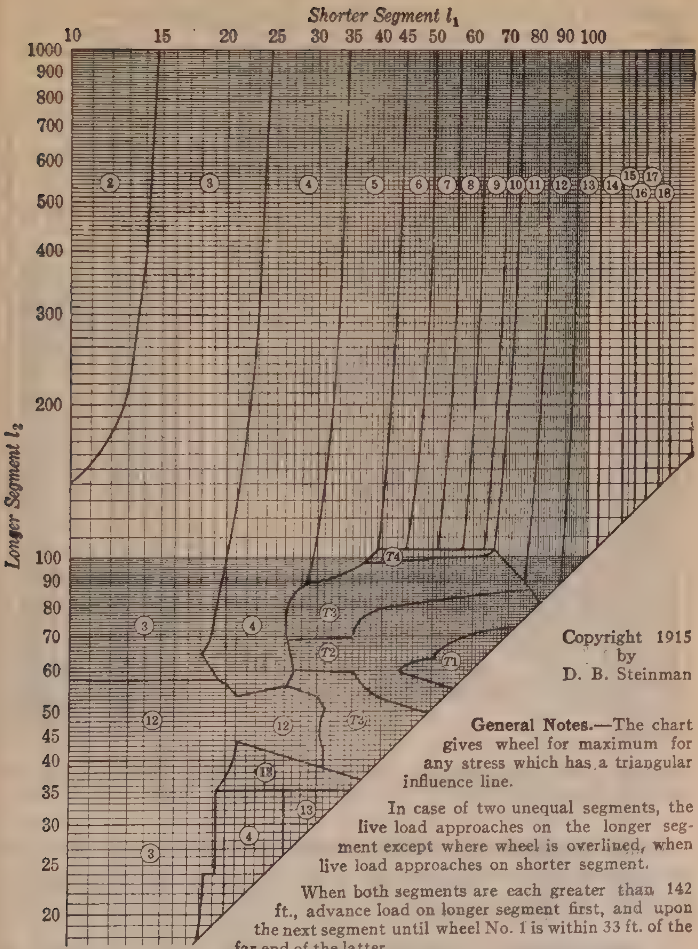
* Note: In the formula for "V" the effect of wheel ○ is neglected. To correct for this, subtract $30\,000\left(1 - \frac{l_2 + 8}{l}\right)$ from the above value of V.

Fig. 25*a*. Equivalent Uniform Loads for Cooper's E-60, for Shears and Reactions ($l_1 = 0$), per Linear Foot of Track.



General Notes.—The chart gives wheel for maximum for any stress which has a triangular influence line.

In case of two unequal segments, the live load approaches on the longer segment except where wheel is overlined, when live load approaches on shorter segment.

When both segments are each greater than 142 ft., advance load on longer segment first, and upon the next segment until wheel No. 1 is within 33 ft. of the far end of the latter.

Fig. 26. Wheel Determining Maximum Stress. Cooper's Loadings

Steel Highway Bridges, and the Standard Specifications, 1926, for Highway Bridges of the A. A. S. H. O. (American Association State Highway Officials) represent the best modern practice which is being followed in many states. Railway and highway bridge specifications differ little in unit stresses and details of design, workmanship and materials. The principal difference lies in loadings and impact.

Fig. 26*M*. Wheel Determining Maximum Stress. *M* Loadings. Equivalent Uniform Loads for Shears and Reactions ($l_1 = 0$), *M*-60 Loading per Linear Foot of Track.

Modern Requirements in Highway Bridge Loadings are clearly shown in the following excerpts from the Am. Soc. C. E. 1924 Specifications. The Standard Specifications of the A. A. S. H. O. for 1926 differ only slightly from these loading requirements.

9. **Traffic Classification of Bridges.** Bridges shall be classified, on the basis of traffic, as follows:

- Class A. City bridges or other bridges carrying a highway traffic of exceptionally heavy load units.
- Class B. Bridges on primary roads.
- Class C. Bridges on secondary roads.
- Class D. Bridges carrying electric railway traffic in addition to highway traffic.

CONVERSION TABLE

To Convert E-Rating to Equivalent M-Rating Multiply by the Coefficients in this Table.
To Convert M-Rating to Equivalent E-Rating Divide by the Coefficients in this Table.

Fig. 27a

10. **Width of Roadway.** The minimum clear width of roadway shall be 9 ft. for each lane of traffic, with a minimum of 12 ft. for one lane of traffic. Bridges designed for two lines of highway traffic preferably shall have a clear width of roadway of not less than 20 ft.

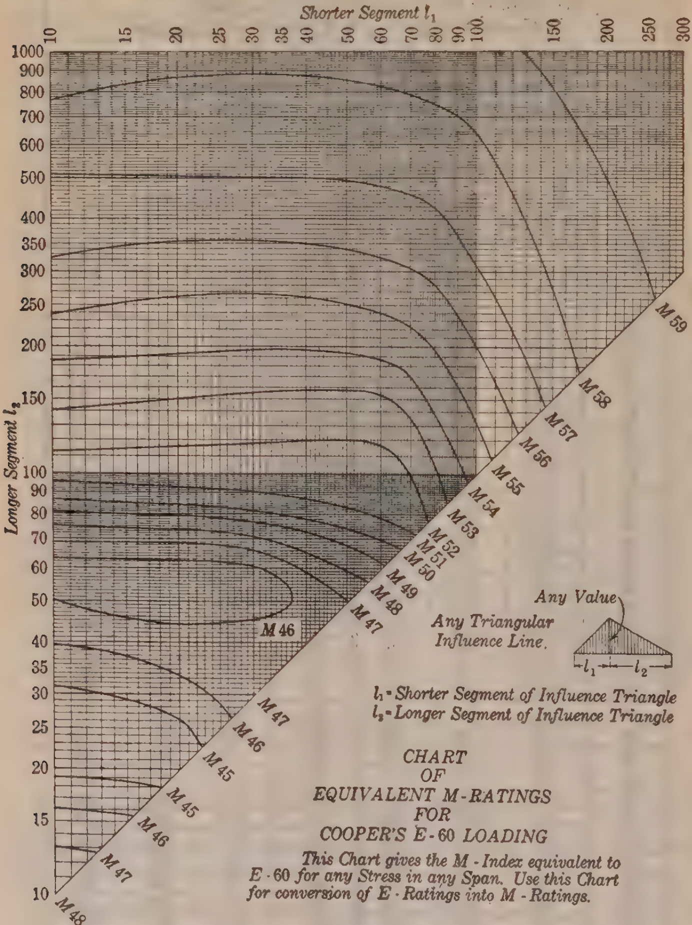

Fig. 27b

103. **Roadway Live Load.** The live loads for roadway shall be represented by typical truck loadings. Each typical truck loading shall be considered as occupying one lane of traffic 9 ft. wide. Typical truck loading shall be designated by the letter H, followed by a numeral indicating the weight in tons of the typical truck loads.

104. **Typical Truck Loadings.**

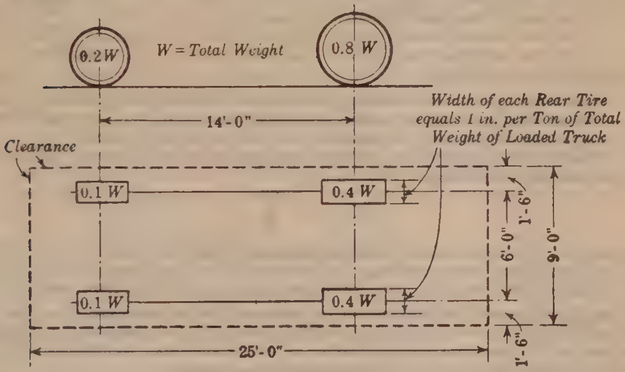
For Floor System:

H–20 .... 20-ton trucks
H–15 .... 15-ton trucks, or one 20-ton truck
H–13 .... 13-ton trucks, or one 15-ton truck

For Girders and Trusses:

H–20 .... 600 lb. per lin. ft. and 28 000 lb. concentrated
H–15 .... 450 lb. per lin. ft. and 21 000 lb. concentrated
H–13 .... 390 lb. per lin. ft. and 18 200 lb. concentrated

The concentrated loads are to be placed so as to cause maximum effect. Typical trucks shall have total loaded weights distributed as in Fig. 2.

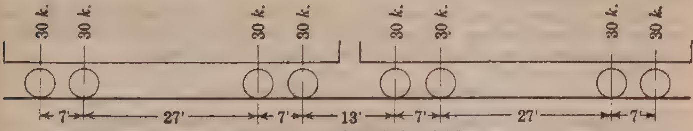


TYPICAL TRUCK

Fig. 2

(Of Report)

105. **Typical Electric Cars.** A train on each track shall be composed of two double-truck cars coupled together, with wheel concentrations and spacing of axles as shown in Fig. 3 or Fig. 4.



TYPICAL PASSENGER CAR

(Of Report)

106. Selection of Live Loads.

Class A Bridges	H-20 loads
Class B Bridges	H-15 loads
Class C Bridges	H-13 loads

107. Application of Loads.

To Floor System:

Floor systems shall be designed for as many trucks, side by side, and headed in the same direction, as the width of roadway will accommodate, with a maximum of four. For floors of Class B and Class C bridges the alternate single-truck load shall also be considered.

In the design of floor beams and floor beam hangers, the following percentages of the resultant live load stresses shall be used:

For one, or two, loaded lanes	100
For three loaded lanes	90
For four loaded lanes	80

To Girders and Trusses:

For the purpose of determining the amount of live load delivered to each girder or truss, each foot of roadway width for roadways 18 ft. or less in width, shall be assumed to carry one-ninth of the load on one traffic lane.

For roadways greater than 18 ft. in width, the number of lanes of traffic shall be determined by the equation:

$$K = 1 + \frac{W}{18}$$

in which K = the number of lanes of traffic, expressed in a whole or mixed number, distributed uniformly over the entire width of roadway; W = the width of roadway that must be loaded to cause maximum stress in the girder or truss.

Class D bridges shall be designed for the highway live loads as herein specified, on any portion of the roadway; or the electric live loads on the car track and the highway live loads on the remaining lanes of traffic. For this condition, the clearance line for electric cars shall be 5 ft. 0 in. from the center line of track.

108. **Sidewalk Loading.** Sidewalk live loads for Class A bridges shall be determined by the following formula:

$$P = \left(25 + \frac{2250}{L}\right)\left(\frac{W + 5}{W}\right)$$

in which P = live load in pounds per square foot; L = loaded length in feet; W = width of sidewalk in feet.

For Class B and C bridges use 80% of this loading. For foot-bridges use the loading for Closs A bridges, making W equal to one-half the width of the roadway.

The maximum value of P shall in no case exceed 100 lb. per sq. ft.

Distribution of Truck Wheel Loads

109. **Shear.** In calculating end shears and end reactions of stringers and floor beams, no lateral or longitudinal distribution of wheel loads shall be assumed.

110. **Bending Moment in Stringers.** In determining bending moments in stringers, each wheel load shall be assumed to be concentrated at a point.

When the floor system is designed for one truck, each interior stringer shall be proportioned to support that part of one rear-wheel load, or those parts of one front-wheel load and one rear-wheel load, represented by a fraction the numerator of which is the stringer spacing, in feet, and the denominator of which is:

- 4 ft. 0 in. for plank floors;
- 5 ft. 0 in. for 4-in. and 6-in. strip floors and wood blocks on a 4-in. plank sub-floor;
- 6 ft. 0 in. for reinforced concrete floors.

When the floor system is designed for two trucks, each interior stringer shall be proportioned to support that part of one rear-wheel load, or those parts of one front-wheel load and one rear-wheel load, represented by a fraction the numerator of which is the stringer spacing, in feet, and the denominator of which is:

3 ft. 6 in. for plank floors;
4 ft. 0 in. for 4-in. and 6-in. strip floors and wood blocks on a 4-in. plank sub-floor;
4 ft 6 in. for reinforced concrete floors.

The live load supported by the outside stringers shall be the reaction of a wheel in the most unfavorable position, assuming the flooring to act as a simple beam, but this live load shall in no case be less than would be required for interior stringers under these requirements.

These distribution rules govern only when the stringer spacing is not greater than the denominator which applies to the particular case under consideration. When the stringer spacing is greater than this distance, the stringer loads shall be determined by the reactions of the truck wheels placed in the most unfavorable position, assuming the flooring between stringers to act as simple beams.

The combined load capacity of the stringers in a panel shall be not less than the total live and dead load in the panel.

111. **Bending Moment in Floor Beams.** In determining bending moments in floor beams, each wheel load shall be assumed as concentrated at a point.

When stringers are omitted and the floor is supported directly on the floor beams, the latter shall be proportioned to carry that fraction of one axle load, when the floor system is designed for one truck, or of two axle loads, when the floor system is designed for two trucks, the numerator of which is the floor beam spacing, in feet, and the denominator of which is:

4 ft. 0 in. for plank floors;
5 ft. 0 in. for 4-in. and 6-in. strip floors and wood blocks on a 4-in. plank sub-floor;
6 ft. 0 in. for reinforced concrete floors.

When the spacing of floor beams exceeds the denominator given, but is less than the axle spacing (14 ft. 0 in.), each beam shall be proportioned to carry the full axle load or loads.

When the floor-beam spacing exceeds the spacing of axles, the load supported on each floor-beam shall be the maximum reaction due to the axle loads, assuming the flooring between floor beams to act as a simple beam.

112. **Distribution of Electric Railway Wheel Loads.** Electric railway wheel loads may be assumed to be uniformly distributed longitudinally over a length of 3 ft. 6 in. In the case of ballasted floors, a lateral distribution of 10 ft. for an axle load may be assumed.

Example. Maximum bending moment at the center of a Class A bridge, span 100 ft., width of roadway 20 ft., is computed as follows: For one lane of traffic, load the entire span with 600 lb. per lin. ft. and place the 28 000 lb. concentration at the center. $M = 600 \times 100^2/8 + 28\,000/2 \times 50 = 1\,450\,000$. $K = 1 + 20/18 = 2.11$. Moment in one girder = $1.05 \times 1\,450\,000 = 1\,525\,000$. For the maximum shear at the 1/4 point, place the 28 000-lb. load at that point, and the uniform load over the part of the span lying to the right of that point. Then maximum shear at 1/4 point in one girder = $1.05\ (600 \times 75^2/200 + 21\,000) = 37\,875$. A 16-ft. roadway will carry $16 \times 1/9 = 1.77$ lanes of traffic, divided equally between the two girders, and the stresses from one lane of traffic will be multiplied by 0.885, instead of 1.05. If there is a 6-ft. sidewalk the adjacent girder will carry the following additional sidewalk loading, placed so as to produce the maximum effect: for center moment, $P = (25 + 2250/100)\ 11/6 = 87.1$ lb. per sq. ft. = 523 lb. per lin. ft. of girder; for shear at the 1/4 point, $P = (25 + 2250/75)\ 11/6 = 100$ lb. per sq. ft. = 600 lb. per lin. ft. For shear in any section to the right of the 1/4 point, use 600 lb. per lin. ft. over the portion of the bridge between the section and the right end.

If the bridge has a concrete floor supported on longitudinal stringers 4 ft. apart, the wheels on one side of a truck, assumed to be moving longitudinally, are placed over the stringer in the position to produce maximum stress, and the stress thus found is multiplied by 4/6, if there is but one lane of traffic, and by 4/4.5 if there are two or more lanes.

Impact is the dynamic effect on a bridge due to the moving load and allowance should be made for it. The usual method is to increase the live load stress by a certain per cent of itself. The Am. Soc. C. E. specifications for highway bridges require, for floor beams and stringers, that this increment be taken as 30%, and for floor beam hangers as 60% of the live load stresses, provided these percentages are not less than would be given by the following formula for girder and truss members of highway bridges:

$$I = \frac{S}{3}\left(\frac{2000 - l}{1600 + 10\,l}\right)$$

where I = impact or dynamic increment to be added to live load stress; S = computed maximum live load stress; l = loaded length of lane of traffic, or of track, in feet, producing the maximum stress in the member. For bridges carrying more than one lane or track, the aggregate loaded length of all lanes or tracks producing the stress shall be used.

The A. A. S. H. O. specifications for highway bridges require an impact allowance of 60% for floor beam hangers. For all other portions of the structure the percentage is determined by the following formulas: for electric railway loads, $I = \dfrac{L + 900}{12\,L + 1200}$; for highway loads, $I = \dfrac{L + 250}{10\,L + 500}$ (when $W \ngtr 18$ ft.), or, $I = \dfrac{36}{W + 18} \cdot \dfrac{L + 250}{10\,L + 500}$ (when $W > 18$ ft.). For highway loads the maximum value to be used is not to exceed 30%. L = loaded length of span producing the maximum stress; W = width of roadway between girders or trusses; I = impact coefficient. Impact is not added to stresses produced by longitudinal, lateral or centrifugal forces, nor generally to those due to sidewalk loads.

Other Forces acting upon a highway bridge are covered by the Am. Soc. C. E. Specifications as follows:

115. **Centrifugal Force.** Bridges carrying electric railway traffic on a curve shall be designed to resist a lateral force equal to 10% of the moving railway load without impact allowance. This load shall be assumed to act 4 ft. above the rail.

116. **Lateral Forces.** Spans of 150 ft. and less shall be designed to resist a lateral force of 300 lb. per lin. ft. on the loaded chord and 150 lb. per lin. ft. on the unloaded chord. For spans of more than 150 ft., for each additional 30 ft. of span there shall be added 10 lb. per lin. ft. for the loaded chord and 5 lb. per lin. ft. for the unloaded chord. (Compare with corresponding A. A. S. H. O. Specifications, below.)

All lateral forces are to be considered as moving loads.

117. Viaduct towers shall be designed for a horizontal wind force of 50 lb. per sq. ft. on one and one-half times the vertical projection of the structure unloaded.

118. **Longitudinal Force.** Provision shall be made for the starting and stopping of electric railway trains, with a coefficient of friction of 15%. (Compare with corresponding A. A. S. H. O. Specifications, below.)

119. **Temperature.** Provision shall be made for movement due to temperature. For thermal stresses in fixed arch bridges provisions shall be made for stresses induced by a temperature range of 120° F.

120. **Alternate Stresses.** Members subject to alternate stresses of tension and compression shall be proportioned for the kind of stress requiring the larger section. If the alternate stresses occur in succession during the passage of live load, as in stiff counters, each stress shall be increased by 50% of the smaller. Connections shall be designed for the sum of the original stresses.

121. **Combined Stresses.** Members subject to both axial and bending stresses shall be proportioned so that the combined fiber stresses will not exceed the unit stresses given in Art. 201 (page 1184). In members continuous over panel points, three-fourths of the bending stress computed as for simple beams shall be added to the axial stress.

122. For stresses produced by combination of longitudinal or lateral forces with live load, dead load, impact, and centrifugal force, the unit stresses may be increased 25% over those specified in Art. 201. When secondary stresses are included the unit stress may be increased 33-1/3%. In no case shall the section be less than that required for deal load, live load, impact, and centrifugal force at the unit stresses specified in Art. 201, or less than that required if secondary stresses are not considered.

The following A. A. S. H. O. Specifications differ slightly from Sections 116 to 118, above:

Traction, or longitudinal force, due to electric trains, 20% of the load on one track only. Provision for wind is as follows:

Lateral Force. The force due to wind and lateral vibrations shall consist of a horizontal moving load equal to 30 lb. per sq. ft. on the side area of any floor construction, the side area of all railings, and 1.5 times the side area of each truss, girder or arch. In addition to the foregoing, a moving load of 150 lb. per lin. ft. shall be considered as acting in the plane of the loaded chord, on highway bridges, and 300 lb. per lin. ft. upon bridges for combined highway and electric railway service. However, in the case of structures having a reinforced concrete floor slab, effectively anchored to the supporting structure, this additional loaded chord load need not be considered.

The transverse bracing and anchorage of trestle towers and bents shall be proportioned to resist the above specified lateral forces acting upon the superimposed spans, plus a pressure of 30 lb. per sq ft. on 1.5 times the side areas of all columns, struts and bracing.

The longitudinal bracing of trestle towers shall be proportioned to resist not less than 0.7 of the transverse lateral forces above described, in addition to the tractive or longitudinal force due to electric railway traffic, when the latter exists.

11. Specifications for Loads and Stresses

The General Specifications for Steel Railway Bridges, 1925, of the American Railway Engineering Association have been adopted, either in their exact or in some modified form, by the majority of American railways. The essential clauses relating to unit stresses, proportioning, detailing, materials, workmanship and inspection apply and are much used in the design of other classes of steel structures, such as highway bridges and buildings (compare unit stresses for buildings, Art. 2). On account of their importance the most important clauses relating to design are here given nearly in full. The Final Report, 1923, of the Am. Soc. C. E. Committee on Specifications for Bridge Design does not differ essentially from the A. R. E. A. Specifications. Where important differences do occur, both clauses will be given, that of the Am. Soc. C. E. being indicated by an *.

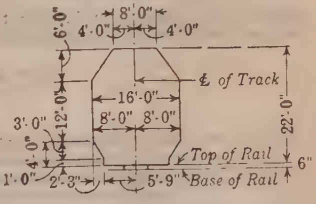

Fig. 1
(Of Report)

(II) General Features of Design

Materials Used. 8. Structures shall be made wholly of structural steel except where otherwise specified. Rivet steel shall be used for rivets only. Cast steel preferably shall be used for shoes and bearings. Cast iron may be used only where specifically authorized by the engineer.

Spacing of Trusses, Girders, and Floor Beams. 12. The width center to center of girders or trusses shall be not less than one-fifteenth of the effective span, and not less than is necessary to prevent overturning under the assumed lateral loading. Panel lengths shall not exceed 1-1/2 times the width center to center of trusses or girders

Clearances. 13. If the alignment is straight, clearances shall be not less than as shown on the diagram, Fig. 1. If the alignment is curved, the width of the diagram shall be so increased as to provide the same minimum clearances for a car 80 ft. long, 14 ft. high and 60 ft. center to center of trucks, allowance being made for curvature and superelevation of rails. The height of rail shall be assumed as 6 in.

(III) Loads

18. Members shall be proportioned for that combination of stresses which gives the maximum total stress, except as otherwise provided.

Dead Load. 19. The dead load shall consist of the estimated weight of the entire suspended structure. Timber shall be assumed to weight 4-1/2 lb. per ft. B. M.; ballast, assumed level with the base of rail and including track ties embedded therein, 120 lb. per cu. ft.; reinforced concrete, 150 lb. per cu. ft.; waterproofing, 150 lb. per cu. ft.; and rails and fastenings, 150 lb. per lin. ft. of track.

***Live Loads.** 103. The live load for each track shall consist of typical engines followed by a uniform train load, according to either Class E series, or Class M series, as may be specified by the engineer.

Loading E–60 or Loading M–50 is recommended for main-line bridges of American railways.

22. A train load of 1200 lb. per lin. ft. of one track shall be used in determining the stability of spans and towers against overturning.

Multiple Tracks. 23. In calculating the maximum stresses due to live load and centrifugal force when two, three or four tracks are loaded simultaneously, the following percentages of the specified live load shall be used:

For two tracks	90%
For three tracks	80%
For four tracks	75%

Floors. 24. Timber cross-ties shall be designed for the maximum wheel load distributed over three ties and with 100% impact added. The fiber stress shall not exceed 2000 lb. per sq. in. The ties shall be not less than 10 ft. in length. They shall be spaced with openings not exceeding 4 in. and shall be secured against bunching. The maximum dap of ties shall be 1-1/4 in.

25. Floors consisting of beams transverse to the axis of the structure shall be designed for a uniform live load of 15 000 lb. per lin. ft. for each track, with 100% impact added, when the minimum live loads specified in Sect. 20 (Cooper's E-60, or two axle loads of 75 000 lb. each spaced 7 ft. apart), is used. When heavier loadings are used, this uniform load shall be increased proportionately.

26. Floors consisting of longitudinal beams shall be designed for the wheel loads specified.

27. In ballasted floor bridges, the live load shall be considered as uniformly distributed laterally over a width of 10 ft.

Impact. 28. The dynamic increment of the live load shall be added to the maximum computed live load stresses and shall be determined by the formula,

$$I = S\frac{300}{300 + \frac{L^2}{100}},$$

in which I = impact or dynamic increment to be added to the live-load stress;
S = computed maximum live-load stress;
L = the length in feet of the portion of the span which is loaded to produce the maximum stress in the member.

***Impact.** 104. The dynamic increment of the live load shall be added to the maximum computed live load stresses and shall be determined by the formula:

$$I = S\frac{2000 - L}{1600 + 10\,L},$$

* No reduction given for multiple tracks as is done in A. R. E. A.
* A. S. C. E. Specifications.

in which I = impact or dynamic increment to be added to live load stresses;
S = computed maximum live-load stress;
L = loaded length of track, in feet, producing the maximum stress in the member. For bridges carrying more than one track, the aggregate length of all tracks producing the stresses shall be used.

29. For bridges designed exclusively for electric traction, the impact stresses shall be taken as one-half of those given by the formula in Sect. 28.

* 105. For bridges designed exclusively for electric traction, impact shall be taken as one-third of that given by the impact formula.

30. Impact shall not be added to stresses produced by longitudinal or lateral forces, or by the train load specified in Sect. 22.

* **Allowance for Increase of Live Load.** 106. Wherever an additional counter would be required, or reversal of stress would be caused, or heavier dimensioning would result, a member and its details shall be designed for a live load 50% greater than that given in Art. 103, with an allowance of 50% increase in unit stresses.

Eccentricity of Load on Curves. 31. For bridges on curves, provision shall be made for the increased load carried by any truss, girder or stringer due to the eccentricity of the load.

Lateral Forces. 32. The wind force on the structure shall be a moving load of 30 lb. per sq. ft. on 1-1/2 times its vertical projection on a plane parallel with its axis, but not less than 200 lb. per lin. ft. at the loaded chord or flange, and 150 lb. per lin. ft. at the unloaded chord or flange.

The wind force on the train shall be a moving load of 300 lb. per lin. ft. on one track, applied 8 ft. above the base of rail.

33. The lateral force to provide for the effect of the sway of the engines and train, in addition to the wind loads specified in Sect. 32, shall be a moving load equal to 5% of the specified live load on one track, but not more than 400 lb. per lin. ft., applied at the base of rail.

34. The lateral bracing between compression chords or flanges and between the posts of viaduct towers shall be capable of resisting a transverse shear in any panel equal to 2-1/2% of the total axial stress in the chords or posts in that panel.

35. In proportioning the bracing, Sects. 32 and 33 shall be combined or Sect. 34 used alone, whichever gives the greater section.

* **Lateral Forces.** 108. All spans shall be designed for a lateral force on the loaded chord of 200 lb. per lin. ft. plus 10% of the specified train load on one track, and 200 lb. per lin. ft. on the unloaded chord, these forces being considered as moving.

* **Wind Force.** 109. Viaduct towers shall be designed for the one of the following loads that causes the greater stress:

Viaduct towers shall be designed for a force of 50 lb. per sq. ft. on 1-1/2 times the vertical projection of the structure unloaded; or 30 lb. per sq. ft. on the same surface plus 400 lb. per lin. ft. of structure applied 7 ft. above the rail for the assumed wind force on the train when the structure is either fully loaded or loaded on either track with empty cars assumed to weigh 1200 lb. per lin. ft., whichever gives the larger stress.

Centrifugal Force. 36. On curves, the centrifugal force (assumed to act 6 ft. above the rail) shall be taken equal to a percentage of the live load, including impact, according to the following table:

Degree of Curve....	0° 20′	0° 40′	1°	2°	3°	4°	5°	6°	7°	8°	9°	10°	11°	12°
Percentage.........	2-1/2	5	7-1/2	10	10	10	10	10	10	10	10	10	10	10
Speed in miles per hour	80	80	80	65	53	46	41	38	35	33	31	29	28	27

* **Centrifugal Force.** 107. Structures on curves shall be designed to resist the centrifugal force of the live load applied 7 ft. above base of rail, as computed by the following formula:

$$C = \frac{0.067\,W V^2}{R},$$

* A. S. C. E. Specifications.

in which C = horizontal centrifugal force;
W = live load, including impact;
R = radius of curve (5730 ÷ degree of curve);
V = speed, in miles per hour = (60 − 2-1/2 times the degree of curve).

Longitudinal Force. 37. Provision shall be made in the design for the effect of a longitudinal force of 20% of the live load on one track only, applied 6 ft. above the top of the rail. In structures (such as ballasted deck bridges of only three or four spans) where, by reason of continuity of members or frictional resistance, the longitudinal force will be largely directed to the abutments, its effect on the superstructure shall be taken as one-half that specified above.

* **Longitudinal Force.** 110. Provision shall be made for the starting and stopping of trains, with a coefficient of friction on the engine drivers at 20% and on the remainder of the train at 10%.

(IV) Unit Stresses and Proportioning of Parts

38. The several parts of structures shall be so proportioned that the unit stresses will not exceed the following, except as modified in Sects. 46 and 47:

	Lb. per sq. in.
Axial tension, net section	16 000 †
Axial compression, gross section	$15\,000 - 50\frac{l}{r}$
but not to exceed	12 500

l = the length of the member in inches.
r = the least radius of gyration of the member in inches.

Tension in extreme fibers of rolled shapes, built sections and girders, net section	16,000
Tension in extreme fibers of pins	24 000
Shear in plate girder webs, gross section	10 000
Shear in power-driven rivets and pins	12 000
Bearing on power-driven rivets, pins, outstanding legs of stiffener angles, and other steel parts in contact	24 000

Rivets driven and bucked by pneumatically or electrically operated hammers are considered power-driven.

The above mentioned values for shear and bearing shall be reduced 25% for countersunk rivets, hand-driven rivets and turned bolts.

Bearing on expansion rollers, per linear inch	$600d$

d = the diameter of the rollers in inches.

	Lb. per sq. in
Bearing on granite masonry	800
Bearing on sandstone and limestone masonry	400
Bearing on concrete masonry	600
* 201. Compression (one diameter)	16 000

Compression on columns:

$$p = \frac{16\,000}{1 + \dfrac{l^2}{13\,500\,r^2}},$$

but not to exceed the value for $\frac{l}{r} = 40$.

* A. S. C. E. Specifications.

† Many engineers favor an increase in unit stresses to 18 000 or 20 000 lb., and in exceptional cases even higher. Accompanying higher unit stresses there should be a liberal allowance for all external forces, impact and all possible combinations of stresses, in consequence of which a more consistent, economical and safe design will result. High unit stresses have been used in some notable bridges. Thus, 20 000 for Blackwell's Island bridge, ordinary loading, and 24 000 congested loading; 20 000 for the Quebec bridge, exclusive of secondary stresses, and 22 000 inclusive of secondary stresses.

Proportioning Web Members. 43. Web members shall be so proportioned that an increase of live load which will increase the total unit stresses in the chords 50% will not produce total unit stresses in the web members more than 50% greater than the designing stresses.

Reversal of Stress. 44. Members subject to reversal of stress under the passage of the live load shall be proportioned as follows:

Determine the resultant tensile stress and the resultant compressive stress and increase each by 50% of the smaller; then proportion the member so that it will be capable of resisting either increased resultant stress. The connections shall be proportioned for the sum of the resultant stresses.

Combined Stresses. 45. Members subject to both axial and bending stresses (including bending due to floor beam deflection) shall be so proportioned that the combined fiber stresses will not exceed the allowed axial stress. In members continuous over panel points, only three-fourths of the bending stress computed as for simple beams shall be added to the axial stress.

46. Members subject to stresses produced by a combination of dead load, live load, impact, and centrifugal force, with either lateral or longitudinal forces, or bending due to lateral action, may be proportioned for unit stresses 25% greater than those specified in Sect. 38; but the section shall not be less than that required for dead load, live load impact, and centrifugal force.

Secondary Stress. 47. Designing and detailing shall be done so as to avoid secondary stresses as far as possible. In ordinary trusses without sub-paneling, no account usually need be taken of the secondary stresses in any member of which width measured in the plane of the truss is less than one-tenth of its length. Where this ratio is exceeded, or where sub-paneling is used, secondary stresses due to deflection of the truss shall be computed. The unit stresses specified in Sect. 38 may be increased one-third for a combination of the secondary stresses with the other stressses, but the section shall not be less than that required when secondary stresses are not considered.

Compression Flanges. 48. The gross area of the compression flanges of plate girders and rolled beams shall not be less than the gross area of the tension flanges, but the stress per square inch of gross area shall not exceed

$$16\,000 - 150\frac{l}{b},$$

in which l = the length in inches of the unsupported flange between lateral connections or knee braces;

b = the flange width in inches.

12. Specifications for Details

(V) Details of Design

Slenderness Ratios. 49. The ratio of length to least radius of gyration shall not exceed:

100 for main compression members;
120 for wind and sway bracing;
140 for single lacing, and for double lacing not riveted at intersections;
170 for double lacing riveted at intersections;
200 for riveted tension members.

Depth Ratios. 50. The depth of trusses preferably shall be not less than one-tenth of the span. The depth of plate girders preferably shall be not less than one-twelfth of the span. The depth of rolled beams used as girders and the depth of solid floors preferably shall be not less than one-fifteenth of the span. If smaller depths that these are used, the section shall be so increased that the maximum deflection will not be greater than if these limiting ratios had not been exceeded.

Effective Area of Angles. 54. The effective area of single angles in tension shall be assumed as the net area of the connected leg plus 50% of the area of the unconnected leg. Single angles connected by lug angles shall be considered as connected by one leg.

Counters. 55. If web members are subject to reversal of stress, their end connections preferably shall be riveted. Adjustable counters shall have open turnbuckles.

Strength of Connections. 56. Connections shall have a strength at least equal to that of the members connected, regardless of the computed stress. Connections shall be made, as nearly as practicable, symmetrical about the axes of the members.

Limiting Thickness of Metal. 57. Metal shall be not less than 3/8 in. thick, except for fillers. Metal subject to marked corrosive influences shall be increased in thickness or protected against such influences.

Sizes of Rivets. 58. Rivets shall be 3/4 in., 7/8 in. or 1 in. in diameter as specified.

Pitch of Rivets. 59. The minimum distance between centers of rivet holes shall be three diameters of the rivet, but the distance preferably shall be not less than 3-1/2 in. for 1-in. rivets, 3 in. for 7/8-in. rivets and 2-1/2 in. for 3 4-in. rivets. The maximum pitch in the line of stress for members composed of plates and shapes shall be 7 in. for 1-in. rivets, 6 in for 7/8-in. rivets, and 5 in. for 3 4-in. rivets. For angles with two gage lines and rivets staggered, the maximum pitch in each line shall be twice the amounts given above. If two or more web plates are used in contact, stitch rivets shall be provided to make them act in unison. In compression members, the stitch rivets shall be spaced not more than 24 times the thickness of the thinnest plate in the direction perpendicular to the line of stress, and not more than 12 times the thickness of the thinnest plate in the line of stress. In tension members, the stitch rivets shall be spaced not more than 24 times the thickness of the thinnest outer plate in either direction. In tension members composed of two angles in contact, a pitch of 12 in. may be used for riveting the angles together.

Edge Distance. 60. The minimum distance from the center of any rivet hole to a sheared edge shall be: 1-3/4 in. for 1-in. rivets, 1-1/2 in. for 7/8-in. rivets, and 1-1/4 in. for 3/4-in. rivets; to a rolled edge 1-1/2 in., 1-1/4 in. and 1-1/8 in. respectively. The maximum distance from any edge shall be 8 times the thickness of the plate, but shall not exceed 6 in.

Sizes of Rivets in Angles. 61. The diameter of the rivets in any angle whose size is determined by calculated stress shall not exceed one-fourth of the width of the leg in which they are driven. In angles the size of which is not so determined 1-in. rivets may be used in 3-1/2-in. legs, 7/8-in. rivets in 3-in. legs, and 3/4-in. rivets in 2-1/2-in. legs.

Long Rivets. 62. Rivets which carry calculated stress and the grip of which exceeds 4-1/2 diameters shall be increased in number at least one per cent for each additional 1/16 in. of grip. If the grip exceeds 6 times the diameter of the rivet, specially designed rivets shall be used.

Pitch of Rivets at Ends. 63. The pitch of rivets at the ends of built compression members shall not exceed 4 diameters of the rivet for a distance equal to 1-1/2 times the maximum width of the member.

Compression Members. 64. In built compression members, the metal shall be concentrated in the webs and flanges. The thickness of each web shall be not less than 1/30 of the distance between the lines of rivets connecting it to the flanges. The thickness of cover plates shall be not less than 1/40 of the distance between the nearest rivet lines.

Outstanding Legs of Angles. 65. The width of the outstanding legs of angles in compression (except when reinforced by plates) shall not exceed the following:

(a) For stringer flange angles, 10 times the thickness.
(b) For main members carrying axial stress, 12 times the thickness.
(c) For bracing and other secondary members, 14 times the thickness.

Stay Plates. 66. The open sides of compression members shall be provided with lacing bars and shall have stay plates as near each end as practicable. Stay plates shall be provided at intermediate points where the lacing is interrupted. In main members, the length of the end stay plates shall be not less than 1-1/4 times the distance between the lines of rivets connecting them to the outer flanges, and the length of intermediate stay plates shall be not less than 3/4 of that distance. Their thickness shall be not less than 1/50 of the same distance.

67. Tension members composed of shapes shall have their separate segments stayed together. The stay plates shall have a length not less than two-thirds of the lengths specified for stay plates on compression members.

Lacing. 68. The lacing of compression members shall be proportioned to resist a shearing stress of 2-1/2% of the direct stress. The section shall be made as required by Sects. 38 and 49, in which l shall be taken as the distance between connections of the lacing to the main sections.

The minimum width of lacing bars shall be 3 in. for 1-in. rivets, 2-3/4 in. for 7/8-in. rivets, 2-1/2 in. for 3/4-in. rivets, and 2 in. for 5/8-in. rivets.

69. In members composed of side segments and a cover plate, with the open side laced, one half the shear shall be considered as taken by the lacing. Where double lacing is used, the shear in the plane of the lacing shall be distributed equally between the two systems.

70. Lacing bars of compression members shall be so spaced that the $\frac{l}{r}$ of the portion of the flange included between their connections will be not greater than 40, and not greater than two-thirds of the $\frac{l}{r}$ of the members.

71. In connecting lacing bars to flanges, 5/8-in. rivets shall be used for flanges less than 2-1/2 in. wide, 3/4-in. rivets for flanges from 2-1/2 to 3-1/2 in. wide, and 7/8-in. rivets for flanges 3-1/2 or more inches wide. Lacing bars with at least two rivets in each end shall be used for flanges over 5 in. wide.

72. The angle of lacing bars with the axis of the member shall be not less than 45 deg. for double lacing, and 60 deg. for single lacing. If the distance between rivet lines in the flanges is more than 15 in. and a single-rivet bar is used, the lacing shall be double and riveted at the intersections.

*315. The latticing of compression members shall be proportioned to resist shearing stress normal to the member not less than that calculated by the formula:

$$R = \frac{Pl}{4000\,y},$$

in which R = normal shearing stress, in pounds;
P = strength of column as a compression member, expressed in pounds;
l = length of column, in inches;
y = distance from neutral axis to extreme fiber, in inches.

In a compression member with a cover-plate, the cover-plate will be assumed to take one-half the shear.

*316. The diameter of the rivets shall not exceed one-third the width of the bar.

Splices. 73. Abutting joints in compression members faced for bearing shall have their component parts spliced. The gross area of the splice material shall be not less than 50% of the gross area of the smaller member. In determining the number of rivets in compression splices, the stress in the splice material shall be taken as 15 000 lb. per sq. in. of gross area.

74. Joints in riveted work not faced for bearing shall be fully spliced.

***Built Chord Splices.** 310. Built chords subjected to compression only, when faced for bearings, shall be spliced on four sides sufficient to hold the abutting members accurately in place and to transmit at least 25% of the stress through splice-plates. Generally, they shall be spliced as near to panel points as practicable. All other joints shall be fully spliced.

Net Section at Pin Holes. 75. In pin-connected riveted tension members, the net section across the pin hole shall be not less than 140% and the net section back of the pin hole not less than 100% of the net section of the body of the member, and there shall be sufficient rivets to make the material effective.

* A. S. C. E. Specifications.

Net Section Defined. 76. The net section of riveted members shall be the least area which can be obtained by deducting from the gross sectional area the areas of holes cut by any plane perpendicular to the axis of the member and parts of the areas of other holes on one side of the plane within a distance of 4 in., which are on gage lines 1 in. or more from those of the holes cut by the plane, the parts being determined by the formula:

$$A\left[1-\frac{P}{4}\right],$$

in which A = the area of the hole;

P = the distance in inches of the center of the hole from the plane.

77. In determining the net section, the diameter of the rivet hole shall be taken 1/8 in. larger than the nominal diameter of the rivet.

Pin Plates. 78. Where necessary to give the required section or bearing area, pin holes shall be reinforced on each segment by plates, one of which on each side must be as wide as the outstanding flanges will permit. These plates shall contain enough rivets and be so connected as to transmit and distribute the bearing pressure uniformly over the full cross-section and to reduce the eccentricity of the segment to a minimum. At least one full-width plate on each segment shall extend to the far edge of the stay plate and the others not less than 6 in. beyond the near edge.

Indirect Splices. 79. If splice plates are not in direct contact with the parts which they connect, rivets shall be used on each side of the joint in excess of the number required in the case of direct contact to the extent of two extra lines for each intervening plate.

Fillers. 80. Where rivets carrying stress pass through fillers, the fillers shall be extended beyond the connected member and the extension secured by additional rivets sufficient to develop the value of the filler.

Forked Ends. 81. Forked ends on compression members will be permitted only where unavoidable. Where forked ends are used, a sufficient number of pin plates shall be provided to make the jaws of twice the sectional area of the member and they shall be extended as far as necessary in order to carry the stress of the main member into the jaws, but shall not be shorter than required by Sect. 78.

Upset Ends. 85. Bars with screw ends shall be upset so that the area at the root of the thread will be at least 15% greater than in the body of the bar.

Expansion Bearings. 88. Spans more than 70 ft. in length shall have rollers at one end. Shorter spans shall be arranged to slide on smooth surfaces.

Fixed Bearings. 89. Bearings and ends of spans shall be secured against lateral motion.

Rollers. 90. Expansion rollers shall be not less than 6 in. in diameter. They shall be coupled together with substantial side bars, which shall be so arranged that the rollers can be cleaned readily. Rollers shall be geared to the upper and lower plates.

Pedestals and Shoes. 91. Pedestals and shoes preferably shall be made of cast steel. The difference between the top and bottom bearing widths shall not exceed twice the depth. For hinged bearings, the depth shall be measured from the center of the pin. Where built pedestals and shoes are used, the web plates and the angles connecting them to the base plate shall be not less than 3/4 in. thick. If the size of the pedestal permits, the webs shall be rigidly connected transversely. The minimum thickness of the metal in cast-steel pedestals shall be 1 in. Pedestals and shoes shall be so constructed that the load will be distributed uniformly over the entire bearing. Spans more than 70 ft. in length shall have hinged bearings at each end.

(VI) Bracing

Spacing of Stringers. 98. Stringers usually shall be spaced 6 ft. 6 in. center to center. If four stringers are used under one track, each pair shall be placed symmetrically about the rail.

I-Beam Girders. 99. Rolled beams supporting timber decks shall be arranged with not more than four, and preferably not less than two beams under each rail.

The beams in each group shall be placed symmetrically about the rail, and shall be spaced far enough apart to permit cleaning and painting. They shall be connected by solid web diaphragms near the ends and at intermediate points, spaced not over 12 times the flange width. Bearing plates shall be continuous under each group of beams. End stiffeners shall be used if required by Sect. 38.

Floor Beam Connections. 100. Floor beams preferably shall be square to the girders or trusses. They shall be riveted directly to the girders or between the posts of through and deck truss spans.

End Connection Angles. 101. The legs of stringer connection angles shall be not less than 4 in. in width, and not less than 5/8 in. in thickness before facing. Shelf angles shall be provided to support the stringers during erection, but the connection angles shall be sufficient to carry the whole load. Stringers in through spans shall be riveted between the floor beams.

Stringer Frames. 102. Where two lines of stringers are used under each track in panels more than 20 ft. in length, they shall be connected by cross frames.

(VII) Bracing

Design of Bracing. 105. Lateral, longitudinal, and transverse bracing shall be composed of shapes with riveted connections. Lateral bracing shall have concentric connections to chords at end joints, and preferably throughout. The connections between the lateral bracing and the chords shall be designed to avoid, as far as practicable, any bending stress in the truss members.

106. When a double system of bracing is used, both systems may be considered simultaneously effective if the members meet the requirements as both tension and compression members.

Lateral Bracing. 107. Bottom lateral bracing shall be provided in all bridges except deck plate girder spans less than 50 ft. long. Continuous steel or concrete floors shall be considered lateral bracing.

108. Top lateral bracing shall be provided in deck spans, and in through spans having sufficient head room.

Portal and Sway Bracing. 109. Deck truss spans shall have sway bracing at every panel point. The top lateral loads preferably shall be carried to the supports by means of a complete top lateral system, or the loads may be considered as transferred to the bottom lateral system at each sway frame.

110. Through truss spans shall have portal bracing, with knee braces, as deep as the specified clearance will allow.

111. Through truss spans shall have sway bracing at every intermediate panel point if the height of the trusses is enough to allow a depth of 6 ft. or more for the bracing. When the height of the trusses will not allow that depth, the top lateral struts shall be of the same depth as the chord and shall have knee braces.

Cross-Frames. 112. Deck plate girder spans shall be provided with cross-frames at each end proportioned to resist centrifugal and lateral forces, and shall have intermediate cross-frames at intervals not exceeding 18 ft.

Laterals. 113. The smallest angle to be used in lateral bracing shall be 3-1/2 by 3 by 3/8 in. There shall be not less than three rivets at each end connection of the angles. Angles shall be connected at their intersections by plates.

(VIII) Plate Girders

Spacing of Girders. 115. The girders of deck bridges usually shall be spaced 6 ft. 6 in. between centers, except that:

(a) In single-track deck spans 75 ft. or more in length, girders shall be spaced in accordance with Sect. 12, but not less than 7 ft. 6 in. between centers.

(b) In bridges on curves, the girders shall be spaced as shown on the plans.

Design of Plate Girders. 116. Plate girders shall be proportioned either by the moment of inertia of their net section including compression side; or by assuming that the flanges are concentrated at their centers of gravity. In the latter case, one-eighth of the gross section of the web, if properly spliced, may be used as flange section. For girders having unusual sections, the moment of inertia method shall be used.

Flange Section. 117. The flange angles shall form as large a part of the area of the flange as practicable. Side plates shall not be used except when flange angles exceeding 1 in. in thickness otherwise would be required.

118. Flange plates shall be equal in thickness, or shall diminish in thickness from the flange angles outward. No plate shall have a thickness greater than that of the flange angles.

119. Where flange cover plates are used, one cover plate of the top flange shall extend the full length of the girder. Other flange plates shall extend at least 18 in. beyond the theoretical end.

Thickness of Web Plates. 120. The thickness of web plates shall be not less than $\frac{1}{20}\sqrt{D}$, where D represents the distance between flanges in inches.

Flange Rivets. 121. The flanges of plate girders shall be connected to the web with a sufficient number of rivets to transfer to the flange section the horizontal shear at any point combined with any load that is applied directly on the flange. Where ties rest on the flange, one wheel load shall be assumed to be distributed over 3 ft.

Flange Splices. 122. Splices in flange members shall not be used except by special permission of the engineer. No two members shall be spliced at the same cross-section. If practicable, splices shall be located at points where there is an excess of section. The net section of the splice shall exceed by 10% the net section of the member spliced. Flange angle splices shall consist of two angles—one on each side.

Web Splices. 123. Web plates shall be spliced symmetrically by plates on each side. The splice plates for shear shall be the full depth of the girders between flanges. The splice shall be equal to the web in strength in both shear and moment. There shall be not less than two rows of rivets on each side of the joint.

End Stiffeners. 124. Plate girders shall have stiffener angles over end bearings, the outstanding legs of which will extend as nearly as practicable to the outer edge of the flange angles. These end stiffeners shall be proportioned for bearing of the outstanding legs on the flange angles, and shall be arranged to transmit the end reaction to the pedestals or distribute it over the masonry bearings. They shall be connected to the web by enough rivets to transmit the reaction. End stiffeners shall not be crimped.

Intermediate Stiffeners. 125. The webs of plate girders shall be stiffened by angles at intervals not greater than:

(a) Six feet.
(b) The depth of the web.
(c) The distance given by the formula

$$d = \frac{t}{40}(12\,000 - S),$$

in which d = the distance between rivet lines of stiffeners in inches;
t = the thickness of the web in inches;
S = web shear in pounds per square inch at the point considered.

126. If the depth of the web between the flange angles or side plates is less than 50 times the thickness of the web, intermediate stiffeners may be omitted.

127. Stiffener angles shall be placed at points of concentrated loads, and shall not be crimped.

128. Intermediate stiffeners shall be riveted in pairs to the web of the girder. The outstanding leg of each angle shall be not less than 2 in. plus 1/30 of the depth of the girder, nor more than 16 times its thickness.

Gusset Plates in Through Girders. 129. In through plate girder spans, the top flanges shall be braced by means of gusset plates or knee-braces with solid webs connected to the floor beams and extending usually to the clearance line. If the unsupported length of the inclined edge of the gusset plate exceeds 18 in., the gusset plate shall have one or two stiffening angles riveted along its edge. The gusset plate shall be riveted to a stiffener angle on the girder. Preferably it shall form no part of the floor beam web.

(IX) Trusses

Type of Truss and Sections of Members. 136. Trusses shall have single intersection web systems and, preferably, inclined end posts. The top chords and end posts shall be made usually of two side segments with one cover plate and with stay plates and lacing on the open side. The bottom chords of riveted trusses shall be made symmetrical, usually of vertical side plates with flange angles. Web members shall be symmetrical in section.

Camber. 137. The length of members of truss spans shall be such that the camber will be equal to the deflection produced by the combined dead and live loads without impact.

Riveted Members in Pin-connected Trusses. 138. In pin-connected trusses, hip verticals (and members with similar functions) and, in single-track spans, the two panels at each end of the bottom chords shall be riveted members.

Eye Bars. 139. The thickness of an eye bar shall be not less than one-eighth of the width nor less than 1 in., and not greater than 2 in. The cross-sectional area of the head through the center of the pin hole shall exceed that of the body of the bar by at least 37-1/2%. The form of the head shall be submitted to the engineer for approval before the bars are made. The diameter of the pin shall be not less than seven-eighths of the width of the widest bar attached.

Packing. 140. The eye bars of a set shall be packed symmetrically about the plane of the truss and as nearly parallel as practicable. In no case shall the inclination of any bar to the plane of the truss exceed 1/16 in. to the foot. They shall be packed close, held against lateral movement, and so arranged that bars in the same panel will not be in contact.

Gusset Plates. 141. The thickness of gusset plates connecting the chords and web members of the truss shall be proportionate to the stress to be transferred, but shall not be less than 1/2 in.

(X) Viaducts

Type of Viaduct. 144. Viaducts shall consist usually of alternate tower spans and free spans of plate girders or riveted trusses supported on bents. The tower spans usually shall be not less than 30 ft. long.

Bents and Towers. 145. Viaduct bents shall be composed preferably of two supporting columns, and the bents usually shall be united in pairs to form towers. In towers having more than two vertical panels, horizontal bracing shall be placed at alternate intermediate panel points. In double track towers, provision shall be made for the transmission of the longitudinal force to both sides.

Single Bents. 146. Where long spans are supported on short single bents, such bents shall have hinged ends, or else have their columns and anchorages proportioned to resist the bending stresses produced by changes in temperature.

Bottom Struts. 147. The bottom struts of viaduct towers shall be proportioned for the calculated stresses, but in no case for less than one-fourth of the dead load reaction on one pedestal, considered as compressive stress. Provision shall be made in the column bearings for expansion of the tower bracing.

Batter. 148. The columns usually shall have a batter transversely of one horizontal to six vertical for single track viaducts, or one horizontal to eight vertical for double track viaducts.

Depths of Girders. 149. The depths of the girders in a viaduct preferably shall be uniform.

Spacing of Girders. 150. In single-track viaducts, the girder spacing usually shall be uniform throughout, and shall be determined by the spacing for the longest span in the viaduct, according to the rules specified for deck plate girder spans.

151. In double-track viaducts, the girders under each track usually shall be spaced 6 ft. 6 in. between centers, and the inner lines of girders shall be supported by cross-girders framed between and riveted to the posts.

Girder Connections and Bracing. 152. The girders of tower spans shall be fastened at both ends to the tops of the posts or cross-girders. Girders between towers shall have one end riveted, and shall be provided with an effective expansion joint at the other end. No bracing or sway frame shall be common to abutting spans.

153. If neither of the girders under a track rests directly over a tower post, bracing shall be provided to carry the longitudinal force into the tower bracing without producing lateral bending stress in the cross-girders or posts.

Sole and Masonry Plates. 154. Sole and masonry plates shall be not less than 3/4 in. thick.

Anchorage for Towers. 155. Anchor bolts for viaduct towers and similar structures shall be designed to engage a mass of masonry the weight of which is at least 1-1/2 times the uplift.

13. Highway Bridge Floors

A Highway Bridge Floor consists of the floor proper, stringers and floor beam (Fig. 28). The upper surface of the floor is the wearing surface. Stringers are beams placed lengthwise of the bridge which carry the loads from floor to floor beams, the latter being transverse to the length of the bridge and connected to the trusses or girders at opposite panel points. Sidewalks are usually of plank supported on stringers which are in turn carried either by brackets at the panel points of the trusses or by extensions of the floor beams. The hand railing at the outer edge of the sidewalk is supported by the brackets, and when the panels are long, an intermediate railing support is also provided at the middle of each panel. The economic panel length for light bridges having plank flooring is from 13 to 15 ft., whereas for heavy traffic it is from 15 to 20 ft., and even as much as 25 ft. for heavy structures of long spans.

Floors on Secondary Country Road Bridges generally consist of one or two layers of planking; one layer is usually 3 in. thick, laid transversely to the length of the roadway; and for two layers the lower is 2 to 4 in. thick and laid transversely, while the 2-in. upper planking is either transverse or diagonal. The lower planking should be pressure treated with creosote oil.

Weights of Floors. For 3-in. yellow pine planking on 3 by 12-in. yellow pine stringers, spaced 2 ft. on centers, the total weight of planking and stringers is 21 lb. per sq. ft.; 2-in. spruce on 3-in. pine with 3 by 12-in. stringers, 28 lb. per sq. ft.; 3-in. yellow pine on 4 by 14-in. stringers spaced 2-1/2 ft., 23 lb.; 3-in. pine on 4 by 14-in. stringers spaced 3 ft., 22 lb., 2-in. spruce on 3-in. pine with 6 by 14-in. stringers spaced 3-ft., 32 lb. per sq. ft. Asphalt laid 2 in. thick on 1 in. of sand and 4 in. of concrete on 5/16-in. buckled plates gives a weight of 85 to 90 lb. per sq. ft. not including stringers.

Steel Stringers are usually made of I beams which are set on the top flanges of the floor beams or connected to the floor-beam webs by hitch or connecting ∟'s. To find the size of I beam compute the required section modulus M/S, and look up in a table of properties of I beams the size and weight of beam corresponding. M = maximum bending moment in inch-pounds, S = allowable unit stress, generally 16 000 lb. per sq. in.

Each stringer should have two hitch ∟'s at each end to connect stringer to floor-beam web. The number of rivets connecting the two ∟'s to the stringer web equals the maximum end shear on one stringer divided by the value of one shop rivet. The rivets through the floor-beam web, connecting hitch ∟'s from a stringer on each side of the floor beam, are field-driven, and their number is obtained by (1) dividing the maximum end shear on one stringer by either the single shearing value of the rivet or the bearing on one thickness of hitch ∟ whichever is the smaller, or (2) by dividing the maximum load going the through connection from both sides of the floor beam by the bearing value of a field rivet on the floor-beam web, or on two thicknesses of

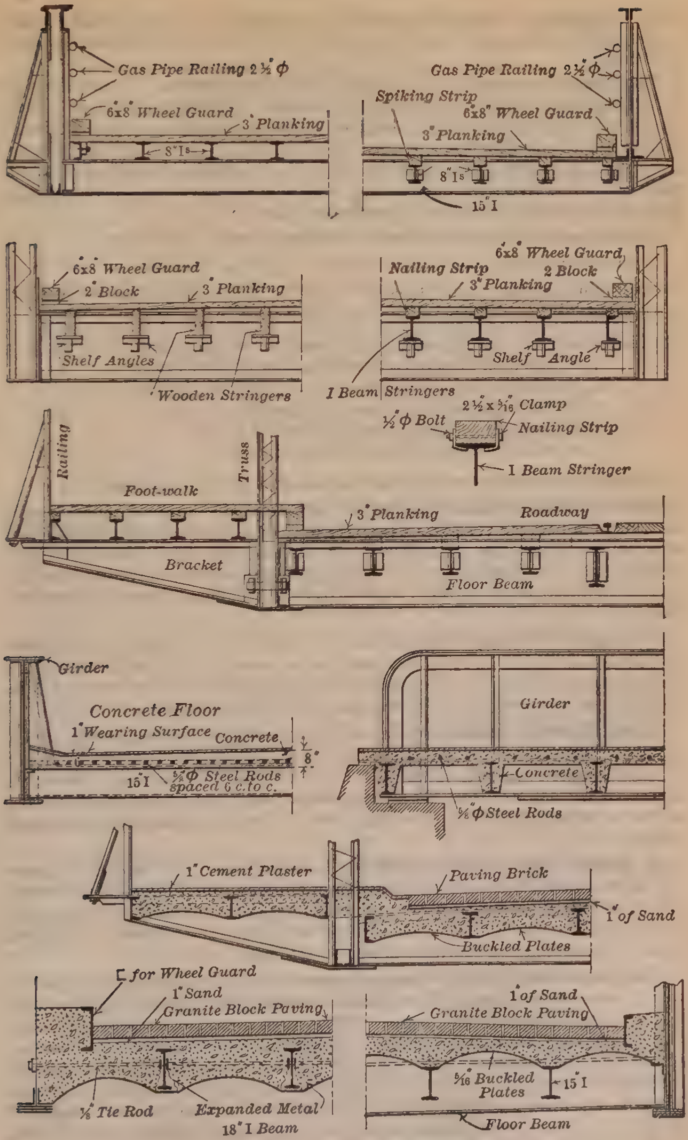

Fig. 28. Floors for Highway Bridges

hitch L if smaller. The greater number of rivets from (1) and (2) should be used. Some engineers claim that double the number just found should be used to allow for bending.

Floor Beams are made of I beams or of built-up beams. I beams require little shop work and should be used if possible. A built-up beam is a plate girder (Arts. 20 and 21) and is designed as such. In any case the maximum moments and maximum shear must be computed. The following formulas are applicable to floor beams where there is a sidewalk on each side of the roadway. The live load per running foot of floor beam and of sidewalk is properly placed to produce the maximum effects.

$$\text{Maximum moment on floor beam} = 1/8\,(p + w)\,d^2 - 1/2\,w_1 e^2$$

$$\text{Maximum moment on sidewalk bracket} = 1/2\,(p_1 + w_1)\,e^2$$

$$\text{Maximum reaction at one truss} = 1/2\,(w + p)\,d + (w_1 + p_1)\,e + p_1 e^2/2d$$

$$\text{Maximum shear on floor beam} = 1/2\,(w + p)\,d + p_1 e^2/2\,d$$

in which w = dead load in pounds per linear foot of floor beam;
p = live load in pounds per linear foot of floor beam;
w_1 = dead load per linear foot of sidewalk brackets;
p_1 = live load per linear foot of sidewalk brackets;
d = distance center to center of trusses in feet;
e = width of each of two sidewalks in feet.

Moments are in foot-pounds and reaction and shear in pounds.

Floors on Primary Road Bridges are now generally built of concrete with some form of wearing surface. The slabs may be supported upon longitudinal stringers, as in the case of wooden floors, or, when the panel length is short, directly upon the floor beams, the stringers being omitted. Wearing surface may be concrete, brick, asphalt, asphalt block, bituminous carpet, or creosoted block.

A Concrete Wearing Surface consists either of an additional thickness (usually about 3/4 in.) of rich concrete placed monolithically with the slab, or of a separately placed wearing surface of rich concrete, varying from 2-1/2 in. in thickness at the edges of the roadway to 4 in. at the center.

A Brick Wearing Surface consists of paving brick laid on edge in successive courses. They are placed, after the concrete is cured and dampened, upon a dry sand-cement bedding course of 1/2 to 1-in. finished thickness. Joints are filled with hot asphalt filler, the surface dressed with a thin surface of dry sand or fine screenings, and a final rolling given to bind the dressing in the asphalt coating.

An Asphalt Block Wearing Surface is constructed in a similar manner. The mortar bed is spread out to a uniform thickness of 1/2 in. and the blocks are immediately laid with close joints and uniform top surface. Clean dry sand is swept into the joints, the residue being allowed to remain 30 days or longer. No rolling is permitted during construction.

The Bituminous Carpet Wearing Surface is placed either upon a wood or upon a concrete sub-floor. The former is thoroughly sealed by calking with oakum, or by other suitable means. Either type must be thoroughly cleaned. The prime coat of thinned tar is applied at the rate of 1/4 gal. per sq. yd. of surface. After 12 hours a second tar coat of slightly different quality, and heated to about 200° F. is applied at the rate of 1/2 gal. per sq. yd. Immediately after application of the tar the surface is covered to a depth of about 1/2 in. with gravel, stone chips or slag aggregate of about 1/2 in. or less in size, and hand tamped or rolled with a heavy hand roller. Successive applications of tar and aggregate are made until a total thickness of about 3/4 in. is reached.

The Creosoted-wood Block Wearing Surface likewise may have either a wood or a concrete sub-floor. The former is calked, cleaned, and mopped with a coat of hot filler upon which is placed a layer of 3-ply roofing felt, laid with 6 in. laps and thoroughly rolled into contact with the filler. The concrete sub-floor is prepared by cleaning and drying, and spreading a thin smooth coating of hot filler of about 1/2 in. in thickness. The creosoted-wood blocks are laid upon this surface in straight parallel courses. After rolling, the joints are filled with hot bituminous filler. The surface is covered with about 1/2 in. of clean, dry sand which is allowed to remain under traffic for several weeks.

Floors on City Bridges differ from those on primary roads in general only in having wider roadways and sidewalks, harder and more durable surfaces, and heavier loading conditions, usually including one or two street-car tracks. The live load will be Class A loading, together with 50 or 60-ton electric railway cars, when tracks are present. The sub-floor may consist of concrete arches enclosing I beam stringers and arching the spaces in between; of steel buckled plates riveted to the stringer flanges and supporting a covering of concrete; or of a reinforced-concrete slab similar to the one used on primary country roads, Fig. 27.

Buckled Plates (Fig. 28) made by pressing dome-shaped buckles in flat steel plates are used for supporting brick, asphalt, or granite blocks. These pavements are laid on 1-in. sand spread on concrete which is laid on the buckled plates. Plates are 1/4, 5/16, 3/8, 7/16 in. thick, 5/16 being most common for roadways and 1/4 for sidewalks; and should be riveted, not bolted, to the stringer flanges with 5/8 or 3/4-in. rivets spaced not over 6 in. Buckles are from 2 to 3-1/2 in. deep, from 2.0 to 5-1/2 ft. on a side, and from 1 to 15 buckles are used in one long plate. Plates are stronger with the buckles turned down.

The Wearing Surface of City Bridges may be any of the types already described, but generally consists of brick, asphalt, or granite blocks. Creosoted-wood blocks have also been much used in some cities, but are not as durable as the more metallic surfaces. Sidewalks of city bridges frequently have a concrete sub-floor and a concrete or granulithic wearing surface.

The Weights of Floors in pounds per cubic foot are: Yellow pine, 48; spruce or white pine, 30; creosoted yellow pine paving blocks, 65; paving bricks, 150; concrete, 150; bituminous concrete, 125; Trinidad asphalt, 140. **Waterproofing** (felt, roofing pitch, sand and road pitch) weighs 12 lb. per sq. ft. Street-car tracks about 100 lb. per lin. ft. Snow, freshly fallen, 8 lb. per cu. ft.; moistened and compacted, 15 lb. Weights of finished floors, exclusive of stringers and floor beams, vary considerably, from 30 to 100 (or more) lb. per sq. ft., and should be computed in each case.

14. Railroad Bridge Floors

In Open Floors of through bridges (Fig. 29) the ties rest directly on steel stringers, one or two of these being under each rail. The stringers are supported by the floor beams. In deck bridges the ties rest on the top flanges of the girders. In solid or ballasted floors the ties are embedded in stone ballast carried either by trough floors or by solid floors of buckled or flat plates, or reinforced-concrete slabs which are supported on I beams. The

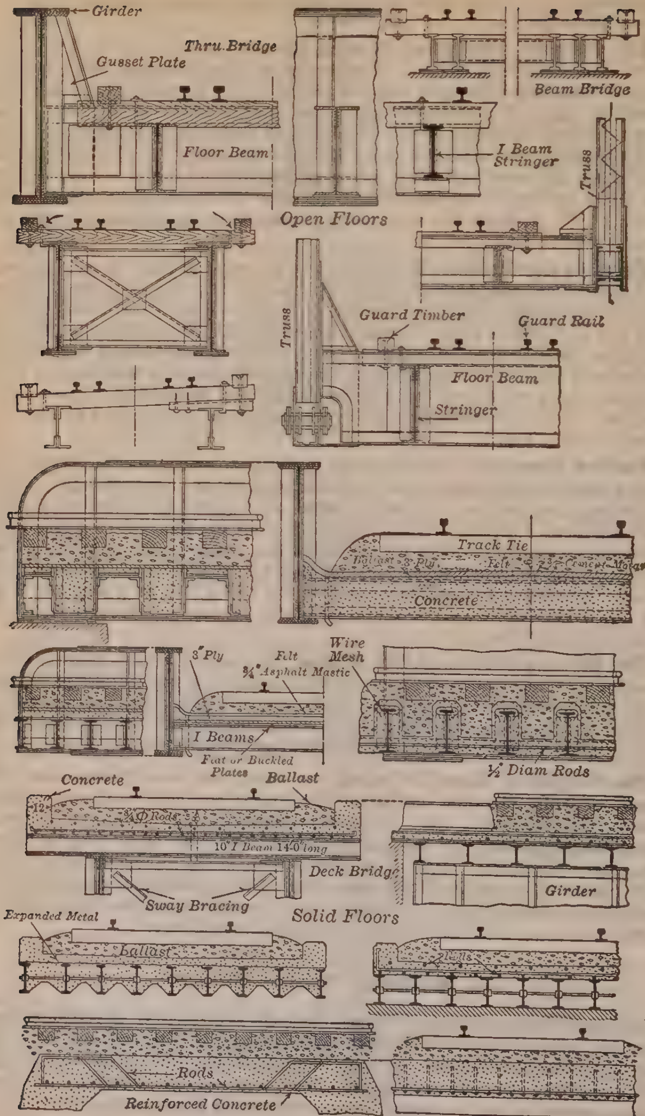

Fig. 29. Floors for Railroad Bridges

I beams for short spans run lengthwise of the track and rest on the abutments, while for long spans they are placed transversely and rest on girders or trusses. On tracks the guard timbers should be notched 1 in. over each tie, should be bolted to every fourth tie and at splices, and spaced at least 20 in. outside of the main rail. **Ties** should be not less than 8 by 8 in., by 10 ft. in length, should be spaced with not more than 6-in. openings, notched over the stringers 1 in. and secured to the same by hook bolts every third tie. Ties should be designed to carry the maximum axle load, with 100% impact, assumed as distributed over three ties with allowable unit stress not over 2000 lb. per sq. in. **Steel guard rails** are spaced 10 in. clear inside of each main rail and extend across the bridge 50 ft. beyond the abutments and around curves if any exist at the bridge. They should be spiked to every tie on the approaches and at least to every other tie on the bridge, and should be provided with a metal cap at the outer ends where they meet.

For Solid Floors troughs were first used to hold the ballast, but more recent bridges have the ballast carried by flat plates 3/8 or 7/16 in. thick riveted to I beams laid transversely to the track. The I beams are spaced 14 to 24 in. on centers, and in through bridges are connected to the girder webs and in deck spans rest on the top flanges of the girders with fascia girders or deep ∟'s along their ends to retain the ballast. The ties are spaced from 18 to 24 in. on centers and the guard rails and timbers are usually omitted. Buckled plates have been used instead of the flat plates; they are stronger and the I beams can be spaced 3 ft. apart, thus diminishing their number. Floors have been built by supporting the flat or buckled plates on the lower flanges of the beams and embedding the ties in ballast between the beams, but in this construction the I beams are almost entirely covered and cannot be inspected or painted without removing the track and ballast, so that best practice places the plates on the top of the I beams. Ties are usually 6 in. deep and have 6 to 8 in. of ballast underneath. Reinforced concrete is also used in place of the floor plates.

A Preservative should be placed between the ballast and steel of ballasted floors. A layer of asphalt-concrete not less than 2 in. thick is sufficient, and the upper surface of the coating should be sloped to allow for drainage. The asphalt should cover all steel parts which otherwise would be in contact with the ballast, and it should be applied only to clean, dry steel surfaces, and if the steel is cold or damp a layer of hot sand should be placed on it and swept off just before the asphalt is applied. The best results are obtained by first coating the steel with hot asphalt, then adding a layer of at least 1 in. of a mixture of one part hot asphalt and four parts hot sand and finally applying a 1/4-in. coating of hot asphalt sprinkled with sand. The layers are each tamped or ironed. Examination of steel surfaces thus treated has been made after 11 years' service and the steel found in good condition.

Stringers for through bridges are I beams or built-up beams; if the latter, the depth should be approximately 1/8 the panel length. When only one line is used per rail the stringers should be not less than 6 ft. 6 in. nor more than 8 ft. on centers, and if two lines are used per rail they should be spaced symmetrically about the rail and from 9 to 15 in. from its center. Sometimes the main stringer is placed under or near the center of the rail and an additional stringer of smaller size is placed outside near the ends of the ties. This outer is called a safety stringer. Deck plate girder bridges generally have no stringers, the ties resting on the top flanges.

Built-up Stringers are designed in the same manner as deck plate girders except that flange plates are not generally needed. Where flange plates are used the ties must be notched to fit over the rivet heads or else the rivets in the top flange plate must be countersunk. Unless the stringer is directly under the rail, flange ∟'s with unequal legs should be used and the long leg should be against the web, or else two rows of rivets must be used in the vertical leg. Placing the long leg horizontal increases the effective depth but also increases the bending due to the deflection of the ties. If the ratio of the length of top flange to its width exceeds 12, cross frames should be added to reduce the unsupported length.

In Proportioning the Cross-section of I-beam stringers or flanges of built-up stringers the **absolute maximum moment** (Art. 17) for the live load should be used and to it should be added the dead load moment at the middle. This is not exact but is on the side of safety and the error is very small. The following formulas are useful in computing the absolute live moments on stringers. They apply for equal loads spaced 5 ft. on centers, and since consolidation locomotives are generally used in design and since more than four wheels would rarely be on a stringer at a time, the formulas cover most panel lengths. There are four cases:

With one wheel on the stringer, $\mathbf{M} = 1/4\, \mathbf{W}l$;

With two wheels on the stringer, $\mathbf{M} = \mathbf{W}\,(2l - 5)^2/8l$;

With three wheels on the stringer, $\mathbf{M} = \mathbf{W}\,(3/4l - 5)$;

With four wheels on the stringer, $\mathbf{M} = \mathbf{W}\,(2l - 5)^2/4l - 5\mathbf{W}$;

where W = the weight on one wheel in pounds;
l = length of stringer in feet;
M = absolute maximum live bending moment in foot-pounds per rail.

With one or with three wheels on the stringer the absolute maximum moment occurs at the middle; with two or with four wheels the absolute maximum is at a wheel 1-1/4 ft. from the middle when the wheel spacings are 5 ft. as assumed above.

Floor Beams are ordinarily built-up beams riveted between the webs of girders or the posts of trusses. In connecting them to pin-connected trusses it is advantageous to place the beams opposite the pins even though this necessitates cutting away the lower corners of the beams (Fig. 29). In addition to its own weight, which is practically uniformly distributed, a floor beam is subjected to a concentrated load at each line of stringers. The distance between centers of girders varies, for different roads and for different girder depths, from 12 to 16 ft. on straight track. For double tracks the stringers are frequently placed 6 ft. on centers and the two girders 28 to 30 ft. on centers. The economic depth of floor beams is much larger than for stringers, but the economic depth usually cannot be used since in through bridges the floor must be kept as shallow as possible and the floor beams are frequently made only slightly deeper than the stringers. In through plate girder bridges a portion of each end of each floor-beam web plate is replaced by a gusset plate of the same thickness but having greater depth at the girder. These gussets extend to the top flanges of the girders to support the flanges laterally (Fig. 29). The gusset and web should be spliced with plates on each side of the web and with sufficient rivets to transmit the shear at the splice and to carry that portion of the moment that the web is allowed to carry. For deep girders the inclined edge of each gusset should be stiffened with two ∟'s. The lower flange of the floor beam should rest on the lateral connecting plate, which in turn should rest on and be riveted to the outstanding leg of the lower flange ∟ of the girder, but there must be sufficient rivets in the hitch ∟'s to carry all the floor-beam reaction into the girder web. The stringers should either rest on the lower flange of the floor beam or else on a small shelf ∟ to aid in erection, but neither the flange nor the shelf should be counted in computing the rivets required to connect stringers to floor beam.

If there is a flange plate on a symmetrical floor beam of a single-track bridge with two lines of stringers the length of the plate can be determined by applying the expression $\frac{2\,ba}{A} + c + 2$, which gives the total length of the plate in feet; b being the distance from girder to stringer and c the distance between stringers, both in feet, a, net area of plate in square inches, A, net area of bottom flange at point of maximum section plus 1/8 gross section of web in square inches. If there are two plates on each flange the above expression also holds for the length of the plate next to the ∟'s if the a is made to include the net area of the second plate as well as of the first.

For a uniform live and dead load the maximum load on a floor beam at a stringer connection is twice the maximum live and dead end shear on one stringer, the panels being all equal, but with a series of wheel loads this is not true. For wheel loads the position of the wheels to give maximum load on floor beam is the same as will give the maximum bending moment at the corresponding point on a span whose length equals the sum of the two adjacent panels. For an end floor beam the maximum load on the floor beam at a stringer connection is equal to the maximum live and dead end shear on one stringer.

15. Transportation and Erection

In Loading on Cars care must be taken not to get the steel so high that it will strike overhead obstructions. In some sections of this country the **clear head room** above top of rail is as low as 14 or 15 ft., but generally more room is available. Posts, chords and other similar members when piled on cars should be braced and bolted in position to prevent displacement. Wherever possible the length of a piece should be such as to overhang one car length by just a few feet.

Long Plate Girders require special attention in loading so that they will not be too high and will be free to ride around curves. They are loaded on flat cars, generally with their webs vertical, and supported at two points only. If a girder is longer than two cars one or more idler or spacer cars carrying no load are used between the end cars on which the whole weight of the girder is carried. Each support consists of a transverse bolster or sill made of one or two timbers laid on the floor of each end car and bolted to the same with one large bolt 2 or 3 in. in diameter, passing through the center of the sill and countersunk in its top. Under the center and each end of the sill is a steel track plate upon which the sill at one support can rotate and by means of a slotted pin hole can rotate or move longitudinally at the other support. The top flange of the girder is braced to the ends of the sills by inclined wooden braces, 6 or 8 in. square, connected together at the top by yoke plates passing over the top flange and connected to the ends of the sills by bent plates and bolts. The ends of the sills are tied to the bottom flange of the girder by diagonal rods, two or four rods being used at each support. For the heaviest girders steel gun-truck cars of 100 000 lb. capacity are used and the distance from top of a vertical girder to top of rail is about 5-1/2 ft. more than the depth of the girder. Girders as long as 125 to 130 ft. and from 9 to 12 ft. deep have been shipped as described above or with slight modifications.

In Designing the following items should be observed to facilitate erection. Avoid details which necessitate telescoping one member into another, as in top chords, connections of floor beams to girders and stringers to floor beams; swinging a member vertically or rotating it horizontally into place is much easier. Place shelf ∟'s or the equivalent on floor beams under all stringer connections where two stringers connect at the same point on opposite sides of the beam. All through spans should be designed so that either trusses and girders or the floor system may be erected first in final position. Avoid notching ties to clear rivet heads and laterals. Ship lateral plates loose or bolt them to members so they will not be bent or broken. Deep gusset plates on floor beams should be stiffened with ∟'s. Tack "loose" fillers with countersunk rivets. Allow clearances for drilling anchor-bolt holes in masonry and for setting the bolts after the steel is all in place. Top chord sections nearest the center should contain at least two panel points. Provide a separate bed plate for each shoe. In riveted bridges the gusset plate at the top of the end post should be shop-riveted to the end post. At pin-connected joints, tie plates should be kept far enough away from the joints and enough rivets should be countersunk to allow the members to swing in place.

The Erection of a Bridge consists in assembling its various parts to complete the whole. A **derrick car** is a car upon which a derrick or similar device is placed and operated, usually by power carried on the car. **Falsework** is the temporary steel or wooden supports upon which the final steel work is erected. A **traveler** is a steel or wooden frame with which the parts of the structure are handled during erection, and which is supported by and moves back and forth upon either the falsework as in ordinary truss bridges, or upon a portion of the finished structure as in cantilever erection. The traveler was formerly much used but is now seldom employed, derrick cars or locomotive cranes being used instead. Very high towers are often erected by means of a creeper derrick, which moves up the columns as the structure increases in height.

Girders and Small Trusses are Erected with gin poles, derrick cars, derricks or gallows frames. Where derrick cars are available they should be used, for with them a girder of ordinary size and weight can be taken from the cars, moved to the proper position and lowered upon its supports. A **gallows frame** consists of a transverse wooden bent guyed at the top and of such shape that a train can pass through it. A frame of this kind is placed at each end of a span and the cars carrying the girder to be erected is run out on falsework, or on an old bridge as the case may be, and the girder is raised from the cars with two tackles at each frame. The cars are then removed and the girder is lowered into position or is placed alongside of its final position and later slid laterally into place. A **gin pole** is a solid or framed pole guyed at the top with at least four guys and with its lower end resting on a support. They are set slightly inclined so that the upper end overhangs the load, which is lifted by hoist lines passing over a sheave at the top. Gin poles are useful for erecting simple girders, beams or small riveted bridge or roof trusses. A framed gin pole 146 ft. long was used in erection of a tower at Manitowoc, Wis., but ordinarily they are single masts 30 to 60 ft. long. Girders are sometimes put in place by blocking and jacks.

Falsework of wood consists of pile or trestle bents spaced from 10 to 50 ft. apart, although the distance apart should generally be equal to the panel length of the truss to be erected. Where piles can be used they make the best falsework and four or more are placed in a bent, the bents being braced transversely and longitudinally. If the height above water is only 10 to 20 ft. the piles are sawed off just below that height and capped, but for greater heights framed bents are built upon the piles, which are sawed off just above water level. Posts in framed bents should be 10 by 10 or 12 by 12 in. and bracings 3 by 10 or 3 by 12. In swift water the bents should be braced in pairs to form towers and the long openings between towers spanned with trusses. If piles cannot be driven the bents must be framed and rest on sills or small timber cribs to distribute the pressure over the bottom. Wooden stringers are bolted to the bents to carry the steel and the tracks for the traveler.

Stringers should be placed about one foot below level of steel to allow for blocking.

Arches, Cantilever Arms, and suspended spans of cantilever bridges are usually erected without falsework by building out, panel by panel, from fixed shore anchorages, anchor arms or adjacent fixed spans. Suspended spans of cantilever bridges are made temporarily continuous with the anchor and cantilever arms. Closure at the center is effected by means of a mechanical device, usually a toggle placed in the line of the chord in the panel at the end of the cantilever arm, or at the ends of the arch, which affords control of the position of the ends of the meeting trusses, both vertically and horizontally. After closure the suspended span is converted into a simple span by relieving one of the end horizontal members. In the case of the Quebec bridge, the 640-ft. suspended span was erected on barges in a sheltered cove several miles from the bridge, floated to the site and hoisted bodily into position. Similarly the 433-ft. suspended span of the Carquinez Straits, Cal., cantilever was lifted into place by means of counterweights.

Where Falsework cannot be used, simple trusses are sometimes erected as cantilevers by building out from either end, but in such cases the members must be specially designed to allow this. Bridges are sometimes erected along the shore and then floated out into position on barges. Long span simple trusses are sometimes erected upon falsework for the first few panels and continued as a cantilever for an equal or greater number of panels, the free end then being supported upon a temporary steel bent. The process of cantilevering and supporting, at intervals, the free end upon bents is continued until the opposite pier is reached. The falsework and temporary bents are then removed. This method was used in erecting the 400 and 600-ft. spans of the Hudson River bridge of the N. Y. C. & H. R. R. R. at Castleton. The 400-ft. span was erected first, the three easterly panels upon timber falsework, and the sixth and eighth panel points upon steel bents. The first four panels of the 600-ft. span were then cantilevered out from the 400-ft. span, used as a temporary anchorage, and later supported under the fourth, eighth, and tenth panel points upon steel bents. The two spans have 14 and 18 panels, respectively.

Paint for Steel Bridges. Parts of bridge members in contact should be given one coat of red-lead paint before being riveted together in the shop. All other surfaces should have one coat of raw linseed oil or one coat of red-lead paint before leaving the shop. After erection two coats of different colors should be applied, the last after the first is dry. Red-lead paint should be mixed 20 to 25 lb. red lead to one gallon raw linseed oil, although some engineers specify as much as 35 lb. per gallon of oil. Graphite paint, made by grinding 12.5 lb. graphite in one gallon linseed oil, is good for either the first or priming coat or for subsequent coats. For one short ton of structural material allow one-half gallon of paint for the first and three-eighths for the second coat.

BEAM AND GIRDER BRIDGES

16. General Arrangement

Beam Bridges are used for short spans up to 35 or 40 ft. in length both for railroad or highway and electric railway structures. They consist of I beams running parallel with the railroad or highway, resting at their ends on abutments and carrying open or solid floors in railroad bridges and plank or paved roadways for highways. The beams must be computed from their section moduli, but their depth for railroad bridges should not be less than 1/15 the span, for electric railway bridges not less than 1/20, and for ordinary highway traffic not less than 1/20. The following spacing of beams is desirable for **railroad spans** with open floors, that is, ties resting directly on the beams:

two I beams under each rail, 12 in. between webs and symmetrically under the rail with a safety stringer 2 ft. from each outermost track stringer. At each end and at center of the span channel braces should be riveted between the beams, and at intervals of 5 ft. channel separators should connect the two beams under each rail. For spans over 10 ft. diagonal braces should also be used. For double-track bridges there should be one safety stringer between tracks. For beam bridges with solid floors the I beams should be spaced apart 18 to 30 in., covered with flat steel plates and ballast, and should have braces at ends and center of span. For **highway bridges** the beams are spaced apart 2 to 3 ft. for wooden floors, and up to 5 or 6 ft. for concrete slab floors, and should be connected together at their ends with ∟'s or ⊏'s.

A Plate Girder is a beam made by riveting a flange, consisting of ∟'s alone or ∟'s and plates, along the upper and lower edges of a solid vertical plate called the **web**. Upright pairs of ∟'s called **stiffeners** are usually riveted to the web at the supports and at certain intermediate points. Plate girders are most suitable for spans between 25 and 100 ft., and even for spans as high as 125 or 130 ft. they make excellent bridges, expensive in first cost but low in maintenance charges.

Tubular Bridges were built by Robert Stevenson, who in 1850 completed the Britannia bridge in Wales and in 1859 the tubular bridge at Montreal, the latter being replaced in 1898 by a truss bridge. The Britannia bridge consists of two parallel independent wrought-iron tubes through which the trains run, each tube having two vertical solid webs connecting to top and bottom chords formed by a series of cells made of plates and ∟'s. Each tube is 15 ft. wide and from 23 ft. deep at the ends to 30 ft. at the center. There are two 460-ft. spans and two 230-ft. spans.

Deck Plate Girder Bridges usually consist of two girders under each track connected by two systems of lateral bracing, one in the plane of the top and the other in the plane of the bottom flanges, and by transverse sway frames at each end and at intermediate points from 15 to 20 ft. apart. For double-track structures the two inner girders should be connected together at the panel points of the top lateral systems by angle struts only without any transverse or lateral bracing between these inner girders. The two girders in single-track deck bridges are spaced 6-1/2 ft. for spans up to 60 ft., about 8 ft. for 120-ft. spans, and proportionate distances for spans between 60 and 100 ft. The deeper the girders the greater should be the spacing. For double-track spans having four girders, the tracks being from 12 to 13 ft. on centers, the inner girders should be 5-1/2 to 6-1/2 ft. apart respectively if the two girders under a track are 6-1/2 ft. apart. Deck spans having floor beams and stringers can be well arranged for single track by placing the girders 9 to 10 ft. apart and connecting the floor beams to the girders at such an elevation that the tops of stringers and girders are in one horizontal plane, the stringers resting on top of the floor beams and spaced 5 or 6 ft. apart. The ties are supported by stringers and girders, the latter serving as safety stringers in case of a derailment, and the stringers are held laterally to the girders by diaphragm plates, that is, vertical plates placed over the floor beams and between the stringers and girders. One lateral bracing system is used at the level of the lower flanges of floor beams.

Through Plate Girder Bridges generally cost more under the same conditions than deck, but they are used where head room under the bridge is essential as in the case of grade-crossing elimination. While for short spans the distance between centers of girders on single track may be as small as 12 ft., this distance is ordinarily 13 to 15 ft. For clearances see Art. 11. Double-track bridges may have two or three girders, the center girder carrying weight from both tracks. Panel lengths vary from 9 to 15 ft., the smaller value being used to secure shallow floor systems. Plate girders for deck spans have the upper corners square, but for long through railroad, and especially for through highway bridges, it is desirable to have them rounded to prevent accidents in the one case and for appearance in the other. The radius of the curve is usually made equal to the length of the bed plate.

Economical Depth for both deck and through girders varies between 1/6.5 of the span length, for short spans, and 1/12 for 125-ft. spans. The latter is not the most economical, but it is the greatest practical depth ratio. For spans up to 80 ft., expansion may be provided by sliding bearing plates. For longer spans, pedestals with pin bearing should be used at each end, and rollers at the expansion end.

Highway Plate Girder Bridges should have two girders for ordinary through spans, and for heavy construction with two sidewalks and one roadway three girders, and in extreme widths even more, are used. Where two girders are used in through spans they should be placed at the curbs to avoid interference with vehicular traffic, and for this same reason deck spans should be used if possible where the width of roadway necessitates three or more girders. The central girder of through bridges projecting up into a roadway interferes with traffic, and where two street railway tracks cross over the bridge the distance between track centers must be increased from the usual 9 or 10 ft. to 13 to 15 ft., thus making undesirable curves in the tracks. For deck spans the tops of floor beams are placed near the top of the girders and the stringers are framed between the floor beams. The **sidewalks** are carried on brackets riveted to the outside girder webs, and since the upper flanges of the brackets are in tension some provision other than tension on rivets must be made to transfer the stress into the floor beam upper flange. This is best done by connecting top of bracket to top of floor beam with a tie plate passing either through or over the main girder.

The Top Lateral System for deck plate girder railroad bridges should be a Warren truss with panel lengths as nearly equal to the distance between the girders as possible and with an angle strut at each panel point, thus making the slope of the diagonals about 45 deg. At alternate panel points the ∟ strut is the top bar of the cross frame, and this spaces the cross frames at the ends and at intermediate points at distances apart equal to twice the distance between girders. No ∟'s less than 3-1/2 by 3 by 3/8 should be used for bracing in railroad, nor less than 2-1/2 by 2-1/2 by 5/16 for highway bridges. For intermediate cross frames of deck bridges two horizontal and two diagonal ∟'s 3-1/2 by 3-1/2 by 3/8 are commonly used, while the end cross frames should be computed to carry the end reaction of the top lateral system. These end frames should have two horizontal ∟'s at top and two at bottom, with two diagonal ∟'s or [’s in each frame. All frames must be riveted to the horizontal lateral bracing plates and to vertical connecting plates which are riveted to stiffeners on the girders. The lower bracing for deck spans should consist of a Warren truss, the ∟ struts being omitted except where they constitute the lower members of the cross frames. For through single-track spans the lateral system should consist of two diagonal ∟'s in each panel riveted to plates which are connected to lower flanges of girders and floor beams; and if there are no end floor beams a strut should connect the stringers and girders together at each end of the span. The laterals are generally connected to the bottom flanges of the stringers. For through double-track railroad or through highway bridges the laterals sometimes run over two panels instead of one.

17. Girders without Floor Beams

Notation. V = shear at section of girder, V_0 = maximum positive live shear in end panel, M = moment at any section, M_C = moment at center of span, l = length of span, a = distance from section to right end of span, g = distance from center of span to any section, w = uniform dead load per unit of length, w_1 = uniform live load per unit of length, W = total load on span, D = increase in shear due to loads coming on span, p = panel length, n = number of panels to right of a given panel, m = number of panels in span, x = distance from resultant load on span to right support.

The Shear on a section is the algebraic sum of all outer forces or components of same acting on one side of and parallel with the given section; it is positive when the resultant force on the left is upward and on the right downward. **Bending moment**, or moment, at a section of a beam is the algebraic sum of the moments of all forces acting on either side of the section. It is positive when the resultant moment on left of section is clockwise and on the right is anti-clockwise, causing the beam to bend convex downward and hence causing compression in upper and tension in lower portion of beam.

Dead Load Shears. With uniform load over entire span the shear at any section distant a from right end is $\mathbf{V} = \mathbf{w}\,(\mathbf{a} - 1/2\,l)$. This is the equation of a straight line having for its ordinate at the left end of span the maximum positive shear of $wl/2$, and for the right end an ordinate of equal amount which is the maximum negative shear. Shear at center is zero. The above equation shows that the shear at any section is also equal to the amount of load between the section and the center of span. If an addition to the uniform load there are one or more concentrated fixed loads the shear at any section is found by subtracting from either reaction the loads, uniform and concentrated, between the reaction and the section, and the moment is a maximum where the shear passes through zero.

Dead Load Moments. With uniform load over entire span the moment at any section distant a from the right support is $\mathbf{M} = 1/2\,\mathbf{wa}\,(l - \mathbf{a})$. This is the equation of a parabola with axis vertical and vertex over the center of the span. The moment is positive at all points and is maximum when $a \doteq l/2$, in which case the maximum moment is $\mathbf{M_c} = \mathbf{w}l^2/8$; if w is in pounds per foot and the span l in feet M is in foot-pounds; where it is necessary to reduce this to inch-pounds multiply by 12, not by 144. If M_C is the moment at center and g is the distance from center to any point, the moment at that point equals $\mathbf{M} = \mathbf{M_c} - 4\,\mathbf{M_c g^2}/l^2$.

Live Load Shears and Moments. With a uniform load the maximum shear at either end occurs for full loading and may be found by use of above formulas for dead load shear. The maximum positive live shear at any point is $\mathbf{V} = \mathbf{w_1 a^2}/2\,l$, and occurs when the live load covers the portion of the girder to right of section. This is the equation of a parabola with axis vertical and vertex at right support. The maximum negative live shear at any section occurs when the left portion of girder is loaded, and may be found by calling a the distance from left instead of from right support. The maximum moment at any point occurs for full loading, and may be found by use of formulas for dead load moments.

Live Load Shears. With a single concentrated load the maximum positive shear at a given section occurs when the load is just to right of section and is equal to the left reaction; the maximum negative occurs when the load is just to the left of section and is equal to the right reaction. With a system of concentrated loads the maximum positive shear at any section occurs when one of the heavy loads is just to the right and most of the remaining loads are also to the right of the section. The problem of finding the greatest shear at a section A (Fig. 30) involves therefore first the location of the loads on the span to produce the maximum. Starting with first wheel at A, the shear will then be the left reaction; and if all the loads are moved to the left a distance d_1 until the second wheel is at A the shear is increased if $\frac{\mathbf{W}\mathbf{d}_1}{l} + \mathbf{D} > P_1$, (see Fig. 30). W is the total load on span at beginning of movement, d_1 the distance loads are moved, D is left reaction due to loads that may come on the right of span during the movement. This same relation holds for any other similar movement and for any section provided no loads leave the span during the operation. To apply to the end of span W must include all loads on except the one which is at the end and which therefore leaves the span during the movement. If $d_1 > l - a$, P_1 will leave the span when P_2 is moved to A, (Fig. 30), in which case the shear at A is greater when P_2 is there if $(W - P_1)d_1/l + D < P_1 a/l$. There is one more case to be considered. Suppose P_2 at A and P_1 on the span and that when P_3 is moved to A, P_1 leaves the span. Then the shear at A will be increased if

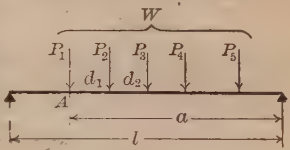

Fig. 30

$$\frac{(\mathbf{W} - \mathbf{P}_1)\,\mathbf{d}_2}{l} + \mathbf{D} + \mathbf{P}_1\frac{(l - \mathbf{a} - \mathbf{d}_1)}{l} > \mathbf{P}_2.$$

Minimum Shear at End of Span. Let it be required to find the maximum shear at the left end of a 40-ft. span with Cooper's E-50 loading (Fig. 23). Placing wheel 1 at the left end the total load on the span exclusive of 1 is 132.5, and moving the wheels 8 ft. to the left until wheel 2 lies at the end the shear at the end is increased, since $132.5 \times 8/40 + D > 12.5$. Moving the loads 5 ft. farther to the left the third wheel lies at the end, and the shear is decreased during this second movement because $140 \times 5/40 + D < 25$, the 140 being total load on span exclusive of wheel 2 when wheel 2 is at the end. Hence with wheel 2 at the end the maximum shear exists there and equals the left reaction or $65 \times 8/40 + 100 \times 32.5/40 = 94.25$ per rail. This shear may be obtained also with the aid of the **moment diagram** (Fig. 34) as follows. The moment of all wheels to the left of the right support about that support is 4370, and, deducting $12.5 \times 48 = 600$, there remains the moment about right support of all wheels that are on the span or 3770 thousand foot-pounds. Dividing this by the span length, 40, the left reaction or shear at left end is 94 250 lb. In the case of a Cooper or similar loading (where a light wheel precedes a series of heavy ones) it is unnecessary to apply the criterion for end shear, since P_1 never gives a maximum and P_2 usually does, the exceptions being unimportant.

Live Load Moments. For a single concentrated load P the maximum moment at a given section will occur when the load is at that section. With a system of concentrated wheel loads the **maximum moment** will occur at a given fixed section when there are as many loads on the span as is possible, consistent with the heavy loads being near, and one of the loads at the section; and this load must be such that when it is just at the right of the section the average load on the left must be less, and when just at the left the average on the left must be greater than the average load on the entire span. Usually several positions of the loads satisfy this criterion, in which case the greatest moment must be determined by inspection or by computing all cases.

The Absolute Maximum Moment is the greatest moment that can occur on a given span under a system of concentrated wheel loads. It will always occur at a wheel which lies at or near the center of the span and the criterion for its determination is as follows. When the center of the span is halfway between the center of gravity of loads on the span and one of the wheels near the center of gravity, then the moment under the wheel where the shear changes sign is a maximum and is the greatest which this combination of loads can produce on the span. When the center of gravity of loads on the span coincides with one of the loads the absolute maximum will occur at the center of span. The method of procedure is then: Assume some loads on the span so as to bring the heavy loads near the center and as many loads on the span as possible. Find the center of gravity of these loads and place the center of span midway between the center of gravity and the nearest load. If all the loads assumed on are now really on the span and the shear changes sign at this load, compute the moment at the nearest load just mentioned. If when the above assumed loads are placed in the position just cited some of the loads assumed on are really off the span, it is then necessary to try again, using a new resultant. Unless one can tell by inspection it is necessary to compute in this manner the moment at several of the wheels until the greatest possible moment is found. In Fig. 31 the maximum occurs at P_2 when the center of span bisects b and therefore $x = 1/2\ (l - b)$ and the expression for the moment at P_2 is

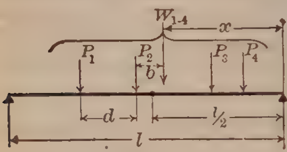

Fig. 31

$$M_2 = \frac{W_{1-4}(l-b)^2}{4l} - \Sigma Pd$$

where W_{1-4} is the resultant of loads on span and ΣPd is the sum of the moments of loads to left of P_2 about P_2. If now the dead load is to be taken into account with the wheel loading, the value of

$$x = \frac{1/2\ l - b(wl + W_{1-4})}{wl + 2\,W_{1-4}}$$

and the maximum moment accurs at P_2. It is however sufficiently accurate to compute the absolute maximum due to live load only as above stated and add the dead moment at the center.

The Exact Equivalent Uniform Live Load, obtained from Art. 10, may be employed conveniently to obtain maximum moments and shears due to a Cooper loading. For maximum moment at a section of a girder, the equivalent uniform load q may be obtained from the chart, Fig. 25, by taking $l_2 = a$ and $l_1 = l - a$, the two segments into which the section divides the span length. The bending moment $\mathbf{M} = 1/2\ \mathbf{q}l_1l_2$.

For maximum positive shear $l_1 = o$ and $l_2 = a$. Instead of extending the chart to include values of q for $l_1 = o$, the latter are given in a separate table, Fig. 25a for the corresponding values of l_2. The q thus obtained is correct for end reactions, and $R = 1/2\ ql$; but for intermediate sections wheel 2 is presupposed to be placed at the section considered and the effect of wheel 1 is disregarded. The maximum shear at a section, upon the above assumption, is $\mathbf{V} = \dfrac{1/2\ \mathbf{q}l_2^2}{l}$. To correct for the effect of wheel 1 subtract $30\,000\left(1 - \dfrac{(l_2 + 8)}{l}\right)$ from the above value of V. This correction and the values of q in Art. 10 are based upon loads per track. For loads per rail divide by two.

For example, to find the maximum shears in an 80-ft. plate girder due to E-60 loading per rail; at the end, $l_2 = 80$, $q = 4657$, $R = 1/2\ ql_2 = 166\,300$; at the 1/4 point, $l_2 = 60$, $q = 4900$, $V = 1/2ql_2 3/4 = 110\,250$; at the 1/2 point, $l_2 = 40$, $q = 5655$, $V = 1/2\ ql_2 1/2 = 56\,550$. To correct for the effect of wheel 1 subtract $1/2 \times 30\,000$ $(1 - (l_2 + 8)/80)$ from the last two values of V or 2250 and 6000 lb. respectively.

18. Girders with Floor Beams

For Notation see beginning of Art. 17

Dead Load Shears. The uniform load here assumed is that due to the floor system only or, in the case of a truss bridge, due to floor system and weight of trusses; in other words, the dead load is assumed to act at the panel points only. For the shears and moments due to the dead weight of a plate girder itself the formulas in Art. 17 may be used. The panels are of equal length unless otherwise stated. The shear in any panel is

$$\mathbf{V} = \mathbf{wp}\,(\mathbf{n} - 1/2\,\mathbf{m} + 1/2)$$

where n is the number of panels to the right of the one in question. The maximum dead positive shear is in the left end panel; that is, when $n = m - 1$, and is $V_0 = wp\,(m - 1)/2$. This is of course equal to the gross left reaction minus the 1/2 panel load at the support. From this maximum positive value the shear decreases by **wp** for every panel towards the right, reaching a maximum negative shear in the right end panel.

Dead Load Moments. The moments at panel points are equal to the moments existing at the corresponding points on a girder without floor beams, and the moments between floor beams are slightly less than without floor beams. Without floor beams all ordinates are those of a parabola, while with floor beams only the ordinates at floor beams fall on a parabola.

Live Load Shears. The neutral point in a panel is that point at which if a single concentrated load is placed, and no other loads act on the span, the shear in the panel is zero. Every panel has a neutral point and its distance from the right end of the panel $= np/(m - 1)$. For maximum positive live shear the load must extend from the neutral point to right end of span, and for maximum negative shear from the neutral point to left end of span. The exact maximum positive live shear in any panel is $\mathbf{V} = \dfrac{V_0 n^2}{(m-1)^2} = \dfrac{w_1 p n^2}{2\,(m-1)}$. The exact equivalent uniform live load for Cooper's loadings for maximum positive live load shear in any panel may be obtained from the chart, Fig. 25 (Art. 10), by letting l_1 = the distance from the neutral point to the right end of the panel and $l_2 = a$ = the distance from the end of the panel to the right end of the span. The maximum negative shear for a given panel is the same as the maximum positive shear in the corresponding panel on the opposite side of center of span. The above is the exact method for finding live shears, but the approximate method is mostly used for uniform loads; this assumes that the full live panel load is applied to each panel point to the right of a panel to produce maximum positive live shear and that no load acts to the left of the panel, thus neglecting the one-half panel load which acts at the left end of the panel. By this method the maximum positive shear is $\mathbf{V} = \dfrac{w_1 p n\,(n+1)}{2m}$.

Live Load Shears. For maximum positive shear in any panel under a system of wheel loads most if not all of the loads should lie to the right of the panel and one of the wheels should be on the floor beam at the right end of the panel and this must be such a wheel that when it is just to the right of the panel the total load on the span must be more than m times the load on the panel, and when this wheel is placed just within the right end of the panel the total load on the bridge must be less than m times the load on the panel. If two or more positions satisfy this criterion the one giving the greatest shear may be determined by inspection, by computing the shear for all the positions that satisfy the criterion, or by computing the change in shear due to a movement of the load system. Thus in Fig. 32 to find the change in shear due to a slight movement suppose that the above criterion for panel A is satisfied by either wheels 1 or 2. Place P_1 at right end of panel A and move the loads till P_2 comes to that point; then if $d_1 < p$ the shear in A is greater for position 2 than 1 if $\dfrac{Wd_1}{l} + D > \dfrac{P_1 d_1}{p}$. If $d_1 > p$ but P_1 does not leave the span while the movement is taking place then the shear is increased if $\dfrac{Wd_1}{l} + D > P_1$. When P_2 is at right end of A and P_3 is then moved to that point the shear is increased if $\frac{Wd_2}{l} + D > \frac{(P_1 + P_2)d_2}{p}$, where $d_1 + d_2 < p$; and is increased if $\frac{Wd_2}{l} + D > \frac{P_2 d_2}{p} + \frac{P_1(p - d_1)}{p}$, where $d_1 + d_2 > p$ but $d_1 < p$ and $d_2 < p$. These expressions do not hold if a load leaves the span during the movement, but similar ones may be written for this case.

Live Load Moments. The criterion for determining the position of loads to give a maximum moment at a panel point is the same as if there were no floor beams, see Art. 17. Clearly the maximum live moment at a panel point next the end as B, (Fig. 32),

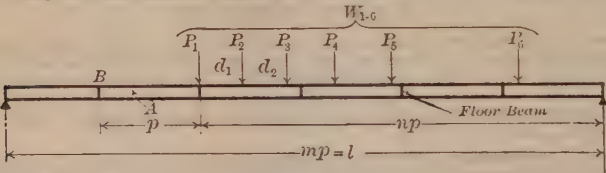

Fig. 32

equals $V_0 p$, and for any point in the end panel the maximum live moment is the maximum live shear in that panel times the distance from the end of span to the point in question. The criterion for maximum moment for a point within a panel such as C (Fig. 33) is $W_1 + \frac{W_2 q}{p} = \frac{W a_1}{l}$, where W_1 is the total load on panel to left of, and W_2 the total load on the panel in question.

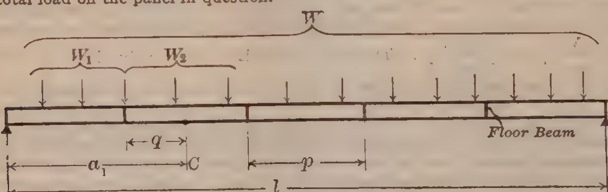

Fig. 33

The Moment Diagram (Fig. 34) aids in computing shears and moments. Its essential parts are weights and wheel spacings for a concentrated load system, distance of each wheel from the first, sum of all loads from the first

Loads are in thousands of pounds per rail

Fig. 34. Moment Diagram for Wheel Loads for Cooper's E–50 Loading

to each succeeding wheel inclusive, sum of moments about each wheel of all loads to the left of that wheel. The wheel spacings should be plotted to scale and the span lengths to the same scale.

To illustrate let it be required to compute maximum moment at center of a 40-ft. span, using the diagram in Fig. 34. The fourth wheel satisfies the criterion in Art. 17 and by inspection gives the greatest moment. To compute this moment find the moment of left reaction about center and deduct the sum of moments of wheels 1, 2 and 3. To do this find the moment of all wheels on the span about right support, 2693.75 + 145(1) = 2838.75 in thousands of foot-pounds; then divide this by the span, 40 ft., and multiply the quotient by the half span, 20 ft.; whence 1419.375 is the moment of left reaction about center. Subtract 600, the moment of wheels 1, 2 and 3 about wheel 4, and 819 375 ft-lb. is the moment at center of span.

19. Plate Girder Webs

Notation. M = bending moment, t = thickness of web, h = depth of web, V = vertical shear on web, S = allowable tensile unit stress, S_s = allowable shearing unit stress, S_b = bearing unit stress on rivets, S_c = allowable compressive unit stress, A = gross area of cross-section of web plate, d = horizontal distance between stiffeners, H = horizontal force on outside rivet in a vertical row, t_1 and h_1 = thickness and depth of web splice plate, M_r = bending moment carried by one row of rivets in web splice, M_w = net moment carried by web, p = pitch in inches, W = number of rivets in a row. Forces in pounds, dimensions in inches, moments in inch-pounds, stresses in pounds per square inch.

The Function of the Web of a girder is to resist the shearing forces acting on the various sections of the girder and also to carry some of the bending moment. The depth and thickness of a web plate must be such that its cross-sectional area will withstand the shear and buckling and at the same time give the girder an economic depth, that is, a depth requiring the least material in the girder. Girders are sometimes made with curved flanges, giving greater depths at the center than at the ends.

The Economic Depth of a Girder varies with the kind and amount of loads, the length of span and the allowable unit stresses. A common rule for girders up to about 40-ft. span is that the depth should be such as to make the weight of flanges equal to the total weight of web with its splice plates and stiffening angles and, in proportion as the span exceeds 40 ft., to make the weight of flanges greater than that of the web and its details. Unless limited by such considerations as headroom, girders having constant cross-section should be given a depth equal to 1/8 or 1/9 their length, and girders of variable sections 1/10 to 1/12 their length. For short built-up girders used as stringers the depth must generally be greater, more nearly 1/6 their length.

The Thickness of Webs must be such as to resist the shear at various sections and also to prevent buckling. The gross cross-sectional area of the web at any section is found by dividing the total shear by the allowable unit shearing stress. The required thickness for shear is $t = V/S_s h$.

Buckling of the Web. The horizontal and vertical shears acting in a web plate produce a tension and a compression of equal intensities on planes making an angle of 45 deg. with the neutral axis. This compression tends to buckle the web plate, and the web must be thick enough to withstand the buckling or else stiffeners must be riveted to the web to increase its compressive strength or, what amounts to the same thing, its shearing strength. Stiffeners are used over bearings, at points of concentrated loading and at other points where the width of the unsupported web between flange angles is greater than 50 times its thickness. These stiffeners are usually made of ∟'s riveted vertically to the web. Having found the required thickness for shearing from the formula just given, the proper **distance between stiffeners** must then be determined; and if the distance in the clear between stiffeners, d, comes equal to or greater than the clear vertical distance between horizontal angles the stiffeners are spaced equal to this vertical distance, with 6 ft. as a maximum. If d comes out very small so that stiffeners are required too close together, a thicker web should be chosen to reduce the number of stiffeners. The horizontal distance in the clear between stiffeners is given by $\mathbf{d} = \dfrac{(12\,000 - \mathbf{s})\mathbf{t}}{40}$, in which s is the average shear per square inch in the web at the section where d is desired.

The Minimum Thickness for Webs of plate girders in buildings is 1/4 in., for highway bridges 5/16 and preferably 3/8 in., and for railroad bridges not less than 3/8 for lightest traffic and 7/16 for heavy traffic. The thickness near the ends of heavy girders is sometimes greater than near the center, and the increase may be made either by riveting reinforcing plates on the sides of the main web plate or by using a thicker plate near each end. In the latter case thin fillers must be used between the flanges and the thin web plates. Webs as thick as 1 in. have been used, but ordinarily they are from 7/16 to 3/4 for railroad bridges, 5/16 to 7/16 for highway, and from 1/4 to 3/8 for buildings. Sheared plates may be obtained as wide as 10 ft., with lengths of 10 or 11 ft., and universal mill plates up to 4 ft. wide by 70 to 80 ft. long. Plates of great width or length are subject to special prices.

Intermediate Stiffeners (Fig. 42) used to stiffen the web of a railway plate girder vary from 3-1/2 × 3-1/2 × 3/8 in. for spans under 50 ft. to 6 × 4 × 3/8 in. for 100-ft. spans. By the A. R. E. A. Specifications the outstanding legs should not be less than 1/30 of the depth of the girder plus 2 in. For girders in buildings and highway bridges they are frequently made lighter. They should be used in pairs, one on each side of the web. In deck bridges intermediate stiffeners should be proportioned to carry the greatest wheel load in compression, should be connected to the web with sufficient rivets to transmit this load, should not be crimped, that is, not bent around the vertical legs of the flange ∟'s and should have outstanding legs as wide as possible and not extend over the edge of the horizontal leg of flange ∟'s. For through spans the connecting ∟'s at floor beams should have outstanding legs of at least 4 in., with rivets arranged so that floor beams may be placed without spreading girders.

End Stiffeners used to connect one girder web to another, as at junction of stringer to floor beam, must be capable of carrying the full end shear on a vertical section through the line of rivets. Where a girder rests upon a support as at abutments the end stiffeners (Fig. 42) usually consist of two pairs of ∟'s, one pair at the extreme end of girder and the other over the bed plate and about 1 in. from its inner edge. For girders with bearings arranged on rockers each pair of ∟'s should be proportioned for one-half the maximum end reactions, but for those resting on flat bearings each pair should be assumed to carry at least three-quarters of the reaction. Stiffeners at the ends and at points of concentrated loading should be proportioned as long columns, in which l is taken equal to one-half the depth of the girder in inches and r is the radius of gyration of the pair of stiffeners about their gravity axis lying in the central plane of the web plate. The outstanding legs should be as wide as the flange angles will allow and should fit tightly against them.

Thus, given an end shear of 319 500 lb., depth of girder 80-1/2 in., thickness of web plate 7/16 in., and thickness of fillers between stiffeners and web 3/4 in. Assume two pairs of 5 × 3-1/2 × 11/16-in. ∟'s with the 5-in. legs outstanding. The 3-1/2-in. legs are separated by the 7/16-in. web and the two 3/4-in. fillers, or 1-15/16 in. in all. For their combined section about the axis in the web r is 3.12 in. $\mathbf{S} = \mathbf{16\,000 - 70}\ l/\mathbf{r} = \mathbf{16\,000 - 70 \times 40.25/3.12 = 15\,000}$ (nearly). Required area = 319 500 ÷ 15 000 = 21.4 sq. in. The actual area of the 4 ∟'s is 21.5 sq. in. The number of rivets in double shear required to transfer the end shear from the angles to the tight fillers is 319 500 ÷ 14 430 = 23. The number used is 30, not counting those through the flange angles. The number of rivets in bearing on the web required to transfer the end shear from fillers to web is 319 500 ÷ 9190 = 35. The number used is 48, making the filler plates a rigid part of the web plate.

For intermediate stiffeners, 1/30 of the depth of girder plus 2 in. requires the outstanding leg to be 5 in. Accordingly each pair of intermediate stiffeners will consist of 5 × 3-1/2 × 3/8-in. L's. The spacing should not exceed 6 ft. nor be greater than $\frac{t\,(12\,000 - S)}{40}$, where t = 7/16 in. and S = total shear at section ÷ gross area of web. The exact position of the several pairs of stiffeners is governed by the location of the cross frames.

End Bearings. Expansion and contraction longitudinally due to changes in temperature must be allowed at one end of all spans, a range of 150° F. being the amount generally used. Taking the coefficient of linear expansion of steel as 0.000007 per degree Fahrenheit and a range of 150°, the expansion amounts to 1/8 in. for 10 ft. of length. Spans less than 80 ft. may have planed sliding bearings at one end (Fig. 42). For spans over 80 ft., long turned

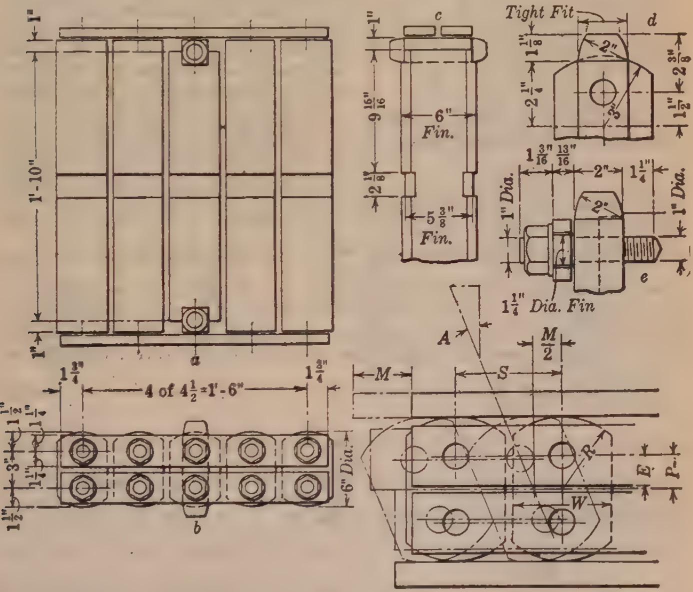

Fig. 35

rollers not less than 6 in. in diameter should be used and each end should rest on a rocker or bolster arranged with a pin to fix the point of application of the reaction. Allowable **pressure per linear inch of rollers** is variously taken at from 600 D to 300 D depending on whether impact is or is not allowed; D is diameter of roller in inches. **Bearing on Masonry** may be safely taken at from 400 to 800 lb. per sq. in. **Segmental rollers** as used for long spans are made by removing portions of cylindrical rollers as shown in Fig. 35.

Fig. 35 is typical of the 6-in. rocker nest of the American Bridge Co. To prevent sliding of the structure on the rollers or base plate, the ends of the middle roller are provided with vertical teeth which mesh into corresponding holes in the top and bottom plates. Lateral slipping is prevented by the groove at the middle of each roller, which exactly fits over a corresponding longitudinal projection left in the planed surfaces of the bearing plates. Fig. 35 shows the locking of rollers and side bars under an extreme longitudinal movement M. Let M = movement of bridge in either direction from the initial vertical position of rollers. Then $A = 28.7\ M/R$ in degrees. Sidebars will lock when $E = P \cos A$. Rollers will lock when $W = S \cos A$. Both will lock at the same time when $E/P = W/S$. W must not be less than M.

Web Splices. Girders over 40 to 50 ft. in length usually have their webs in two or more pieces, the web plates being spliced generally with one plate on each side of the web at each joint, and sometimes in addition thereto a plate riveted at each joint to the vertical leg of each of the four flange angles.

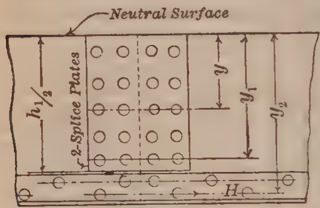

Fig. 36

Web plate splices should always be designed for moment, and when shear acts simultaneously it should likewise be considered, although generally when a splice is sufficient to carry the full bending moment of the net section of the web shear may be neglected. To design a web splice consisting of two plates (Fig. 36), one on each side of the web: (1) Make the two splice plates as deep as the vertical distance in the clear between flange ∟'s, and then compute their thickness so that the combined net moment of resistance of the two plates equals that of the web; but no plate less than 3/8 in. should be used. Thickness of each splice plate is $t_1 = \frac{th^3}{2\,h_1^3}$. (2) Next space the rivets in one vertical row uniformly if possible; if any uneven spaces are required place the larger spaces near the neutral axis of the girder. The pitch in a row should not be less than 3 and not over 4 in. (3) Compute the bending moment that one vertical row of rivets in the splice plates can carry, using $\mathbf{M_r} = \left(\frac{2\,\mathbf{H}}{\mathbf{y_2}}\right)\sum_0^{y_1}\mathbf{y}^2$, where H is the value of the outermost flange rivet in bearing on the web (Fig. 36) and $\sum_0^{y_1}\mathbf{y}^2$ is the sum of the squares of the distances from neutral axis to the rivets on one side of this axis only. (4) Compute the net moment of resistance of the web $= \mathbf{M_w} = \frac{\mathbf{Sth^2}}{8}$, S being the allowed unit stress in the tension flange. (5) The number of rows of rivets on each side of the joint is $\frac{\mathbf{M_w}}{\mathbf{M_r}}$. If the number of rows thus found involves a fraction of a row, as 2-1/2 rows, the rivet spacing in each row may be changed accordingly, or better, use only the full rows for each side of joint, two in this case, and place the splice at a point where the flanges have sufficient excess area to carry a moment equal to the difference between the net moment of the web and the moment of the two full rows. In case the splice cannot be so placed, then additional plates having a net area equal to that just mentioned should be placed on each flange.

With a uniform pitch, the bending moment a row of rivets will carry is given by $\mathbf{M_r} = \frac{\mathbf{Hp(N+1)(N+2)}}{6}$, where H is the horizontal force on the rivet farthest from the neutral surface and which is included as carrying moment. If H is in pounds, p inches, and N the number of rivets in one full row, then M_r is in inch-pounds.

20. Plate Girder Flanges

Notation. M = bending moment in inch-pounds, d_1 = distance in inches between center of gravity of flanges, S = allowable unit tensile or compressive stress in pounds per square inch, A = net area of cross-section of tension flange in square inches, t = thickness and h = depth of web, l = unsupported length and w = width of compression flange, p = pitch of rivets all in inches, V = vertical shearing force on girder, r = value of rivet in pounds, v = resultant shear per running inch of flange in pounds, W = maximum wheel load in pounds, v_1 = exact longitudinal shear per running inch of flange in pounds, m = statical moment in inch units, I = moment of inertia of entire cross-section of girder in inch units.

The Flanges of a beam or plate girder carry the greater part of the bending moment acting on the girder, and as they receive stress from the web they serve to prevent its deformation. One flange, usually the lower, is in tension and the other is in compression. The latter is a horizontal column receiving its stress from the web at points throughout its length, and held in a vertical direction by the web, and in a horizontal direction, usually, though not always, by bracing. The function of the flanges of a girder, then, is to carry moment and they must be designed for this purpose.

The Composition of Flanges varies in different girders and also usually at different sections of the same girder. For light loads or for short spans each flange may be made of two ∟'s alone (Fig. 37) or for heavier work two ∟'s with one or more horizontal flange or cover plates riveted to the outstanding legs of the ∟'s (Fig. 38). To secure larger cross-sections vertical flange

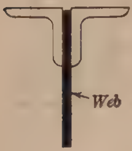

Fig. 37

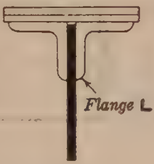

Fig. 38

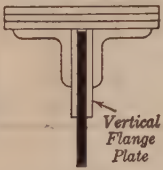

Fig. 39

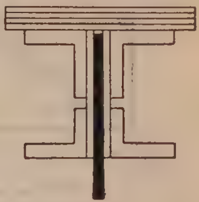

Fig. 40

plates between the ∟'s and web are used, and these plates are run the entire length of the span, while the horizontal flange plates are made of different lengths (Fig. 39). For heavy sections an arrangement such as is shown in Fig. 40 may be used for the top flange. In this case the lower flange is generally given the more usual section consisting of two ∟'s with cover and vertical plates (Fig. 39). Railroad bridge girders with over 150 sq. in. of gross cross-section in each flange have been built.

Proportioning Tension Flanges. The design of a flange (Fig. 42) consists in finding the required cross-section at the point of maximum bending moment, selecting proper sizes of ∟'s and plates and then finding the lengths of the plates. If the web could carry no moment the compression in one flange and the tension in the other would resist the full moment and would form a couple the arm d_1 of which is the distance between centers of gravity of the two flanges, and each flange stress would be $\mathbf{M/d_1}$. The flange stress divided by the allowable tensile unit stress S would give the required net area for the tension flange, that is, $\dfrac{M}{d_1S}$. But since the web does carry a moment $= \dfrac{Sth^2}{6}$ if there is no vertical row of rivets at or near the section considered, and approximately $Sth^2/8$ if there is, then the equivalent area, which if placed in each flange will carry the same moment as the web can carry, is $th/6$ or $th/8$ respectively. The correct required net area of the tension flange is usually based on the latter value and is $\mathbf{A} = \frac{\mathbf{M}}{\mathrm{d_1 S}} - \frac{\mathbf{th}}{8}$. In applying this formula care must be taken to use the proper numerical values. Thus if d_1, t and h are inches and S is pounds per square inch, then M is inch-pounds, and the result A will be square inches.

With following data, to proportion the cross-section of a tension flange: maximum M in foot-pounds = 1 500 000 live, 360 000 dead, 1 210 000 impact, total 3 070 000; web 84 by 1/2 in., distance back to back of flange ∟'s 84-1/2 in., maximum tensile stress, 16 000 lb. per sq. in. Assume the distance center to center of gravity of flanges, called the effective depth, as 83.0 in., then the required net flange area = $\frac{3\,070\,000\ (12)}{83.0\ (16\,000)} - \frac{84}{2\ (8)} = 22.5$. Two 6 by 6 by 5/8 ∟'s with gross area of 14.2 sq. in. have a net area of 14.2 − 4 (1) 5/8 = 11.7 sq. in., which deducted from 22.5 leaves 10.8 as the required net area of plates. Assuming plates 14 in. wide with two 7/8

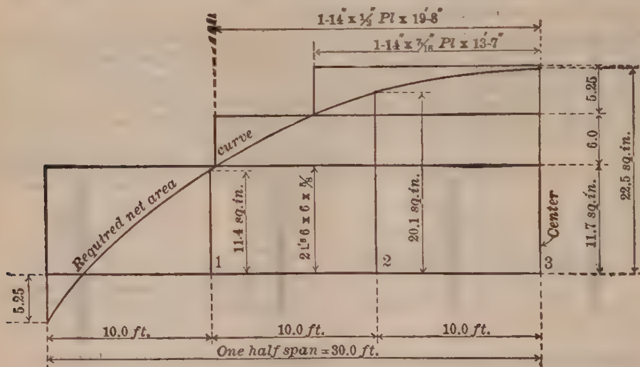

Fig. 41

rivets in one section the net width is 12 in. Required thickness for plates = 10.8/12 = 0.9 in. Hence one plate 14 by 1/2 and one 14 by 7/16 and two 6 by 6 by 5/8 ∟'s are to be used. In computing the net area of the two ∟'s the two holes for 7/8 rivets in each ∟ are taken as 1/8 larger in diameter than the rivet, namely 1 in.; similarly in the plates. The position of the center of gravity of this flange must be computed to check the effective depth, and if the assumed effective depth is in appreciable error the design must be revised.

The Compression Flange should not be of less and is generally of the same gross section as the tension flange. It is usually supported laterally at points with distance apart not exceeding 12 times its width. When the compression flange consists of angles, or of angles and flat cover plates, it is proportioned by the column formula, $S = 16\,000 - 150\ l/b$, where S = allowable unit stress on the gross section of the flange, l = unsupported length, and b = flange width.

Lengths of Flange Plates. Following is a graphic solution for a single-track through railroad girder bridge of 60-ft. span divided into 6 equal panels. By means of above formula for A compute the required net flange area at each of the panel points, 1, 2, 3 (Fig. 41), these being the points at which the live and dead moments are previously computed; suppose their net areas to be 11.4, 20.1 and 22.5 sq. in. respectively. Plot these values at points 1, 2, 3 to any convenient scale, such as 1/8 in. = 1 sq. in. For the horizontal scale 1/4 in. = 1 ft. is convenient. At the end lay off on opposite side of the horizontal axis the web equivalent, that is, $th/8$, here assumed 5.25 sq. in., and then draw a smooth curve through the four points located. Proportion bottom flange at point of maximum moment, finding the sizes of ∟'s and plates as described above, and, beginning at the horizontal axis, lay off first the net area of the two ∟'s, 11.7 sq. in., and then of each succeeding plate, placing the thickest plate next to the ∟'s. The half lengths of plates may now be scaled from the diagram, and to each half length should be added 1 ft. or enough to get in at least two rows of rivets. The plates on the top flange may be made the same length as on the bottom except that the one next to the ∟'s should run the entire length of the girder.

With a uniform load over span L and a uniform depth of girder the length x of any plate is $\mathbf{x = L\sqrt{a/A_1}}$, where A_1 is the total area of the flange at the maximum section plus the web equivalent, and a is the area of the plate being cut plus the areas of all plates outside of it. If there are several plates, a is first the area of outside plate; second, this plus the area of the next plate; third, these two plus the area of third plate.

The Pitch of Flange Rivets (Fig. 42) is the distance from the center of one rivet to the center of the next whether in the same row or not. In bottom flanges of deck girders and in both flanges of through girders the rivets connecting the flanges to web plates transmit longitudinal shear only, whereas these rivets in the top flanges of deck girders or stringers carry, in addition to the longitudinal, a vertical shear due to the pressure from the wheel loads and track. The required pitch for horizontal flange rivets which connect the flange ∟'s to the web in girders without loads on the top flange is, according to the usual approximate method, $\mathbf{p = rd_1/V}$, where r is the value of the rivet, namely, the bearing value on web plate or bearing on two ∟'s or double shear whichever is the least. If the rivets carry vertical loads in addition to the longitudinal shear, as in top flanges of stringers or deck girders, the resultant shear per running inch is $\mathbf{v} = \sqrt{\left(\frac{\mathbf{V}}{\mathbf{d_1}}\right)^2 + \left(\frac{\mathbf{W}}{\mathbf{36}}\right)^2}$, in which W is the maximum wheel load, here assumed distributed over 36 in. of flange length. And the pitch is $\mathbf{p = r/v}$. This approximate method for finding the pitch of horizontal rivets in flanges gives spacing slightly smaller than the true value and is on the safe side. The exact **longitudinal shear** existing between the flange and web or between the flange plates and ∟'s is $\mathbf{v_1 = Vm/I}$, in which m is the statical moment about the neutral axis of that part of the flange outside of the section on which the horizontal shear is desired, in other words, that part of the flange section which is connected to the remainder of the flange or to the web by means of the rivets the pitch of which is required.

In Spacing Rivets in Flanges the pitch is computed at intervals of from 2 to 5 ft. for stringers and deck girders, and the spacing is varied in accordance with those computed values. For through girders the pitch throughout any one panel is made constant since the shear is constant except for dead weight of girder. Vertical rivets which connect flange plates to flange ∟'s are generally given the same pitch as the horizontal rivets. The pitch can be computed by the above exact formula.

A Good Method for Finding Pitch of flange rivets is illustrated by the following modification of the above approximate method. Required the pitch of horizontal flange rivets at the end of a through girder having a web 60 by 1/2 in.; at the end each flange consists of two 6 by 6 by 1/2 ∟'s and one cover plate 14 by 1/2. Rivets 7/8 in. in diameter; bearing 24 000 lb. per sq. in.; shearing 12 000 lb. per sq. in. End shear including live, impact and dead, 200 000 lb. Effective depth 58.6 in. The gross area of two ∟'s and one cover plate is 11.5 + 7.0 = 18.5 sq. in. and including the web equivalent is 18.5 + 3.75 = 22.25 sq. in.; hence the longitudinal shear per running inch between flange ∟'s and web is **(18.5/22.25) 200 000/58.6 = 2850 lb.** The least value of the rivet is 7/8 × 1/2 × 24 000 = 10 500 lb., and the required pitch at end of girder is **10 500/28.0** = 3-3/4 in.

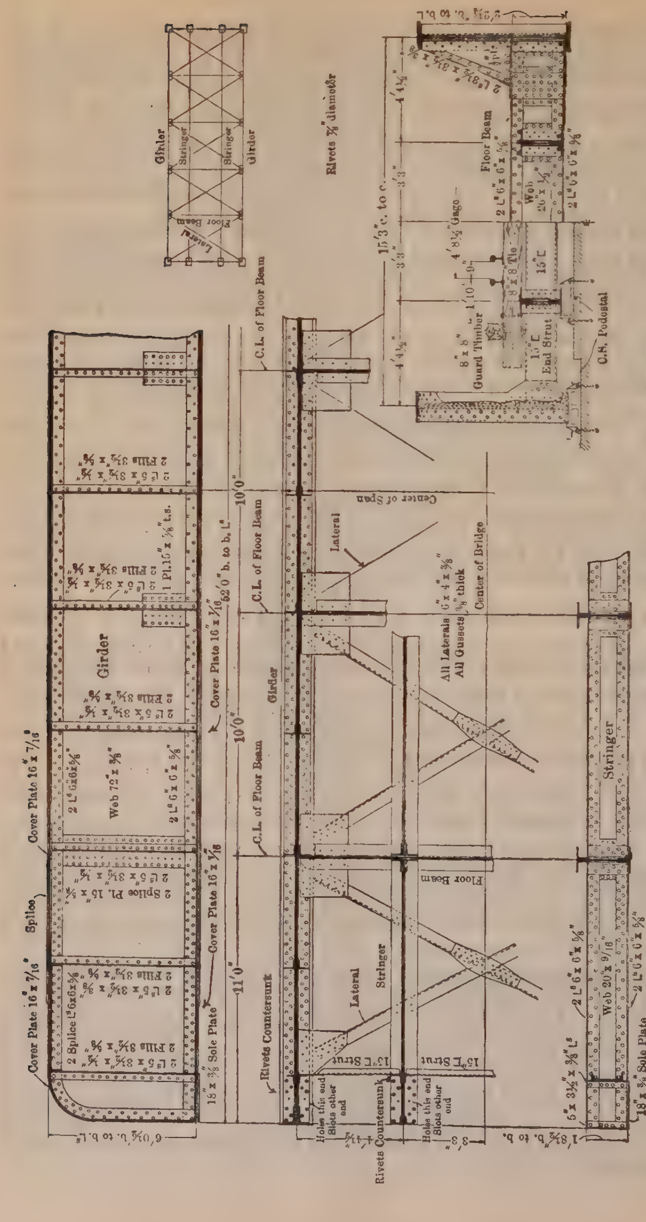

Fig. 42. Design of a Single Track Through Plate Girder Bridge

21. Riveted Joints

Notation. S_c, S_s and S_t are the allowable unit bearing, shearing and tensile stresses in pounds per square inch; d, diameter of rivet; l, end distance; t, thickness, and w width of main plate; all dimensions in inches; n, number of rivets on each side of joint.

Before being driven, a rivet consists of a shank, or cylindrical portion, and a head which may be either conical or nearly hemispherical, the latter form being called buttonheads. The process of riveting consists of heating the rivet and while it is hot placing it in the hole and upsetting the shank end to form a second head. A countersunk rivet is used where it is desired that the head of the rivet must be flush with the surface of the part into which it is driven, but to secure a surface free from obstruction the countersunk head must be slightly chipped.

Lap Riveted Joints are shown in Figs. 43 and 44, the first being single and the second double riveted. Butt joints are shown in Figs. 45–48, those with two cover plates being better because of less bending in the rivets. Butt

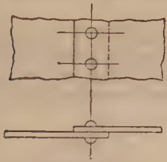

Fig. 43

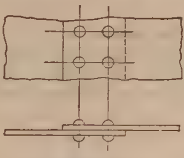

Fig. 44

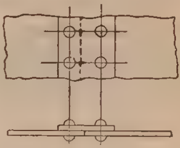

Fig. 45

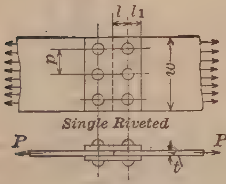

Fig. 46

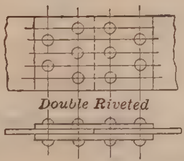

Fig. 47

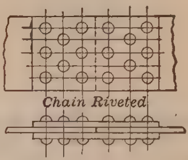

Fig. 48

joints with a single strap require twice as many rivets as lap joints to transfer a stress from the one main plate into the other. In lap joints, and in butt joints with a single strap or cover, the rivets are in single shear, while in butt joints with double covers all rivets are in double shear.

Design of Riveted Joints. In Fig. 46 the main plate has a tension of P and is spliced with two covers each of which must have a thickness of at least $t/2$, although usually each would be made from $2/3\,t$ to $3/4\,t$. There must be sufficient net area in the main plate on its cross-section through the row of rivets to carry the force P in tension, that is, $(\mathbf{w} - \mathbf{nd})\,\mathbf{tS_t} = \mathbf{P}$. The number of rivets on each side of the joint must transmit the force P in double shear, that is, $\mathbf{n} = \dfrac{2\,\mathbf{P}}{\pi \mathbf{d}^2 \mathbf{S_s}}$; or in bearing on the main plate, $\mathbf{n} = \dfrac{\mathbf{P}}{\mathbf{tdS_c}}$. The distances l and l_1, Fig. 46, must be sufficient to prevent shearing or tearing of the main plate and two covers respectively. For bridge work, rivets of 3/4 and 7/8-in. diameter are commonly used; for buildings, generally 3/4-in. The minimum pitched used for structural work is $3\,d$, and the minimum $\mathbf{l} = \mathbf{1.5\,d}$. Distance between rows in Fig. 47 should not be less than $\mathbf{2\,d}$. Bearing value of one rivet on plate having thickness $\mathbf{t} = \mathbf{tdS_c}$. Single shearing value of one rivet is $\dfrac{\mathbf{S_s} \pi \mathbf{d}^2}{\mathbf{4}}$.

The Efficiency of a Joint is the ratio of the strength of a given width of joint to that of a solid plate of equal width, and is usually expressed as per cent; for example, single-riveted lap joints show efficiencies of from 50 to 70% and double-riveted lap joints 60 to 80%. Joints with drilled or reamed holes show higher efficiencies than those with punched holes. Values of from 60 to 70% are what may usually be expected. By careful design the rivets may be arranged so that higher efficiencies may be obtained. Tests on full-size angles show that tensile strength on the net area varies from 75 to 90% depending on the arrangement of rivets and on whether or not both legs of the angles are connected to the end plates by which stress is transmitted into the angles. Both legs of angles should be riveted at connections. **Friction** between the main and splice plates in butt joints and between the two main plates of lap joints should not be relied upon, for although under quiescent loads it may continue to exist, it is uncertain and for movable loads it may be destroyed altogether.

The American Bridge Co.'s Standards show for button-head rivets: diameter of head 1-1/2 times diameter of shank plus 1/8 in.; height of head = 0.425 times diameter of head; for countersunk heads the slope is 30 deg. from axis of shank and the depth of head is 1/2 the diameter of shank. **Cambria Steel Company's standards** give for

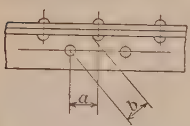

Fig. 49

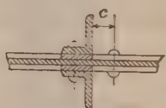

Fig. 50

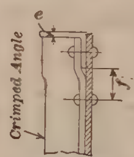

Fig. 51

button-heads: height of head = 6/10 times diameter of shank, radius of head = 3/4 times diameter of shank + 1/16 in.; for countersunk heads the diameter is the same as for button-heads and the slope is 30 deg. For required clearances see Figs.

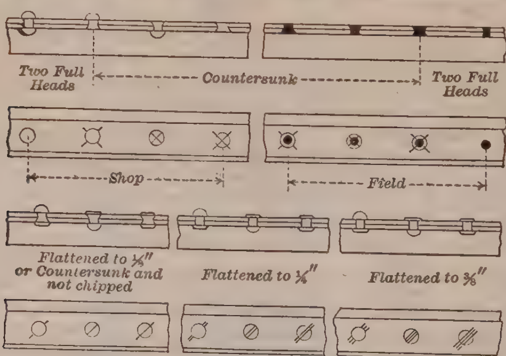

Fig. 52. Conventional Signs for Rivets

49, 50 and 51. In Fig. 49, a must be sufficient to make b at least 1-1/4 and 1-3/8 in. for 3/4 or 7/8 rivets respectively. In Fig. 50, minimum c is 1-1/4 and 1-3/8 for 3/4 or 7/8 rivets respectively. In Fig. 51 f is 1-1/2 in. plus 2 e but never less than 2 in.

Shearing and Bearing Values of Rivets in Pounds

Stress, lb. per sq. in.	Diam. Rivet in.	Value for Single Shear	Bearing Values for plate thickness in inches

22. Welded Joints

Welded Joints. The art of welding joints has, within the past few years, developed with great rapidity and may now be economically applied in repair work, in reinforcing old structures in the field, and in replacing difficult riveted connections both in shop and field. Growth in use for light industrial trusses and for joints in steel pipes is very rapid at present. It cannot yet compete, economically, with riveting for heavy building and bridge work. Elimination of the noise of riveting in cities is an important advantage which is causing an urge for the use of welding.

Welded joints are made by fusion, using either oxy-acetylene gas or an electric arc. The former, on account of the comparatively low first cost, is well adapted to repair work where the amount of welding is not large, but the high operating cost makes it less economical for large work. In electric welding the heat required to fuse the edges of the parts to be joined is produced by a sustained electric spark or arc formed between a metallic wire clamped to a negative electrode, held in the hand and guided by the operator, and the work itself, which forms the positive electrode. In the process the wire is melted and fuses with the adjoining edges of the parts, forming the joint.

Figs. 53, 53*a*, 54, 54*a* show four different kinds of weld. For the butt weld, Figs. 53 and 53*a*, the edge of two plates are butted together and the weld is made by depositing welding metal between the abutting edges. The edges of the plates may be scarfed either to a single or to a double weld. In the single and double welds, Figs 54 and 54*a*, a fillet weld is deposited along the ends of the plates, as shown. If one of the plates is narrower than the other, fillet welds may also be made along the side edges. Fillets are designated by the height of their sides, as 5/16, 3/8 in., etc. The strength of the weld is based upon the strength of the fillet per lineal inch. A working value of 2500 lb. per lin. in. of a 5/16-in. weld is equivalent to 8000 lb. per sq. in. of contact weld surface. Tests have been made by the Westinghouse Co. and other electric companies interested in the development of electric welding and it has beeen shown conclusively that it is possible to develop the full strength of the members joined. The Lincoln Electric Co., in "Arc Welding," 1926, publishes a chart which shows that for fillets varying in thickness from 1/8 in. to 9/16 in. the rupturing force ranges from 5000 to 20 000 lb. per inch length of weld, respectively, in direct tension, Fig. 53; 3000 to 14 600 lb. in single shear, Fig. 54; and 2500 to 11 300 lb. in longitudinal shear when the fillets are placed along the side edges of the plate. These correspond to about 40 000, 25 000, and 20 000 lb. per sq. in. of surface of contact, respectively. With a factor of safety of 4, a 5/16-in. fillet in cross shear should have a safe strength of about 2000 lb. per lin. in. The application of the art of welding to industrial construction is too new for working stresses to have become standardized, but the American Welding Society and other national organizations, through their research committees, are seeking tangible data for use in structural design.

Fig. 53

Fig. 53a

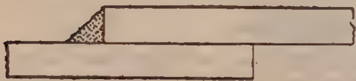

Fig. 54

Fig. 54a

The obvious economical **advantages of electric welding** are: Use of the entire gross section of tension members, since there are no rivet holes to be subtracted; less material for end connections, since webs of beams and girders can be welded direct to other girders or to columns without the use of connecting angles; use of outstanding plates instead of angles for stiffeners; and reduced cost of making shop drawings, since required welds can be indicated in a much simpler manner than can the location and spacing of rivets. In some cases, because of the fixed end condition of beams and girders due to the ability of end welds to take direct tension, it is possible to design such members as continuous girders in flexure, thus effecting some economy in material. On the other hand, the weight of welding wire electric consumed is considerable, amounting in the case of the Sharon, Pa., building to about one per cent of the weight of the structural steel. There is more difficulty in plumbing the framework and holding it in proper position during erection, since there are fewer connection angles to bolt to. Overhead welding is difficult and should be avoided.

A number of important structures have been erected by the all-welded process. As examples may be mentioned the five-story 70 × 220-ft. building for the Westinghouse Co. at Sharon Pa.; numerous shops and manufacturing buildings; the reinforcement of a railroad bridge across the Missouri River at Leavenworth; the addition of a second deck to a highway bridge across the Susquehanna River at Havre de Grace; and a skew railway truss bridge at Chicopee Falls.

SIMPLE TRUSS BRIDGES

23. Types of Trusses

Historical. The following are important steps in the development of American metallic truss bridges. The first iron truss bridge was built in 1840 over the Erie Canal by Earl Trumbull; some members were cast and some were wrought iron. In 1840 Squire Whipple built the first bowstring truss and in 1847 published the first work on stresses in bridge trusses; in 1852–53 he built a railroad span of 146 ft. on the Rensselaer and Saratoga R. R. which had the first double intersection trusses. In 1845 the first iron truss railroad bridge was built on the Reading R. R. by R. B. Osborne. In 1844 Thomas and Caleb Pratt patented the Pratt combination truss of wood and iron, and by 1850 Pratt trusses were made entirely of metal The first Fink truss in 1852 at Fairmont, W. Va., had three spans each 205 ft., with cast chord and wrought-iron diagonals. Longest Fink truss at St. Charles, Mo., built 1871, span

306-1/2 ft. First long Bollman truss built in 1852 at Harper's Ferry, Va.; span 124 ft. In 1858–59 John W. Murphy built for Lehigh Valley R. R. a Whipple truss with pin connections throughout, and in 1863 he first used all wrought iron compression and tension members in a pin-connected bridge with cast-iron chord blocks and pedestals. Howard Carroll began building riveted lattice trusses entirely of wrought iron on New York Central R. R. in 1859. In 1861 J. H. Linville first used wide forged eye-bars and wrought-iron web posts, the upper chords being cast iron. First Baltimore or Pettit truss 1871 at Mt. Union, Pa., designed by bridge department of Pennsylvania R. R. The first Post truss 1865; built by S. S. Post for Erie R. R. About 1870 C. H.

† Highway traffic. § Reconstructed in 1926

Parker modified the Pratt truss, using inclined upper chords, thus originating the Parker truss. Steel was first used 1874 in Eads' arch bridge at St. Louis. In 1879 first bridge was built entirely of steel at Glasgow over Missouri River. Pegram truss introduced by G. H. Pegram, 1887. The longest simple truss bridge is one of 720-ft span built over the Ohio River at Metropolis, Ill., in 1917; it has Pennsylvania trusses.

Types of Bridge Trusses are the Pratt (Fig. 59), Parker (Fig. 72), Warren (Figs. 60 and 63), Pennsylvania (frequently called Pettit) (Fig. 73). The Post, Bollman and Whipple are no longer built, and the Fink, in modified form, is used only for roof trusses. When the span is long enough to require subdivided panels, it is economical to curve the top chord, using the Pettit rather than the Baltimore type. In the Howe truss the verticals are in tension and the diagonals in compression. It was formerly much employed for wood, or combination wood-iron, bridges, but, like the Fink, is now principally used in roof construction. In the Pratt the verticals are in compression except the end suspender or **Hip Vertical**, *s* in Fig. 59, which is a tension member; and the diagonals are in tension except the two end ones called end posts. Pratt trusses are sometimes made with vertical end posts even in through bridges, in which case the diagonal in each end panel slopes downward toward the center and is in tension. The dotted bars in Fig. 59 are counters, or counter diagonals, and they come into action when the live load shear in the panel is greater than and of opposite kind from the dead shear in that panel. For greater rigidity it is better practice to omit the counter diagonals and to make the main diagonals in the panels requiring counter bracing, compression members. In Fig. 60 the dotted lines represent **sub-verticals** which are frequently used to reduce the panel length, and the short verticals and diagonals of the Baltimore truss (Fig. 68) are for the same purpose. The **collision strut**, *c* in Fig. 58, is used to brace the end post, but is now seldom employed. **Pratt** and **Warren** trusses, of riveted construction, are economical types for spans up to 150 to 200 ft. For spans larger than about 200 ft., the inclined or curved chord trusses with pin connections are most economical, and the Parker (Fig. 72) and Pennsylvania (Fig. 73) types are the best forms. For very long spans, necessitating great depth of truss and long panel length, the **Pettit truss** with subdivided panels is used. When a limited underclearance requires a shallow floor the economical lower span limit for this type may be as low as 300 ft., but under ordinary conditions it is generally much higher. The most recent type, suitable for long spans, is the K truss. It has been used for the 230-ft. span built by the Atchison, Topeka & Santa Fe Ry. across the Arkansas River at Pueblo, Colo. The webbing is arranged as shown in Fig. 70. Trusses of this type are economical only for spans of 300 ft. or over. The most notable use of this type of webbing is in the cantilever and anchor arms of the Quebec bridge. The chief superiority of the K type over the Pennsylvania is in the lower secondary stresses and in the avoidance of the use of the short horizontal struts required, in the Pennsylvania truss, to brace the vertical posts.

The Economic Depth of a Truss is that which makes the material in the bridge a minimum. It varies from one-fifth to one-eighth of the span depending on the form of truss, the length and number of panels and the allowable unit stresess. For short-span through bridges the minmum depth is fixed by the required clear head room. As the depth of a truss increases the weights of the chords become less and the weights of the web members greater, hence there must be a depth for each bridge for which the weight of material is the least. Ordinary spans of 250 ft. or less usually have depths of about one-sixth the span. Longer spans are generally relatively shallower in order to avoid excessively long web members and the increased cost of handling and erecting the deeper truss. The greater the live load and the wider the bridge the greater may the relative depth be made. In the 523-ft. spans of the Ohio Connecting bridge the center depth is 91 ft. or 1/5.75 of the span; in the 552-ft. spans of the Metropolis bridge it is 83 ft. or 1/6.65 of the span; in the 720-ft. span of the same bridge it is 110 ft. or 1/6.54 of the span; and in the 640-ft. suspended span of the Quebec bridge it is 110 ft. or 1/5.82 of the span. End depth of trusses is fixed by the clearance plus depth of portal, which latter increases with the length of span. The parabola gives a satisfactory curve for the chord.

The Economic Length of Panel is more or less independent of the truss depth since in the longer spans, subdivided panels may be used, whereas for the shorter trusses without subdivided panels there is a practical advantage in the use of long panels, inasmuch as the heavier floor system is stiffer and freer from vibration. The inferior limit of span length for trusses with subdivided panels varies from 240 ft. for highway to about 300 ft. for railway bridges. Panel lengths for ordinary highway bridges vary between 15 and 25 ft.; for railway bridges between 25 and 40 ft. Panels are generally kept of uniform length. In the Municipal bridge at St. Louis the panel lengths vary from 30 ft. near the end to 48 ft. at the center of the span. By varying the panel length greater freedom in truss design is gained at the expense of greater shop cost of the floor system.

24. Stresses in Pratt Trusses

Notation. V = shear on a given panel, θ = angle between diagonal and vertical, W = live plus dead panel load, W_1 = live panel load, p = panel length, m = number of panels in span, n = number of panels to right of a given panel, M_n and M_{n+1} = moments at right and left end of a panel respectively, q = equivalent uniform live load, l = length of a bar, A = area of cross-section, E = modulus of elasticity.

Stresses in Bridge Trusses are determined graphically (Sect. 2) or algebraically; for the latter there are two general methods: that of moments and that of resolution of forces. The second method may be subdivided into method of joints and method of sections. The **method of moments** consists in passing a section through the truss so as to cut the bar in which the stress is to be found, then writing an equation of moments for all forces on one side of the section and solving this equation for the unknown stress. The **method of joints** consists in passing a section around each joint and finding the forces acting at each joint successively. In the **method of sections** a section is passed through the bar in question, and by applying to one side of the section either or both of the conditions that the algebraic sum of horizontal forces must equal zero or that the algebraic sum of the vertical forces must equal zero, the unknown stresses in the bars cut by the section may be found. To illustrate: consider the single-track through Pratt truss bridge in Fig. 74 having a dead load of 400 lb. per ft. for the track and 1000 + 10 L = 1000 + 10 (120) = 2200 lb. per ft. for the steel in the bridge; total 2600 lb. per ft. of bridge or 1300 × 20 = 26 000 lb. per panel per truss. Assume all on loaded chord. Live load 3000 lb. per ft. per truss or 60 000 lb. per panel per truss. Find maximum stress in bar 8 by method of moments; bar 2 by joints; and bar 5 by sections. The loads in Fig. 74 and the following computations are expressed in units of 1000 lb.

Method of Moments. For bar 8 pass a section vertically through 8 and consider forces on left of section. The origin of moments is at intersection of other two main bars cut, namely, at lower panel point 3. Maximum moment at 3 and therefore maximum stress in 8 occur for full live and dead load. $R_1 = 215$. Assume 8 in tension and place algebraic sum of moments of all forces on left of section a–a equal to zero; 215 (60) − 86 (20 + 40) + 24 $P_8 = 0$. $P_8 = -322.5$. The minus sign denotes that the stress is opposite to that assumed, and is compression.

Method of Joints. For bar 2 pass a section around lower end of 2 and consider the vertical forces acting upon the part below the section. Since the panel load is the only vertical force other than the stress P_2 acting on this part of truss the stress P_2 must be equal to this force; hence P_2 is maximum for full panel load and equals 86. It is tension since it acts away from the lower joint.

Method of Sections. For bar 5 pass a section vertically through 5. Imagine P_5 resolved into horizontal and vertical components, and since the algebraic sum of the outer forces on left of a–a, that is, the shear on the panel, together with the vertical component of P_5 equals zero, it follows that $P_5 = V \sec\theta$. For a truss having horizontal chords the vertical component of a diagonal is equal to the shear in the panel. When shear is positive P_5 is tension, and its maximum value occurs for maximum positive shear, which by the approximate method, Art. 18, paragraph 3, occurs when all panel points to right of the panel in question are loaded with live load and dead load covers whole span. Under this loading the positive shear due to 86 on points, 1, 2, 3 is 86 (1 + 2 + 3)/6 = 86, and the negative shear due to 26 on 4 and 5 is 26 (1 + 2)/6 = 13, hence maximum positive shear = 86 − 13 = 73 and maximum $P_5 = 73 \times 31.24/24 = 95.0$ tension. If negative shear occurs in panel 3–4, P_5 will be in compression, or if it cannot stand compression a counter as shown by the dotted line in panel 3–4 will be needed, and for symmetry one will also be needed in panel 2–3. For maximum negative shear place live load on points 4 and 5 only, then negative shear on panel 3–4 = 17, and P_5 will be 17 $\sec\theta$ = compression, or else a counter must be used, in which case maximum stress in counter = 17 $\sec\theta$ = tension.

For Concentrated Wheel Loadings the computation of stresses is the same in principle as with uniform or panel loads and the determination of the various moments and shears is simplified with the aid of the moment diagram (Art. 18). For trusses with parallel chords the maximum stress in a diagonal is the maximum shear on the panel containing the diagonal, multiplied by $\sec\theta$, and the maximum chord stress in a bar is the maximum moment about its origin of moments divided by the lever arm of the bar. For the verticals of trusses with parallel chords the maximum stress is the greatest shear on an inclined plane cutting the vertical and not cutting any diagonal in action for the loading producing the shear.

Let it be required to find maximum live load tension in diagonal 5 (Fig. 74) using Cooper's loading E–50 (Fig. 34). To produce the greatest shear the loads must lie partly on panel 3–4 and principally to right of 3, and the total load on the bridge must equal m (here 6) times the load on panel 3–4. Wheel 1 being small, place wheel 2 just to right of joint 3, then load on span is 215.0, which is greater than 6 × 12.5 = 75.0; now with wheel 2 just to left of joint 3, 215.0 is less than 6 × 37.5 = 225.0. Hence wheel 2 and joint 3 satisfies criterion for maximum shear in panel 3–4. With wheel 3 at joint 3 the criterion is also satisfied. Starting with wheel 2 at joint 3 and moving up the loads till wheel 3 is at joint 3 the shear is increased because 215 × 5/120 + 25 × 4/120 > 37.5 × 5/20, hence position 3 gives more shear than position 2.

Fig. 76 gives the influence lines for shear in the several panels of the truss of Fig. 74. An **influence line** shows the variation in a stress function, such as a moment, shear, floorbeam load or stress as a single load rolls across the structure. In Fig. 76 the triangles $0–3_1–g$ and $g–4_2–6$ are the influence diagrams for the positive and negative shears, respectively, in the panel 3–4. g is the neutral point in the panel; l_1, l_2 and l'_1, l'_2 are the segments of the positive and negative triangles, respectively. The position of the live load for

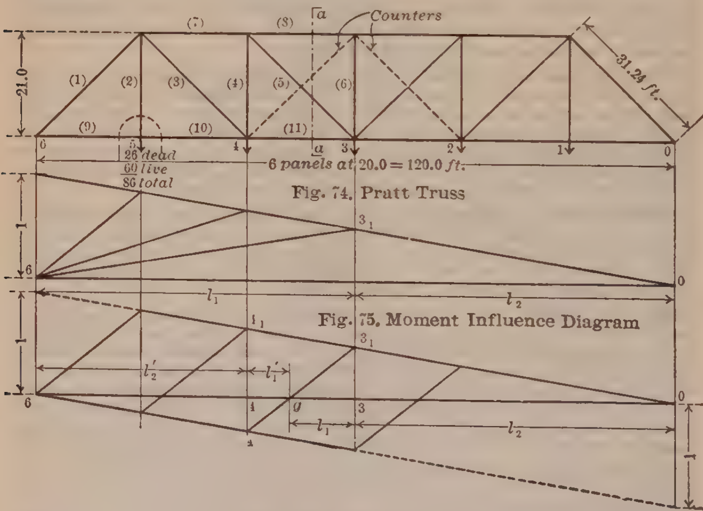

Fig. 74. Pratt Truss

Fig. 75. Moment Influence Diagram

Fig. 76. Shear Influence Diagram

maximum tension in the diagonal 5 may be obtained from the chart, Fig. 26 (Art. 10). The distance of the neutral point from joint 3 = $np/(m - 1)$ = 3 × 20/5 = 12 (Art. 18). Entering the chart for $l_1 = 12$ and $l_2 = np = 60$, it is found that wheel 3 should stand at 3.

The Shear in Panel 3–4 (Fig. 74) with wheel 3 at joint 3 = left reaction minus floorbeam reaction at 4. Using the moment diagram the shear = (8385 + 240 × 4)/120 − 287.5/20 = 63.5. Maximum tension in diagonal 5 = 63 500 sec θ = 63 500 × 31.24/24 = 82 700 lb. In this manner live load stresses in all diagonals may be found, and after adding impact and dead load stresses the diagonals can then be designed. The maximum stress in vertical 4 equals the maximum shear on the inclined section cutting bars 7–4–11. This occurs for the same loading, and is of the same magnitude as for maximum shear just found, hence compression in bar 4 = vertical component of diagonal 5 or 63 500 lb.

The shear in panel 3–4 can also be found by multiplying the corresponding triangular influence area, Fig. 76, by the exact equivalent uniform load obtained from Fig. 25 (Art. 10). This shear may be expressed by $V = 1/2 q l_1 l_2 / p$. Thus for maximum positive shear in panel 3–4, $l_1 = 12$, $l_2 = 60$. From Fig. 25 (Art. 10) the exact equivalent uniform load $q = 3600$ for E–50, and $V = 1/2 \times 3600 \times 12 \times 60/20 = 64\,800$. The small error is due to wheel 1, being 1 ft. in the negative area. Similarly the maximum negative shear $= 1/2 \times q'l'_1l'_2/p$, where q' is obtained from Fig. 25 for $l'_1 = 8$ and $l'_2 = 40$. Actual stresses are obtained by multiplying the shear by sec θ.

The hip-vertical bar 2 has a maximum tension equal to the floorbeam reaction and hence receives its stress only for loads on the two adjacent panels 4–5 and 5–6. The position of the loads must be the same as will cause maximum bending moment at center of a span of length 4–6, and after the loads are so placed the stress in bar 2 = $(M_4 - 2\,M_5)/p$, where M_4 is the moment about 4 of all wheels on distance 4–6 and M_5 the moment about 5 of loads on 5–6. This position can be obtained from the chart, Fig. 26 (Art. 10), by taking l_1 and l_2 each equal to 20 ft., the adjacent panel lengths. It is found that wheel 3 should stand at joint 5. The live load tension in the hip-vertical can be taken directly from the table in Art. 10. It is the maximum pier (or floor-beam) reaction for two adjacent 20-ft. spans and equals 81 900 lb.

The Moment Influence Lines are shown in Fig. 75, that for member 8 being 0–3_1–6, with the apex at 3_1 under the center of moments at joint 3. $l_1 = 60$, $l_2 = 60$. Fig. 26 shows that wheel 11 at joint 3 is the governing position for maximum moment. From Fig. 25 is obtained the equivalent uniform load $q = 3210$ for E–50. The bending moment for a triangular influence diagram is $\mathbf{M = 1/2\, q l_1 l_2}$. Whence $P_8 = 1/2 \times 3210 \times 60 \times 60/24 = 240\,750$.

The Moment at a Joint due to any load P standing anywhere on the span is equal to the product (called the load product) of the load and the influence ordinate at P multiplied by the distance of the center of moments from the left end of the span. If several wheels stand on the span the moment is equal to the algebraic sum of all of these products. For any series of wheel loads the position of the loading producing a maximum moment can be found by trial and is the one which makes the algebraic sum of the load products a maximum. The stress is equal to the sum of the load products multiplied by e/h, where e = the distance of the center of moments from the left support and h = the lever arm of the stress with reference to the center of moments.

25. Warren and Baltimore Trusses

Notation the same as that at beginning of Art 24.

To Compute Maximum Stresses for all bars of the Warren truss in Fig. 77, let dead panel load on each bottom chord joint be 20 (thousands of pounds) and live panel load 40. Place dead load of 20 at each bottom joint, and beginning at center and using method of joints write on each web member and then on each chord member a coefficient from which the true stresses for uniform full loading may be found. Since the truss is symmetrical each diagonal meeting at panel point 2 has a vertical component of 10.0 and this component or coefficient is written on the bar as shown. Then the joint at the upper end of this diagonal is considered and the vertical component or coefficient for the next diagonal (3) obtained, 10.0 in this case, and so on to the end where the vertical component of the end post should equal the reaction. By applying the method of joints to point 4 the horizontal component of P_7 is found to be 30.0 tan θ, so the coefficient 30.0 is written on the lower chord member; and similarly at joint 3 the actual tension $P = (30.0 + 30.0 + 10.0)$ tan θ = 70.0 tan θ and the coefficient 70.0 is written on the bar. All diagonal coefficients must be multiplied by sec θ = 22.36/20; all chord coefficients by tan θ = 10/20. Thus dead load stress in end post = 30 × 22.36/20 = 33.5 compression; and $P_7 = 30.0 \times 10/20 = 15.0$ tension. For live load chord stresses multiply dead chord stresses by ratio of live panel load to dead panel load. For live web stresses find maximum live shears by method of sections, Art. 24, and multiply these shears by sec θ. Thus for panel 3–4 maximum shear = 40 (1 + 2 + 3)/4 = 60; for panel 2–3, maximum positive shear = 40 (1 + 2)/4 = 30 and maximum negative shear = 40 (1)/4 = 10. The following table shows the final stresses.

Stresses for Truss in Fig. 77 in Thousands of Pounds

	P_1	P_2	P_3	P_4	P_5	P_6	P_7	P_8
Dead......	− 33.5	+ 33.5	−11.2	+11.2	−30.0	− 40.0	+15.0	+ 35.0
Live.......	− 67.1	+ 67.1	+11.2 −33.5	−11.2 +33.5	−60.0	− 80.0	+30.0	+ 70.0
Max.......	−100.6	+100.6	−44.7	+44.7	−90.0	−120.0	+45.0	+105.0
Min.......	− 33.5	+ 33.5	0.0	0.0	−30.0	− 40.0	+15.0	+ 35.0

− denotes compression. + denotes tension.

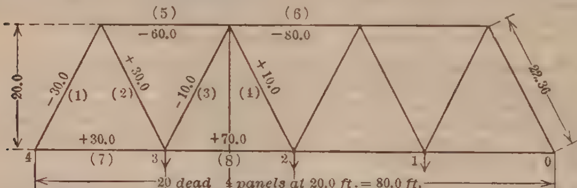

Fig. 77. Warren Truss

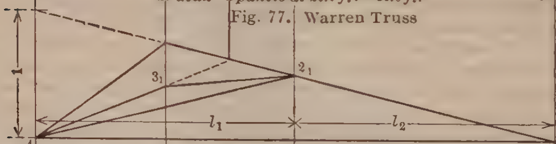

Fig. 78. Moment Influence Diagram

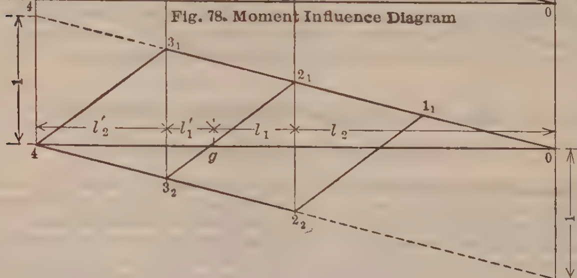

Fig. 79. Shear Influence Diagram

The influence lines for shears, (Fig. 79), and for moments at the loaded joints, (Fig.78), for the Warren truss, (Fig.77), are the same as for a Pratt truss of equal length and number of panels. For example, that for the moment for P_6 is $0–2_1–4_1$ (Fig. 78); l_1 and l_2 are the segments of the influence triangles; maximum moment $\mathbf{M} = 1/2\ q l_1 l_2$; maximum shear in a panel, $\mathbf{V} = \dfrac{1/2\ q l_1 l_2}{p}$. The influence line for moments about the unloaded joint opposite P_8 is $0–2_1–3_1–4$ (Fig. 78). P_6 and P_8 may be found by multiplying the respective influence areas by e/h, where h = depth of truss; e = horizontal distance from the center of moments to the left support (= 2 p for P_6 and 1-1/2 p for P_8). The charts, Figs. 25 and 26, apply exactly only when the influence diagram is a triangle. When the latter is not a triangle, as in the case of $0–2_1–3_1–4$ for P_8,

(Fig. 78), the charts may still be applied with sufficient accuracy by assuming a triangular influence diagram coinciding as nearly as possible with and having the same area as the actual influence diagram. l_1 and l_2 to be used in the charts are then the two segments of this triangle, and the governing wheel obtained from Fig. 26 stands at the loaded joint nearest the apex of the triangle.

The Baltimore Truss (Fig. 68) may have its sub-verticals and sub-diagonals arranged as in Fig. 80 or in Fig. 81 which represent panels without counters on left of center of truss. In Fig. 80 maximum $\mathbf{P_1} = \dfrac{\mathbf{Wp \sec \theta_1}}{\mathbf{(p + p_1)}}$ and is compression; if $p_1 = p$ (as is usual) then $P_1 = \dfrac{(\mathbf{W \sec \theta})}{2}$; in other words the vertical component of $P_1 = 1/2\ W$, as may be easily seen by studying the forces below the dotted section and taking moments at a. In Fig. 81, for members in action as shown, $P_4 = (W \sec \theta)/2$ and is tension. Maximum tension in P_2 (Fig. 80) occurs when live load extends from right end of span up to and including b, and if $p_1 = p$, $P_2 = (V - W/2) \sec \theta$. Maximum tension, P_3 (Fig. 81), occurs when the live load extends from right end of span up to and including c and $\mathbf{P_3} = \left(\dfrac{\mathbf{V + W}}{2}\right) \mathbf{\sec \theta}$. If n = number of panels to right of b (Fig. 80) or to right of c (Fig. 81), and m = number of panels in

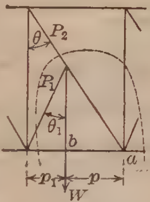

Fig. 80

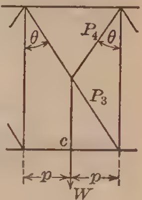

Fig. 81

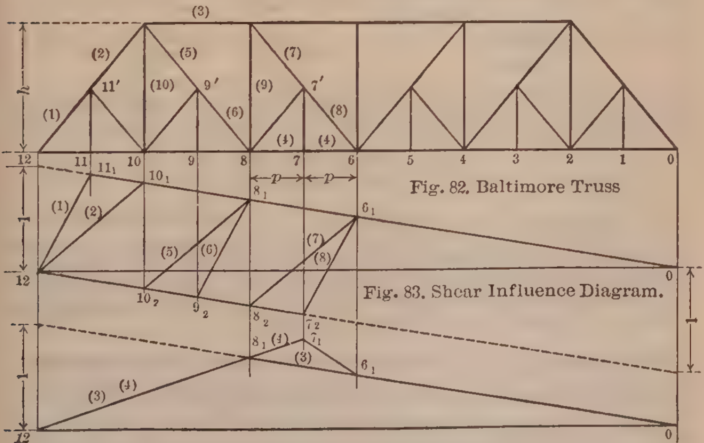

Fig. 82. Baltimore Truss

Fig. 83. Shear Influence Diagram.

Fig. 84. Moment Influence Diagram

the span, all equal, then maximum live load tension in P_2 and also in P_3 is given by the formula $\mathbf{1/2\ W} \left[\dfrac{\mathbf{n(n+1)}}{\mathbf{m}} - \mathbf{1}\right] \sec \theta$.

Influence lines for shears in the main web members of the Baltimore truss, (Fig. 82), are shown in Fig. 83, and for moments, in Fig. 84. Maximum live load shear in the upper diagonals (of type P_2, P_5), and in the vertical posts (of type $\mathbf{P_9}$) $= \mathbf{V} = \frac{1/2\, q l_1 l}{2p}$; that in the lower half of the main diagonals (of type P_1, P_6) $= \mathbf{V} = \frac{1/2\, q l_1 l_2}{p}$. For actual stress multiply by sec θ.

The influence line for moments about joint 8, for P_3, is $0 - 8_1 - 12$, Fig. 84. That for P_4 is $0 - 6_1 - 7_1 - 12$. Maximum live load stresses may be found by multiplying these areas by the equivalent uniform load q and by e/h; where e = distance from center of moments to the left support; h = depth of truss. $e = 4\,p$ for either P_3 or P_4. e/h = sec θ for all web members of a truss with horizontal chords. l_1 and l_2, for use in the chart, Fig. 25 (Art. 10), are the lengths of the two segments of the triangular influence diagram, or of the triangle approximating in outline and area the actual influence diagram (see also Warren truss, above). For all triangular moment influence diagrams $\mathbf{M} = 1/2\, q l_1 l_2$.

26. Other Types of Trusses

Notation the same as that given at beginning of Art. 24

Stresses in Trusses having Inclined Chords are found by methods of moments. Maximum chord stresses occur for full live and dead loads over entire span. Referring to Fig. 85, showing a through Parker truss, the maximum live and dead load stresses in upper and lower chord bars P_1 and P_2 are given by the following formulas:

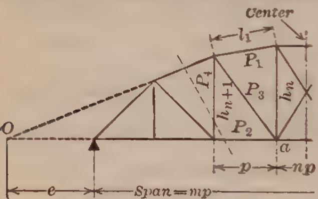

Fig. 85

$$P_1 = \frac{M_n}{h_n}\frac{l_1}{p} = \frac{W l_1 n(m-n)}{2\,h_n}$$

$$P_2 = \frac{M_{n+1}}{h_{n+1}} = \frac{Wp(m-n-1)(n+1)}{2\,h_{n+1}}$$

Maximum tension in P_3 occurs for live panel loads on all panels from right end of span up to and including a, with dead load over whole span, and

$$P_3 = \left(\frac{M_n}{h_n} - \frac{M_{n+1}}{h_{n+1}}\right)\frac{l_3}{p}$$

where l_3 is length of P_3, and M_n and M_{n+1} are simultaneous moments at right and left ends of panel respectively. Maximum compression in P_4 occurs for same loading as for maximum tension in P_3 and is found by methods of moments using all forces to left of dotted section with origin of moments at O. Some verticals in inclined chord bridges are in tension for certain positions of live load and these stresses must be computed.

Chord Stresses due to Wheel Loads are found by method of moments. For example, in Fig. 85 the maximum chord stress P_1 would be found by dividing the maximum moment at the origin of moments a by the lever arm of the bar P_1, that is, by the perpendicular distance from a to the bar. Instead of using the lever arm of the bar, however, it is often more convenient to use the arm of one of the components of the stress and then find the stress from the component. Thus in the case of P_1 its horizontal component $= \mathbf{M_a/h_n}$ and its stress $= \mathbf{M_a l_1/p h_n}$. The criterion for determining the position of loads to secure maximum moments is given in Art. 18.

Influence for Moments in the Parker truss, (Fig. 86), are similar to those for a Pratt truss and are not here shown. The influence line for a web member, (Fig. 87), is constructed by laying off h'_0/h_0 downward from 0; where h'_0 and h_0 are the vertical distances at the right and left supports, respectively, to the continuation of the top chord member cut by the section passing through the web member. For example, to find the stress in the diagonal 9 due to Cooper's E–60 a vertical section a–a through the diagonal also cuts the upper chord member 8, the continuation of which gives the vertical intercepts $h'_0 = 44$ ft. and $h_0 = 30$ ft.; $h'_0/h_0 = 44/30 = 1.467$. The influence line for P_9 is $0-4_1-5_2-7$. g is the neutral point in the panel. The distance $g-4 = l_1 = np/(n + (m - n - 1)\, h'_0/h_0) = 4 \times 28.57/(4 + 1.467 \times 2) = 16.5$. $l_2 = 4 \times 28.57 = 114.28$. From Fig. 25 (Art. 10), $q = 4020$. The area of the triangle $0-4_1-g-0 = 1/2 \times 4/7 \times 130.78 = 37.37$. The center of moments for P_9 lies 428.55 ft. to the left of the left support; the lever arm for P_9 about the center of moments = 393.7 ft. $e/h = 428.55/393.7 = 1.088$. $P_9 = 37.37 \times 4020 \times 1.088 = 164\,000$.

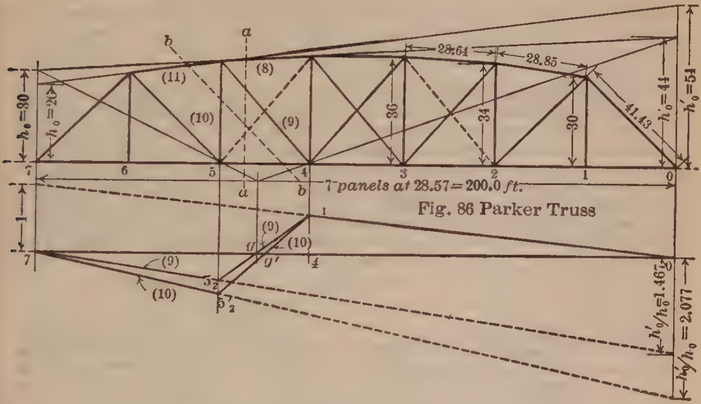

Fig. 86 Parker Truss

Fig. 87. Influence Diagram for Web Members

For the vertical 10, the section $b-b$ cuts the top chord member 11, and $h'_0/h_0 = 54/26 = 2.077$ which is laid off downward from 0, (Fig. 87), to furnish the influence line $0-4_1-5'_2-7$. The distance from the neutral point g' to the right end of the panel $= np/(n + (m - n - 1)\, h'_0/h_0) = 4 \times 28.57/(4 + 2.077 \times 2) = 15.6 = l_1$. $l_2 = 114.28 : q = 4030$. The area of the triangle $0-4_1-g'-0 = 1/2 \times 4/7 \times 129.88 = 37.11$. $e/h = 185.71/242.84 = 0.765$. $P_{10} = 37.11 \times 4030 \times 0.765 = -114\,000$.

The neutral point for a web member can also be found graphically. Thus, to find the neutral point g, for the diagonal 9, connect the tops of the end verticals, $h'_0 = 44$, $h_0 = 30$, with the right and left panel points, 4 and 5, respectively, at the ends of the cut panel. The vertical through the intersection of these lines gives g. To find g', the neutral point for the vertical 10, join the tops of $h'_0 = 54$, $h_0 = 26$, with 4 and 5 respectively, the ends of the panel cut by $b-b$.

Statically Indeterminate Trusses are those in which the stresses cannot be found by the principles of statics. Some trusses are statically determinate as regards the outer forces but are statically indeterminate as regards the inner forces or stresses. A **redundant member** in a truss is one that is not necessary for the stability of the truss. The condition that a truss is statically determinate is $\mathbf{b = 2\,j - 3}$, where b is total number of necessary bars, j the number of joints in the truss. The equation applies to the whole or any part of the truss. If $b > 2j - 3$ the system is statically indeterminate; if $b < 2j - 3$ it is unstable. Stresses in statically indeterminate trusses are found either by making the assumption that the truss is divided into its separate systems and that each system acts independently, or by the principle of least work.

The Double-system Warren Truss in Fig. 88, also called a lattice truss, is statically indeterminate because 26 bars > 2 (14) − 3 = 25. Assume the web to be divided into two systems as shown by heavy and light lines and let it be required to compute

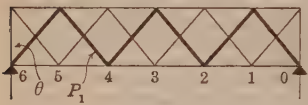

Fig. 88

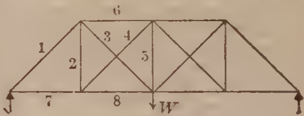

Fig. 89

the maximum tension in P_1 under a dead panel load of 6 and a live panel load of 12 thousands of pounds on the lower chord. Maximum positive shear on panel 4–6 of web with heavy lines occurs for live panel load on points 2 and 4 and stress P_1 = [(2 + 4) 18/6] sec θ.

The Principle of Least Work requires that the total internal work performed by the stresses in the members of a truss must be a minimum; hence an outer load acting on a statically indeterminate truss will be distributed on the different systems of the truss in such a way that the total internal work done by the stresses will be a minimum. **Work** is the product of force times its displacement. The work performed by a stress P on a bar having length l, area A, and modulus of elasticity E is **1/2 P^2l/AE** and total internal work in truss is **1/2 $\Sigma P^2l/AE$.** The truss in Fig. 89 carrying the load W at the center can be separated into two trusses as in Figs. 90 and 91, one with the force kW and the other with a force $(1 - k) W$ at the center respectively. The value of k

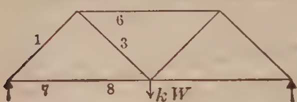

Fig. 90

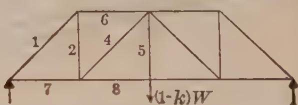

Fig. 91

must be such as to make the total internal work a minimum. The stresses in various bars of Fig. 90 and Fig. 91 in terms of the unknown loads **kW** and **(1 − k) W** respectively can be found and substituted in the formula. The differential coefficient of the work with respect to k is then placed equal to zero and solved for k. The final expression for k involves the dimensions of the truss and the areas of the bars. This process can be applied for a load of unity at each of the panel points in succession and a table of stresses prepared from which the stresses for any panel load may be determined. Since the areas of the bars must be known before the principle of least work can be applied, the process of design is a tentative one.

27. Design of Tension Members

Notation. S = allowable tensile unit stress, P = direct tension in a member in pounds, S_1 = maximum stress in pounds per square inch in eyebar due to combined tension and bending, t = thickness, l = length, and h = width of eyebar; all in inches.

Pin-connected Trusses were generally used in America until about 1890 for spans of all lengths. Since that date the **riveted truss** has come to be the standard for railroad bridges having spans less than 150 to 250 ft. The railroad bridge over the Missouri River at Kansas City has riveted trusses of 425 ft. 6-1/2-in. span. The longest riveted simple truss is the 720-ft. channel span of the Metropolis bridge. The 552-ft. spans of this same bridge are likewise riveted. For highway bridges the pin-connected type is often used for shorter lengths. Short pony trusses for country highway bridges are now invariably riveted, for greater lateral stiffness. The riveted structure is the stiffer form and the individual members thereof are more nearly free from objectionable vibration and rattling. The pin-connected truss usually is somewhat lighter than the riveted and can be more easily and more quickly erected. The ideal truss has hinged joints without friction. Neither of the types used fulfills this requirement, for as the truss deflects the rigidity of the riveted joints and the friction on the pins of a pin joint cause bending or secondary stresses in the truss members. The most complete analysis of secondary stresses that has as yet been made for any riveted truss is given in the paper " Stress Measurements on the Hell Gate Arch Bridge," by Dr. D. B. Steinmann, Proc. Am. Soc. C. E., Oct., 1917.

Tension Members may be eyebars or built-up sections. An **eyebar** has a uniform rectangular cross-section throughout the greater part of its length and at each end has a head or enlarged portion through which the pin passes. It is the most efficient means of transmitting tension and is economical of material but deficient in rigidity. Eyebars should not be used where the minimum stresses are light or where compression is possible, as in the first two lower chord panels, for hip verticals, or for diagonals subject to counter stress. Counters are sometimes used in light highway bridges and are composed of one or two adjustable eyebars or square rods with looped ends, but whenever possible adjustable bars should be avoided.

Built-up or Riveted Tension Members may be made in any of the forms suitable for compression members but less emphasis need be placed upon lateral stiffness. For light construction one ∟, or two ∟'s placed with their backs together, or separated to form a built channel (Fig. 92), or four ∟'s (Fig. 93), are used. In the last two cases the ∟'s may be separated by tie plates, but lacing or a solid web plate should be used for good work. For heavier construction some form of box section composed of rolled or built channels connected by lacing and tie plates (Fig. 94, 95) is used. The sections may be further enlarged by the addition of one or more side plates riveted to the web of each channel. In riveted trusses the flanges are often turned in to permit the member to go inside of the connecting joint gusset plates. In built-up tension members the rivets should be so placed as to reduce the section as little as possible. The net section will generally occur at the first row of rivets in a splice, end gusset or pin plate. In computing net sections the diameter of the rivet holes should be taken 1/8 in. larger than the nominal diameter of rivet.

Eyebars vary in size from 2 in. in width having a minimum thickness of 5/8 in. to 10 in. in width for usual construction, and even more for the largest structures; 16-in. bars have been used in several of the largest bridges, the maximum size used in the 668-ft. span of the Municipal bridge at St. Louis being 16 × 2-1/16 in. For wide bars the thickness rarely exceeds 2-1/2 in. Generally the ratio of width of bar to thickness lines between the limits of 4 and 7. If bars are made too thin their heads may buckle, due to the compression at the pins, and if made too thick the bending moments on the pins are increased unnecessarily. The dimensions of eyebar heads as given in steel companies' handbooks are such that the bars break in the body when tested to destruction. Eyebar heads are forged or upset in a die, and the net cross-sectional area through the pin hole is from 33 to 40% larger than that of the body. The heads are finished the same thickness as the body.

To Proportion tension members subjected to direct stress the required net area of the cross-section is P/S. For an eyebar under the tension P the maximum unit stress S_1 on the bottom fibers due to combined tension and bending caused by the weight of the bar is

$$\mathbf{S_1 = \frac{P}{th} + \frac{4\,700\,000\,h}{P/th + 22\,400\,000\,(h/\mathit{l})^2}}$$

28. Design of Compression Members

Notation. S = maximum or allowable unit stress, A = cross-section of a member, P = direct stress in a member, M = bending moment, c = distance from gravity axis to most stressed fiber, I = moment of inertia, l = length of column, r = radius of gyration of column, e = distance from center of gravity of cross-section to point of application of eccentric load, E = modulus of elasticity, w = weight of compression member per unit of length, I_D and I_C = moments of inertia of one ⊏ about gravity axis perpendicular and parallel to web respectively, A_1 = area of one ⊏, x = distance from back of ⊏ to center of gravity.

Compression Members should be proportioned, whenever possible, to be of equal strength about the two principal axes A–A and B–B (Fig. 94), if there is only direct compression in the member; and if there is transverse bending in addition, the strength about the axis around which bending takes place should be the greater. The cross-sectional area should be as far removed

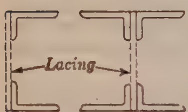

Fig. 92 Fig. 93

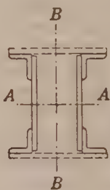

Fig. 94

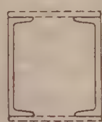

Fig. 95

Fig. 96

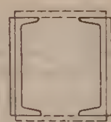

Fig. 97

from the center of gravity of the section as possible, consistent with proper thickness of materials and proper bracing of the different segments. Figs. 92 to 97 show typical sections of web compression members and Figs. 98 to 101 of compression chords and end-posts for bridge trusses, the smaller ones being suitable for light highway or railroad construction and the larger ones

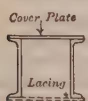

Fig. 98

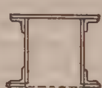

Fig. 99

Fig. 100

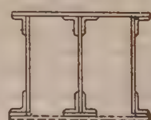

Fig. 101

for heavy work. All of the sections shown except the H-section in Fig. 96 require lacing or lattice bars to connect the segments together. In Fig. 99 and Fig. 101, flat bars are riveted to the lower ∟'s to keep the center of gravity of the section at or near the mid-height axis. Chord sections as in Fig. 99 are called **box sections,** the vertical plates are called **webs** and the upper horizontal plate is the **cover plate.** See also Art. 36. Compression members should not have l/r exceed 100 for main members nor 120 for laterals.

Short Columns are those having l/r less than 40; if the load is concentric, that is, applied at the centers of gravity of the end cross-sections or uniformly over these sections, the stress is one of simple compression distributed uniformly over the various cross-sections of the column, and the unit compression is $\mathbf{S = P/A}$. If the load is eccentric, that is, not applied at the axis of the column, the maximum unit stress is $\mathbf{S = P/A + Mc/I}$ and the minimum unit stress on the same section may be found from the same formula by changing the + to a − sign, using for c in each case the distance from the gravity axis to the maximum or minimum stressed fiber. $M = Pe$, where e is the eccentricity of the load, and I is the moment of inertia of the section about the axis through the center of gravity and $\perp$ to the plane of M.

The strength of a short column depends primarily upon the elastic limit of the steel and also in large measure upon the effectiveness with which its segments are tied together. The ultimate strength of a column never exceeds and is often considerably less than the yield point of the steel. The results of extensive tests made at the Bureau of Standards under the direction of the Special Committee on Steel Columns and Struts of the Am. Soc. C. E. (Final Report, Procs. Am. Soc. C. E., Dec., 1917) indicate that the elastic limit of columns made of carbon steel having a tensile strength of 60 000 lb. per sq. in. may be as low as 19 500 lb. per sq. in. This committee recommends 12 000 lb. per sq. in. as the maximum unit stress to be used when $l/r < 60$. The A. R. E. A. specifications permit the use of 12 500 up to $l/r = 50$, and the Am. Soc. C. E. specifications, 14,300 up to $l/r = 40$.

Long Columns are additionally weakened by their tendency to buckle in the plane of the maximum l/r. Their strength, for ordinary values of l/r, is affected by too many accidental and uncertain conditions to permit its expression by a rational formula. Two types of empirical formulas have been used, the straight line and the Rankine formulas. The former gives good results between $l/r = 50$ and $l/r = 240$, and it has been adopted by the A. R. E. A. (1925) in the form, $S = 15\,000 - 50\,l/r$, with a maximum value of $S = 12\,500$, for $l/r = 50$ or less. The Rankine formula also gives good results for $l/r > 40$, and approaches the Euler curve for very large values of l/r. It has been adopted by the Am. Soc. C. E. Committee in the form $S = 16\,000/(1 + l^2/13\,500\,r^2)$, with a maximum value of 14 300, for $l/r = 40$ or less. With the A. R. E. A. formula, $S = 9000$ for $l/r = 120$, $S = 10\,000$ for $l/r = 100$, $S = 11\,500$ for $l/r = 70$, $S = 12\,500$ for $l/r = 50$. With the Am. Soc. C. E. formula, $S = 7740$ for $l/r = 120$, $S = 9190$ for $l/r = 100$, $S = 11\,740$ for $l/r = 70$, $S = 13\,500$ for $l/r = 50$, $S = 14\,300$ for $l/r = 40$. The A. R. E. A. formula gives the larger unit stresses for the higher values of l/r, and the smaller unit stresses for the lower values of l/r. The two curves cross at $l/r = 76$ and $S = 11\,200$. On account of the deflection of structures and the distortions at the joints all columns are regarded as pin-ended.

For columns subjected to combined compression and bending, and for tension members under combined tension and bending, the maximum unit compression or tension is

$$\mathbf{S} = \frac{\mathbf{P}}{\mathbf{A}} + \frac{\mathbf{Mc}}{\mathbf{I} \pm \mathbf{P}l^2/\mathbf{a}_2\mathbf{E}},$$

in which a_2 is a constant depending on the condition of the ends and the kind of loading causing bending moment M. For members having hinged ends $a_2 = 9.6$ for uniformly distributed loading and 12 for a concentrated load at the middle; for members having fixed ends $a_2 = 32$ for uniform loading and 24 for a concentrated load at middle. The minus sign in the denominator must be used when P is compression and the plus sign when P is tension. This formula may also be used for members having eccentric loads, in which case M is the bending moment due to the eccentric loads and a_2 should be taken for a uniformly distributed loading.

Proportioning Top Chord. Let it be required to proportion the top chord of the 7 panel, 200-ft. typical pin-connected truss of the American Bridge Co., shown in Fig. 109.

The maximum compressions from dead, live and impact stresses are: $U_1U_2 = 870\,000$; $U_2U_3 = 980\,000$; $U_3U_4 = 978\,000$. The lengths are 28.85, 28.64 and 28.57 ft. respectively. The section for U_2U_3 will also answer for U_3U_4. Allowable unit stress $= 16\,000 - 70\,l/r$.*

* The A. R. E. A. Specifications, 1910 and 1920.

Design of U_1U_2. Let the chord be of box section as in Fig. 102. The least radius of gyration is approximately 4/10 the depth of the section which is here assumed to be 25 in., or $r = 10$. With $l = 346$ and a trial r of 10 the allowable average unit stress is 13 580 lb. per sq. in. A trial section must have 870 000/13 580 = 64 sq. in. The section shown in Fig. 102 with 66.44 sq. in. as determined below has its gravity axis $A–A$ above the mid-height axis $B–B$ a distance $d = 169/66.44 = 2.53$ in., 169 being the statical moment about axis $B–B$. $I_{A-A} = 6602 - 66.44 \times (2.53)^2 = 6177$ and radius of gyration about gravity axis $A–A = (6177/66.44)^{1/2} = 9.65$ and allowable

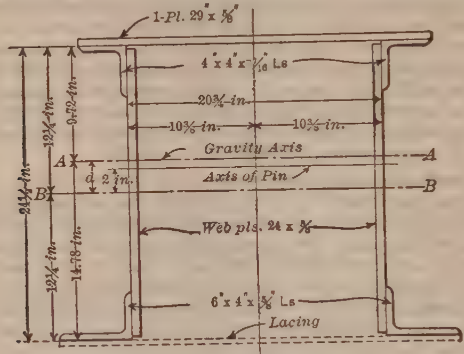

Fig. 102. Section Top Chord U_1U_2

average unit stress is 13 480 lb. per sq. in. The column has an actual average stress of 870 000/66.44 = 13 100 lb. per sq. in. and is therefore of sufficient size for the compression. The statical moment and moment of inertia about mid-height axis $B–B$ are found as follows:

	A	Stat. Mom.	I_{B-B}
1 Pl. 29 × 5/8	= 18.10 × 12.56 =	227.5 × 12.56 =	2862
2 ∟'s 4 × 4 × 7/16	= 6.62 × 11.09 =	73.5 × 11.09 =	815
2 ∟'s 6 × 4 × 5/8	= 11.72 × 11.22 =	− 132.0 × 11.22 =	1485
2 Pls. 24 × 5/8	= 30.00	00.0	1440
	66.44	169.0	6602

In this computation the moments of inertia of the ∟'s and horizontal plates about their gravity axes have been omitted. The radius of gyration about axis $A–A$ is less than that about the vertical gravity axis, and since $A–A$ is a principal axis, the radius used, 9.65, is the least radius of the section.

The center of the pin = 2.53 − 2.0 = 0.53 in. below axis $A–A$. The upward moment due to eccentricity = 870 000 × 0.53 = − 461 000 in-lb.; the downward moment due to the weight of the member = $wl^2/8$ = about 302 000 in-lb. The resultant moment = − 159 000 in-lb. and the additional compressive stress in the lowest fiber of the section is $S = Mc/I = 159\,000 \times 14.78/6177 = 380$ lb. per sq. in. The required sectional area = 870 000/(13 480 − 380) = 66.3 sq. in. Actual area = 66.4 sq. in.

Design of U_2U_3 and U_3U_4. The same section as for U_1U_2 will be used except that the web plates will be 13/16 in. thick instead of 5/8 in. By the method of computation employed above the following data are obtained: $I_{A-A} = 6534$; $r = 9.3$; $l/r = 37$; $S = 16\,000 - 70 \times 37 = 13\,410$; required area = 980 000/13 410 = 73 sq. in.; actual area = 75.48 sq. in.; $d = 2.24$ in. and the center of the pin = 2.24 − 2.0 = 0.24 in. below axis $A–A$. The moment from the weight of the member is 348 000 in-lb. and the resultant moment = 348 000 − 980 000 × 0.24 = 103 000 in-lb. The additional compressive stress on the upper fiber of the section is $S = Mc/I = 103\,000 \times$

10.63/6534 = 170 lb. per sq. in. The required sectional area = 980 000/(13 410 − 170) = 74.0 sq. in. Actual area = 75.48 sq. in. By the specifications the thickness of the cover plate must be at least 1/50 the distance between the rivets connecting it to the flanges = 1/50 × 25.25 = 0.50 in.; and the thickness of the web plate must be at least 1/40 the distance between the rows of rivets = 1/40 × 20 = 0.50 in. The sections chosen satisfy these requirements.

Proportioning Compression Vertical. Let it be required to proportion the vertical U_2L_2 composed of two ⊏'s (Fig. 103), carrying a maximum concentric dead, live and impact stress of 221 000 lb. The center of the pins is in the axis D–D. Assume two ⊏'s 15 in. 40 lb. having a combined gross area of 23.52 sq. in. and a radius of gyration for the two ⊏'s about a gravity axis perpendicular to the web of 5.4 in. l/r = 408/5.4 = 76; S = 16 000 − 70 × 76 = 10 680 lb. per sq. in. Required area = 221 000/10 680 = 20.7 sq. in. The ⊏'s are spaced 12.5 in. back to back. To make r about axis B–B equal that about D–D (Fig. 103), the distance z must be $x + \sqrt{(I_D - I_C)/A_1}$ which in this case is less than 12 in. If the flanges of the ⊏'s are turned outward z is the same as above except that x is negative. z may also be obtained directly from the Steel Co. handbooks. Since the floorbeam and the top strut reduce the unsupported length of the column for bending about the axis B–B, z may be less than this value for equal values of l/r. Axis D–D therefore decidedly governs in this present case. With flanges turned in as in Fig. 103 the distance in the clear between flanges should not be less than 2-1/2 in. if lattice bars are to be hand riveted nor less than 4 in., if machine riveted.

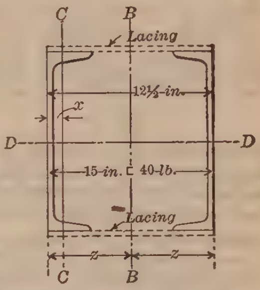

Fig. 103. Section Vertical Post U_2L_2

Inclined End-posts of Through Bridges are subjected to a direct compression from live, dead and impact stresses and also, at times, to a slight increased direct compression due to wind and to a considerable transverse bending due to wind in a plane perpendicular to the plane of the truss, these wind stresses being due to the action of the wind on the upper portion of the truss. The end-post is a part of the portal system and as such carries to the supports the wind pressure brought to the hip joint by the top lateral system. The cross-sectional area of the post must be such that the actual average unit stress P/A, due to live, dead and impact stresses shall not exceed that given by the column formula $\mathbf{P/A = 16\,000 - 70\ l/r}$,* where l is the length in inches between pin centers and r the radius of gyration of cross-section about the gravity axis parallel to the cover plate, as axis A–A, Fig. 102. The maximum unit stress on the outermost fiber due to live, dead, impact and wind stresses may exceed by not more than 25% the allowed axial unit stress; that is, for railroad bridges the maximum combined unit stress, S in formula below, should not exceed 16 000 + 25% of 16 000 = 20 000 lb. This maximum fiber stress due to axial compression, the tendency to buckle in the plane of the truss and the bending moment in the plane of the portal due to transverse wind forces is given with sufficient accuracy by

$$\mathbf{S} = \frac{\mathbf{P}}{\mathbf{A}} + 70\frac{l}{\mathbf{r}} + \frac{\mathbf{Mc}}{\mathbf{I}}\dagger$$

In this formula P must include the direct compression due to all loads,

* A. R. E. A. Specifications, 1910 and 1920. Changed to P/A = 15 000 − 50 l/r in 1925.

† A. R. E. A. Specifications, 1910 and 1920. With the 1925 specifications the middle term becomes 50 l/r.

including wind; c is 1/2 the extreme width of end-post, I is moment of inertia of section about gravity axis perpendicular to cover plate, l_1 is length of end-post from bottom of knee-brace to lower bearing of end-post; $\mathbf{M} = \frac{\mathbf{W}l_1}{4}$ or $\frac{\mathbf{W}l_1}{2}$ depending on whether the bottom of the post is fixed or is not fixed, l/r has the value used in the column formula for direction compression. The post may be considered as fixed at lower end if the end floorbeam is rigidly connected to it, or if the moment due to one-half the direct compression in post acting with a lever arm equal to the distance between bearings on the pin is greater than $Wl_1/4$. W is the total wind load in pounds acting at the hip joint including that brought to that joint by the top lateral system.

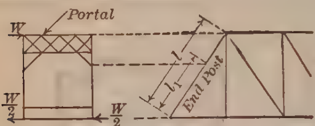

Fig. 104

If the weight of the member is also considered S will containan other Mc/I term in which M is the bending moment due to the weight of the post, c is the distance from the gravity axis parallel to the cover plate to the uppermost fiber, and I is the moment of inertia about the same axis.

Design of L_0U_1. The section of U_1U_2 will be used except that the web plates will be increased to 3/4 in. P = 873 000; l = 41.4 ft.; l_1 = 31.4 ft. By the preceding method of computation it is found that I_{A-A} = 6501; r = 9.5; l/r = 52.5; S = 16 000 − 70 × 52.1 = 12 325; required area = 873 000/12 325 = 70.7 sq. in.; actual area = 72.44 sq. in. d = 2.31 in. and the center of the pin = 2.31 − 2.0 = 0.31 in. below the gravity axis $A-A$. The negative moment from eccentricity = 873 000 × 0.31 = −270 630; the positive moment from its own weight = about 370 000, and the resultant moment = about 100 000 in-lb. The additional compression on the upper fiber = Mc/I = 100 000 × 10.88/6501 = 170 lb. per sq. in. The required sectional area = 873 000/(12 325 − 170) = 72.0 sq. in., which is less than the actual area.

It is necessary to test the section when the wind stresses are included. The wind load along the top chord is 200 lb. per lin. ft. W = 200 × 3 × 28.57 = 17 200; $Wl_1/4$ = 17 200 × 31.4 × 12/4 = 1 630 000 in-lb. The direct compression from dead and live load is 610 000 lb. and from wind 26 400 lb.; the distance between bearings on the shoe = 21 in. and the available moment of restraint at the shoe = 636 400 × 21/2 = 6 700 000. Since this exceeds the moment from the wind the end may be considered fixed and the point of contraflexure taken at the mid-point between pin and foot of knee-brace. The moment at the knee-brace likewise = 1 630 000 in-lb. Further, it is found that I_{C-C} (about the axis perpendicular to the cover plate) = 7600; c (to the extreme fiber of the bottom flange ∟'s) = 16.37 in.; l/r (in the plane of the truss) = 52.5; 70 l/r = 3675. The maximum unit stress upon the outer fiber of the lower flange ∟ (neglecting effect of weight of member and eccentricity, which is slight) is

$$S = \frac{873\,000 + 26\,400}{72.44} + 3675 + \frac{1\,630\,000 \times 16.37}{7600} = 19\,485 \text{ lb. per sq. in.}$$

Since this is less than the allowable 16 000 + 25% = 20 000 the section does not need to be increased on account of the wind stresses.

29. Design of Details

Notation. D = diameter of pin, S_b = allowable unit fiber stress for bending, S_c for bearing on pins, S_t for tension, S_s = actual average unit shearing stress on pins, t = required thickness for bearing of a built-up member, w = width of the widest eyebar on a pin, P = direct tension or compression in a member.

In Pin-connected Bridges (Fig. 109) there is at each joint a cylindrical steel pin which has at each end screw-threads upon which hexagonal nuts are placed, the Lomas nut, Fig. 106, being most common form. Cotter pins, Fig. 105, are seldom used. Pilot nuts, Fig. 107, and driving nuts, Fig. 108, are placed on pins to protect threads during erection. For ordinary trusses, pins with Lomas nuts vary from 2 to 9 in. in diameter, but pins of greater diameters are used for large trusses. In **packing,** that is, arranging bars on a pin, the bars should be packed as closely as possible, allowing clearances of 1/16 in. between two eyebars and from 1/8 to 1/4 in for built-up members; bars having horizontal components should be close together, similarly those having vertical components; bars should run parallel to plane of truss if possible and maximum deviation should not exceed 1/8 in. per foot, better 1/16 in. per foot; generally a bar with small stress should be on the outside; bars running in same direction should have a space of at least 1 in. between them.

Fig. 105

Fig. 106

Fig. 107

Fig. 108

To Determine Diameter of Pin after all joints of the truss are packed, assume the diameter, then compute thicknesses of reinforcing or pin plates for built-up members, and then, taking the forces as concentrated at the centers of the eyebars and at the centers of the bearings of built-up members, compute the diameter of pin to withstand the maximum bending moment. If this diameter agrees with the assumed diameter the maximum shear on the pin should be investigated; if not, the computation should be revised. Not more than one or two diameters should be used in a truss. The trial and final diameter of pin must be equal to or larger than $(S_t/S_c)\, w$ or otherwise the bearing on the eyebar is excessive. The value of S_t/S_c is often taken at 3/4. In designing pins to carry moments it is best to assume forces concentrated at centers of bearings, but in investigating the strength of an existing structure this assumption may in some cases lead to a resulting extreme fiber stress larger than the ultimate strength of the material in bending and yet the structure stands. In such a case if an assumption can be made which results in safe unit stresses throughout, the joint is safe. The total required thickness of a built-up member in bearing on a pin is $\mathbf{t = P/S_cD}$.

The **maximum bending moment,** M, at a section of a pin is the resultant of the moment at that section due to horizontal forces, M_h, and that due to vertical forces, M_v, or $M = \sqrt{M_h^2 + M_v^2}$. And the diameter of pin required to withstand this moment is $D = \sqrt[3]{10.2\, M/S_b}$. Tables showing bending moments of pins of various diameters are given in structural handbooks, so that the value of D can be easily taken from the tables as soon as M is known. The **maximum shear,** V, at a section of a pin is the resultant of the shear at that section due to horizontal forces, V_h, and that due to vertical forces, V_v, or $\mathbf{V = \sqrt{V_h^2 + V_v^2}}$. The shear is usually assumed distributed, in which case $\mathbf{S_s = 1.27\, V/D^2}$, but the intensity of maximum shearing stress on the neutral plane is $\mathbf{1.70\, V/D^2}$.

In Riveted Trusses (Fig. 114) the members are connected together at the joints by gusset plates which must be of sufficient size and thickness to transmit the stresses, and there must be a sufficient number of rivets in each member to develop its full strength. The stress is assumed to be equally distributed over the various rivets, hence they should be spaced with this in view. **Gusset plates** are frequently made too thin. They must be computed to carry the compression and tensile stresses brought on them by the main truss members, and as these stresses are frequently applied eccentrically to the gussets the eccentricity must be allowed for. In such cases as the lower chord joints of Pratt trusses the gussets must have sufficient net area along the horizontal row of

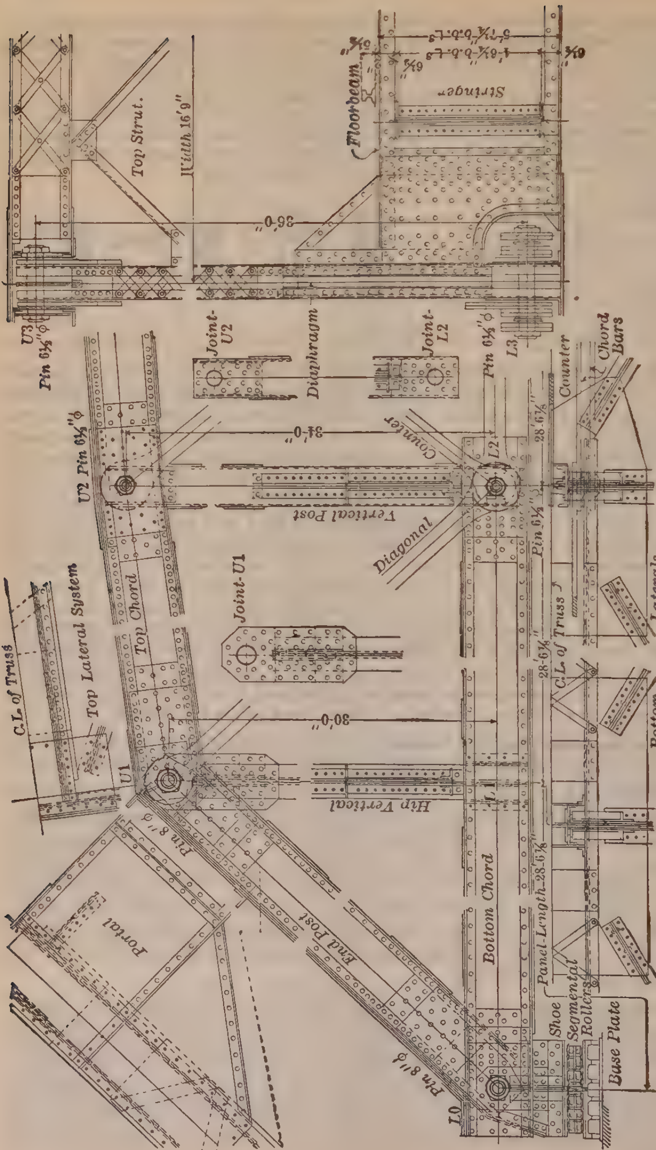

Fig. 109. 200-ft. Through Pin Connected Span

rivets connecting the plates to the chord to carry the shearing force on that section and similarly at the vertical row of rivets connecting gusset plates to the vertical. Ordinarily two gusset plates are used at each joint, although in light trusses only one is used. Center of gravity lines of all members should meet at a point, and the center of gravity of rivets connecting a member to a gusset plate should coincide with the center of gravity of the member.

Lattice Bars must be of sufficient strength to brace the segment of a compression member so that the segments will act as a unit and in doing this they are subjected to tension or compression due to shear resulting from the bending of the column. Formerly the design of the lacing of a column was largely a matter of judgment, but since the failure of the first Quebec bridge, by column shear, many attempts have been made to devise a rational formula. The best known method is based upon the analogy between the bent column, under axial load, and a beam of equal length and section and bearing a uniformly distributed transverse load of such an amount as to deflect the beam the same amount at its center, as the column is deflected under buckling action. The maximum end shear of the beam is assumed to be the maximum shear in the column. The Am. Soc. C. E. formula, $R = Pl/4000\,y$ (Art. 11), was obtained in this manner. About the only thing that is certain about maximum shear in a column is that it is equal to $P \sin\theta$, where P = axial load on column and θ = maximum slope of bent column to the originally straight axis. The A. R. E. A. specifications (Art. 11) assume a maximum value for $\sin\theta = .025$, corresponding to $\theta = 1.5$ deg. nearly. Maximum θ may occur either at the ends, in case of single curvature, or at either the ends or the center, in case of double curvature. The shear in the column is assumed to be carried equally by all of the lattice bars cut by a normal section, when the column is open on both sides; and half the shear is assumed to be so carried by the latticing when the column is open only on one side and a cover plate is used on the other. The stress in any bar is **V** cosec θ, where V is the shear carried by the bar, and θ is the angle which the bar makes with the axis of the column.

30. Deflection, Camber, and Bracing

Notation. P = direct tension or compression in a member, l = length of member, A = area of cross-section of member, E = modulus of elasticity, u = stress in member due to load of unity, L = span of truss, p = panel length, p_1 = increase in panel length, H = depth and R = radius of truss, c = camber of truss.

Deflection of a Truss may be due to elastic deformation of the members caused by stresses within them, to imperfect workmanship such as the play in pin holes of a pin-connected truss, and to deformation of the members caused by changes of temperature. The deflection in any direction of any joint of a truss due to any cause may be computed by the following method provided the change in length of each bar can be determined. Place a load of unity at the joint and acting in the direction in which the deflection is wanted and compute the stress in all bars due to this load; call this stress u; then the deflection is given by $\Delta = \Sigma u l_1$, where Δ denotes the deflection of the joint in the direction desired, and Σ denotes the summation of the various products of the stress u due to load unity by the change in length l_1 for each bar successively. The change of length l_1, in any bar due to a series of loads upon a truss is $\mathbf{P}l/\mathbf{AE}$, hence the deflection for this case is given by $\Delta = \Sigma \mathbf{Pu}l/\mathbf{AE}$. In applying this formula, tensile stresses should be given the positive sign and compressive stresses negative, both for stresses due to the loads on the truss and for the imaginary load of unity. If all the bars are of the same material the E may be placed on the outside of the summation sign. A is usually the gross area of the cross-section, even for tension bars. To find the **absolute deflection** of a joint with respect to its original position it is necessary first to find the vertical movement by placing the load of unity vertically at the joint, then the horizontal movement by placing it horizontally at the same joint, and the resultant of these two component movements will give the magnitude of the true deflection.

The **Camber of a Truss** is the distance the center of a chord is raised above the ends to allow for the deflection of the truss. It is usually expressed in inches and varies from 1/1000 to 1/2000 of the span length. Camber is used so that when the maximum load is on the bridge the truss will have the form assumed in the design, and is usually obtained by making the panel lengths of the top chords, or their horizontal projections, longer than the corresponding panels of lower chord in the proportion of 1/8 in. in 10 ft. Camber is sometimes made equal to the deflection due to full live and dead loading by increasing or decreasing the lengths of the truss members by amounts equal to their corresponding deformations. When the camber is made equal to this maximum deflection the radius, R, to which the lower chord of the truss is curved and the increase, p_1, in panel length of the upper chord are given with sufficient accuracy by the following formulas respectively:

$$\mathbf{R = L^2/8\,c} \quad \text{and} \quad \mathbf{p_1 = 8\,cpH/L^2}$$

Bracing for Deck Bridges usually consists of a horizontal truss in the plane of the top and also of the bottom chords, together with a vertical transverse system at each panel point. The transverse bracing is also called sway bracing, and the horizontal trusses are called the top and bottom lateral systems. The chords of the main trusses constitute the chords of the lateral system, and the floorbeams usually act as the struts of the top system. With a sway bracing at each panel point the bottom laterals are not really necessary, although desirable, and sometimes are omitted in all or in alternate panels, in which case the sway bracing must be designed to carry the wind loads from bottom to top panel points. When both lateral systems are used, the function of the sway bracing is to equalize the deflection of the trusses when the latter are subjected to unequal loading as when only one track of a double-track bridge is loaded. Since the wind loads on top and bottom panel points are unequal the sway bracing receives stress due to unequal lateral deflection of these points. The sway or portal bracing at each end of the bridge must be heavier than at intermediate points.

Through Bridges have top and bottom lateral systems and also have sway bracing at each top panel point extending down as low as the required head-

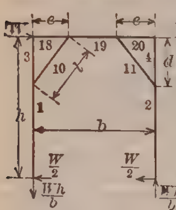

Fig. 110

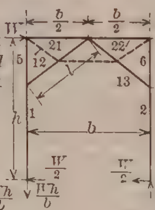

Fig. 111

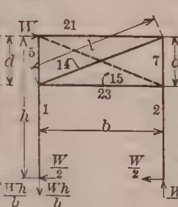

Fig. 112

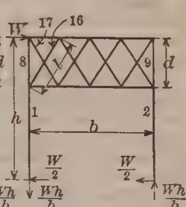

Fig. 113

room allows. When the end-posts are inclined the end sway bracing or **portal** is placed in the inclined plane of the end posts. In the best construction all members of the bracing systems are rigid, that is, made of angles or other similar shapes. Simple portals are shown in Figs. 110, 111, 112 and 113, and the following formulas give the stresses due to wind load W when the posts are hinged at bottom:

For P_1 tension $= Wh/b$, shear $= W/2$, moment $= W(h - d)/2$. For P_2 compression $= Wh/b$, shear $= W/2$, moment $= W(h - d)/2$. For P_3 compression $= Wh(1/2\,e - 1/b)$, shear $= W(h - d)/2\,d$, moment $= W(h - d)/2$. For P_4 tension

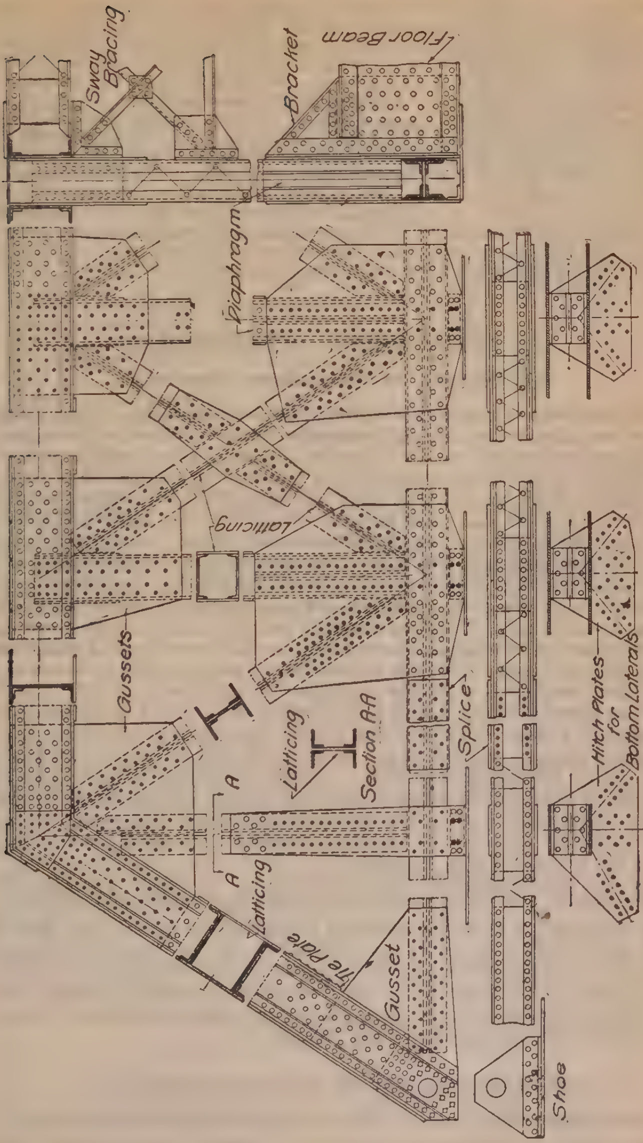

Fig. 114. Partial Detail Drawing of a Through Riveted Railroad Bridge.

$= Wh\,(1/2\,e - 1/b)$, shear $= W(h-d)/2\,d$, moment $= W(h-d)/2$. For P_5 and P_6 direct stress = zero, shear $= W(h-d)/2\,d$, moment $= W(h-d)/2$. For P_7 compression $= Wh/b$, shear $= W(h-d)/2\,d$, moment $= W(h-d)/2$. For P_8 tension $= Wh/2\,b$, shear $= W(h-d)/2\,d$, moment $= W(h-d)/2$. For P_9 compression $= Wh/2\,b$, shear $= W(h-d)/2\,d$, moment $= W(h-d)/2$. For P_{10} tension $= Whl/2\,de$. For P_{11} compression $= Whl/2\,de$. For P_{12} tension $= Whl/bd$. For P_{13} compression $= Whl/bd$. For P_{14} tension $= Whl/bd$. For P_{15} assumed zero. For P_{16} tension $= Whl/2\,bd$. For P_{17} compression $= Whl/2\,bd$. For P_{18} compression $= W(h+d)/2\,d$, shear $= Wh\,(1/2\,e - 1/b)$, moment $= Wh\,(1/2 - e/b)$. For P_{19} compression $= W/2$, shear $= Wh/b$, moment $= Wh\,(1/2 - e/b)$. For P_{20} tension $= W(h-d)/2\,d$, shear $= Wh\,(1/2\,e - 1/b)$, moment $= Wh\,(1/2 - e/b)$. For P_{21} compression $= W(h+d)/2\,d$. For P_{22} tension $= W(h-d)/2\,d$. For P_{23} compression $= Wh/2\,d$. Chord stresses in Fig. 113 may be obtained by use of moments. Dotted bars in Fig. 111 have no stress. If posts are fixed at the lower ends, h in above formulas should be replaced by distance from top of post to point of contraflexure, which is usually $h/2 + d/2$.

SECONDARY STRESSES

31. Nature of Secondary Stresses

The members of a truss form the sides of a series of triangles. Under stress one or more sides in each triangle are shortened by compression and the others lengthened by tension. As the angles of a triangle depend on the relative length of its sides, the angles at joints of a truss tend to change. This change in angle is wholly prevented by rivet and gusset-plate connections, mostly prevented by rivets alone, and partially—often to a very material extent—prevented by friction on pins of pin-connected joints. The members are therefore bent instead of continuing to be straight sides of true triangles and the resulting bending stresses are called secondary stresses. In an ideal truss with frictionless pins every member would remain straight and no secondary stresses would result. The **total stress** in any fiber is the algebraic sum of the secondary, or bending, and the primary, or axial, stress and is a maximum in certain outer fibers. The ratio of secondary to primary stress in chords and main web members is ordinarily not large, generally less than 20%, but in short members, and those having small primary stresses, such as the auxiliary members of trusses with subdivided panels, the ratio may be several times the above amount. For this reason trusses of the Baltimore or Pennsylvania types should be avoided, if possible. Likewise short bracing struts, such as are used in Pennsylvania trusses to brace the vertical columns at mid-height, or the collision struts sometimes used in end panels of Pratt trusses, create high secondary stresses in all adjoining members. The latter are now used much less commonly than formerly.

Mention has already been made of the growing movement to increase the present unit stresses. If higher unit stresses are adopted it will become increasingly important to know the maximum stress that can occur in any fiber of any member—that is, the worst combination of secondary and primary stresses. Maximum secondary and maximum primary stresses do not necessarily occur at the same time—with the same condition of loading—but generally maximum primary stress, with its accompanying secondary stress, gives the maximum or governing combination.

32. Computation of Secondary Stresses

Exact Computation of the secondary stresses in an ordinary structure is a tedious affair, necessitating the solution of as many simultaneous equations as there are joints, for each governing position of the live load. As there are many such positions the work becomes staggering. It is not surprising, therefore, that designers avoid such laborious computations and seek safety in the use of low unit stresses.

Approximate Method. The method of successive approximations is so simple, and gives results so closely approximating those by the exact method that it will be illustrated here by an example occurring in "Statically Indeterminate Stresses," by Parcel and Maney. The bending moments in the members meeting at the hip joint, C, of the 518-ft. span of the Kenova bridge, N. & W. R. R., will be determined (Fig. 114*a*).

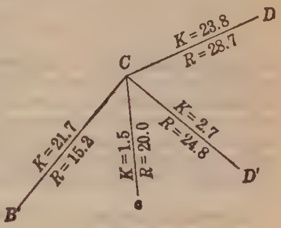

Fig. 114*a*

$K = 4\,EI/L$; $R = D/L$; where $E =$ 29 000 000, I = moment of inertia about the axis perpendicular to plane of truss, in inch-pounds, L = length of member in inches, D = deflection in inches of far end of member, relative to C, measured normal to the axis of the member. The values of K given in Fig. 114*a* should be multiplied by 1 000 000 000, and those of R divided by 10 000. Thus for CD, $I = 83\,000$, $D = 1.16$, $L = 405$, $K = 4 \times 29\,000\,000 \times 83\,000/405 = 23.8 \times 1\,000\,000\,000$, $R = 1.16/405 = 28.7/10\,000$. D can be most readily obtained from a Williot diagram, as will be explained later. K and R are thus known in advance for every member of the truss.

The assumption is first made that the angles of rotation ϕ of the joints at C, D, D', c, B' are all equal. Let ϕ_1 be this angle, in radians, the subscript meaning first approximation. Then $\phi_1 = \Sigma KR/\Sigma K$, the summations to include all of the members meeting at C, thus,

$$\begin{aligned}
CD &= 23.8 \times 28.7 = 683\\
CD' &= 2.7 \times 24.8 = 67\\
Cc &= 1.5 \times 20.0 = 30\\
CB' &= 21.7 \times 15.2 = 330\\
\Sigma K &= 49.7 \qquad \Sigma KR = 1110\\
\phi_1 &= 1110/49.7 = 22.3
\end{aligned}$$

Taking account of the units assumed for R, the true value of ϕ_1 at $C = 22.3/10\,000$. A similar calculation is made for each joint of the truss. Designating the angle of rotation at each of the joints adjacent to C by ϕ'_1 to distinguish it from ϕ_1 at C, the following values of ϕ'_1 were obtained: ϕ'_1 at $D = 23.2$; at $D' = 18.4$; at $c = 23.8$; at $B' = 28.4$.

For the second approximation at C use the formula, $\phi_2 = \phi_1 - 1/2\, \Sigma K(\phi'_1 - R)/\Sigma K$, where ϕ_1 = first approximate value at C; ϕ_2 = second approximate value at C; ϕ'_1 = first approximate value at each of the adjacent joints. Thus, $1/2\, K(\phi'_1 - R)$ at

$$\begin{aligned}
D &= 1/2 \times 23.8 \times (23.2 - 28.7) = -\ 65\\
D' &= 1/2 \times 2.7 \times (18.4 - 24.8) = -\ 9\\
c &= 1/2 \times 1.5 \times (23.8 - 20.0) = +\ 3\\
B' &= 1/2 \times 21.7 \times (28.4 - 15.2) = +\ 143\\
\Sigma K &= 49.7 \quad 1/2\, \Sigma K(\phi'_1 - R) = +\ 72\\
\phi_2 &= 22.3 - 72/49.7 = 22.3 - 1.4 = 20.9
\end{aligned}$$

A similar operation is performed for each joint of the truss. The results at the joints adjacent to C may be designated by ϕ'_2 to distinguish them from ϕ_2 at C. These values were found to be as follows: ϕ'_2 at $D = 25.3$; at $D' = 17.2$; at $c = 22.2$; at $B' = 25.0$.

For the third approximation use the formula $\phi_3 = \phi_2 - 1/2\ \Sigma K(\phi'_2 - \phi'_1)/\Sigma K$, where ϕ_2 and ϕ_3 are the values of ϕ at C resulting from the second and third approximations, and ϕ'_1 and ϕ'_2 the values of ϕ at each of the joints adjacent to C resulting from the first and second approximations, respectively. Thus, $1/2\ K\ (\phi'_2 - \phi'_1)$ at

$$
\begin{aligned}
D\ &= 1/2 \times 23.8 \times (25.3 - 23.2) = +25 \\
D'\ &= 1/2 \times 2.7 \times (17.2 - 18.4) = -2 \\
c\ &= 1/2 \times 1.5 \times (22.2 - 23.8) = -1 \\
B'\ &= 1/2 \times 21.7 \times (25.0 - 28.4) = -37
\end{aligned}
$$

$$\Sigma K = 49.7 \quad 1/2\Sigma K(\phi'_2 - \phi'_1) = -15$$

$$\phi_3 = 20.9 + 15/49.7 = 21.2$$

In a similar manner ϕ_3 is found for every joint of the truss. It is thus seen that the values of ϕ at C have converged practically to a constant and that nothing would be gained by further successive substitutions. This method of solution is not applicable to every set of simultaneous linear equations, but it is generally available for secondary stresses when there is a degree of uniformity in the values of ϕ at adjacent joints. The test of its practicality is the rapidity with which the successive values of ϕ converge to a constant quantity.

The **bending moment** at the C end of CD is expressed in general terms by

$$\mathbf{M_{CD} = 1/2K_{CD}\,[2\,\phi_C + \phi_D - 3\,R_{CD}]}.$$

Using the results of the third approximation, $\phi_C = 21.2$, $\phi_D = 25.4$, $M_{CD} = 1/2 \times 23.8\ [42.4 + 25.4 - 3 \times 28.7] = -220$. Since the scale is 1 000 000 000/10 000 = 100 000, $M_{CD} = -$ 22 000 000 in-lb. $f = Mc/I$ = 22 000 000 $\times$ 24/83 000 = $-$ 6400 lb. f = extreme fiber stress per square inch from secondary effects. The primary unit stress for this member under the same condition of loading is 13 600 lb. Percentage of secondary to primary stress = 6400/13 600 = 47. This truss is of the Pennsylvania type with many short, relatively low stressed members. The percentages run high throughout the truss, especially in the vicinity of the auxiliary members, showing clearly the damaging effect of the latter.

The **Deflection D** of one end of a member relative to the other and its original direction, due to the distortion of the truss under the load, can readily be scaled from a Williot displacement diagram (Art. 40 and Figs. 132, 133, 134, page 1267). For example in the cantilever truss shown in Fig. 132, let it be desired to find the deflection of G, relative to F, normal to the horizontal line passing through the new position of F. The displacement diagram, (Fig. 133, p. 1267), was drawn on the assumption that the joint A and the bar AB are fixed in space, the pier at e being removed to allow free movement of the rest of the truss. $A'F'$ then represents the motion of the point F, and $A'G'$ the motion of the point G. The distance $F'G'$ is the actual motion of G relative to F, and the projection of $F'G'$ upon a line normal to FG (of the truss), a vertical in this case, is the required value of D. D is positive when the deflection of one end, relative to the other, is clockwise. Thus, standing at joint F and imagining the other end of FG to move in a direction parallel to $F'G'$, if FG turns in a clockwise direction, as in the present case, D is positive. For the member cd, D is the projection of $c'd'$ (in the displacement diagram) upon a normal to cd. The lines representing these projections are all present in the diagram and may at once be scaled. Standing at c and putting in the displacement $c'd'$ at d normal to cd, the member cd will swing about c in an anti-clockwise direction, and D is minus. The sign of ϕ is obtained from the numerical solution of the equations and is to be interpreted by the same convention as for D. Thus, when ϕ is positive the joint is twisted in a clockwise direction. Negative M means tension in the outer fiber first met with, in a member, as one passes around the joint in a clockwise direction. Thus, $M_{CD} = -$ 22 000 000 in-lb. means a tension of 6400 lb. per sq. in. in the upper fiber of CD at the C end.

MOVABLE AND CANTILEVER BRIDGES

33. Types of Movable Bridges

A Draw or Movable Bridge is one which can be moved from its normal position to allow the unobstructed passage of vessels. Movable bridges are classified into the five following types: swing, bascule, retractile, lift, and ferry bridges. Those of the **swing type** revolve horizontally about a vertical axis, which may be at the center, at one end or at an intermediate point of the span. **Bascule bridges** include all movable bridges which move in a vertical plane, rolling back from the opening or rotating about a horizontal axis. **Retractile drawbridges** are those which are supported on wheels resting on tracks on shore, and which are rolled horizontally backward from the opening either along the approach of the bridge or at an angle thereto. **Lift bridges** can be raised vertically to a sufficient height to allow vessels to pass underneath. **Ferry bridges** consist of a movable car which is suspended from, and which moves back and forth under an overhead fixed bridge supported on towers, the overhead portion being so high above water level as to afford proper clearance for navigation.

Swing Bridges generally consist of two or more plate girders or trusses supported on a center or pivot pier in such a manner that they can be revolved on a circular track or pivot resting upon and attached to the pier. When the bridge is open there is a passageway for vessels on either side of the pier and the draw, and the trusses act as cantilevers overhanging the middle support. To prevent the open bridge from being struck by a vessel approaching or passing through the channel, a **fender pier** of piles and timber is built around the supporting pier, thus protecting the open draw span and guiding the vessel into the channel. The fender pier extends lengthwise of the stream and must be longer and wider than the open draw. Sometimes the pivot is placed on one side of the center between the center and the end of the draw, and the bridge then has two arms of unequal length, the shorter arm being counterweighted to balance the longer. Unequal arms may be used where the stream is too narrow for a central pier; the short counterweighted arm hanging over the shore and the long arm over the water when the bridge is closed. **Double swing bridges** have been used in a few instances. They consist of two swing spans each supported by a pier on each side of the stream and having their outer ends connected at the center of the channel when the bridges are closed. Swing bridges are the simplest and most economical of the various types and where there is ample room for operation they should generally be used. In locations where the pivot pier takes up too much space in the stream, or where room is not available for turning, the swing bridge cannot be used and some form of bascule bridge is preferable.

The **Jack-knife or Folding Drawbridge** is a swing bridge used only for railroad traffic, and as usually built has one Howe truss or steel truss under each rail, the rail being fastened directly to the upper chord of the truss. The trusses are connected together by small pivoted bars every few feet apart along the top chords, and each truss revolves horizontally about a pivot at one end, while the movable end is supported during operation by a needle beam which is guyed to the top of a tower or bent located on the shore at the pivot end of the span. When the bridge is open the trusses are parallel with the bank and are folded closely together. Since jack-knife draws cannot have floors, such bridges should not be used.

Bascule Bridges of various designs are in use, some being patented. Their merits lie in the speed with which they are operated and in the small amount of room required for their erection and operation. One to two minutes is the time often required for opening or closing a bridge although many structures cannot be made ready and opened in this time. Bascule bridges are used when conditions are unfavorable for a swing bridge, such as when a waterway is too narrow for a center pier in the river, and the abutting property is too valuable to afford space for swinging the span when the pier is placed on one shore (as is the case in Chicago). As such conditions arise only in cities, most bascule bridges are of the highway type. They are well adapted for railway service when the number of tracks is likely to increase in the future, for several parallel bridges may be built side by side at different times. A bascule bridge may have one or two leaves. When the required opening is not too great the former is to be preferred on account of economy in first cost and because the free end has a firm support when the leaf is closed. When two leaves are used they must be locked together at the center when the bridge is closed.

Bascule bridges are generally either of the trunnion or the rolling lift type. **Trunnion bridges** rotate about a horizontal and, usually, fixed axis placed near one end. There are several types differing in the manner of support of the counterweight and the mode of operation. The main trusses or girders may be continued back of the trunnion a short distance, and the counterweight be placed in this extension below the floor as far back of the trunnion as possible (as in the City of Chicago type); or the counterweight may be

Fig. 115

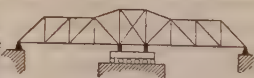

Fig. 116

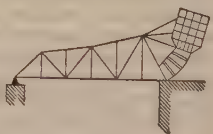

Fig. 117

carried overhead at one end of a moving framework pivoted to and supported by an independent tower placed back of the trunnion, and operating somewhat as a walking beam (as in the Strauss and Brown types). The river end of the walking beam is attached to the moving leaf at some point beyond the trunnion, by linkages or cables. In some cases, as in the earlier Brown type, the counterweight moves vertically and is supported by cables which pass over sheaves at the top of a fixed vertical tower and thence down to the point of attachment on the moving leaf. In all cases the counterweights are of such size and move in such paths that the power required for opening or closing the draw is only that necessary to overcome inertia, frictional resistance, wind and snow. The Scherzer **rolling lift** bridges, (Fig. 117), are of the bascule type, but instead of rotating on trunnions they roll back on a horizontal track, the ends of the main girders or trusses being curved for this purpose. As the curved portion rolls backward on the track the outer portion or bascule leaf rises, leaving the channel clear. **Bascule bridges** are operated by racks and pinions placed in the most favorable position for speed of operation and minimum expenditure of power.

Retractile, Direct Lift and Ferry Bridges are not common types. Retractile bridges may have one or two leaves overhanging the stream when closed and extending back over the abutments far enough to serve as a counterweight. This type is applicable to short spans only. The direct lift bridge consists of a simple truss structure which when closed rests on the abutments similar to any fixed span, but it is opened by being raised vertically by means of cables or chains passing over sheaves at the top of a tower at either end of the span. Counterweights are used to reduce the work of moving the bridge. The only ferry bridge in the United States is that across the ship canal at Duluth. It has two riveted steel trusses of about 390-ft. clear span supported on a steel tower on either side of the canal. The clear height is about 135 ft. above the water level. These two fixed trusses carry the track from which are suspended a steel frame and a ferry car, both of which travel back and forth across the canal. The retractile, direct lift and ferry bridges are used for highway traffic only.

Swing Bridges, which are generally supported at the center of the span, are either center-bearing, (Fig. 115), or rim-bearing (Fig. 116). While in motion a **center-bearing structure** is supported at the pivot pier on a turntable consisting of some transverse girders which carry the dead weight of the bridge to a center pivot or casting about which the structure revolves. When the bridge is closed wedges are inserted under the trusses at the center so as to carry no dead load but to carry all the live load reaction on the center pier. Trailing wheels placed under the turntable steady the bridge while swinging but receive no load otherwise. From 4 to 8 wheels varying in diameter from 12 to 20 in. are used. The center pivot consists of an upper and a lower casting, the upper one supporting the weight of the bridge by means of cross or diaphragm girders, the lower one being fixed to the masonry center pier. The pivot turns on 2 or 3 disks, 15 to 50 in. in diameter. When two disks are used the lower one is of hard tempered steel, with an upper spherical concave surface of slightly smaller radius than the lower disk. When three disks are used, the top and bottom ones are of hardened steel, with concave surfaces, and the middle one is of hard bronze, with both surfaces convex. An oil ring on the lower pedestal feeds grooves cut in the turning surfaces, and permits the disks to run in a bath of boil. **Rim-bearing** swing bridges have their trusses supported at the center pier directly on the drum or on distributing girders from which the load is carried to the drum. The **drum** is a circular girder resting on conical wheels which in turn are supported on a circular track of the pier. The center-bearing swing bridge, except for very wide city bridges, is distinctly superior to the rim-bearing type, and has nearly superseded the latter. **Combined rim- and center-bearing** swing bridges are those in which part of the weight is carried by the center pivot. This arrangement is preferable to that where all the weight is taken by the drum, as the center load helps to anchor the center pivot and prevent lateral motion under horizontal dynamic forces.

The heaviest swing bridge in the United States, up to 1926, and at present, 1928, the heaviest center-bearing bridge, is the double-track, double-deck structure of the Southern Pacific Co. across the Sacramento River at Sacramento, Calif. The span is 390 ft. 3 in., center to center of end supports; the maximum load on the center pivot is 6 748 000 lb.; that on each end wedge is 868 000 lb.; that on each center wedge is 1 528 000 lb. The center disks are 52 in. in diameter. It is believed that heavier spans of this type are practicable. The present longest and heaviest swing bridge in the United States is the double-track, double-deck railway and highway bridge of the At. T. & S. F. Railway System across the Mississippi River at Fort Madison, Iowa. The span is 525 ft. and the weight of the swinging parts is 10 000 000 lb. It is a combination rim- and center-bearing structure.

Center-bearing swing bridges, when closed and ends raised ready for the passage of the live load, are continuous girders over three points of support.

Rim-bearing swing bridges are nearly always built as partially continuous girders over four points of support. The diagonals in the panel between the

* Single leaf; other bascule bridges not marked, double leaf.

two central supports are omitted, or are very light, thus allowing moment but no shear to be transmitted across this panel.

Drawbridge Trusses whether center or rim-bearing may have their ends simply supported, latched, or raised. The **ends** are **simply supported** when the end supports are so placed that the ends of the trusses will just come to a bearing without producing any dead load reactions and the entire dead weight is carried by the center pier either when the bridge is open or closed. The live load can thus produce upward end reactions only, and when it is in such a position as to cause a downward end reaction the truss will rise from the bearing, and, in such cases, when the live load passes over the bridge the ends hammer on the bearings. This is not a good arrangement. To prevent this the **ends** should either be **latched** or **raised** by suitable machinery until upward end reactions are created equal to the greatest possible downward live load reaction. Efficient latches are complicated and it is the general practice to raise the ends until the upward dead load reaction is equal to 1.5 times the maximum negative live load reaction when one arm is loaded.

34. Design of Movable Bridges

The determination of stresses in continuous swing bridges is based on the usual method for continuous beams but the members have also to be designed for the loads when the ends of the bridge are swung off the support. The extra height of truss over center supports is owing to this latter condition. Trunnions and pivots offer special problems in bearing and friction.

For a full explanation see Treatise on Movable Bridges, by Otis E. Hovey, Wiley, 1927.

Notation. W = equals total uplift of swing bridge at both ends in pounds, HP = total horsepower required for raising ends of swing bridge, h = total lift in feet, t = time for lifting in seconds, R = radius of center line of track in feet, t_1 = time for opening in seconds, W_1 = weight on rollers under drum of rim-bearing or total revolving weight on pivot of center-bearing bridge in pounds, r = radius of pivot in feet, b = width and l = length of bridge in feet.

Machinery for Operating a Swing Bridge includes that necessary for turning the bridge and for lifting and lowering the ends of the truss or girders. All swing bridges should be so arranged that they can be operated by hand power, and all but the smallest that are opened infrequently should be provided with motive power. The motor may be a steam engine, an electric motor or a gasoline engine. Where electric current is available the electric motor is the simplest and most economical, for it takes up little room, is easily installed and the cost of maintenance is low. For the larger bridges where electric current is not available the steam engine gives the most satisfactory power, especially if the bridge is to be opened frequently, but with light spans and infrequent openings the gasoline engine is best.

Turning Machinery. Whatever form of power is used for turning the bridge it is usually applied through a vertical shaft which is attached to the drum of a rim-bearing turntable and to some girder or floorbeam of the center-bearing type. On the lower end of the shaft is a pinion engaging in the circular rack which is attached to the pivot pier or to the lower track on which the turntable revolves. The rotation of the shaft causes the bridge to revolve. Electric motors are usually set on top of the drum or on a platform projecting from the side of the drum, and they are usually of the railway type, series wound and waterproof. The armature speed varies in different bridges from about 450 to 650 r.p m. and generally should not exceed 600 r.p.m. The controllers for the motors should be placed in the operator's house, together with the switchboard and necessary switches, meters, circuit-breakers and fuses. Friction brakes are used for most movable bridges, although where the motor is close to the rack of swing bridges they are not absolutely necessary but even here are desirable. When two motors are used, as in most heavy bridges, they are placed on opposite sides of the drum. Fig. 118 shows the turning mechanism for the swing span of the Charlestown

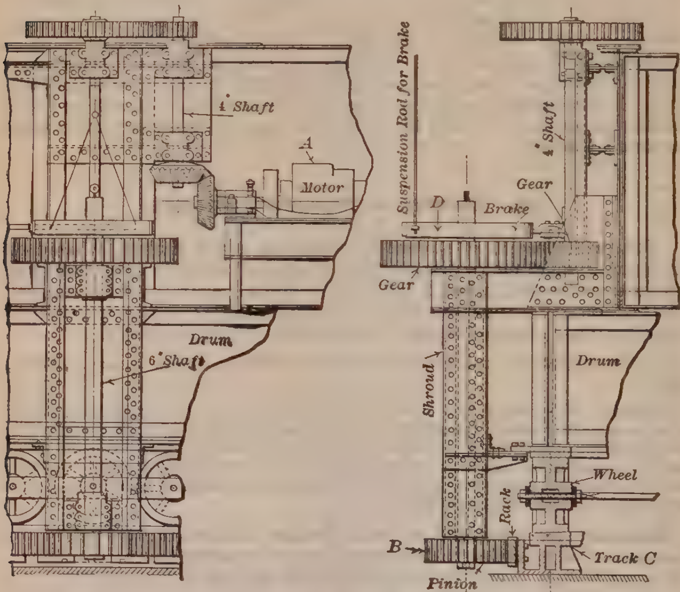

Fig. 118. **Turning Mechanism, Charlestown Bridge, Boston. Mass.**

bridge in Boston, Mass., which has two trains of gears driven by electric motors, one of which is shown. The motor *A* is attached to a steel supporting frame and drives the reduction gearing which transmits the power through the pinion shaft to pinion *B* engaging the circular rack bolted to the base casting or track *C*. A brake *D* is attached to each pinion shaft and is operated by compressed air.

End-Lifting Mechanisms. Swing bridges require some form of end-lifting device which will lift the ends of the trusses or girders when the bridge is closed and which lowers them when the bridge is to be opened. Lifting may be done in small bridges by allowing the ends to run up on wheels which are mounted on the fixed piers, but for ordinary cases some better arrangement, such as **toggle joints** or **hydraulic jacks**, is necessary for raising the ends sufficiently to allow **wedges** or other similar supports to be inserted.

The present practice is to make the end lifting device as simple as possible and to depend upon wedges, operated by a toggle mechanism, both to lift the bridge and to support the loading after the ends are lifted.

Figs. 119 and 119*a* are reproduced, with the author's permission, from Hovey's Movable Bridges. Fig. 119 shows a diagrammatic sketch of the principle of the end

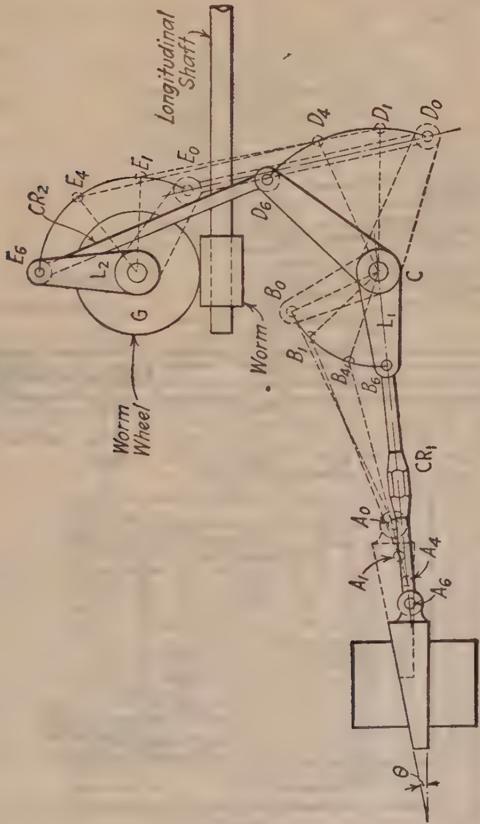

Fig. 119

wedge operation. The longitudinal shaft may run to the center of the bridge, but with electrically operated bridges a motor is placed very near the end lifting mechanism. Fig. 119*a* shows the end wedging mechanism of the Kalan bridge, Columbia River Crossing of the Union Pacific System. The upper operating lever in section *A–A* is a crank which will pass its dead center and withdraw the wedges if the motor is not stopped when the wedges are fully driven. The bridge is a single-track center-bearing swing span, 280 ft. between end supports. The center has two disks, 24 in. in diameter, the lower of hard steel and the upper of hard bronze. The turning and wedging motors have a normal capacity of 35 hp., and there is a gasoline auxiliary with a nominal rating of 53 hp.

Rail-lifts for railroad bridges are generally provided to raise the ends of

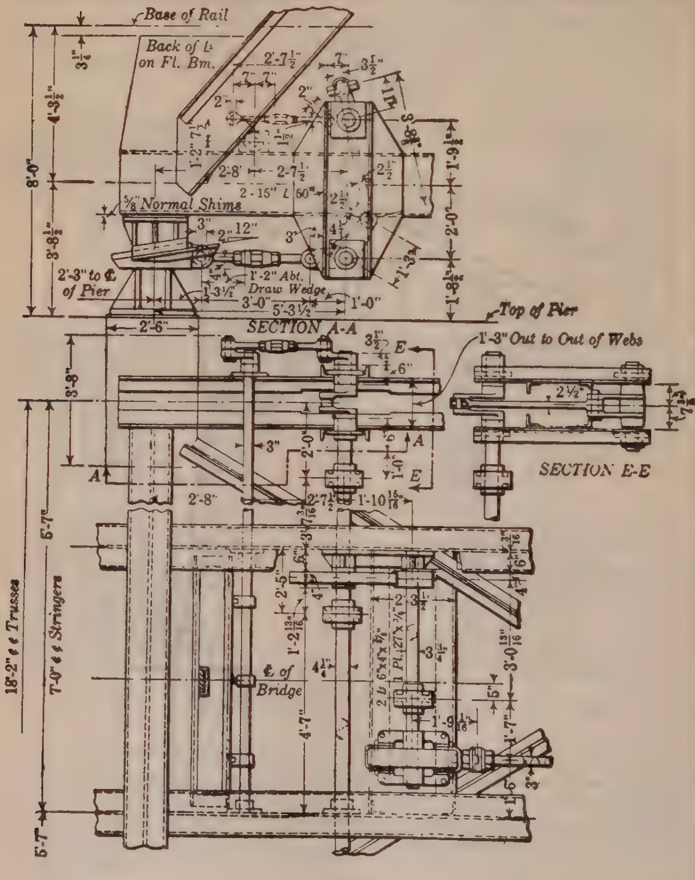

Fig. 119a

the rails on the swing span so that as the bridge revolves they will be above the rails on the adjoining fixed spans. This is usually done by means of shafting connected with the end-lifting device, and there should be automatic home and distant **signals** on each side of the bridge interlocked with the end-lifting mechanism and rail lifts so that the signals can be set at safety only when the ends of the bridge and the rails are in their proper positions. Rail-lifts are objectionable because the rails are not properly held during the passage of trains, and those forms of **rail-locks** which insure proper alignment of rails and allow the rails to be securely fastened to the track are better. **End latches** to bring the bridge into proper alignment when closed should be arranged to work automatically but only when the ends of the bridge are slowly approaching the supports.

The Power Required for operating a swing bridge is that for lifting the ends and for turning the bridge. These two operations are not performed at the same time, so that the maximum power necessary is the greater of the two, not their sum. To **lift the ends** the resistance varies from zero at the beginning to a maximum at the end of the operation, and the total horsepower required, excluding the frictional resistances of shafting and all other movable parts of the end-lifting mechanism, is $\mathbf{HP = Wh/550\ t}$. In this formula W must be taken as the total end uplift; for example, if the uplift at each end of a truss is 30 000 lb. and there are two trusses, W would be 120 000 lb. The frictional resistances to be overcome in lifting the ends vary greatly and are estimated at from 100 to 250% of the above value of P. If friction at 100% is allowed, then the horsepower required for lifting and overcoming frictional resistances in the lifting mechanism is $\mathbf{Wh/275\ t}$.

In Turning the Bridge the resistances to be overcome are those due to friction, unequal wind pressure and inertia of the mass. The frictional resistance in a rim-bearing bridge is caused by friction between the wheels and the upper and lower tracks, also at the axles of the wheels and at the center pivot. The **coefficient of the total friction** for rim-bearing bridges was found by C. Shaler Smith to be from 0.004 to to 0.008 of the load on the wheels; by Boller and Schumacher to be 0.0035 for the Thames River bridge in Connecticut, and by Theodore Cooper to be 0.0038 for the Second Avenue bridge in New York. In center-bearing structures the friction is principally at the center pivot, and the coefficient of frictional resistance at the circumference of the pivot was found by C. Shaler Smith to be 0.09 of the weight turned; and by C. C. Schneider to be 0.067 at the start and 0.045 to maintain motion at uniform speed for a bridge with a center-bearing of hardened steel and phosphor-bronze disks carrying a pressure of 3000 lb. per sq. in. The last-named engineer also found the highest coefficient of total friction on new bridges, including that of shafts and gearing for hand operation, to be 0.115 for starting and 0.08 for maintaining motion. The resistance due to an **unbalanced wind pressure** of from 4 to 5 lb. per square foot of surface of one arm of the draw is sometimes allowed for in determining the power required, and sometimes this is provided for by using larger coefficients of friction than those given above. To overcome the inertia of the bridge and to accelerate the motion the power required depends on the time allowed for opening the bridge. The motion may be accelerated during the first half and retarded during the last half of the movement, as is usual; or it may be accelerated during the first third, then maintained at a uniform velocity for the second third, and retarded for the last third.

The Horsepower required for overcoming all frictional and wind resistances of a rim-bearing bridge while turning is given approximately by $\mathbf{WR/11671\ t_1}$, in which the coefficient of resistance is assumed to be 0.015. And for a center-bearing bridge while turning with an assumed coefficient of resistance of 0.15 the horsepower is $\mathbf{W_1 r/1167\ t_1}$. The horsepower required for overcoming inertia is approximately $\mathbf{W_1(b^2 + \mathit{l}^2)/10\,767\ t_1{}^3}$. In the three formulas just given it is assumed that the motion is accelerated during the first half and retarded during the last half of the time of swinging; and in the first two formulas the force is applied at the center of the track and in the last it is applied at the center of gyration.

35. Cantilever Trusses

Historical. Bridges which have cantilever, that is, projecting, arms are called cantilever bridges and the principle involved in their construction is very old. The first European cantilever structure of note was a highway bridge of 124-ft. span designed and built by Gerber in 1867 over the river Main at Hassfurt, and the first cantilever railroad bridge was a span of 148 ft. completed in 1876 over the Warthe at Posen. **In America the first iron cantilever** bridge was the Kentucky River bridge of the Cincinnati Southern R.R., built in 1876–7 by C. Shaler Smith of the Baltimore Bridge Co. The Michigan Central R.R. bridge over Niagara River was the second important

* Known as Queensboro bridge. † Continuous bridge.

American cantilever and was completed in 1883. The bridge of this type having the longest span in the world at the time of its construction in 1918 is the Quebec bridge, which has a span of 1800 ft. center to center of river piers. The Quebec bridge which collapsed Aug. 29, 1907, during construction also was being built with a span of 1800 ft. Until the successful construction of the present Quebec bridge, the largest bridge of the cantilever type and the one having the longest span was the Forth bridge in Scotland, which has among others two spans each of 1700 ft. center to center of bearings.

The Modern Cantilever Truss is the outgrowth of the continuous truss, the change being brought about by the use of hinges which fix the points of contraflexure in the cantilever truss, thus removing some of the uncertainties in the calculations. The ordinary cantilever bridge, Fig. 120, of three spans on four supports consists of two **anchor arms,** one at each shore, two **cantilever arms,** and one **suspended span** and the suspended span is supported at the outer ends of the cantilever arms, whereas for bridges of great lengths, one or more intermediate spans, Fig. 122, are used in combination with some of the parts just mentioned. An **intermediate span** is one which extends unbroken between two piers and beyond which it projects to form a cantilever arm in

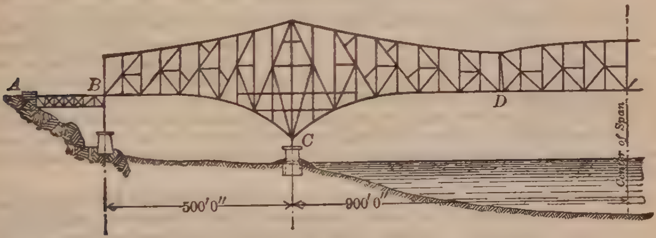

Fig. 120. Quebec Bridge, 1907

each of the adjoining spans. A **hinge** is a junction between a cantilever arm and a suspended span where the bending moment is zero after the bridge is complete, and for trusses is usually made by connecting the two portions by a pin at one chord and either omitting the opposite chord bar of the truss or arranging it so that it cannot carry stress after the bridge is self-supporting. Hinges can transmit shear but no moment after the bridge is complete, but during erection they are arranged to carry both. In **plate girder cantilever** bridges links connecting the suspended span to the cantilever arm have been used as hinges. Cantilever bridges have the advantage over simple trusses that the span containing the cantilever arm and suspended span can be erected without falseworks by being built out from the adjacent spans piece by piece, and the advantage over continuous trusses that the stresses are more accurately determined and are not altered by any reasonable settlement of the foundations.

Typical Trusses of five large American cantilever structures are shown in Figs. 120–124. Fig. 120 shows one half side elevation of the Quebec bridge which collapsed on account of the failure of the lower chord in the anchor arm, while being built in 1907 over the St. Lawrence River about 6 miles above Quebec. It consisted of two trusses 67 ft. between centers, each having two anchor arms *BC*, two cantilever arms *CD* and one suspended span hung from the cantilever arms at *D*. At each end was a short approach span *AB*. The structure was designed to carry two railroad tracks, two electric railway tracks, two highways and two sidewalks. Clearance above highest tide 150 ft.; maximum depth of water about 180 ft. Main trusses were pin-connected with pins as large as 12 in. in diameter and eyebars as wide as 18 in. Depth of truss: suspended span, at center 130 ft., at hinge D about 97 ft.; anchor arm, at end B about 97 ft., at pier C 315 ft. Panel lengths: anchor arm, 10 at 50 ft.; cantilever arm, 10 at 56 ft. 3 in.; suspended span, 12 at 56 ft. 3 in.

The New Quebec Bridge, Fig. 121, is built at the same site and has the same channel span, 1800 ft. center to center of river piers, as the bridge which collapsed. The length of the main structure is 2830 ft. and the total length, face to face of abutments is

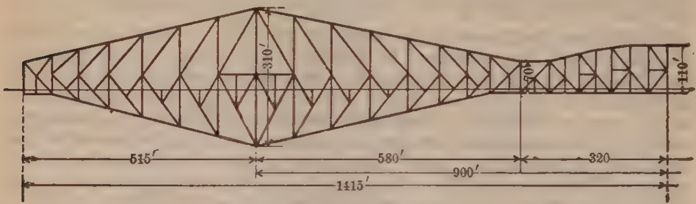

Fig. 121. Quebec Bridge, 1917

3239 ft. The depth of truss at the river pier is 310 ft.; at the ends of the anchor and cantilever arms, 70 ft.; at the center of the suspended span, 110 ft. The main structure consists of two trusses of the K type, 88 ft. between centers. It carries two railroad tracks and two 3-ft. walks, one on the side of each track. It is designed for a live load consisting of two E–60 engines and 5000 lb. per lin. ft. on each track. Main trusses are pin-connected with the pins varying from 8 in. to 30 in. in diameter and maximum width of eyebars 16 in. There are thirty-two 16 in. by 2-3/16-in. eyebars, with a net cross-sectional area of 1120 sq. in., in the top chord panel adjoining the vertical post over the river pier.

The Thebes Cantilever Bridge, Fig. 122, crosses the Mississippi River at Thebes, Ill., and consists of a steel structure of five spans with several approach spans of concrete arches at each shore. One-half the steel structure in shown in Fig. 122. The

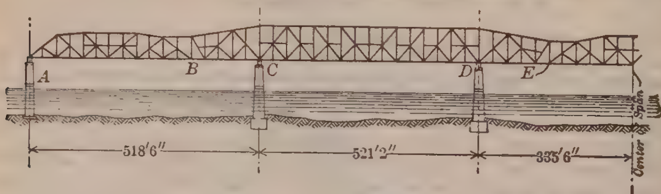

Fig. 122. Thebes Bridge

suspended span AB is supported on pier A and on the cantilever arm BC. Span CD is an intermediate span and DE is another cantilever arm which supports the central suspended span. Clearance above high water 65 ft., above low water 103 ft. There are two lines of trusses 32 ft. on centers carrying two railroad tracks. Each of the three suspended spans is 366 ft. long, each of the four cantilever arms 152 ft. 6 in. long and each of the two intermediate spans is 521 ft. 2 in. center to center of bearings. Depth of truss: suspended span, at center 55 ft.; cantilever arms at B and E 50 ft.; intermediate spans, 27 ft. throughout.

The New Memphis Bridge is located about 200 ft. upstream from the structure built in 1892. It has the same length of channel span as the older bridge, 790 ft. 5 in. In arrangement of spans, outline and type of truss it is very similar to the portion of the Thebes bridge shown in Fig. 122. But whereas the latter is symmetrical about the center of the channel span, the Memphis bridge terminates with a 186-ft. anchor arm on the right of the channel span. The span lengths are, beginning at the left, Fig. 122;

suspended span, 417 ft. 9-3/4 in.; cantilever arm, 186 ft. 3-3/4 in.; fixed span, 621 ft.; cantilever arm, 186 ft. 3-3/4 in.; suspended span, 417 ft. 9-3/4 in.; cantilever arm, arm, 186 ft. 3-3/4 in.; anchor arm, 186 ft. 3-3/4 in. Total length of main structure, not including a 345-ft. simple approach deck span, is 2201 ft. 10-1/2 in. It consists of two lines of trusses, 32 ft. between centers, carrying two railroad tracks and two 14-ft. cantilever highways. Superstructure is 76 ft. in the clear above high water level. Depths of truss are: at center of suspended spans, 67 ft.; at ends of cantilever arms, 55 ft.; throughout fixed span, 88 ft. It was designed for Cooper's E–50 loading on each of the railroad tracks, and a 17-1/2-ton road roller and 100 lb. per sq. ft. on the highways. Maximum diameter of pin is 20 in. and width of eyebars is 16 in.

The Wabash R. R. Bridge over Monongahela River at Pittsburgh, Pa., is a cantilever bridge 1504 ft. long exclusive of the steel viaduct approach on each shore. Fig. 123 shows one-half of the main structure which consists of two trusses 32 ft. on centers carrying two railroad tracks spaced 13 ft. on centers. The anchor arm AB is 346 ft. long, the cantilever arm BC 226 ft., and the suspended span, which is supported at

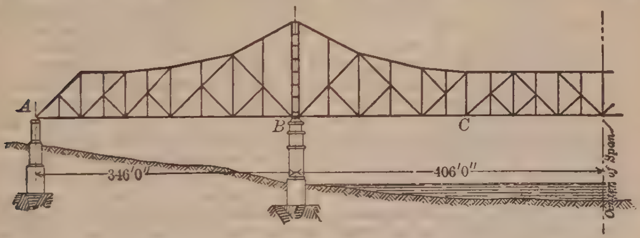

Fig. 123. Wabash R.R. Bridge, Pittsburgh, Pa.

C, is 360 ft. in length. Depth of truss: at portals, 60 ft.; suspended span, 60 ft. throughout; at main piers, 126 ft. 6 in. The tracks are on a 1% grade, so that the clearance under the central span near one pier is 70 ft., and near the other is 77.86 ft. above "full pool" level, which is below extreme high water. Panel lengths vary from 30 to 40 ft. Eyebars are from 12 to 14 in. wide, the latter having heads 33 in. in diameter. Pins 12 and 14 in. in diameter.

Queensboro or Welfare Island Bridge spans the East River and Welfare Island at New York and is a cantilever bridge on six masonry piers, two on each shore and two on the island. Fig. 124 shows the outline of that part of truss from the center of the island span at A to the end E in Borough of Queens. The total length of the cantilever

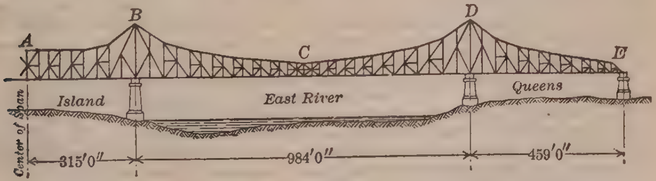

Fig. 124. Queensboro Bridge

portion of the bridge is 3724 ft. 6 in., divided into an intermediate span of 630 ft. on the island, two cantilever arms each of 492 ft. on the east, two cantilever arms each of 591 ft. on the west, one each anchor arm of 459 ft. and one west anchor arm of 469 ft. 6 in. Longest span 1182 ft. Depth of truss over each of the four intermediate piers such as B and D, 185 ft. There are two trusses 60 ft. on centers, made partially continuous by having the two cantilever arms joined together by rockers at C, thus making the structure statically indeterminate.

36. General Data for Cantilevers

Live Loads on Large Bridges. Firth of Forth: 2240 lb. per lin. ft. for each of two tracks. **Memphis**: 4000 lb. per lin. ft. per track; single track. **New Memphis**: Cooper's E–50 loading per track, 17-1/2-ton road roller and 100 lb. per sq. ft. on highways. **Wabash R.R.** over Monongahela River at Pittsburgh: two consolidation locomotives followed by 4500 lb. per lin. ft. for each of two tracks. **Thebes**: for floor system, one concentrated load of 50 000 lb. followed by 5000 lb per lin. ft. for each of two tracks; for trusses 20% less. **First Quebec**: trusses in general, (a) on each steam railway track 3000 lb. per lin. ft. for unlimited length, or (b) on each steam railway track two Cooper's Class E–33 locomotives followed by a train of 3300 lb. per lin. ft., total length of train 900 ft., or (c) on each steam railway track one Cooper's Class E–40 locomotive followed by a train of 4000 lb. per lin. ft., total length of train 550 ft.; no loading on electric railway tracks, roadways or sidewalks; hangers, subdiagonals and floor system, (a) on each steam railway track two Cooper's Class E–40 locomotives followed by a train of 4000 lb. per lin. ft., and (b) on each electric railway track 50 000 lb. on two axles 10 ft. apart with 20 ft. to leading axle of car following, and (c) on each roadway 24 000 lb. on two axles 10 ft. apart. **New Quebec**: two Cooper's E–60 engines and 5000 lb. per lin. ft. on each track. **Queensboro**: main trusses, original specifications for "congested" load of 12 600 lb. per lin. ft. of bridge as follows, two elevated railway tracks at 1700 lb. per lin. ft. each, four trolley tracks at 1000 lb. per lin. ft. each, 35.5-ft. roadway at 100 lb. per sq. ft. or 3550 lb. per lin. ft. of bridge, two 11-ft. sidewalks at 75 lb. per sq. ft. or 1650 lb. per lin. ft. of bridge, and a "regular" live load of 6300 lb. per lin. ft.; two elevated railway tracks added later increased original truss live loading from 12 600 to 16 000 and from 6300 to 8000 lb. per lin. ft. of bridge for "congested" and "regular" loadings respectively; floor systems and secondary trusses, on each elevated railway track cars of four axles spaced 6–10–6 ft. with 26 000 lb. per axle, on each street car track cars of two axles spaced 10 ft. with axle load of 26 000 lb. or 1800 lb. per lin. ft. of track, on any part of roadway 48 000 lb on two axles 10 ft. apart and 5-ft. gage covering a space 12 ft. by 30 ft. and on the remaining roadway surface 100 lb. per sq. ft., on the sidewalks 100 lb. per sq. ft. When nearly completed the Queensboro bridge was found to be too weak to carry the above loads, so that it is not being used as originally planned.
